This expression shows that, when $E_2 - E_1 \gg k_{\rm B}T$, that is, for optical, UV, or X-ray frequencies, spontaneous emission dominates. But in low-frequency regimes, that is, IR, microwave, or radio waves, stimulated emission is more important. Note that even when stimulated emission dominates, spontaneous emission is always present and plays an important role, for example, in processes ultimately limiting the emission bandwidth of lasers.

23.2.6 Absorption spectrum for a single atom

Every light source has a certain spectral width. Conventional light sources, such as incandescent bulbs or plasmas have relatively broad emission bands compared to atomic or molecular absorbers, at least when the latter ones are studied in dilute gases. Even when we use pure spectral sources, such as a laser tuned to the peak of a resonance, the transition line always exhibits an intrinsic width associated with the interruption of the phase evolution of the excited state. Phase interruptions such

as spontaneous or stimulated emission and collisions are common examples of line broadening mechanisms. The emission or absorption of radiation occurs within a frequency distribution centered about $\omega_0 \equiv \omega_2 - \omega_1$, and we must account for this spectral distribution in our calculation of the energy transfer.

On the other hand, as we will see in Sec. 39.1.3 and Sec. 39.4.1, spontaneous decay at a rate Γ of the excited level causes a finite linewidth for the atomic transition. Consequently, even perfectly monochromatic light will be absorbed according to a probability distribution given by the spectral absorption profile of the atomic transition. This profile is called the frequency-dependent *optical cross section* and reads [8],

$$\boxed{\sigma(\omega) = \frac{g_2}{g_1}\lambda^2 \frac{\Gamma}{2\pi} \frac{\frac{1}{4}\Gamma}{(\omega-\omega_0)^2 + \frac{1}{4}\Gamma^2} = \frac{g_2}{g_1}\lambda^2 \frac{\Gamma}{4}\mathcal{L}_\Gamma(\omega-\omega_0)\ ,} \tag{23.72}$$

where we defined the Lorentzian profile as,

$$\mathcal{L}_\beta(\Delta) \equiv \frac{\beta}{2\pi}\frac{1}{\Delta^2 + (\beta/2)^2} \qquad \text{with} \qquad \int_{-\infty}^{\infty} \mathcal{L}_\beta(\Delta) d\Delta = 1\ . \tag{23.73}$$

The total power P absorbed by a two-level atom with resonance frequency ω_0 from a radiation field with the spectral intensity distribution $I(\omega)$ and with the total intensity of the laser beam $\bar{I} = \int I(\omega)d\omega$ can now be expressed as the integral,

$$\boxed{P = \int \sigma(\omega) I(\omega) d\omega}\ , \tag{23.74}$$

Example 181 (*Limiting cases*): Let us analyze the two limiting cases when either one of the spectral distributions $I(\omega)$ or $\sigma(\omega)$ is much narrower than the other.

For a *narrow laser*, we may assume a δ-peaked spectral intensity distribution,

$$I(\omega) = \bar{I}\delta(\omega - \omega_{\text{las}})\ . \tag{23.75}$$

When it drives a *broad transition* described by an optical cross section given by (23.72), the scattered power is,

$$P = \bar{I}\sigma(\omega_{\text{las}})\ . \tag{23.76}$$

For a *narrow transition*, we may substitute the Lorentzian in (23.72) by a Dirac δ-function,

$$\sigma(\omega) \xrightarrow{\Gamma\to 0} \frac{g_2}{g_1}\lambda^2\frac{\Gamma}{4}\delta(\Delta)\ . \tag{23.77}$$

When it is driven by a *broad laser*, for which we assume a spectral intensity distribution,

$$I(\omega) = \bar{I}\mathcal{L}_\beta(\omega - \omega_{\text{las}}) \qquad \text{with} \qquad \bar{I} = \int I(\omega)d\omega = \frac{I(\omega_{\text{las}})}{\mathcal{L}_\beta(0)} = \frac{\pi\beta}{2} I(\omega_{\text{las}}) \tag{23.78}$$

we obtain for the scattered power,

$$P = \int \frac{g_2}{g_1}\lambda^2\frac{\Gamma}{4}\delta(\omega-\omega_0)\bar{I}\mathcal{L}_\beta(\omega-\omega_{\text{las}})d\omega = \frac{g_2}{g_1}\lambda^2\frac{\Gamma}{4}\bar{I}\mathcal{L}_\beta(\omega_0-\omega_{\text{las}})\ . \tag{23.79}$$

[8] At low saturation.

23.2.6.1 Broad laser driving a broad transition

Until now we assumed a fixed laser frequency $\omega_{\rm las}$ (with finite emission bandwidth) driving a fixed resonance frequency ω_0. What we call *absorption spectrum* is what we obtain when we tune either the laser frequency or when we (somehow) vary the resonance frequency, such that $\Delta \equiv \omega_{\rm las} - \omega_0$ is ramped. Assuming Lorentzian profiles with finite linewidths for both, $\bar{I}$ and σ, we get,

$$\begin{aligned} P(\Delta) = P(\omega_{\rm las} - \omega_0) &= \int \sigma(\omega) I(\omega) d\omega = \int \frac{g_2}{g_1} \frac{\lambda^2 \Gamma}{4} \mathcal{L}_\Gamma(\omega - \omega_{\rm las}) \bar{I} \mathcal{L}_\beta(\omega - \omega_0) d\omega \\ &= \frac{g_2}{g_1} \frac{\lambda^2 \Gamma}{4} \bar{I} \int \mathcal{L}_\Gamma(\omega' + \omega_0 - \omega_{\rm las}) \mathcal{L}_\beta(\omega') d\omega' \ . \end{aligned} \tag{23.80}$$

That is, the absorption spectrum is obtained as a convolution of both profiles,

$$\boxed{P(\Delta) = \frac{g_2}{g_1} \frac{\lambda^2 \Gamma \bar{I}}{4} (\mathcal{L}_\Gamma \star \mathcal{L}_\beta)(\Delta)} \ . \tag{23.81}$$

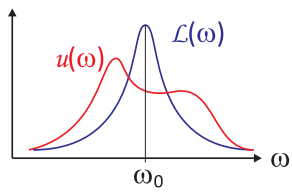

Figure 23.11: Absorption spectrum (blue) and spectral energy distribution of the source (red).

This result reproduces the two limiting cases discussed in the above example, since for narrow transitions, $\Gamma \to 0$, that is $\mathcal{L}_\Gamma \to \delta$, we recover the results (23.79), and for narrow lasers, $\beta \to 0$, that is, $\mathcal{L}_\beta \to \delta$, we recover (23.76). Obviously, this formula holds for other line profiles e.g. when the resonance is broadened by some perturbations [9].

23.2.6.2 Two-level atom in a blackbody radiation field

When considering a two-level atom interacting with a blackbody a radiation field, we describe the spectral intensity distribution by (23.61),

$$I(\omega) = \frac{\omega^2}{\pi^2 c^2} \frac{\hbar\omega}{e^{\hbar\omega/k_{\rm B}T} - 1} \tag{23.82}$$

$$\text{with} \qquad \bar{I} = \int I(\omega) d\omega = \frac{\hbar}{\pi^2 c^2} \left(\frac{k_{\rm B}T}{\hbar}\right)^4 \int_0^\infty \frac{x^3 dx}{e^x - 1} = \frac{\pi^2}{15 c^2 \hbar^3} (k_{\rm B}T)^4 \ .$$

[9] Let us here remind the following identities holding for Lorentzian and Gaussian line profiles:

$$(\mathcal{L}_\gamma \star \mathcal{L}_\beta)(\Delta) = \mathcal{L}_{\gamma+\beta}(\Delta) \qquad \text{and} \qquad (\mathcal{G}_\Gamma \star \mathcal{G}_\beta)(\Delta) = \mathcal{G}_{\sqrt{\gamma^2+\beta^2}}(\Delta) \ .$$

Since the width of the transition is negligibly small in comparison with the blackbody spectrum, $\Gamma \to 0$, we may evaluate the scattered power as,

$$P = \int \frac{g_2}{g_1}\frac{\lambda^2\Gamma}{4}\mathcal{L}_\Gamma(\omega-\omega_0)\frac{\omega^2}{\pi^2c^2}\frac{\hbar\omega}{e^{\hbar\omega/k_\mathrm{B}T}-1}d\omega \tag{23.83}$$
$$\xrightarrow{\Gamma\to 0} \frac{g_2}{g_1}\frac{\lambda^2\Gamma}{4}\frac{\omega_0^2}{\pi^2c^2}\frac{\hbar\omega_0}{e^{\hbar\omega_0/k_\mathrm{B}T}-1} \ .$$

23.2.7 Absorption in a gas

We are often interested in the attenuation of the intensity of a beam of light traversing a dilute gas of resonant scattering atoms. The Einstein rate equation yields the *temporal* transition rates, but does not say how they relate to the *spatial* attenuation length of the light beam. Let us now generalize the previous results to a gas of two-level atoms. As long as the transition linewidth is narrow [case (23.77)], the power is removed from the system only by spontaneous emission; absorption only converts radiation into atomic excitation which, subsequently, can be returned to the radiation field by stimulated emission. At steady-state the Einstein rate equation (23.65) reads,

$$0 = -N_1B_{12}u(\omega_0) + N_2B_{21}u(\omega_0) + N_2A_{21} \ . \tag{23.84}$$

Using the result (23.69), we can write the amount of power removed from the system by spontaneous emission as,

$$P = N_2A_{21}\hbar\omega_0 = u(\omega_0)B_{12}(N_1 - \tfrac{g_1}{g_2}N_2)\hbar\omega_0 \ . \tag{23.85}$$

The second part of the equation describes the energy loss of the beam, i.e. the difference between energy removed by absorption and energy returned to the beam by stimulated emission.

On the other hand, the power absorbed from the radiation field $u(\omega_0)$ by atoms whose transition is described by the cross section (23.72), is given by,

$$P = \int (N_1 - \tfrac{g_1}{g_2}N_2)\sigma(\omega)I(\omega)d\omega \ . \tag{23.86}$$

Remembering $I(\omega) = cu(\omega)$ and assuming a *large radiation spectrum*, $I(\omega) \simeq I(\omega_0)$, a comparison of equations (23.85) and (23.86) yields,

$$\boxed{B_{12} = \frac{c}{\hbar\omega_0}\int \sigma(\omega)d\omega} \ . \tag{23.87}$$

23.2.7.1 Lambert-Beer law

In the expression (23.86) the absorption probability distribution $\sigma(\omega)$ is convoluted with the spectral energy distribution of the light source, $u(\omega) = d\bar{u}/d\omega$, which in turn is related to the energy *density* via, $\bar{U} = V\bar{u}$, where V is the mode volume of the light field. Considering a thin slab of the absorber with volume ΔV, we have $d\bar{U} = \Delta V d\bar{u}$. Assuming that the light propagates in z-direction across the absorber and converting the time dependence into a spatial dependence, we have on one hand,

$$P = -\frac{d\bar{U}}{dt} = -\frac{d\bar{u}}{dt}\Delta V = -c\frac{d\bar{u}}{dz}\Delta V = -\frac{d\bar{I}}{dz}\Delta V \ . \tag{23.88}$$

On the other hand, assuming that the light field be a *laser with narrow emission bandwidth*, $I(\omega) = \bar{I}\delta(\omega - \omega_{\text{las}})$, we get from (23.86),

$$P = \int (N_1 - \tfrac{g_1}{g_2} N_2)\sigma(\omega) I(\omega) d\omega = \bar{I}(N_1 - \tfrac{g_1}{g_2} N_2)\sigma(\omega_{\text{las}}) \ , \tag{23.89}$$

Now comparing both results,

$$\frac{d\bar{I}}{\bar{I}} = -\frac{N_1 - \frac{g_1}{g_2} N_2}{\Delta V} \sigma(\omega_{\text{las}}) dz \simeq -n\sigma(\omega_{\text{las}}) dz \ , \tag{23.90}$$

where the approximation holds for low saturation, that it, if $N_1 \gg N_2$. The solution of this differential equation is,

$$\boxed{\bar{I} = \bar{I}_0 e^{-\sigma(\omega_{\text{las}})nz}} \ . \tag{23.91}$$

Here, z is the total distance, over which absorption takes place. The last equation is the *Lambert-Beer law* for light absorption. It is very useful for measuring atomic densities in gas cells or of atomic beams [626, 590, 963]. Solve the Excs. 23.2.9.9 to 23.2.9.11.

23.2.8 Saturation

Strong driving of a transition leads to its saturation and causes line broadening. To see this, we go back to Einstein's rate equations in steady-state (23.65) additionally simplified by assuming $g_1 = 1 = g_2$, such that $B_{12} = B_{21}$. Resolving these equations by N_1 and N_2 and using $N_1 + N_2 = N$ and $N_1 - N_2 \equiv \Delta N$, we get,

$$N_1 = N \frac{B_{21} u(\omega) + A_{21}}{2B_{21} u(\omega) + A_{21}} \qquad \text{and} \qquad N_2 = N \frac{B_{12} u(\omega)}{2B_{21} u(\omega) + A_{21}} \ . \tag{23.92}$$

For vanishing pump rate we expect, $N_1 \overset{u\to 0}{\longrightarrow} N$ and $N_2 \overset{u\to 0}{\longrightarrow} 0$. In contrast, when the pump rate becomes much larger than the relaxation rates, $N_1, N_2 \overset{u\to\infty}{\longrightarrow} \frac{1}{2}$. This means that the absorption coefficient $\alpha = \sigma(N_1 - N_2)$ goes to zero, and the medium becomes completely transparent. The difference in the populations of the ground and excited states,

$$\Delta N = N \frac{A_{21}}{2B_{21} u(\omega) + A_{21}} = \frac{N}{1 + s(\omega)} \ , \tag{23.93}$$

can be expressed via a *saturation parameter*

$$s(\omega) \equiv \frac{2B_{12} u(\omega)}{A_{21}} \ , \tag{23.94}$$

which represents the ratio of pump rate to the relaxation rate. The pump rate due to a monochromatic wave with intensity $\bar{I}$ is obtained by comparing (23.85) with (23.89),

$$B_{12} u(\omega) = \frac{\sigma(\omega)\bar{I}}{\hbar\omega} \ . \tag{23.95}$$

We obtain for the saturation parameter,

$$s(\omega) = \frac{2\sigma(\omega)\bar{I}}{\hbar\omega A_{21}} \ . \tag{23.96}$$

According to (23.85) and (23.93) the power absorbed per unit volume on the transition by atoms with the populations $N_{1,2}$ in a radiation field with a broad spectral profile and spectral energy density $u(\omega)$ is,

$$P = \hbar\omega B_{12} u(\omega) \Delta N = \hbar\omega B_{12} u(\omega) \frac{N}{1 + s(\omega)} \ . \tag{23.97}$$

With (23.94) this can be written as,

$$P = \hbar\omega \frac{A_{21}}{2} \frac{N}{1 + s(\omega)^{-1}} \ . \tag{23.98}$$

Let us now remember that the absorption cross section (23.72) of a homogeneously broadened line is Lorentzian. This means that the saturation parameter (23.96) itself becomes Lorentzian. We can assume that the relaxation rate A_{21} is independent of ω within the frequency range of the line profile,

$$\boxed{s(\omega) = s(\omega_0) \frac{(\Gamma/2)^2}{\Delta^2 + (\Gamma/2)^2}} \ . \tag{23.99}$$

Substituting this into (23.98) yields the frequency dependence of the absorbed radiation power per unit frequency interval $d\omega$,

$$P = \hbar\omega \frac{A_{21} N}{2} \frac{s(\omega_0)(\Gamma/2)^2}{(\omega - \omega_0)^2 + (\Gamma/2)^2 [1 + s(\omega_0)]} = N \bar{I} \sigma(\omega_0) \frac{(\Gamma/2)^2}{\Delta^2 + (\gamma_{\rm sat}/2)^2} \ , \tag{23.100}$$

where we introduced the increased halfwidth of the Lorentzian profile,

$$\boxed{\gamma_{\rm sat} \equiv \Gamma \sqrt{1 + s(\omega_0)}} \ . \tag{23.101}$$

Apparently, the halfwidth of the saturation-broadened line increases with the resonant saturation parameter $s(\omega_0)$. If according to (23.94) the induced transition rate at resonance equals the total relaxation rate $A_{21}/2$, the resonant saturation parameter becomes $s(\omega_0) = 1$, which increases the linewidth by a factor $\sqrt{2}$, compared to the unsaturated linewidth Γ for weak radiation fields. Starting from (23.100) we can define a *saturated* absorption cross section,

$$\boxed{\sigma_{\rm sat}(\omega) = \sigma_{\rm sat}(\omega_0) \frac{(\gamma_{\rm sat}/2)^2}{\Delta^2 + (\gamma_{\rm sat}/2)^2} = \sigma(\omega_0) \frac{(\Gamma/2)^2}{\Delta^2 + (\gamma_{\rm sat}/2)^2} = \sigma(\omega) \frac{1}{1 + s(\omega)}} \ , \tag{23.102}$$

where the unsaturated absorption profile is,

$$\sigma(\omega) = \sigma(\omega_0) \frac{(\Gamma/2)^2}{\Delta^2 + (\Gamma/2)^2} \ . \tag{23.103}$$

This shows that the saturation decreases the absorption coefficient by the factor $1 + s(\omega)$. At the line center, this factor has its maximum value $1 + s(\omega_0)$, while it decreases to 1 for increasing $|\Delta|$, see (23.101), see Fig. 23.12. This is the reason why the line broadens.

From (23.96) we see, that unity saturation, $s(\omega_0) = 1$, corresponds to a light intensity of,

$$\bar{I}_{\text{sat}} \equiv \frac{\hbar\omega}{2\sigma(\omega_0)}\Gamma = \frac{2\pi^2 c\hbar}{3\lambda^3}\Gamma \ . \tag{23.104}$$

This intensity is called *saturation intensity*. Taking account of the degeneracies g_j of the levels the saturation intensity becomes [10],

$$\boxed{I_{\text{sat}} = \frac{g_1}{g_2}\frac{2\pi^2 c\hbar}{3\lambda_0^3}\Gamma} \ . \tag{23.105}$$

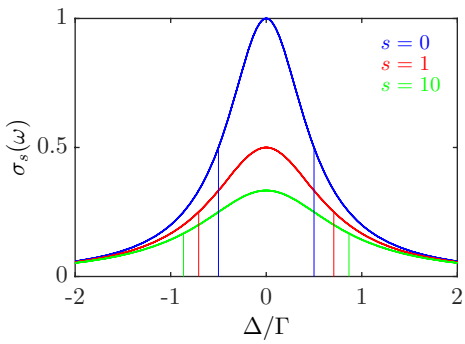

Figure 23.12: (code) Optical cross section for absorption at various saturation parameters. The reduction of absorption is understood by considerable depletion of the ground state at the profit of the excited state, $N_1, N_2 \overset{s\to\infty}{\longrightarrow} \frac{1}{2}$, in which case absorption is totally compensated by stimulated emission.

Finally, we anticipate that the resonant saturation parameter is basically a measure for the ratio between the stimulated population transfer rate, given by a quantity called *Rabi frequency* Ω, which will be thoroughly introduced in Secs. 27.4.3 and 39.3.2, and the spontaneous decay rate Γ,

$$s(\omega_0) = \frac{2\Omega^2}{\Gamma^2} \ . \tag{23.106}$$

We thus obtain the important relationship between laser intensity and Rabi frequency,

$$\boxed{\Omega^2 = \sigma(\omega_0)\frac{\bar{I}}{\hbar\omega_0}\Gamma} \ . \tag{23.107}$$

23.2.9 Exercises

23.2.9.1 Ex: Resistance of vacuum

Show that $\sqrt{\mu_0/\varepsilon_0}$ has the dimension of a resistance and the value of $376.7\,\Omega$.

[10] Some authors define the saturation for $s = 2$, as happens when $\Omega = \Gamma$.

23.2.9.2 Ex: The laws of Planck and Rayleigh-Jeans

Show that Planck's law reproduces the Rayleigh-Jeans law in the low-frequency limit.

23.2.9.3 Ex: The laws of Wien and Stefan-Boltzmann

a. Derive the parametrization of Planck's law in terms of frequency ν and wavelength λ.
b. Derive the law of *Stefan-Boltzmann* according to which the total power radiated per unit surface area of a black body across all wavelengths (also known as the blackbody radiant emittance) is given by σT^4, where $\sigma \equiv \pi^2 k_{\mathrm{B}}^4/60c^2\hbar^3$ is called the Stefan-Boltzmann constant.
c. Derive *Wien's displacement law* according to which the maximum emission of a blackbody spectrum occurs at $\lambda_{\max}T = 2.898\times10^{-3}\,\mathrm{Km}$ in the wavelength parametrization and $\nu_{\max}/T = 0.0588\,\mathrm{THz/K}$ in the frequency parametrization. Determine the frequency of the maximum emission for the 2.7 K background radiation of the universe.

23.2.9.4 Ex: Radiometric thermometry

Modern radiometric thermometers measure the blackbody radiation emitted by a hot body. Calculate the variation of the blackbody radiant emittance of a person having fever (40° instead of 37° body temperature). How much does the maximum emission wavelength change? In which spectral range should the thermometer be sensitive?

23.2.9.5 Ex: Photons in a resonator

a. The light power emitted by a laser ($\lambda = 633\,\mathrm{nm}$) be $P = 1\,\mathrm{nW}$. How many photons does the laser emit per second? How many photons of the emitted laser beam are in a mode volume of $L = 10\,\mathrm{cm}$ length?
b. How many photons on average are inside an optical cavity having the same mode volume at ambient temperature, when there is no incident light?

23.2.9.6 Ex: Number of modes in a cavity

a. How many modes do fit into a cubical box of 10 cm size for a frequency interval of 1000 Hz centered at a wavelength of 500 nm?
b. How many photons are in the box supposing it has a temperature of $T = 300\,\mathrm{K}$, respectively, $T = 6000\,\mathrm{K}$?

23.2.9.7 Ex: Number of photons emitted from lasers and blackbodies

a. Calculate the total number of photons per area per unit time emitted by a blackbody at temperature T.
b. The linewidth of a helium-neon laser is $\Delta\nu = 1000\,\mathrm{Hz}$. The operating wavelength is $\lambda = 632.8\,\mathrm{nm}$, the power is $P = 1\,\mathrm{mW}$, and the beam size $w_0 = 1\,\mathrm{mm}$. How many photons are emitted per second?

c. What would be the temperature of a blackbody radiator emitting the same number of photons from an equal area and over the same frequency interval as the laser?

23.2.9.8 Ex: Number of photons per radiation mode

Assume the isotropic emission of a pulsed flashlamp with spectral bandwidth $\Delta\lambda = 100\,\text{nm}$ around $\lambda = 400\,\text{nm}$ amounts to $P_0 = 100\,\text{W}$ peak power out of a volume of $1\,\text{cm}^3$. Calculate the spectral power density $u(\nu)$ and the spectral intensity $I(\nu)$ through a spherical surface $r = 2\,\text{cm}$ away from the center of the emitting sphere. How many photons per mode are contained in the radiation field?

23.2.9.9 Ex: Atoms in an optical cavity

a. Consider a closed optical cavity at $T = 600°\,\text{C}$. The cavity has the shape of a $L = 1\,\text{m}$-long and $d = 3\,\text{cm}$-diameter tube. Calculate the total energy of the blackbody radiation inside the cavity.
b. Inside the cavity there is a gas with strontium atoms (1 fundamental level and 3 degenerate excited levels, $\lambda = 461\,\text{nm}$). Using the expression (23.67), assuming thermal equilibrium, calculate the number of excited atoms for a partial pressure of the strontium gas of $10^{-3}\,\text{mbar}$.
c. Calculate the optical density for a laser in resonance with the transition traversing the cavity along the symmetry axis.

23.2.9.10 Ex: Sodium atoms in an optical cavity

A sodium atom is placed in a cavity of volume $V = 1\,\text{cm}^3$ with walls at the temperature T, producing a thermal radiation field with spectral energy density $u_P(\nu)$. At what temperature T are the spontaneous and induced transition probabilities equal
a. for the transition $3P \to 3S$ with the transition wavelength $\lambda = 589\,\text{nm}$ and the excited state lifetime $\tau_{3P} = 16\,\text{ns}$;
b. for the hyperfine transition $3S$ $(F = 3 \to F = 2)$ with the transition frequency $\nu = 1772\,\text{MHz}$ and the excited state lifetime $\tau_{3F} \simeq 1\,\text{s}$?

23.2.9.11 Ex: Applying the Lambert-Beer law

The beam of a monochromatic laser passes through an absorbing atomic vapor with path length $L = 5\,\text{cm}$. If the laser frequency is tuned to the center of an absorbing transition $|i\rangle \to |k\rangle$ with absorption cross section $\sigma_0 = 10^{-14}\,\text{cm}^2$, the attenuation of the transmitted intensity is 10%. Assuming low saturation calculate the atomic density n_i in the absorbing level $|i\rangle$.

23.3 Basic notions

As we have seen in the precedent section, the important message of quantum mechanics is that matter propagates as a wave and light, when localized, only changes its energy in discrete units. Once we understand (or at least accept) this fact, a large part of quantum mechanics follows just as a corollary. The idea expressed by de Brogie, that matter would be a wave led to the first quantization. Interestingly, the concept

of light underwent a reverse evolution. Classically described as a wave, it was divided by Planck and Einstein into quantized corpuscles, today called 'photons'.

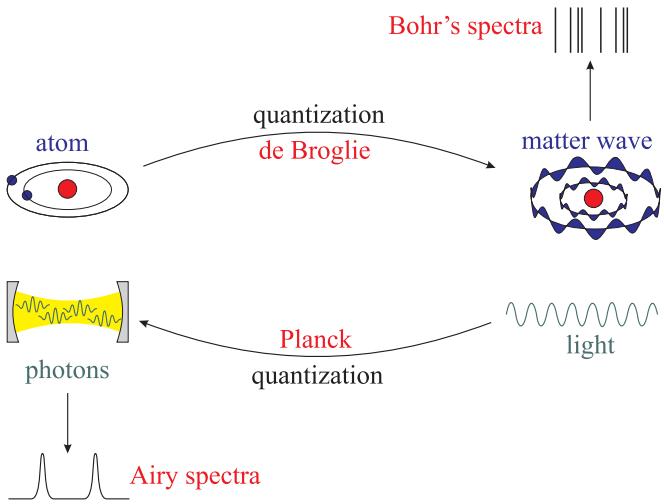

Figure 23.13: Illustration of particle-wave duality for matter and light.

In this chapter, we will introduce step by step the formalism of quantum mechanics by gradually increasing the degree of abstraction. Applications of the formalism will be shown in consecutive chapters (watch talk).

The aim of this section is to give 'feeling' for the new concepts introduced and used by quantum mechanics. We will first motivate the fundamental quantum equations of motion by linking them to classical dispersion relations and then spend some time to discuss the probabilistic concept proposed by Max Born.

23.3.1 Dispersion relation and Schrödinger equation

A fundamental problem in physics is the issue of the propagation of physical entities. On one hand, we have the light, whose propagation in the vacuum is described by the dispersion relation $\omega = ck$ or,

$$\omega^2 - c^2 k^2 = 0 \ . \tag{23.108}$$

Since light is a wave, in the most general form, assuming the validity of the superposition principle, it can be described by a wave packet, $A(\mathbf{r}, t) = \int e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega t)} a(\mathbf{k}) d^3k$. It is easy to verify that the *wave equation*,

$$\frac{\partial^2}{\partial t^2} A - c^2 \nabla^2 A = 0 \ , \tag{23.109}$$

reproduces the dispersion relation.

On the other hand, we have slow massive particles possessing kinetic energy,

$$E = \frac{p^2}{2m} \ . \tag{23.110}$$

With the hypothesis of de Broglie that even a massive particle has wave quality, we can try an *ansatz* [11] of a wave equation satisfying the dispersion relation (23.110). From Planck's formula, $E = \hbar\omega$, and the formula of *Louis de Broglie*, $\mathbf{p} = \hbar\mathbf{k}$, describing the particle by a wave packet $\psi(\mathbf{r}, t) = \int e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)}\varphi(\mathbf{k})d^3k$ not subject to external forces, it is easy to verify that the equation,

$$\imath\hbar\frac{\partial}{\partial t}\psi = \left(-\frac{\hbar^2}{2m}\nabla^2\right)\psi \ , \tag{23.111}$$

reproduces the dispersion relation. If the particle is subject to a potential, its total energy is $E = \mathbf{p}^2/2m + V(\mathbf{r}, t)$. This dispersion relation corresponds to the famous *Schrödinger equation*,

$$\imath\hbar\frac{\partial}{\partial t}\psi = \left(-\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{r}, t)\right)\psi \ . \tag{23.112}$$

23.3.2 Relativistic particle waves

Despite the similarities between light particles and material particles, there are notable differences: The photon is a relativistic particle with no rest mass. How can we establish a relationship between such different objects?

To clarify this relationship we now consider particles that are similar to light in the sense that they have high velocities, that is, relativistic particles. From the relativistic principle of the equivalence of mass and energy, we obtain for a massive particle $E^2 = m^2c^4 + c^2p^2$ or,

$$\omega^2 - c^2k^2 = \frac{m^2c^4}{\hbar^2} \ . \tag{23.113}$$

This dispersion relation can be obtained from the differential equation,

$$\frac{\partial^2}{\partial t^2}A - c^2\nabla^2 A = -\frac{m^2c^4}{\hbar^2}A \ , \tag{23.114}$$

inserting, for example, the already proposed wave packet $A(\mathbf{r}, t) = \int e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)}a(\mathbf{k})d^3k$, supposed not to be subject to external forces. The equation (23.114) is a wave equation called *Klein-Gordon equation*. For particles without rest mass, as in the case of photons, the equation is reduced to the wave equation of light (23.109).

Now, making the transition to non-relativistic velocities, $v \ll c$, we can expand the dispersion relation,

$$E = \sqrt{m^2c^4 + c^2m^2v^2} = mc^2\left(1 + \frac{v^2}{2c^2} + ..\right) \qquad \text{or} \qquad \hbar\omega \simeq mc^2 + \frac{\hbar^2k^2}{2m} \ . \tag{23.115}$$

In analogy with the Klein-Gordon equation we can derive the approximate dispersion relation (23.115) from a wave equation,

$$\imath\hbar\frac{\partial}{\partial t}A = \left(mc^2 - \frac{\hbar^2}{2m}\nabla^2\right)A \ . \tag{23.116}$$

[11] Trial, working hypothesis.

With the transformation $\psi = e^{-\imath mc^2 t/\hbar} A$, we rediscover the Schrödinger equation (23.111),

$$\imath\hbar \frac{\partial}{\partial t}\psi = -\frac{\hbar^2}{2m}\nabla^2\psi \tag{23.117}$$

as the non-relativistic limit of the Klein-Gordon equation.

It is interesting to note that in all cases discussed, obviously the dispersion relations and the differential equations can be interconverted by the substitutions,

$$E \longrightarrow \imath\hbar\frac{\partial}{\partial t} \qquad \text{and} \qquad \mathbf{p} \longrightarrow -\imath\hbar\nabla\ . \tag{23.118}$$

We will discuss this later in the context of Ehrenfest's theorem in Secs. 23.3.6, 23.3.7, and 23.6.6.

Example 182 (*Demystifying Quantum Mechanics 1.0*): The essence of quantum mechanics can be boiled down to the particle-wave duality. That is the fact that the building blocks of matter must be considered as de Broglie waves. Once this fact is understood and assimilated, quantum mechanics loses much of its mystery. For example delocalization of an atom, that is, the fact that it can be at two locations at the same time irritates us only as long as we try to imagine it as an indivisible solid block. In contrast we are not surprised to encounter the same ocean wave or tsunami in different continents.

The misconception is already rooted in the statement that *a quantum particle can be simultaneously in two places*. What we really mean when we say a particle is delocalized is, that the way it is embedded in space-time (which is the frame in which we can (or cannot) attribute locations and velocities to it) resembles a wave, and that the way this wave evolves or propagates in space is wave-like and described by a Schrödinger equation. Note that position-velocity is just one property that a particle can have. Spin is another one, and the appropriate space in which a spin is embedded is not necessarily position space, but can be an abstract configuration space. An atom can have an internal structure, whose dynamics is totally independent of how the atom moves as a whole. Thus, a particle IS not a wave, but PROPAGATES like one in space-time. Still, its evolution will follow a Schrödinger-type equation.

At first the Schrödinger equation seems weird, because it is complex and thus rules the behavior of an unphysical quantity, the wave function. But we should keep in mind the Schrödinger equation is the non-relativistic approximation of the Klein-Gordon equation, which resembles much more a classical wave equation, and applies also to particles propagating at velocities nearly as fast as light. With regard to these facts, a terminology that suits much better the features of quantum mechanics is simply wave mechanics, how Schrödinger termed it. This terminology also has the advantage of avoiding confusion with light wave effects erroneously attributed to quantum mechanics, such as light tunneling which is totally understood within Maxwell's theory.

We must however be aware that the simple wave picture is not sufficient to understand all of quantum mechanics. As we will see in the next sections, it is necessary to complement wave mechanics with a measurement theory, and phenomena genuine to what today is called Quantum Mechanics 2.0, in particular, entanglement are difficult to understand in wave mechanics.

23.3.3 Born's interpretation

The first part of this script is devoted to *individual particles* or systems of distinguishable *massive particles*, and we will only turn our attention to *light* and *indistinguishable particles* when discussing the (second) *quantization of fields*.

According to our current conviction, the complete reality (neglecting relativistic effects) on any system is contained in the Schrödinger equation (23.112). That statement does not make us smarter without having to explain the meaning of the *wavefunction* ψ. In an attempt to marry the concepts of particles and waves, *Max Born* proposed in 1926 the interpretation of the quantity

$$\int_V |\psi(\mathbf{r},t)|^2 d^3r \tag{23.119}$$

as probability of finding the particle inside the volume V.

If $|\psi(\mathbf{r},t)|^2$ has the meaning of a *probability density* or *probability distribution*, the square of the wavefunction must be integrable,

$$\|\psi(\mathbf{r},t)\|^2 \equiv \int_{\mathbb{R}^3} |\psi(\mathbf{r},t)|^2 d^3r < \infty \ . \tag{23.120}$$

This allows us to proceed to a *normalization* of the wave function,

$$\tilde{\psi}(\mathbf{r},t) \equiv \frac{\psi(\mathbf{r},t)}{\sqrt{\int_{\mathbb{R}^3} |\psi(\mathbf{r},t)|^2 d^3r}} \ , \tag{23.121}$$

such that $\|\tilde{\psi}(\mathbf{r},t)\| = 1$.

23.3.4 Continuity equation

In quantum mechanics we associate the wavefunction that describes a quantum system to a *probability wave*. As the Schrödinger equation describes a time evolution, in order to be useful, the wavefunction must allow for probability flows. We define the probability density and the probability flow by,

$$\begin{aligned} \rho(\mathbf{r},t) &\equiv \psi^*(\mathbf{r},t)\psi(\mathbf{r},t) \ , \\ \mathbf{j}(\mathbf{r},t) &\equiv \frac{\hbar}{2m\imath}\left[\psi^*(\mathbf{r},t)\nabla\psi(\mathbf{r},t) - \psi(\mathbf{r},t)\nabla\psi^*(\mathbf{r},t)\right] \ . \end{aligned} \tag{23.122}$$

Starting from the Schrödinger equation we can easily derive the *continuity equation* (see Exc. 23.3.8.1),

$$\dot{\rho}(\mathbf{r},t) + \nabla\cdot\mathbf{j}(\mathbf{r},t) = 0 \ , \tag{23.123}$$

or in the integral form,

$$-\frac{d}{dt}\int_V \rho d^3r = \int_V \nabla\cdot\mathbf{j} d^3r = \oint_{\partial V} \mathbf{j}\cdot d\mathbf{S} \ , \tag{23.124}$$

using Gauß' law. With $I \equiv \int_{\mathrm{S}} \mathbf{j}\cdot d\mathbf{S}$, the *probability current* which flows through the surface S delimiting the *probability charge* $Q \equiv \int_V \rho(\mathbf{r},t)d^3r$, we obtain,

$$-\dot{Q} = I \ . \tag{23.125}$$

The continuity equation is obviously similar to that of electromagnetism.

23.3.5 Distributions in space and time

So far we only spoke of spatial distributions, $\psi(\mathbf{r},t)$. But we could also consider velocity or moment distributions. In classical mechanics, a particle has a well-defined position and velocity. Knowing the position and velocity, Newton's equations allow predicting its coordinates at future times. Let us now investigate whether the Schrödinger equation allows this as well.

In the absence of an external potential the most general solution of the Schrödinger equation can be written as a superposition of plane waves $e^{\imath(\mathbf{r}\cdot\mathbf{k}-\omega t)}$ with frequencies $\omega = \mathbf{p}^2/2\hbar m$ and wave vectors $\mathbf{k} = \mathbf{p}/\hbar$. Each plane wave has an individual amplitude $\varphi(\mathbf{p})$, such that,

$$\psi(\mathbf{r},t) = \tfrac{1}{h^{3/2}}\int d^3p\varphi(\mathbf{p})e^{\imath(\mathbf{r}\cdot\mathbf{k}-\omega t)} = \int d^3p\tfrac{1}{h^{3/2}}\varphi(\mathbf{p})e^{\imath(\mathbf{r}\cdot\mathbf{p}/\hbar-\mathbf{p}^2t/2m\hbar)} \ , \tag{23.126}$$

with $h \equiv 2\pi\hbar$. At time $t = 0$, this expansion is nothing more than a Fourier transform,

$$\psi(\mathbf{r},0) = \tfrac{1}{h^{3/2}}\int d^3p\varphi(\mathbf{p})e^{\imath\mathbf{r}\cdot\mathbf{k}} \ , \tag{23.127}$$

that we can reverse,

$$\varphi(\mathbf{p}) = \tfrac{1}{h^{3/2}}\int d^3r\psi(\mathbf{r},0)e^{-\imath\mathbf{r}\cdot\mathbf{k}} \ . \tag{23.128}$$

In the absence of forces the momentum distribution becomes stationary. We can now use the momentum distribution $\varphi(\mathbf{p})$ as coefficients of the expansion of the temporal wavefunction $\psi(\mathbf{r},t)$, as shown above. Thus, the expansion represents a general solution of the Schrödinger equation. The magnitude $|\varphi(\mathbf{p})|^2$ is the probability density in *momentum space*.

Example 183 (*Normalization of the wave function in momentum space*): It is easy to show that the probability density in momentum space is also normalized:

$$\begin{aligned}\int|\varphi(\mathbf{p})|^2d^3p &= \tfrac{1}{h^3}\int d^3p\int d^3r\psi^*(\mathbf{r})e^{\imath\mathbf{r}\cdot\mathbf{k}}\int d^3r'\psi(\mathbf{r}')e^{-\imath\mathbf{r}'\cdot\mathbf{k}}\\ &= \int d^3r\int d^3r'\psi^*(\mathbf{r})\psi(\mathbf{r}')\tfrac{1}{(2\pi)^3}\int d^3ke^{\imath\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')}\\ &= \int d^3r\int d^3r'\psi^*(\mathbf{r})\psi(\mathbf{r}')\delta^3(\mathbf{r}-\mathbf{r}') = \int|\psi(\mathbf{r})|^2d^3r = 1 \ ,\end{aligned}$$

knowing that the Fourier transform of a plane wave is nothing more than the Dirac distribution.

Since the probability distributions $|\psi(\mathbf{r})|^2$ and $|\varphi(\mathbf{p})|^2$ are interconnected by Fourier transform, we already know that we can not localize [12] both simultaneously. If one is well localized, the other is necessarily delocalized. Do the Exc. 23.3.8.2.

[12] Localize: Restrict the distribution volume indefinitely.

23.3.6 Eigenvalues

We have already seen that the position and momentum distributions of a particle are spread. We calculate the mean values of these distributions, denoted by $\langle \mathbf{r} \rangle$ and $\langle \mathbf{p} \rangle$, as *first moments* of the respective distributions:

$$\langle \mathbf{r} \rangle = \int d^3r |\psi(\mathbf{r},t)|^2 \mathbf{r} \qquad \text{and} \qquad \langle \mathbf{p} \rangle = \int d^3p |\varphi(\mathbf{p},t)|^2 \mathbf{p} \ . \tag{23.129}$$

Using the expansions (23.126) and (23.127), we can calculate,

$$\begin{aligned}
\langle \mathbf{p} \rangle = \int \varphi^*(\mathbf{p}) \mathbf{p} \varphi(\mathbf{p}) d^3p &= \int \tfrac{1}{h^{3/2}} \int \psi^*(\mathbf{r}) e^{\imath \mathbf{k}\cdot\mathbf{r}} d^3r \mathbf{p} \varphi(\mathbf{p}) d^3p \\
&= \tfrac{1}{h^{3/2}} \int \psi^*(\mathbf{r}) \int \varphi(\mathbf{p}) \mathbf{p} e^{\imath \mathbf{k}\cdot\mathbf{r}} d^3p d^3r \\
&= \tfrac{1}{h^{3/2}} \int \psi^*(\mathbf{r}) \tfrac{\hbar}{\imath} \nabla \int \varphi(\mathbf{p}) e^{\imath \mathbf{k}\cdot\mathbf{r}} d^3p d^3r = \int \psi^*(\mathbf{r}) \tfrac{\hbar}{\imath} \nabla \psi(\mathbf{r}) d^3r \ .
\end{aligned}$$

This calculation shows that the expectation value, called *eigenvalue*, of the momentum can be expressed through an operator $\hat{p} \equiv (\hbar/\imath)\nabla$ acting on the wavefunction [13,14].

More generally, we can compute the eigenvalue of a function in $\mathbf{r}$ and $\mathbf{p}$ via,

$$\langle f(\hat{\mathbf{r}}, \hat{\mathbf{p}}) \rangle = \int d^3r \psi^*(\mathbf{r}) f(\mathbf{r}, \hat{\mathbf{p}}) \psi(\mathbf{r}) \ . \tag{23.130}$$

However, it is important to note that the operators $\hat{\mathbf{r}}$ and $\hat{\mathbf{p}}$ do not necessarily commute.

Example 184 (*Non-commutation of space and momentum*): Considering a one-dimensional motion, we verify,

$$\hat{p}_x x \psi = \frac{\hbar}{\imath} \frac{d}{dx} x \psi = \frac{\hbar}{\imath} \psi + x \frac{\hbar}{\imath} \frac{d}{dx} \psi \neq x \frac{\hbar}{\imath} \frac{d}{dx} \psi = x \hat{p}_x \psi \ .$$

23.3.7 Temporal evolution of eigenvalues

We now consider the temporal evolution of the position of a particle. We will use in the following the partial integration rule $\int_V \psi \nabla \xi = \oint_{\partial V} \psi \xi - \int_V \nabla \psi \xi = -\int_V (\nabla \psi) \xi$, assuming that at least one of the functions, ψ or ξ, disappears at the edge of the volume, which can be guaranteed by choosing the volume large enough. To begin with, we will concentrate on the x-component of the position, the time derivative of which is computed using the continuity equation (23.123),

$$\frac{d}{dt} \langle \hat{x} \rangle = \int d^3r \frac{d}{dt} |\psi|^2 x = -\int d^3r \ x \nabla \cdot \mathbf{j} = -\cancelto{0}{\int d\mathbf{S} \cdot \mathbf{j} \, x} + \int d^3r \ \mathbf{j} \cdot \nabla x = \int d^3r \ \mathbf{j}_x \ , \tag{23.131}$$

[13] From now on, the hat over a physical magnitude will denote quantum operators.

[14] We note here that the rules $\langle \psi | \hat{x} | \psi \rangle \leftrightarrow \langle \phi | - \frac{\hbar}{\imath} \nabla_p | \phi \rangle$ and $\langle \psi | \frac{\hbar}{\imath} \nabla_{\mathbf{r}} | \psi \rangle \leftrightarrow \langle \phi | \hat{p} | \phi \rangle$ from the Fourier transformation are useful for numerical simulations of the Schrödinger equation: Instead of calculating the spatial derivative $\left(\frac{\hbar}{\imath} \nabla \right)^2$ of the wavefunction, one makes a Fast Fourier Transform (FFT) to momentum space, multiplies with $\mathbf{p}$, and transforms back.

Generalizing to three dimensions, we can write,

$$\frac{d}{dt}\langle m\hat{\mathbf{r}}\rangle = m\int d^3r\ \mathbf{j} = m\int d^3r\frac{\hbar}{2mi}[\psi^*\nabla\psi - \psi\nabla\psi^*] \tag{23.132}$$
$$= \tfrac{1}{2}\int d^3r[\psi^*\hat{\mathbf{p}}\psi + \psi\hat{\mathbf{p}}\psi^*] = \int d^3r\psi^*\hat{\mathbf{p}}\psi = \langle\hat{\mathbf{p}}\rangle\ ,$$

since the eigenvalue of $\hat{\mathbf{p}}$ is a real quantity.

Now, we define the abbreviation:

$$\hat{H} \equiv -\frac{\hbar^2}{2m}\nabla^2 + V(\hat{\mathbf{r}},t)\ , \tag{23.133}$$

called the *Hamilton operator* or *Hamiltonian* and we calculate the second derivative of the position using the Schrödinger equation (23.112),

$$\frac{d}{dt}\langle\hat{\mathbf{p}}\rangle = \int d^3r\left[\left(\tfrac{1}{i\hbar}\hat{H}\psi\right)^*\hat{\mathbf{p}}\psi + \psi^*\hat{\mathbf{p}}\tfrac{1}{i\hbar}\hat{H}\psi\right] = \tfrac{i}{\hbar}\int d^3r\ \psi^*(\hat{H}\hat{\mathbf{p}} - \hat{\mathbf{p}}\hat{H})\psi = \tfrac{i}{\hbar}\langle[\hat{H},\hat{\mathbf{p}}]\rangle\ , \tag{23.134}$$

introducing the *commutator* $[\hat{a},\hat{b}] \equiv \hat{a}\hat{b} - \hat{b}\hat{a}$ as an abbreviation. After that,

$$\tfrac{i}{\hbar}\langle[\hat{H},\hat{\mathbf{p}}]\rangle = \tfrac{i}{\hbar}\langle[\hat{V},\hat{\mathbf{p}}]\rangle = \tfrac{i}{\hbar}\int d^3r\psi^*\left[\hat{V}\tfrac{\hbar}{i}\nabla\psi - \tfrac{\hbar}{i}\nabla(V\psi)\right] = -\int d^3r\psi^*\psi\nabla V = \langle\hat{\mathbf{F}}\rangle\ . \tag{23.135}$$

In summary, we found a law,

$$\langle\hat{\mathbf{F}}\rangle = \frac{d^2}{dt^2}\langle m\hat{\mathbf{r}}\rangle\ , \tag{23.136}$$

much like *Newton's law*, but instead of applying to localized particles, the law applies to the eigenvalues of probability distributions. Similar laws can be derived for angular momentum and energy conservation.

The observation made by *Paul Ehrenfest*, that in quantum mechanics the mean values follow the same laws of classical mechanics, is called *Ehrenfest theorem*.

23.3.8 Exercises

23.3.8.1 Ex: Conservation of probability

Demonstrate the conservation of local probability through the definitions of probability densities, $\rho(\mathbf{r},t)$, and probability current $\mathbf{j}(\mathbf{r},t)$.

23.3.8.2 Ex: Fourier theorem

The spatial distribution of a particle is given by a Gaussian function with the width Δx. Calculate the momentum distribution and its width Δp. Just consider one spatial dimension. Show that $\Delta x\Delta p = \hbar$ using the *rms* definition for the widths.

23.4 Postulates of quantum mechanics

In this section we will introduce the fundamentals and main methods of quantum mechanics. We will learn what are observables and get to know the postulates which establish the foundation of quantum mechanics, as well as Heisenberg's famous principle of uncertainty.

23.4.1 Superposition principle (1. postulate)

A physical system can be found in several states. For example, a particle may be at rest or in motion, an atom may be excited or deexcited. In quantum mechanics, every possible state is described by a *wavefunction* ψ. Wavefunctions can be functions of various types of coordinates, for example, of position $\psi = \psi(\mathbf{r})$, of momentum $\psi = \psi(\mathbf{p})$, or of energy $\psi = \psi(E)$. The choice of the coordinates is called *representation*.

One peculiarity of quantum systems is that they may be in a *superposition of states*. That is, if $\psi_1, \psi_2, ..., \psi_k$ are possible states with amplitudes c_k, automatically the functions,

$$\psi = \sum_k c_k \psi_k \qquad \text{or} \qquad \psi = \int dk\ c(k)\phi(k) \tag{23.137}$$

are possible states as well. This is called *superposition principle*, and means, for example, that a particle may be *simultaneously* in several places or that an atom may be *at the same time* excited and deexcited.

There are systems that can only exist in a *restricted number* of states, such as the two-level atom. Others may exist in an *infinite number* of states or even in a *continuous distribution* of states.

23.4.2 Interpretation of the wavefunction (2. postulate)

A *state function* (or wavefunction) characterizes a system of which we may calculate various properties. The function can adopt complex values devoid of immediate physical interpretation. In fact, the wavefunction is above all a mathematical construct. On the other hand, the norm $|\psi|^2$ has the meaning of a probability of the system to be in the state ψ. This is the famous interpretation of *Max Born* of the wave function (see Sec. 23.3.3).

If ψ_k with $k = 1, 2, \ldots$ are all possible states of a system, the interpretation as a probability requires,

$$\sum_k |\psi_k|^2 = 1\ . \tag{23.138}$$

Analogically, for a continuous distribution, for example, in spatial representation,

$$\int_{-\infty}^{\infty} |\psi(x)|^2 dx = 1\ . \tag{23.139}$$

That is, the probability needs *normalization*.

23.4.3 Dirac bra-ket notation and vector representation

In order to distinguish more easily the amplitudes (which are complex numbers) and the wavefunctions we will now use the Bra-Ket notation introduced by *Paul Dirac*. The functions are represented by *kets*,

$$|\psi\rangle = \sum_k c_k |k\rangle\ . \tag{23.140}$$

The complex transpositions of these states are represented by *bras*,

$$\langle\psi| = |\psi\rangle^\dagger = \sum_k c_k^* \langle k| \ . \tag{23.141}$$

But the notation has other advantages. For example, let us suppose that we know the three possible states of a system, $|1\rangle$, $|2\rangle$, and $|3\rangle$, which are linearly independent. Then we can define the states as vectors:

$$|1\rangle = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \quad , \quad |2\rangle = \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} \quad , \quad |3\rangle = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} \ . \tag{23.142}$$

These three states can be interpreted as the basis of a *vector space* representing the system. Now, each wavefunction can be expanded on this basis and expressed by a vector. An arbitrary ket state of this system will then be,

$$|\psi\rangle = \begin{pmatrix} c_1 \\ c_2 \\ c_3 \end{pmatrix} \ . \tag{23.143}$$

The corresponding bra state will be,

$$\langle\psi| = \begin{pmatrix} c_1^* & c_2^* & c_3^* \end{pmatrix} \ . \tag{23.144}$$

Now we can easily calculate the probability for a system to be in a state $|\psi\rangle$,

$$||\psi\rangle|^2 = \langle\psi|\psi\rangle = \begin{pmatrix} c_1^* & c_2^* & c_3^* \end{pmatrix} \cdot \begin{pmatrix} c_1 \\ c_2 \\ c_3 \end{pmatrix} = |c_1|^2 + |c_2|^2 + |c_3|^2 \ . \tag{23.145}$$

23.4.4 Observables (3. postulate)

The only way to get information about a system is to *measure* the values of characteristic quantities of the system, e.g. energy or linear momentum. In classical mechanics we have learned that a system can be completely characterized by a set of measurable physical quantities. For example, the motion of a rigid body of mass m and inertial moment $\mathbf{I}$ is defined by its position $\mathbf{r}$, its moment $\mathbf{p}$, and its angular momentum $\mathbf{L}$. In quantum mechanics we describe observable physical quantities by *operators* acting on the *Hilbert space* of wavefunctions, $|\psi\rangle \mapsto \hat{\mathbf{p}}|\psi\rangle$, where $\hat{p}$ would be the operator of the linear momentum. To better distinguish the observables, we decorate their symbols with a hat. We will see more ahead (see Sec. 23.5.5) that every quantum system is completely described by a complete set of observables.

To find the current values a_ψ of any *observable* $\hat{A}$ in a specific situation given by a wave function ψ, we need to solve an equation of eigenvalues,

$$\hat{A}|\psi\rangle = a_\psi|\psi\rangle \ . \tag{23.146}$$

We can rewrite the equation as $a_\psi = \langle\psi|\hat{A}|\psi\rangle$. The values a_n are real numbers, if the observable is a *Hermitian operator*, that is,

$$\hat{A} = \hat{A}^\dagger \quad \Longrightarrow \quad a_\psi = a_\psi^* \ . \tag{23.147}$$

We leave proof of this for the Exc. 23.4.9.1.

Thus, we postulate the substitution of the *dynamic variables* characterizing a classical system by abstract objects called operators. These operators can be understood as mathematical prescriptions, e.g., differential operators acting on a state of the system. The expectation value of any operator $\hat{A}$ characterizing a system in a state $|\psi\rangle$ is $a_\psi \equiv \langle\hat{A}\rangle_\psi \equiv \langle\psi|\hat{A}|\psi\rangle/\langle\psi|\psi\rangle$. Such operators are specific for a system, but independent of its state. The dynamical variables for a specific state are obtained as eigenvalues of the respective variable in that specific state. The temporal evolution of the operators or of the states is governed by equations of motion (see Sec. 23.6) [15].

23.4.5 Representation of operators as matrices

In the same way as we already represented wavefunctions by vectors, we can also represent operators by matrices,

$$\hat{A} \equiv \sum_{i,j} |i\rangle a_{ij} \langle j| = \begin{pmatrix} & \vdots & \\ .. & a_{ij} & .. \\ & \vdots & \end{pmatrix} = \begin{pmatrix} & \vdots & \\ .. & \langle j|\hat{A}|i\rangle & .. \\ & \vdots & \end{pmatrix} . \tag{23.148}$$

To extract components from a matrix we do, $\langle i|\hat{A}|j\rangle$, for example,

$$\langle 1|\hat{A}|1\rangle = \begin{pmatrix} 1 & 0 & .. \end{pmatrix} \cdot \hat{A} \cdot \begin{pmatrix} 1 \\ 0 \\ \vdots \end{pmatrix} = a_{11} . \tag{23.149}$$

Projectors are particular operators defined by,

$$\hat{P}_k \equiv |k\rangle\langle k| = \begin{pmatrix} 0 & \vdots & 0 \\ .. & 1 & .. \\ 0 & \vdots & 0 \end{pmatrix} . \tag{23.150}$$

The eigenvalue of a projector, $\langle\hat{P}_k\rangle = \langle\psi|\hat{P}_k|\psi\rangle = |\langle k|\psi\rangle|^2$, is nothing more than the probability of finding a system, whose general state is $|\psi\rangle$, in the particular state, since expanding as done in (23.140), we have,

$$\langle\hat{P}_k\rangle = \sum_{m,n} c_m^* c_n \langle m|k\rangle\langle k|n\rangle = |c_k|^2 . \tag{23.151}$$

Using the matrix formalism we can define other interesting operators and verify their properties. For example, choosing the basis,

$$|1\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad , \quad |2\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} , \tag{23.152}$$

we find,

$$\begin{aligned} |1\rangle\langle 1| &= \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad , \quad |2\rangle\langle 2| = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \\ |1\rangle\langle 2| &= \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \quad , \quad |2\rangle\langle 1| = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \end{aligned} . \tag{23.153}$$

[15] Note that there are theoretical attempts to generalize the concept of observables to non-Hermitian operators [74, 75] only displaying $\mathcal{PT}$-symmetry.

Obviously, these matrices can be used to expand any 2×2 matrix. An equivalent set of matrices are the *Pauli spin matrices*,

$$\boxed{\mathbb{I} \equiv \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad , \quad \hat{\sigma}_x \equiv \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad , \quad \hat{\sigma}_y \equiv \begin{pmatrix} 0 & \imath \\ -\imath & 0 \end{pmatrix} \quad , \quad \hat{\sigma}_z \equiv \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}} \, . \tag{23.154}$$

An important property of the Pauli matrices is their behavior under commutation and anti-commutation,

$$\begin{aligned} [\hat{\sigma}_k, \hat{\sigma}_m]_- &\equiv \hat{\sigma}_k \hat{\sigma}_m - \hat{\sigma}_k \hat{\sigma}_m = 2\imath \epsilon_{kmn} \hat{\sigma}_n \\ [\hat{\sigma}_k, \hat{\sigma}_m]_+ &\equiv \hat{\sigma}_k \hat{\sigma}_m + \hat{\sigma}_k \hat{\sigma}_m = 2\delta_{km} \ , \end{aligned} \tag{23.155}$$

with $x, y, x = m, n$.

Defining so-called ladder operators or rising, respectively, lowering operators, depending on the arrangement of the level system via,

$$\boxed{\hat{\sigma}^{\pm} = \tfrac{1}{2}(\hat{\sigma}_x \pm \imath \hat{\sigma}_y)} \, , \tag{23.156}$$

we may represent the matrices as,

$$\begin{aligned} |1\rangle\langle 1| &= \tfrac{1}{2}(\mathbb{I}_2 - \hat{\sigma}_z) = \hat{\sigma}^- \hat{\sigma}^+ \quad , \quad |2\rangle\langle 2| = \tfrac{1}{2}(\mathbb{I}_2 + \hat{\sigma}_z) = \hat{\sigma}^+ \hat{\sigma}^- \\ |2\rangle\langle 1| &= \tfrac{1}{2}(\hat{\sigma}_x + \imath \hat{\sigma}_y) = \hat{\sigma}^+ \quad , \quad |1\rangle\langle 2| = \tfrac{1}{2}(\hat{\sigma}_x - \imath \hat{\sigma}_y) = \hat{\sigma}^- \end{aligned} \ , \tag{23.157}$$

and write down the *Pauli vector* [16],

$$\hat{\vec{\sigma}} \equiv \begin{pmatrix} \hat{\sigma}_x \\ \hat{\sigma}_y \\ \hat{\sigma}_z \end{pmatrix} = \begin{pmatrix} \hat{\sigma}^- + \hat{\sigma}^+ \\ \imath(\hat{\sigma}^- - \hat{\sigma}^+) \\ [\hat{\sigma}^+, \hat{\sigma}^-] \end{pmatrix} \tag{23.158}$$

and the vector

$$\vec{\rho} \equiv \begin{pmatrix} \langle \hat{\sigma}_x \rangle \\ \langle \hat{\sigma}_y \rangle \\ \langle \hat{\sigma}_z \rangle \end{pmatrix} \ , \tag{23.159}$$

which is called *Bloch vector* [17,18]. The eigenvalue of the Bloch vector has a fixed length (see Exc. 23.4.9.2).

The representation of physical quantities by matrices is essential for the description of quantum superposition states.

[16] Note that other definitions of the Pauli matrices, e.g. $\hat{\sigma}_y \to -\hat{\sigma}_y$ and $\hat{\sigma}_z \to -\hat{\sigma}_z$ are also found in literature. They simply correspond to a change of basis $|1\rangle \leftrightarrow |2\rangle$.

[17] The Bloch vector is widely used in describing the interaction of a two-level system with a light field.

[18] Schrödinger invented the *wave mechanics* when he derived his wave equation from the dispersion relation for massive particles. Heisenberg invented a mechanics (detailed in later sections), which he called *mechanics of matrices*. Later, he showed the formal equivalence of both theories.

23.4.6 Correspondence principle (4. postulate)

Operators do not necessarily commute. We have already seen in Sec. 23.3.6, that in one dimension the position and the momentum operators do not commute. We can generalize to three dimensions via,

$$[\hat{p}_j, \hat{x}_k] = -\imath\hbar\delta_{jk} \qquad \text{and} \qquad [\hat{p}_j, \hat{p}_k] = 0 = [\hat{x}_j, \hat{x}_k] \ , \tag{23.160}$$

which is easily verified by replacing the operators with $\hat{x}_k = x_k$ and $\hat{p}_k = \frac{\hbar}{\imath}\nabla$ and allowing the commutators to act on a wavefunction $\psi(x)$.

Conversely, quantum mechanics follows from classical mechanics with the prescription, $A(q_k, p_k, t) \longrightarrow A(\hat{q}_k, \hat{p}_k, t) = \hat{A}$. Letting the smallest amount of energy possible go to zero, $\hbar \longrightarrow 0$, the commutator disappears and, as we will see later, discrete energy spectra become continuous, quantum noise disappears, and we recover classical mechanics.

23.4.7 Schrödinger equation and quantum measurements (5. postulate)

The time evolution is given by the Schrödinger equation,

$$\boxed{\imath\hbar\frac{\partial}{\partial t}|\psi\rangle = \hat{H}|\psi\rangle} \ . \tag{23.161}$$

A closed system, disconnected from the rest of the world (we will now call the rest of the world *reservoir*) is not subject to dissipation, i.e., it does not lose energy to the reservoir. Such a system is always described by a hermitian Hamiltonian. Unfortunately, this system also does not allow information leakage, that is, we can not measure the system. This is reflected in the fact that the Schrödinger equation does not allow to describe the process of a *quantum measurement*. This is because before the measurement, the system can be in several states or even in a superposition of states, while after the measurement we know exactly the state. This amounts to a reduction of entropy, which is not allowed in a closed system.

The famous *postulate* of *state reduction* or *projection of the wavefunction* formulated by *John von Neumann* describes the quantum measurement process as a sequence of two distinct steps [19]. In a first step, the measuring apparatus projects the measured operator $\hat{A}$ on an eigenvector basis. That is, if the measurement is compatible with the operator [20], we obtain a distribution of probability amplitudes of the results,

$$\hat{A} \quad \curvearrowright \quad \langle\hat{A}\rangle = \langle\psi|\hat{A}|\psi\rangle = \langle\psi|\hat{A}|\sum_k c_k|k\rangle = \sum_k a_k c_k \langle\psi|k\rangle = \sum_k a_k |c_k|^2 \ , \tag{23.162}$$

with $\langle\psi|\psi\rangle = \sum_k |a_k|^2 = 1$. Therefore, we can understand $|\langle k|\psi\rangle|^2$ as the probability of the system to be in the eigenstate $|k\rangle$. In other words, this first step of

[19] For simplicity, we only consider pure state, here.

[20] To understand the meaning of *compatible*, we must establish a more complete theory of measurement including the reservoir in the quantum description.

the measurement process removes in an irreversible manner all coherences from the observable,

$$\hat{A} \quad \curvearrowright \quad \sum_k |k\rangle\langle k|\hat{A}|k\rangle\langle k| \ . \tag{23.163}$$

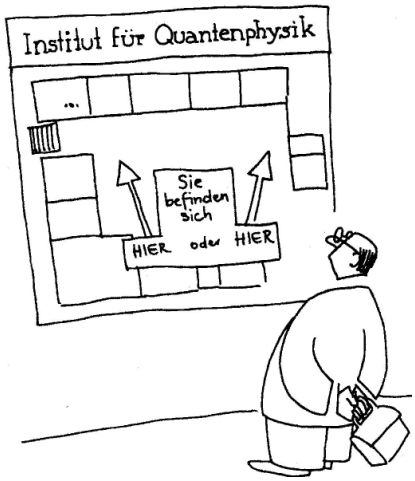

Figure 23.14: Superposition.

In a second step, the observing scientist will *read* the measuring device and note the result, which will necessarily be one of the possible a_k,

$$\langle\hat{A}\rangle \quad \curvearrowright \quad a_k \ . \tag{23.164}$$

If the state is stationary, it will never change any more. That is, each subsequent measurement will yield the same result. The Exc. 23.4.9.3 illustrates the process of quantum measurement at the example of a measurement of the excitation energy of a two-level atom.

23.4.8 Stationary Schrödinger equation

The general form of the Schrödinger equation in one dimension is,

$$\hat{H}\Psi(t,x) = \imath\hbar\frac{\partial}{\partial t}\Psi(t,x) \ , \tag{23.165}$$

with $\hat{H} \equiv \frac{\hat{p}^2}{2m} + V(x,t)$ and $\hat{p} \equiv -\imath\hbar\frac{\partial}{\partial x}$. If the potential is independent of time, $V(x,t) = V(x)$, we can do the following ansatz, $\Psi(x,t) \equiv \psi(x)f(t)$. Insertion into the Schrödinger equation yields,

$$\frac{1}{\psi(x)}\left(-\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + V(x)\right)\psi(x) = \frac{\imath\hbar}{f(t)}\frac{d}{dt}f(t) = const. \equiv E \ . \tag{23.166}$$

The solution of the right-hand side of the equation is $\imath\hbar(\ln f - \ln f_0) = E(t - t_0)$. Hence,

$$f(t) = f(0)e^{-\imath E(t-t_0)/\hbar} \ . \tag{23.167}$$

Obviously, $|\Psi(x,t)|^2 = |\psi(x)|^2$.

Now, we can see that the stationary Schrödinger equation,

$$\hat{H}\psi(x) = E\psi(x) \ , \tag{23.168}$$

is nothing more than an eigenvalue equation. This means that the Schrödinger wave mechanics is equivalent to the mechanics of the Heisenberg matrices. The Excs. 23.4.9.4 and 23.4.9.5 are first simple calculations of the eigenvalues and eigenvectors of a two-level system.

23.4.9 Exercises

23.4.9.1 Ex: Reality of eigenvalues

Show that the eigenvalues of an observable are real.

23.4.9.2 Ex: Normalization of the Bloch vector

Calculate the expectation value of the length of the Pauli vector and the length of the Bloch vector (23.156).

23.4.9.3 Ex: Quantum measurement

Explain the idea of quantum measurement at the example of a measurement of the excitation energy of a two-level atom.

23.4.9.4 Ex: Two-level atom

Consider a two-level atom. The Hamiltonian is given by,

$$\hat{H} = \begin{pmatrix} 0 & 0 \\ 0 & \hbar\omega_0 \end{pmatrix} \ .$$

Using the stationary Schrödinger equation, calculate the eigenvalues and eigenvectors.

23.4.9.5 Ex: The ammonium molecule

Consider the two states $|1\rangle$ and $|2\rangle$ of the ammonium molecule outlined in the figure. Suppose they are orthonormal, $\langle i|j\rangle = \delta_{ij}$, and that only these two states are accessible to the system, so that we can describe it using the basis formed by $|1\rangle$ and $|2\rangle$. On this basis the Hamiltonian $\hat{H}$ of the system is given by,

$$\hat{H} = \begin{pmatrix} E_0 & -E_1 \\ -E_1 & E_0 \end{pmatrix} \ .$$

a. If the system is initially in state $|1\rangle$, will it remain in that state at a later time? How about if the initial state is $|2\rangle$?

b. Obtain the eigenvalues E_{I} and E_{II} and the respective eigenvectors $|I\rangle$ and $|II\rangle$ of

$\hat{H}$, expressing them in terms of $|1\rangle$ and $|2\rangle$.
c. What is the probability of measuring an energy $E_{\rm I}$ in the following state,

$$|\psi\rangle = \tfrac{1}{\sqrt{5}}|1\rangle - \tfrac{2}{\sqrt{5}}|2\rangle \ ?$$

d. Based on the above result, we can predict at least one possible electromagnetic radiation emission frequency for an ammonia sample. What is this frequency?

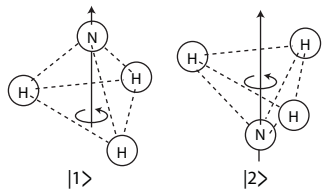

Figure 23.15: The two states of the ammonium molecule.

23.5 Abstract formalism of quantum mechanics

The formal development of quantum mechanics will be the subject of this section. We will learn how to find a complete set of observables characterizing a system, discuss the role of symmetries in quantum mechanics and show how to switch between several representations of the same system.

23.5.1 Lie algebra

The quantum mechanical operators form a *Lie algebra* $\mathcal{L}^2$. This means that $\mathcal{L}^2$ is at the same time a complex and linear *vector space* with respect to addition and scalar multiplication and a *non-commutative ring* with scalar internal product. In particular, $\mathcal{L}^2$ is unitary, normalized, and complete and acts on a *Hilbert space* of quantum states,

$$\begin{aligned}(\hat{A}+\hat{B})|\psi\rangle &= \hat{A}|\psi\rangle + \hat{B}|\psi\rangle, \\ (\alpha\hat{A})|\psi\rangle &= \alpha(\hat{A}|\psi\rangle)\ , \\ (\hat{A}\hat{B})|\psi\rangle &= \hat{A}(\hat{B}|\psi\rangle)\ .\end{aligned} \tag{23.169}$$

The properties of the Hilbert space are,

$$\begin{aligned}\hat{A}|\psi+\varphi\rangle &= \hat{A}|\psi\rangle + \hat{A}|\varphi\rangle\ , \\ \hat{A}|a\psi\rangle &= a\hat{A}|\psi\rangle\ .\end{aligned} \tag{23.170}$$

For a *Hermitian operator*, $\hat{A} = \hat{A}^\dagger$, we have $\langle\psi|\hat{A}|\psi\rangle = \langle\hat{A}\psi|\psi\rangle$ or $\langle\hat{A}\rangle \equiv \langle\psi|\hat{A}|\psi\rangle = \langle\hat{A}\rangle^*$, using the Dirac bra-ket notation,

$$\langle\psi|^\dagger \equiv |\psi\rangle\ . \tag{23.171}$$

There are identity and nullity operators,

$$\mathbb{I}|\psi\rangle = |\psi\rangle \qquad \text{and} \qquad \hat{0}|\psi\rangle = 0 \ . \tag{23.172}$$

We define the *(anti-)commutator* as,

$$[\hat{A}, \hat{B}]_{\mp} \equiv \hat{A}\hat{B} \pm \hat{B}\hat{A} \ , \tag{23.173}$$

which can be $\neq 0$. The sum of two Hermitian operators is Hermitian, but the product is not, since,

$$(\hat{A} + \hat{B})^\dagger = \hat{A}^\dagger + \hat{B}^\dagger = \hat{A} + \hat{B} \qquad \text{but} \qquad (\hat{A}\hat{B})^\dagger = \hat{B}^\dagger\hat{A}^\dagger = \hat{B}\hat{A} \neq \hat{A}\hat{B} \ . \tag{23.174}$$

On the other hand, the following relations of Hermitian operators are always Hermitian,

$$\hat{A}\hat{B} + \hat{B}\hat{A} \qquad \text{and} \qquad \imath(\hat{A}\hat{B} - \hat{B}\hat{A}) \ . \tag{23.175}$$

We define the *scalar product* as,

$$\langle\psi|\varphi\rangle \ . \tag{23.176}$$

Two states are called *orthogonal*, if $\langle\psi|\varphi\rangle = 0$. The norm is written as,

$$|\psi|^2 = \langle\psi|\psi\rangle \ , \tag{23.177}$$

the deviation is,

$$\Delta A \equiv \sqrt{\langle\hat{A}^2\rangle - \langle\hat{A}\rangle^2} \ . \tag{23.178}$$

A *unitary operator* is defined by,

$$\hat{A}^{-1} = \hat{A}^\dagger \ . \tag{23.179}$$

23.5.2 Complete bases

If it is impossible to find a set of amplitudes c_n,

$$\nexists\{c_n\} \quad \text{such that} \quad \sum_n c_n|n\rangle = 0 \ , \tag{23.180}$$

the functions are called *linearly independent*. A set of linearly independent functions may form a *basis*. The space opened by a set of linearly independent functions is called *Hilbert space*.

An operator $\hat{A}$ is completely characterized by its *eigenvalues* and *eigenfunctions*. If a set of eigenfunctions $|n\rangle$ is *complete*, every allowed state of the system can be expanded in these eigenfunctions,

$$|\psi\rangle = \sum_n c_n|n\rangle \qquad \text{and} \qquad \hat{A}|n\rangle = a_n|n\rangle \ . \tag{23.181}$$

To calculate properties of a specific system, we often want to find a matrix representation for the operator $\hat{A}$. For this, we solve the stationary Schrödinger equation,

that is, we calculate the eigenvalues and *eigenvectors*. When all eigenvalues are different, $a_n \neq a_m$, we know that the corresponding eigenvectors are orthogonal, $\langle n|m\rangle = 0$,

$$\begin{aligned} &\hat{A}|n\rangle = a_n|n\rangle \quad , \quad \hat{A}|m\rangle = a_n|m\rangle \quad , \quad \forall\{n,m\}\ a_n \neq a_m \\ \Longrightarrow\ &\forall\{n,m\}\ \langle n|m\rangle = \delta_{m,n}\ . \end{aligned} \tag{23.182}$$

Exc. 23.5.9.1 asks for demonstrating this.

Frequently, for example, in the case of a particle confined to a potential, there exist discrete eigenvalues (for $E < 0$) simultaneously with continuous eigenvalues (for $E > 0$). Assuming $\langle m|m'\rangle = \delta_{m,m'}$, $\langle m|\mathbf{k}\rangle = 0$ and $\langle \mathbf{k}|\mathbf{k}'\rangle = \delta^{(3)}(\mathbf{k}-\mathbf{k}')$, with a complete base,

$$\sum_m |m\rangle\langle m| + \int d^3k|\mathbf{k}\rangle\langle\mathbf{k}| = \mathbb{I}\ , \tag{23.183}$$

an arbitrary vector can be expanded on an orthogonal basis,

$$|\psi\rangle = \sum_m |m\rangle\langle m|\psi\rangle + \int d^3k\ |\mathbf{k}\rangle\langle\mathbf{k}|\psi\rangle\ . \tag{23.184}$$

This also applies to observables,

$$\hat{A} = \sum_{m,n} |m\rangle\langle m|\hat{A}|n\rangle\langle n| + \int d^3k d^3l\ |\mathbf{k}\rangle\langle\mathbf{k}|\hat{A}|\mathbf{l}\rangle\langle\mathbf{l}|\ , \tag{23.185}$$

and functions of observables,

$$f(\hat{A}) = \sum_{m,n} |m\rangle f(\langle m|\hat{A}|n\rangle)\langle n| + \int d^3k d^3l\ |\mathbf{k}\rangle f(\langle\mathbf{k}|\hat{A}|\mathbf{l}\rangle)\langle\mathbf{l}|\ . \tag{23.186}$$

23.5.3 Degeneracy

The eigenvectors form a natural basis for the Hilbert space. However, a problem arises in the case of *degeneracy*, that is, when some eigenvalues are equal, $a_n = a_m$. In this case, the eigenvectors that correspond to degenerate eigenvalues are not completely defined, and we have to construct a basis verifying that all constructed eigenvectors are orthogonal. For this, there exists the method of *orthogonalization by Schmidt*, which works like this: We assume that we have already solved the eigenvalue equation, that we found a degenerate eigenvalue, $\hat{A}|a_k\rangle = a|a_k\rangle$ for every $k = 1,..,g_k$, where g_k is the degree of degeneracy, and that we also found a complete basis of eigenvalues $|a_m\rangle$, but which is not orthogonal, that is, $\exists\{m,n\}$ with $\langle a_n|a_m\rangle \neq 0$. The task is to build another basis $|b_m\rangle$ satisfying $\langle b_n|b_m\rangle = \delta_{n,m}$.

The first vector of the orthogonal base can be chosen freely, e.g.,

$$|b_1\rangle \equiv |a_1\rangle\ . \tag{23.187}$$

Since the basis $\{|a_k\rangle\}$ is assumed to be complete, the second vector is necessarily a linear combination of vectors $|a_k\rangle$, that is, $|b_2\rangle = |a_2\rangle + \lambda|b_1\rangle$. With the condition $\langle b_1|b_2\rangle = 0 = \langle b_1|a_2\rangle + \lambda\langle b_1|b_1\rangle$ we can determine the parameter λ, and obtain for the second vector,

$$|b_2\rangle \equiv |a_2\rangle - |b_1\rangle\frac{\langle b_1|a_2\rangle}{\langle b_1|b_1\rangle}\ . \tag{23.188}$$

In the same way, we can derive for a third vector, $|b_3\rangle = |a_3\rangle + \mu|b_1\rangle + \nu|b_2\rangle$, the conditions, $\langle b_1|b_3\rangle = 0 = \langle b_1|a_3\rangle + \mu\langle b_1|b_1\rangle$ and $\langle b_2|b_3\rangle = 0 = \langle b_2|a_3\rangle + \nu\langle b_2|b_2\rangle$, and obtain,

$$|b_3\rangle \equiv |a_3\rangle - |b_1\rangle\frac{\langle b_1|a_3\rangle}{\langle b_1|b_1\rangle} - |b_2\rangle\frac{\langle b_2|a_3\rangle}{\langle b_2|b_2\rangle} \ . \tag{23.189}$$

An overall way of writing this down is,

$$|b_k\rangle \equiv \left(1 - \frac{|b_1\rangle\langle b_1|}{\langle b_1|b_1\rangle} - \frac{|b_2\rangle\langle b_2|}{\langle b_2|b_2\rangle} - \ldots - \frac{|b_{k-1}\rangle\langle b_{k-1}|}{\langle b_{k-1}|b_{k-1}\rangle}\right)|a_k\rangle \ . \tag{23.190}$$

In the Exc. 23.5.9.2 we practice the orthogonalization of a set of three linearly independent but non-orthogonal vectors, and in the Exc. 23.5.9.3 we find an orthogonal basis for a partially degenerate three-level system.

23.5.4 Bases as unitary operators

One way to formulate the eigenvalue problem is as follows: Let $|n\rangle$ be an orthonormal basis with the respective eigenvalues a_n of an operator $\hat{A}$:

$$\hat{A}|n\rangle = a_n|n\rangle \qquad \text{with} \qquad \langle n|m\rangle = \delta_{mn} \ . \tag{23.191}$$

We construct the matrices,

$$\mathcal{U} \equiv \begin{pmatrix} |1\rangle & |2\rangle & \cdots \end{pmatrix} \qquad \text{and} \qquad \hat{E} \equiv \begin{pmatrix} a_1 & 0 & \cdots \\ 0 & a_2 & \\ \vdots & & \ddots \end{pmatrix} \ . \tag{23.192}$$

With the definition of $\mathcal{U}^\dagger$ we have,

$$\mathcal{U}^\dagger = \begin{pmatrix} \langle 1| \\ \langle 2| \\ \vdots \end{pmatrix} \qquad \text{and} \qquad \mathcal{U}^\dagger\mathcal{U} = \begin{pmatrix} \langle 1|1\rangle & \langle 1|2\rangle & \cdots \\ \langle 2|1\rangle & \langle 2|2\rangle & \cdots \\ \vdots & \vdots & \ddots \end{pmatrix} = \mathbb{I} \ . \tag{23.193}$$

Therefore,

$$\begin{aligned} \mathcal{U}^\dagger\mathcal{U} = \mathbb{I} \quad &\Longrightarrow \quad \mathcal{U}^\dagger\mathcal{U}\mathcal{U}^{-1} = \mathbb{I}\mathcal{U}^{-1} \quad \Longrightarrow \quad \mathcal{U}^\dagger = \mathcal{U}^{-1} \\ \mathcal{U}^\dagger\mathcal{U} = \mathbb{I} \quad &\Longrightarrow \quad \mathcal{U}\mathcal{U}^\dagger\mathcal{U}\mathcal{U}^{-1} = \mathcal{U}\mathbb{I}\mathcal{U}^{-1} \quad \Longrightarrow \quad \mathcal{U}\mathcal{U}^\dagger = \mathbb{I} \ . \end{aligned} \tag{23.194}$$

An important property of unitary matrices is,

$$|\det\mathcal{U}| = 1 \ . \tag{23.195}$$

Also,

$$\boxed{\hat{A}|n\rangle = \hat{E}|n\rangle \qquad \text{and} \qquad \hat{A}\mathcal{U} = \mathcal{U}\hat{E}} \ . \tag{23.196}$$

That is, by knowing the *unitary matrix* (or *transformation matrix*) $\mathcal{U}$, we can solve the eigenvalue problem simply by $\hat{E} = \mathcal{U}^{-1}\hat{A}\mathcal{U}$.

Note, that this does not apply to a non-orthonormal basis. In this case, we need to do a Schmidt orthogonalization and use the condition $\det\mathcal{U} = 1$. We apply the technique detailed in this section to solve Excs. 23.5.9.4, 23.5.9.5, and 23.5.9.6.

23.5.5 Complete set of commuting operators

Even for simple systems, we can ask various types of questions (measurements). Considering, for example, a particle flying freely in space, we can gather its position or its velocity. Let a be the result of a measurement of the observable $\hat{A}$, that is, $a = \langle\psi_a|\hat{A}|\psi_a\rangle$. Due to the measurement we know that the system is in the state $|\psi_a\rangle$. Immediately after this first measurement we perform another measurement of *another* observable $\hat{B}$ giving $\langle\psi_a|\hat{B}|\psi_a\rangle$. The result of this measurement can only yield an eigenstate, $b = \langle\psi_a|\hat{B}|\psi_a\rangle$, if the operators commute, $[\hat{A}, \hat{B}] = 0$. That is, *if two operators $\hat{A}$ and $\hat{B}$ commute, and if $|\psi\rangle$ is an eigenvector of $\hat{A}$, then $\hat{B}|\psi\rangle$ is also an eigenvector of $\hat{A}$ with the same eigenvalue*:

$$\begin{aligned} &[\hat{A}, \hat{B}] = 0 \quad , \quad a = \langle\psi|\hat{A}|\psi\rangle \\ \Longrightarrow\ &\hat{A}(\hat{B}|\psi\rangle) = a(\hat{B}|\psi\rangle) \quad \text{and} \quad \langle\psi|\hat{B}|\psi\rangle \in \mathbb{R} \ . \end{aligned} \tag{23.197}$$

In addition, we observe that, if two operators commute, the orthonormal basis constructed for one of the operators is also orthonormal for the other. That is, *if two operators $\hat{A}$ and $\hat{B}$ commute and if $|\psi_1\rangle$ and $|\psi_2\rangle$ are two eigenvectors of $\hat{A}$ with different eigenvalues, then the matrix element $\langle\psi_1|\hat{B}|\psi_2\rangle$ is equal to zero:*

$$\begin{aligned} &[\hat{A}, \hat{B}] = 0 \quad , \quad a_1 = \langle\psi_1|\hat{A}|\psi_1\rangle \neq \langle\psi_2|\hat{A}|\psi_2\rangle = a_2 \\ \Longrightarrow\ &\langle\psi_1|\hat{B}|\psi_2\rangle = 0 \ . \end{aligned} \tag{23.198}$$

Finally, we affirm that, *if two operators $\hat{A}$ and $\hat{B}$ commute, we can construct an orthonormal basis $\{|\psi_{a,b}\rangle\}$ with common eigenvectors of $\hat{A}$ and $\hat{B}$*:

$$\begin{aligned} &[\hat{A}, \hat{B}] = 0 \\ \Longrightarrow\ &\exists\ \{|\psi_{a,b}\rangle\} \quad \text{tal que} \quad \hat{A}|\psi_{a,b}\rangle = a|\psi_{a,b}\rangle \quad \text{and} \quad \hat{B}|\psi_{a,b}\rangle = b|\psi_{a,b}\rangle \ . \end{aligned} \tag{23.199}$$

The statements (23.197) to (23.199) are verified in Exc. 23.5.9.7.

The fact that commuting operators have a common system of eigenvectors authorizing sharp eigenvalues can be used to construct and characterize a state.

Example 185 (*Measuring momenta in orthogonal directions*): For example, the obvious solutions of the eigenvalue equations,

$$\hat{p}_x|\psi_{p_x}\rangle = \frac{\hbar}{\imath}\frac{d}{dx}|\psi_{p_x}\rangle = p_x|\psi_{p_x}\rangle \quad \text{and} \quad \hat{p}_y|\psi_{p_y}\rangle = \frac{\hbar}{\imath}\frac{d}{dy}|\psi_{p_y}\rangle = p_y|\psi_{p_y}\rangle$$

are the plane waves $e^{\imath p_x x/\hbar}$ and $e^{\imath p_y y/\hbar}$. Therefore, the total state of the particle can be described by,

$$|\psi_{p_x,p_y,p_z}\rangle = |\psi_{p_x}\rangle|\psi_{p_y}\rangle = e^{(\imath/\hbar)(p_x x + p_y y)} f(z) \ .$$

However, these eigenfunctions are infinitely degenerate, since the linear momentum in z-direction is not specified. A third operator $\hat{p}_z|\psi\rangle = p_z|\psi\rangle$ commutes with the others,

$$[\hat{p}_k, \hat{p}_m] = 0 \ .$$

Hence,

$$|\psi_{p_x,p_y,p_z}\rangle = e^{(\imath/\hbar)(p_x x + p_y y + p_z z)} \ ,$$

is a possible state of the system.
On the other hand, choosing $\hat{p}_z^2 = -\hbar^2 \frac{\partial^2}{\partial z^2}$ as the third operator, giving the eigenvalues p_z^2, the state would have been,

$$|\psi_{p_x,p_y,p_z^2}\rangle = e^{(\imath/\hbar)(p_x x + p_y y)} \cos \tfrac{p_z z}{\hbar} \quad \text{or} \quad |\psi_{p_x,p_y,p_z^2}\rangle = e^{(\imath/\hbar)(p_x x + p_y y)} \sin \tfrac{p_z z}{\hbar} \ . \tag{23.200}$$

Therefore, there are two solutions with the same eigenvalues, p_x, p_y, p_z^2. To lift this degeneracy, we need to introduce yet another observable. This observable can be, for example, the *parity* $\hat{P}$, that is, the behavior of the wave function upon mirroring $z \longrightarrow -z$ in the x-y plane. The fact that the set of operators p_x, p_y, p_z on one hand and p_x, p_y, p_z^2, $\hat{P}$ on the other are equivalent, shows that the required number of observables for a complete characterization depends on their judicious choice.

Also, the number needed for a *complete set of commuting operators* (*CSCO*) depends on the number of *degrees of freedom* and the symmetry of the system. In the case of the free particle in one dimension it is enough to consider one observable only, for example, $\hat{x}$ or $\hat{p}$. In three dimensions, we already need at least three commuting observables. In Exc. 23.5.9.8 we will try to find a CSCO for a matrix with partially degenerate eigenvalues.

23.5.6 Uncertainty relation

We have already learned that observables that do not commute can not be measured with arbitrary precision. This principle can be quantified as follows: If $\hat{A}$ and $\hat{B}$ are two observables, then,

$$\boxed{\Delta\hat{A}\Delta\hat{B} \geq \tfrac{1}{2}|\langle[\hat{A},\hat{B}]\rangle|} \ . \tag{23.201}$$

This is Heisenberg's famous *uncertainty principle*. For example, $[\hat{p},\hat{x}] = -\imath\hbar$, and hence, $\Delta p \Delta x \geq \hbar/2$. We will see later (see Sec. 25.3.1), that $[\hat{l}_x, \hat{l}_y] = \imath\hbar\hat{l}_z$ such that $\Delta l_x \Delta l_y \geq \hbar|\langle l_z\rangle|/2$. More difficult to show, since time has no simple quantum operator, is $\Delta E \Delta t \geq \hbar/2$. In the Exc. 23.5.9.9 we will show the *Schwartz inequality*, and in the Exc. 23.5.9.10 we ask for a formal derivation of Heisenberg's uncertainty principle.

23.5.7 Representations

23.5.7.1 Spatial representation

A Hilbert space can be discrete or, as in the case of the momentum of a free particle, continuous. In this latter case, the eigenvalues are continuously distributed, since the equation,

$$-\imath\hbar\nabla_{\mathbf{r}}\psi(\mathbf{r}) = \mathbf{p}\psi(\mathbf{r}) \ , \tag{23.202}$$

has solutions for each value of E. The eigenfunctions are $\psi(\mathbf{r}) = ae^{\imath\mathbf{p}\cdot\mathbf{r}/\hbar}$. Eq. (23.202) clearly has the form of an eigenvalue equation, for which we have already introduced the Heisenberg matrix formalism. The question now is how these descriptions combine.

Observables that do not commute correspond to expansions on different bases and generate alternative representations. For example, we can represent quantum mechanics in *position space* or *linear momentum space*. If $|\mathbf{r}\rangle$ is a basis of the space of the particles' state,

$$\hat{\mathbf{r}}|\mathbf{r}\rangle = \mathbf{r}|\mathbf{r}\rangle \quad , \quad \langle\mathbf{r}'|\mathbf{r}\rangle = \delta^3(\mathbf{r}'-\mathbf{r}) \quad , \quad \int_{\mathbb{R}^3} |\mathbf{r}\rangle\langle\mathbf{r}|d^3r = \mathbb{I} \ , \tag{23.203}$$

we can expand the position operator on a position basis as,

$$\hat{\mathbf{r}} = \int_{\mathbb{R}^3} \mathbf{r}|\mathbf{r}\rangle\langle\mathbf{r}|d^3r \ , \tag{23.204}$$

and any state vector as,

$$\boxed{|\psi(t)\rangle = \int_{\mathbb{R}^3} |\mathbf{r}\rangle\psi(t,\mathbf{r})d^3r} \ . \tag{23.205}$$

The quantities $\langle\mathbf{r}|\psi(t)\rangle = \psi(t,\mathbf{r})$ Schrödinger wave functions. We can also say that the wavefunctions are the coordinates of the state in the particular base $|\mathbf{r}\rangle$. Consequently,

$$\begin{aligned} \langle\mathbf{r}|\hat{\mathbf{r}}|\mathbf{r}'\rangle &= \mathbf{r}\delta^3(\mathbf{r}-\mathbf{r}') \\ \langle\mathbf{r}|f(\hat{\mathbf{r}})|\mathbf{r}'\rangle &= f(\mathbf{r})\delta^3(\mathbf{r}-\mathbf{r}') \ . \end{aligned} \tag{23.206}$$

It is also true that,

$$\boxed{\langle\mathbf{r}|\hat{A}|\psi(t)\rangle = \int_{\mathbb{R}^3} A(\mathbf{r},\mathbf{r}')\psi(t,\mathbf{r}')d^3r'} \ , \tag{23.207}$$

where the quantity $A(\mathbf{r},\mathbf{r}') \equiv \langle\mathbf{r}|\hat{A}|\mathbf{r}'\rangle$ is called *kernel* of the operator. The transition from Heisenberg's abstract mechanics to Schrödinger's wave mechanics is done by the substitutions $|\psi(t)\rangle \to \psi(t,\mathbf{r})$ and $\hat{A} \to A(\mathbf{r},\mathbf{r}')$.

23.5.7.2 Momentum representation

The uncertainty relation is symmetric in $\hat{\mathbf{r}}$ and $\hat{\mathbf{p}}$. Nothing prevents us from choosing as a basis,

$$\hat{\mathbf{p}}|\mathbf{p}\rangle = \mathbf{p}|\mathbf{p}\rangle \quad , \quad \langle\mathbf{p}'|\mathbf{p}\rangle = \delta^3(\mathbf{p}'-\mathbf{p}) \quad , \quad \int_{\mathbb{R}^3} |\mathbf{p}\rangle\langle\mathbf{p}|d^3p = \mathbb{I} \ , \tag{23.208}$$

in which we can expand the momentum operator on a momentum basis as,

$$\hat{\mathbf{p}} = \int_{\mathbb{R}^3} \mathbf{p}|\mathbf{p}\rangle\langle\mathbf{p}|d^3p \ , \tag{23.209}$$

with the wavefunctions,

$$\boxed{|\psi(t)\rangle = \int_{R^3} |\mathbf{p}\rangle\varphi(\mathbf{p},t)d^3p} \ , \tag{23.210}$$

where $\langle \mathbf{p}|\psi(t)\rangle = \varphi(t,\mathbf{p})$. The formulas are analogous to the ones in the spatial representation. In particular, in the momentum representation the position operator is $\mathbf{r} = \imath\hbar\nabla_{\mathbf{p}}$.

The representations follow from one another by Fourier transformation. Since $-\imath\hbar\nabla_{\mathbf{r}}\langle \mathbf{r}|\mathbf{p}\rangle = \mathbf{p}\langle \mathbf{r}|\mathbf{p}\rangle$, we know,

$$\boxed{\langle \mathbf{r}|\mathbf{p}\rangle = \tfrac{1}{h^{3/2}}\exp(\tfrac{\imath}{\hbar}\mathbf{r}\cdot\mathbf{p})}\ , \tag{23.211}$$

where the prefactor $\hbar^{-3/2}$ is introduced to take account of the unit of the states [21]. ψ and φ are different representations of the same quantum state related by,

$$\begin{aligned}\langle \mathbf{r}|\psi(t)\rangle &= \int_{\mathbb{R}^3}\langle \mathbf{r}|\mathbf{p}\rangle\langle \mathbf{p}|\psi(t)\rangle d^3p = \tfrac{1}{h^{3/2}}\int_{\mathbb{R}^3} e^{\imath\mathbf{r}\cdot\mathbf{p}/\hbar}\varphi(\mathbf{p},t)d^3p = \psi(\mathbf{r},t) \\ \langle \mathbf{p}|\psi(t)\rangle &= \int_{\mathbb{R}^3}\langle \mathbf{p}|\mathbf{r}\rangle\langle \mathbf{r}|\psi(t)\rangle d^3r = \tfrac{1}{h^{3/2}}\int_{\mathbb{R}^3} e^{-\imath\mathbf{r}\cdot\mathbf{p}/\hbar}\psi(\mathbf{r},t)d^3r = \varphi(\mathbf{p},t)\ .\end{aligned} \tag{23.212}$$

Normalization ensures that $\psi = \mathcal{F}^{-1}\mathcal{F}\psi$ with the relation,

$$\delta(x) = \lim_{t\to\infty}\tfrac{1}{2\pi}\int_{-t}^{t} e^{\imath kx}dk\ . \tag{23.213}$$

Using the wavevector $\hbar\mathbf{k} = \mathbf{p}$ we can also write,

$$\psi(\mathbf{r}) = \tfrac{1}{(2\pi)^{3/2}}\int_{\mathbb{R}^3} e^{\imath\mathbf{r}\cdot\mathbf{k}}\tilde{\varphi}(\mathbf{k})d^3k \quad \text{and} \quad \tilde{\varphi}(\mathbf{k}) = \tfrac{1}{(2\pi)^{3/2}}\int_{\mathbb{R}^3} e^{-\imath\mathbf{r}\cdot\mathbf{k}}\psi(\mathbf{r})d^3r\ , \tag{23.214}$$

defining the function $\tilde{\varphi}(\mathbf{k}) \equiv \hbar^{3/2}\varphi(\mathbf{p})$. Applying the Fourier transform to functions of operator we can calculate,

$$\begin{aligned}\langle \mathbf{r}|G(\hat{\mathbf{p}})|\mathbf{r}'\rangle &= \int d^3p\langle \mathbf{r}|G(\hat{\mathbf{p}})|\mathbf{p}\rangle\langle \mathbf{p}|\mathbf{r}'\rangle = \int d^3pG(\mathbf{p})\langle \mathbf{r}|\mathbf{p}\rangle\langle \mathbf{p}|\mathbf{r}'\rangle \\ &= \tfrac{1}{\hbar^{3/2}}\int d^3pG(\mathbf{p})e^{\imath\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} = \tfrac{1}{\hbar^3}(\mathcal{F}G)(\mathbf{r}-\mathbf{r}')\ .\end{aligned} \tag{23.215}$$

In Exc. 23.5.9.11 we will show $\langle \mathbf{r}|\hat{\mathbf{p}}|\psi\rangle = (\hbar/\imath)\nabla_{\mathbf{r}}\langle \mathbf{r}|\psi\rangle$, thus justifying that we can understand an operator as a rule to determine what happens to a function. For example, the rule $\hat{p}_x$ asks for a derivation of the wavefunction by x.

23.5.8 Spanning a Hilbert space with several degrees of freedom

All systems analyzed up to this point were characterized by a single degree of freedom (e.g., energy, momentum, or angular momentum), which could have a continuous or discrete spectrum. Even when we treated systems exhibiting various degrees of freedom (motion of a particle in 3D space, electron orbitals in the hydrogen atom),

[21] Note that the units of the wavefunctions are defined by normalization: $\langle \mathbf{r}'|\mathbf{r}\rangle = \delta^3(\mathbf{r}-\mathbf{r}')$. Introducing the parenthesis [...] to extract the unit of a physical quantity, we find, $[|\mathbf{r}\rangle] = [\psi(\mathbf{r})] = [r^{-3/2}]$ and $[|\mathbf{p}\rangle] = [\varphi(\mathbf{p})] = [p^{-3/2}]$. We do not assign a unit to the abstract state $|\psi\rangle$, that is, $[|\psi\rangle] = 1$.

we always found a way to separate the degrees of freedom into orthogonal Hilbert spaces, which allowed us to treat the dynamics of the degrees of freedom separately. In this chapter, we will establish the theoretical foundations allowing us to analyze systems, where degrees of freedom can not be separated because they are entangled or interact. In particular, we will consider the system of two spins and the coupling of angular momenta in general.

23.5.8.1 Projection and internal sum

A *projector* is an operator which *reduces* the domain of an operator, originally acting on a Hilbert space $\mathbb{H}$ to the *subspace* defined by the projector. We consider an operator $\hat{A}$ with the matrix representation,

$$\hat{A} \equiv \sum_{\substack{i,j \\ |i\rangle,|j\rangle\in\mathbb{H}}} |i\rangle A_{ij} \langle j| = \begin{pmatrix} & \vdots & \\ .. & A_{ij} & .. \\ & \vdots & \end{pmatrix} , \tag{23.216}$$

acting on wavefunctions $|\psi\rangle \in \mathbb{H}$ which can be expanded on a basis $|i\rangle$ of $\mathbb{H}$. Now, we consider a subspace $\mathcal{R} \subset \mathbb{H}$ defined by the base $|k\rangle$. Then the projector $\hat{P}_{\mathcal{R}}$ can be represented by,

$$\boxed{\hat{P}_{\mathcal{R}} \equiv \sum_{\substack{k \\ |k\rangle\in\mathcal{R}}} |k\rangle\langle k| = \begin{pmatrix} 0 & 0 & 0 \\ 0 & \begin{pmatrix} 1 & & \\ & .. & \\ & & 1 \end{pmatrix} & 0 \\ 0 & 0 & 0 \end{pmatrix}} . \tag{23.217}$$

Applied to the operator $\hat{A}$,

$$\hat{A}_{\mathcal{R}} \equiv \hat{P}_{\mathcal{R}}\hat{A} = \hat{P}_{\mathcal{R}}\hat{A}_{\mathcal{R}} = \sum_{k,l} |k\rangle A_{kl} \langle l| = \begin{pmatrix} 0 & 0 & 0 \\ 0 & \begin{pmatrix} & \vdots & \\ .. & A_{kl} & .. \\ & \vdots & \end{pmatrix} & 0 \\ 0 & 0 & 0 \end{pmatrix} . \tag{23.218}$$

Applied to a state $|i\rangle$,

$$|\psi\rangle_{\mathcal{R}} = \hat{P}_{\mathcal{R}}|\psi\rangle = \hat{P}_{\mathcal{R}}|\psi\rangle_{\mathcal{R}} = \sum_k c_k |k\rangle = \begin{pmatrix} 0 \\ \begin{pmatrix} \vdots \\ c_k \\ \vdots \end{pmatrix} \\ 0 \end{pmatrix} . \tag{23.219}$$

We study an example in Exc. 23.5.9.12.

Consequently, we can understand the Hilbert space as the sum of its subspaces,

$$\hat{A} = \bigoplus_{\mathcal{R}} \hat{A}_{\mathcal{R}} \qquad \text{and} \qquad \bigoplus_{\mathcal{R}} \hat{P}_{\mathcal{R}} = \mathbb{I} . \tag{23.220}$$

The dimensions of the subspaces are additive,

$$\dim \hat{A} = \sum_{\mathcal{R}} \dim \hat{A}_{\mathcal{R}} \ .$$

Example 186 (*Projection for a three-level atom*): The Hamiltonian of a three-level atom with excitation of two transitions is given by,

$$\hat{H} = \begin{pmatrix} \omega_1 & \Omega_{12} & 0 \\ \Omega_{12} & \omega_2 & \Omega_{23} \\ 0 & \Omega_{23} & \omega_3 \end{pmatrix} \ .$$

The projector,

$$\hat{P} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

reduces the Hamiltonian to a two-level transition,

$$\hat{H}_{\mathcal{R}} = \begin{pmatrix} \omega_1 & \Omega_{12} & 0 \\ \Omega_{12} & \omega_2 & 0 \\ 0 & 0 & 0 \end{pmatrix} \ .$$

As another example we can cite the Jaynes-Cummings model introduced in Sec. 40.1.2 and describing the interaction between a single atom and a single light mode. In this model the total Hilbert space is constructed as a sum of orthogonal subspaces characterized by different fixed excitation numbers.

Obviously, the concatenation (23.220) only serves to increase the Hilbert space of a given degree of freedom described by a given observable, e.g., when we add one more level of energy to the spectrum of an atom described by a Hamiltonian. If, in contrast, we want to add another degree of freedom, we need the external sum or external product discussed below.

23.5.8.2 Tensorial product

We have previously worked with systems exhibiting more than one degree of freedom and therefore having to be characterized by more than one observable with its spectrum of eigenstates. One example are the electronic orbitals of the hydrogen atom $|n\ell m\rangle$, which need three quantum numbers to be labeled unambiguously. Obviously, each quantum number increases the dimensionality of the Hilbert space. Another example is the system $|\alpha\beta\rangle$ of two particles with spin $\frac{1}{2}$, each spin being defined on its respective space,

$$|\alpha\rangle = \begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} = (\alpha_i)_i \in \mathbb{H}_A \qquad \text{and} \qquad |\beta\rangle = \begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix} = (\beta_k)_k \in \mathbb{H}_\mathrm{B} \ . \tag{23.221}$$

The combined state is,

$$|\alpha\beta\rangle \in \mathbb{H}_A \otimes \mathbb{H}_\mathrm{B} \qquad \text{with} \qquad \dim \mathbb{H}_A \otimes \mathbb{H}_\mathrm{B} = \dim \mathbb{H}_A \dim \mathbb{H}_\mathrm{B} \ . \tag{23.222}$$

The symbol $\otimes$ denotes the *outer tensorial product* of two vectors (states) [22]. Now, in order to represent the multidimensional space $\mathbb{H}_A \otimes \mathbb{H}_\mathrm{B}$ by a matrix, we use the fact that it is isomorphic to the space $\mathbb{H}_\mathbb{I} \otimes \mathbb{H}_{A\otimes B}$, that is, we proceed to a reorganization of the quantum numbers identifying,

$$|\gamma\rangle \equiv |\alpha\rangle|\beta\rangle = |\alpha\rangle \otimes |\beta\rangle = |\alpha\beta\rangle = \begin{pmatrix} \alpha_1|\beta\rangle \\ \alpha_2|\beta\rangle \end{pmatrix} = \begin{pmatrix} \alpha_1\beta_1 \\ \alpha_1\beta_2 \\ \alpha_2\beta_1 \\ \alpha_2\beta_2 \end{pmatrix} = (\gamma_m)_m \in \mathbb{H}_A \otimes \mathbb{H}_\mathrm{B} \ , \tag{23.223}$$

where $m = 1, 2, 3, 4$ is identified with $(i, k) = (1, 1), (1, 2), (2, 1), (2, 2)$. The new vector is element of the 4-dimensional vector space $\mathbb{H}_A \otimes \mathbb{H}_\mathrm{B}$. If $\{|\alpha\rangle_i\}$ and $\{|\beta\rangle_k\}$ are bases in their respective spaces $\mathbb{H}_A$ and $\mathbb{H}_\mathrm{B}$, then $\{|\gamma\rangle_m\}$ is a basis of the product space $\mathbb{H}_A \otimes \mathbb{H}_\mathrm{B}$.

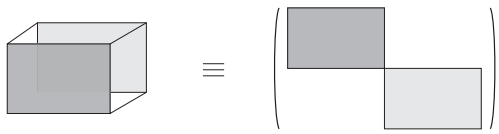

Figure 23.16: Illustration of the isomorphism between $\mathbb{H}_A \otimes \mathbb{H}_\mathrm{B}$ and $\mathbb{H}_\mathbb{I} \otimes \mathbb{H}_{A\otimes B}$ for matrices of rank 2.

For observables we proceed in the same way: The external product of two commutators spans a Hilbert product space with the dimension corresponding to product of the dimensions of the sub-spaces. Assuming that,

$$\hat{A} \equiv \sum\nolimits_{i,j} |i\rangle A_{ij} \langle j| \qquad \text{and} \qquad \hat{B} \equiv \sum\nolimits_{k,l} |k\rangle B_{kl} \langle l| \ . \tag{23.224}$$

[22] The tensorial product of two states should not be confused with other definitions of products, such as the inner (or scalar) product of two states,

$$\langle\alpha|\beta\rangle \equiv \alpha_1\beta_1 + \alpha_2\beta_2 \ ,$$

the outer product,

$$|\alpha\rangle\langle\beta| \equiv \begin{pmatrix} \alpha_1\beta_1 & \alpha_1\beta_2 \\ \alpha_2\beta_1 & \alpha_2\beta_2 \end{pmatrix}$$

$$\begin{pmatrix} A_{11} \\ A_{12} \\ A_{21} \\ A_{22} \end{pmatrix} \begin{pmatrix} B_{11} \\ B_{12} \\ B_{21} \\ B_{22} \end{pmatrix}^\dagger = \begin{pmatrix} A_{11}B_{11} & A_{11}B_{12} & A_{11}B_{21} & A_{11}B_{22} \\ A_{12}B_{11} & A_{12}B_{12} & A_{12}B_{21} & A_{12}B_{22} \\ A_{21}B_{11} & A_{21}B_{12} & A_{21}B_{21} & A_{21}B_{22} \\ A_{22}B_{11} & A_{22}B_{12} & A_{22}B_{21} & A_{22}B_{22} \end{pmatrix} \ ,$$

the exterior (cross) product,

$$|\alpha\rangle \times |\beta\rangle = \begin{pmatrix} \alpha_2\beta_3 - \alpha_3\beta_2 \\ \alpha_3\beta_1 - \alpha_1\beta_3 \\ \alpha_1\beta_2 - \alpha_2\beta_1 \end{pmatrix} \ ,$$

nor the point-wise or *Hadamard product*,

$$\hat{A} \circ \hat{B} \equiv \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \circ \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} = \begin{pmatrix} A_{11}B_{11} & A_{12}B_{12} \\ A_{21}B_{21} & A_{22}B_{22} \end{pmatrix} \ .$$

then

$$\hat{A} \otimes \hat{B} \equiv \sum_{(ik)(jl)} |ik\rangle A_{ij} B_{kl} \langle jl| \ , \tag{23.225}$$

such that

$$\dim \hat{A} \otimes \hat{B} = \dim \hat{A} \dim \hat{B} \ .$$

For example, $|i\rangle\langle j| \otimes |k\rangle\langle l| = |ik\rangle\langle jl|$.

For two two-dimensional operators $\hat{A}$ and $\hat{B}$, the *tensorial external product* is defined by,

$$\hat{A} \otimes \hat{B} = \begin{pmatrix} A_{11}B_{11} & A_{11}B_{12} & A_{12}B_{11} & A_{12}B_{12} \\ A_{11}B_{21} & A_{11}B_{22} & A_{12}B_{21} & A_{12}B_{22} \\ A_{21}B_{11} & A_{21}B_{12} & A_{22}B_{11} & A_{22}B_{12} \\ A_{21}B_{21} & A_{21}B_{22} & A_{22}B_{21} & A_{22}B_{22} \end{pmatrix} \ , \tag{23.226}$$

and can be decomposed as,

$$\boxed{\hat{A} \otimes \hat{B} = (\hat{A} \otimes \mathbb{I})(\mathbb{I} \otimes \hat{B}) = \begin{pmatrix} A_{11} & & A_{12} & \\ & A_{11} & & A_{12} \\ A_{21} & & A_{22} & \\ & A_{21} & & A_{22} \end{pmatrix} \begin{pmatrix} B_{11} & B_{12} & & \\ B_{21} & B_{22} & & \\ & & B_{11} & B_{12} \\ & & B_{21} & B_{22} \end{pmatrix}} \ . \tag{23.227}$$

The concept (23.225) can be generalized to more degrees of freedom like,

$$\hat{A} \otimes \hat{B} \otimes \hat{C} \equiv \sum_{(ikm)(jln)} |ikm\rangle A_{ij} B_{kl} C_{mn} \langle jln| \ , \tag{23.228}$$

Obviously, the external product is associative $(\hat{A} \otimes \hat{B}) \otimes C = \hat{A} \otimes (\hat{B} \otimes C)$, but does not commute, even though the operators acting on different spaces do commute, $[\hat{A}, \hat{B}] = 0$. Nevertheless, we can reverse the order of the product of two operators using,

$$\hat{A} \otimes \hat{B} = \mathbb{S}(\hat{B} \otimes \hat{A})\mathbb{S} \qquad \text{with} \qquad \mathbb{S} \equiv \begin{pmatrix} 1 & & & \\ & 0 & 1 & \\ & 1 & 0 & \\ & & & 1 \end{pmatrix} \ . \tag{23.229}$$

The operator $\mathbb{S}$ is also called *SWAP-gate*.

We note, that it is important to distinguish from what space the vector came from. In our notation, the vector *before* the symbol of the tensorial product ($\otimes$) is belongs to the space $\mathbb{H}_A$, and the one *after* the $\otimes$ belongs to the space $\mathbb{H}_\mathrm{B}$. With the definition (23.224) we can verify that the operators only act on their respective states:

$$(A \otimes B)(|\alpha\rangle \otimes |\beta\rangle) = A|\alpha\rangle \otimes B|\beta\rangle \ . \tag{23.230}$$

Example 187 (*Tensorial product*): We can check the relationship (23.230)

by the definitions (23.223) and (23.226) of the external product,

$$\begin{aligned}
&\left[\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \otimes \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}\right]\left[\begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} \otimes \begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix}\right] \qquad (23.231)\\
&= \begin{pmatrix} A_{11}B_{11} & A_{11}B_{12} & A_{12}B_{11} & A_{11}B_{12} \\ A_{11}B_{21} & A_{11}B_{22} & A_{12}B_{21} & A_{11}B_{22} \\ A_{21}B_{11} & A_{11}B_{12} & A_{22}B_{11} & A_{22}B_{12} \\ A_{21}B_{21} & A_{11}B_{22} & A_{22}B_{21} & A_{22}B_{22} \end{pmatrix} \begin{pmatrix} \alpha_{11}\beta_{11} \\ \alpha_{11}\beta_{21} \\ \alpha_{21}\beta_{11} \\ \alpha_{21}\beta_{21} \end{pmatrix}\\
&= \begin{pmatrix} A_{11}B_{11}\alpha_{11}\beta_{11} + A_{11}B_{12}\alpha_{11}\beta_{21} + A_{12}B_{11}\alpha_{21}\beta_{11} + A_{11}B_{12}\alpha_{21}\beta_{21} \\ A_{11}B_{21}\alpha_{11}\beta_{11} + A_{11}B_{22}\alpha_{11}\beta_{21} + A_{12}B_{21}\alpha_{21}\beta_{11} + A_{11}B_{22}\alpha_{21}\beta_{21} \\ A_{21}B_{11}\alpha_{11}\beta_{11} + A_{11}B_{12}\alpha_{11}\beta_{21} + A_{22}B_{11}\alpha_{21}\beta_{11} + A_{22}B_{12}\alpha_{21}\beta_{21} \\ A_{21}B_{21}\alpha_{11}\beta_{11} + A_{11}B_{22}\alpha_{11}\beta_{21} + A_{22}B_{21}\alpha_{21}\beta_{11} + A_{22}B_{22}\alpha_{21}\beta_{21} \end{pmatrix}\\
&= \begin{pmatrix} (A_{11}\alpha_1 + A_{12}\alpha_2)(B_{11}\beta_1 + B_{12}\beta_2) \\ (A_{11}\alpha_1 + A_{12}\alpha_2)(B_{21}\beta_1 + B_{22}\beta_2) \\ (A_{21}\alpha_1 + A_{22}\alpha_2)(B_{11}\beta_1 + B_{12}\beta_2) \\ (A_{21}\alpha_1 + A_{22}\alpha_2)(B_{21}\beta_1 + B_{22}\beta_2) \end{pmatrix}\\
&= \begin{pmatrix} A_{11}\alpha_1 + A_{12}\alpha_2 \\ A_{21}\alpha_1 + A_{22}\alpha_2 \end{pmatrix} \otimes \begin{pmatrix} B_{11}\beta_1 + B_{12}\beta_2 \\ B_{21}\beta_1 + B_{22}\beta_2 \end{pmatrix} = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}\begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} \otimes \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}\begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix} .
\end{aligned}$$

Example 188 (*Mathematical definition of the tensor product*): If α belongs to the Hilbert space $\mathbb{H}_\alpha$ and β belongs to $\mathbb{H}_\beta$, then the equivalence class of (α, β) is denoted by $\alpha \otimes \beta$ and called the tensor product of α with β. This use of the $\otimes$-symbol refers specifically to the outer product operation. An element of $\mathbb{H}_\alpha \otimes \mathbb{H}_\beta$ that can be written in the form $\alpha \otimes \beta$ is called a pure tensor. In general, an element of the tensor product space is not a pure tensor, but rather a finite linear combination of pure tensors. For example, if α_1 and α_2 are linearly independent, and β_1 and β_2 are also linearly independent, then $\alpha_1 \otimes \beta_1 + \alpha_2 \otimes \beta_2$ cannot be written as a pure tensor. The number of pure tensors required to express an element of a tensor product is called the tensor rank. The rank should not be confused with the tensor order, which is the number of spaces one has taken the product of (in this case two), and which corresponds to the number of indices. For linear operators or matrices, thought of as $(1, 1)$ tensors (elements of the space $\mathbb{H}_\alpha \otimes \mathbb{H}_\alpha^*$), the tensor rank agrees with matrix rank.
Given bases $\{\alpha_i\}$ and $\{\beta_j\}$ for $\mathbb{H}_\alpha$ and $\mathbb{H}_\beta$ respectively, the tensors $\{\alpha_i \otimes \beta_j\}$ form a basis for $\mathbb{H}_\alpha \otimes \mathbb{H}_\beta$. Therefore, if $\mathbb{H}_\alpha$ and $\mathbb{H}_\beta$ are finite-dimensional, the dimension of the tensor product is the product of dimensions of the original spaces; for instance $\mathbb{R}^m \otimes \mathbb{R}^n$ is isomorphic to $\mathbb{R}^{nm}$.
The tensor product also operates on linear maps (called operators in quantum mechanics) between vector spaces. Specifically, given two linear maps $\hat{A} : \mathbb{H}_\alpha \to \mathbb{H}'_\alpha$ and $\hat{B} : \mathbb{H}_\beta \to \mathbb{H}'_\beta$ between vector spaces, the tensor product of the two linear maps $\hat{A}$ and $\hat{B}$ is a linear map,

$$\hat{A} \otimes \hat{B} : \mathbb{H}_\alpha \otimes \mathbb{H}_\beta \to \mathbb{H}'_\alpha \otimes \mathbb{H}'_\beta \ ,$$

defined by,

$$(\hat{A} \otimes \hat{B})(\alpha \otimes \beta) = \hat{A}(\alpha) \otimes \hat{B}(\beta) \ .$$

In this way, the tensor product becomes a bifunctor from the category of vector spaces to itself, covariant in both arguments. If $\hat{A}$ and $\hat{B}$ are both injective,

surjective or (in the case that $\mathbb{H}_\alpha$, $\mathbb{H}'_\alpha$, $\mathbb{H}_\beta$, and $\mathbb{H}'_\beta$ are normed vector spaces or topological vector spaces) continuous, then $\hat{A} \otimes \hat{B}$ is injective, surjective or continuous, respectively.
By choosing bases of all vector spaces involved, the linear maps $\hat{A}$ and $\hat{B}$ can be represented by matrices. Then, depending on how the tensor $\alpha \otimes \beta$ is vectorized, the matrix describing the tensor product $\hat{A} \otimes \hat{B}$ is the Kronecker product of the two matrices. For example, if $\mathbb{H}_\alpha$, $\mathbb{H}'_\alpha$, $\mathbb{H}_\beta$, and $\mathbb{H}'_\beta$ above are all two-dimensional and bases have been fixed for all of them, and $\hat{A}$ and $\hat{B}$ are given by the matrices,

$$\hat{A} = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \quad , \quad \hat{B} = \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}$$

respectively, then the tensor product of these two matrices is,

$$\begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \otimes \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} = \begin{pmatrix} A_{11} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} & A_{12} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} \\ A_{21} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} & A_{22} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix} \end{pmatrix} .$$

The resultant rank is at most 4, and thus the resultant dimension is 4. Note that rank here denotes the tensor rank i.e. the number of requisite indices (while the matrix rank counts the number of degrees of freedom in the resulting array). Note $\mathrm{Tr}\ \hat{A} \otimes \hat{B} = \mathrm{Tr}\ \hat{A} \times \mathrm{Tr}\ \hat{B}$.
A dyadic product is the special case of the tensor product between two vectors of the same dimension.

23.5.8.3 Direct external sum

Using the nomenclature (23.224) we define the external direct sum by,

$$\hat{A} \oplus \hat{B} \equiv \sum_{(ik)(jl)} |ik\rangle (A_{ij} + B_{kl}) \langle jl| \ , \tag{23.232}$$

that is,

$$\hat{A} \oplus \hat{B} = \begin{pmatrix} A_{11} + B_{11} & A_{11} + B_{12} & A_{12} + B_{11} & A_{12} + B_{12} \\ A_{11} + B_{21} & A_{11} + B_{22} & A_{12} + B_{21} & A_{12} + B_{22} \\ A_{21} + B_{11} & A_{21} + B_{12} & A_{22} + B_{11} & A_{22} + B_{12} \\ A_{21} + B_{21} & A_{21} + B_{22} & A_{22} + B_{21} & A_{22} + B_{22} \end{pmatrix} . \tag{23.233}$$

It can be decomposed as,

$$\boxed{\hat{A} \oplus \hat{B} = \hat{A} \oplus \mathbb{O} + \mathbb{O} \oplus \hat{B} = \hat{A} \otimes \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} + \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \otimes \hat{A} \ .} \tag{23.234}$$

Again, using the definition (23.229) of the unitary operator $\mathbb{S}$, we can reverse the order of the operator by,

$$\hat{A} \oplus \hat{B} = \mathbb{S}(\hat{B} \oplus \hat{A})\mathbb{S} \ . \tag{23.235}$$

Example 189 (*Direct external sum of two diagonal Hamiltonians*): As an example we consider a two-level atom excited by radiation and trapped in an external harmonic potential. We assume that the degrees of freedom do not interact. As the Hamiltonian of the HO is diagonal, the total Hamiltonian is organized into a diagonal matrix of quadratic subspaces,

$$\hat{H} = \hbar\omega(n+\tfrac{1}{2}) \oplus \begin{pmatrix} 0 & \hbar\Omega \\ \hbar\Omega & \hbar\Delta \end{pmatrix} = \begin{pmatrix} \frac{\hbar\omega}{2} & \frac{\hbar\omega}{2}+\hbar\Omega & 0 & 0 & \vdots \\ \frac{\hbar\omega}{2}+\hbar\Omega & \frac{\hbar\omega}{2}+\hbar\Delta & 0 & 0 & \vdots \\ 0 & 0 & \frac{3\hbar\omega}{2} & \frac{3\hbar\omega}{2}+\hbar\Omega & \vdots \\ 0 & 0 & \frac{3\hbar\omega}{2}+\hbar\Omega & \frac{3\hbar\omega}{2}+\hbar\Delta & \vdots \\ \dots & \dots & \dots & \dots & \ddots \end{pmatrix} .$$

It acts on the product state $|n\rangle|i\rangle$, where the first ket denotes the vibrational level and the second ket the electronic excitation of the atom.

Other examples are studied in Excs. 23.5.9.13 and 23.5.9.14.

23.5.8.4 Collective spins

Two spins $\hat{A}$ and $\hat{B}$ sum up according to the rule,

$$\boxed{\hat{A}\otimes\mathbb{I}+\mathbb{I}\otimes\hat{B} = \begin{pmatrix} A_{11}+B_{11} & B_{12} & A_{12}+B_{12} & \\ B_{21} & A_{11}+B_{22} & & A_{12} \\ A_{21} & & A_{22}+B_{11} & B_{12} \\ & A_{21} & B_{21} & A_{22}+B_{22} \end{pmatrix}} . \tag{23.236}$$

The procedure can be arbitrary extended to several spins, $\hat{A}\otimes\mathbb{I}\otimes\mathbb{I}+\mathbb{I}\otimes\hat{B}\otimes\mathbb{I}+\mathbb{I}\otimes\mathbb{I}\otimes\hat{C}$.

23.5.8.5 Trace

The *trace* of an operator over a subspace reduces its domain to the remaining dimensions (the $\cdot$ -symbol is a place holder for the dimension over which we do NOT want to trace):

$$\begin{aligned} \mathrm{Tr}_{\mathrm{B}}\hat{A}\otimes\hat{B} &= \sum_{(ik)(jl)(\cdot m)} \langle\cdot\, m|ik\rangle A_{ij}B_{kl}\langle jl|\cdot m\rangle = \sum_{(ik)(jl)(\cdot m)} |i\rangle A_{ij}B_{kl}\langle j|\delta_{km}\delta_{lm} \\ &= \sum_{(i)(j)(m)} |i\rangle A_{ij}B_{mm}\langle j| = \hat{A}\sum_m B_{mm} = \hat{A}\ \mathrm{Tr}_{\mathrm{B}}\hat{B} . \end{aligned} \tag{23.237}$$

For example, $\mathrm{Tr}_\rho\hat{A}\otimes\hat{\rho} = \hat{A}$. See the Excs. 23.5.9.15 and 23.5.9.16.

It can be shown,

$$\mathrm{Tr}\ \hat{A}\hat{B} = \mathrm{Tr}\ \hat{B}\hat{A} . \tag{23.238}$$

23.5.9 Exercises

23.5.9.1 Ex: Orthogonality

Show that two eigenvectors of a Hermitian operator associated with two different eigenvalues are orthogonal.

23.5.9.2 Ex: Orthonormalization

Orthonormalize the base $\langle a_1| = \begin{pmatrix}1 & -1 & 0\end{pmatrix}$, $\langle a_2| = \begin{pmatrix}0 & 1 & 0\end{pmatrix}$, $\langle a_3| = \begin{pmatrix}0 & 1 & 1\end{pmatrix}$.

23.5.9.3 Ex: Orthonormal base

Construct an orthonormal basis for the following operator describing a partially degenerate three-level system,

$$\hat{A} = \begin{pmatrix}1 & 1 & 1\\ 1 & 1 & 1\\ 1 & 1 & 1\end{pmatrix} .$$

23.5.9.4 Ex: Eigenvalue equation

Calculate the unitary matrix $\mathcal{U}$ transforming the Hamiltonian $\hat{H} = \begin{pmatrix}1 & -\imath\\ \imath & 1\end{pmatrix}$ into a diagonal matrix $E = \mathcal{U}^\dagger \hat{H}\mathcal{U}$.

23.5.9.5 Ex: Spin rotation operators

Prove the following relations for the spin rotation operator: $e^{-\imath\pi\hat{\sigma}_x/4}\hat{\sigma}_z e^{\imath\pi\hat{\sigma}_x/4} = -\hat{\sigma}_y$ and $e^{-\imath\pi\hat{\sigma}_x/4}\hat{\sigma}_y e^{\imath\pi\hat{\sigma}_x/4} = \hat{\sigma}_z$.

23.5.9.6 Ex: Eigenvalues and eigenvectors

Find the eigenvalues and -vectors of the operator $\hat{A} = \begin{pmatrix}1 & 1 & 1\\ 1 & 1 & 1\\ 1 & 1 & 1\end{pmatrix}$ and construct the unitary matrix which transforms this operator into a diagonal matrix.

23.5.9.7 Ex: Commuting operators

a. Show that if two operators $\hat{A}$ and $\hat{B}$ commute and if $|\psi\rangle$ is an eigenvector of $\hat{A}$, $\hat{B}|\psi\rangle$ also is an eigenvector of $\hat{A}$ with the same eigenvalue.
b. Show that if two operators $\hat{A}$ and $\hat{B}$ commute and if $|\psi_1\rangle$ and $|\psi_2\rangle$ are two eigenvector of $\hat{A}$ with different eigenvalues, the matrix element $\langle\psi_1|\hat{B}|\psi_2\rangle$ is equal to zero.
c. Show that if two operators $\hat{A}$ and $\hat{B}$ commute, we can construct an orthonormal basis of eigenvectors common to $\hat{A}$ and $\hat{B}$.

23.5.9.8 Ex: Eigenvalues

a. Find the eigenvalues and eigenvectors of the operator,

$$\hat{A} = \begin{pmatrix} 1 & 0 & 1 \\ 0 & \mu & 0 \\ 1 & 0 & 1 \end{pmatrix} \qquad \text{for} \qquad 0 < \mu < 2 \ .$$

b. Write down the unitary matrix $\mathcal{U}$ satisfying the eigenvalue equation: $\hat{A}\mathcal{U} = \mathcal{U}E_A$, where E_A is the matrix that has all eigenvalues of $\hat{A}$ in its diagonal.
c. Now consider the case $\mu = 0$. Find a complete set of commuting operators (CSCO). That is, calculate the components of a second operator $\hat{B}$, which commutes with $\hat{A}$, as a function of its eigenvalues λ_1, λ_2, and λ_3, and verify $[\hat{A}, \hat{B}] = 0$. Find the most general form of operator $\hat{B}$.

23.5.9.9 Ex: Schwartz inequality

Demonstrate the Schwartz inequality $|\langle u|v\rangle|^2 \leq \langle u|u\rangle\langle v|v\rangle$.

23.5.9.10 Ex: Heisenberg's uncertainty principle

Develop the formal derivation of Heisenberg's uncertainty principle.

23.5.9.11 Ex: Fourier transform

Show that $\langle \mathbf{r}|\hat{\mathbf{P}}|\psi\rangle = \frac{\hbar}{\imath}\nabla\langle \mathbf{r}|\psi\rangle$ reproduces the Schrödinger equation in position representation.

23.5.9.12 Ex: Projection of the motion of a particle

Project the Hamiltonian of the motion of a free particle onto the plane x-y at the position $z = z_0$ using the projection operator $\hat{P} = |z_0\rangle\langle z_0|$ and the trace defined in (23.232) generalized to continuous variables.

23.5.9.13 Ex: Complete system of commuting operators

Construct the Hilbert space of two independent two-level systems a and b. Consider observables $\hat{X}_a$ and $\hat{Y}_b$ acting on their respective systems. What will be their shapes $\hat{X}_{ab}$, respectively $\hat{Y}_{ab}$, in the total Hilbert space? Construct the expanded state $|\psi_{ab}\rangle$ from the basis of the individual systems. Verify $[\hat{X}_{ab}, \hat{Y}_{ab}] = 0$. Verify that the expanded observables obey the same eigenvalue equations as the original ones.

23.5.9.14 Ex: Liouville equation

Show that $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \otimes \hat{A} + \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \otimes \hat{B} = \hat{A} \oplus \hat{B}$.

23.5.9.15 Ex: Liouville equation

Show at the example of a two-level system that the von Neumann equation, $\dot{\hat{\rho}} = -\frac{\imath}{\hbar}[\hat{H}, \hat{\rho}]$, can be written, $\dot{\vec{\rho}} = -\frac{\imath}{\hbar}(\hat{H} \otimes \mathbb{I} - \mathbb{I} \otimes \hat{H})\vec{\rho}$, using the definition of the external product and $\vec{\rho} \equiv \begin{pmatrix} \rho_{11} \\ \rho_{12} \\ \rho_{21} \\ \rho_{22} \end{pmatrix}$. **Help:** For this exercise the physical interpretation of $\hat{\rho}$ as the density operator does not matter. It may be regarded as a common observable.

23.5.9.16 Ex: Unitary transformation of singlet states

Consider two spins a and b that do not interact. Applying to each spin the same transformation to another base, show that the singlet state has in each base the following form: $|\psi\rangle = \frac{1}{\sqrt{2}}\left(|\uparrow\rangle_a|\downarrow\rangle_b - |\downarrow\rangle_a|\uparrow\rangle_b\right)$.

23.6 Time evolutions

Quantum systems may evolve in time, as predicted by the time-dependent Schrödinger equation (23.161). In this section we show different equivalent but complementary descriptions of the temporal evolution of quantum systems depending on whether the time dependence is attributed to the state function of to observables.

23.6.1 Unitary transformations

The best we can do to characterize a system is, obviously, to measure all its observables. However, neither the state functions nor the observables are fixed unambiguously, since defining a unitary operator, $\mathcal{U}^\dagger = \mathcal{U}^{-1}$, we can do,

$$\langle\psi|\hat{A}|\psi\rangle = \langle\psi|\mathcal{U}^\dagger\mathcal{U}\hat{A}\mathcal{U}^\dagger U|\psi\rangle = \langle\mathcal{U}\psi|\mathcal{U}\hat{A}\mathcal{U}^\dagger|U\psi\rangle \ . \tag{23.239}$$

That is, exchanging $|\psi\rangle$ by $\mathcal{U}|\psi\rangle$ and at the same time $\hat{A}$ by $\mathcal{U}\hat{A}\mathcal{U}^\dagger$, we obtain quantities describing the same physical reality, since the eigenvalues are unchanged. This allows us to choose the best mathematical representation for a specific problem. As an example, we will apply the temporal unitary transformation to solve the dynamics of a coupled two-level system in Exc. 23.6.7.1.

23.6.2 Schrödinger picture

Important examples of how the same system can be represented in different ways (related by unitary transformations) are the Heisenberg, Schrödinger, and interaction pictures.

The *Schrödinger picture*, denoted by the subscript S, is defined by the choice of a Hamiltonian,

$$\hat{H}_{\mathrm{S}} = \hat{H}(t, \hat{p}_{\mathrm{S}}, \hat{r}_{\mathrm{S}}) \qquad \text{with} \qquad \frac{d}{dt}\hat{p}_{\mathrm{S}} = \frac{d}{dt}\hat{r}_{\mathrm{S}} = 0 \ . \tag{23.240}$$

That is, the observables of the system $\hat{A}_{\rm S}(t,\hat{p}_{\rm S},\hat{r}_{\rm S})$ can only depend *explicitly* on time, but not via other operators, for instance $\hat{p}_{\rm S}$ and $\hat{r}_{\rm S}$, which are stationary,

$$\frac{d}{dt}\hat{A}_{\rm S}=\frac{\partial\hat{A}_{\rm S}}{\partial t}+\cancelto{0}{\dot{\hat{p}}_{\rm S}}\frac{\partial\hat{A}_{\rm S}}{\partial p_{\rm S}}+\cancelto{0}{\dot{\hat{p}}_{\rm S}}\frac{\partial\hat{A}_{\rm S}}{\partial r_{\rm S}}\ . \tag{23.241}$$

This is,

$$\boxed{\frac{d}{dt}\hat{A}_{\rm S}(t)=\frac{\partial}{\partial t}\hat{A}_{\rm S}(t)}\ . \tag{23.242}$$

In the context of a moving particle, this means that the Hamiltonian $\frac{1}{2m}\hat{p}_{\rm S}^2+V(\hat{r}_{\rm S})$ is time-independent (unless the potential $V(\hat{r}_{\rm S},t)$ is itself time-dependent). In this case, the formal solution of the Schrödinger equation,

$$\boxed{\imath\hbar\frac{d}{dt}|\psi_{\rm S}(t)\rangle=\hat{H}_{\rm S}|\psi_{\rm S}(t)\rangle}\ , \tag{23.243}$$

can be written,

$$|\psi_{\rm S}(t)\rangle=e^{-(\imath/\hbar)\hat{H}_{\rm S}t}|\psi_{\rm S}(0)\rangle\equiv\mathcal{U}(t)|\psi_{\rm S}(0)\rangle\ . \tag{23.244}$$

Apparently, the temporal dynamics is completely within the wave functions.

Example 190 (*The time evolution operator*): Generalizing to an arbitrary initial time t_0 we write the temporal translation operator,

$$\mathcal{U}(t,t_0)|\psi(t_0)\rangle=|\psi(t)\rangle\ . \tag{23.245}$$

By the expression (23.244) we find immediately, with $t_0<t_1<t_2$,

$$\mathcal{U}(t_2,t_0)=\mathcal{U}(t_2,t_1)\mathcal{U}(t_1,t_0)\quad\text{and}\quad\mathcal{U}(t_0,t)=\mathcal{U}^\dagger(t,t_0)=\mathcal{U}^{-1}(t,t_0)=\mathcal{U}(t,t_0)^{-1}\ .$$

The conjugate operator of time evolution acts on the vector 'bra',

$$\langle\psi(t)|=\langle\psi(t_0)|\mathcal{U}^\dagger(t,t_0)\ .$$

23.6.3 Heisenberg picture

As unitary transformations do not change the physics, the system described by,

$$|\psi_{\rm S}(t)\rangle\longrightarrow\mathcal{U}(t)^\dagger|\psi_{\rm S}(t)\rangle\equiv|\psi_{\rm H}\rangle\quad\text{and}\quad\hat{A}_{\rm S}(t)\longrightarrow\mathcal{U}(t)^\dagger\hat{A}_{\rm S}(t)\mathcal{U}(t)\equiv\hat{A}_{\rm H}(t) \tag{23.246}$$

with the transformation defined by equation (23.244), is equivalent. The subscript H means the *Heisenberg picture*. In particular, we obviously have,

$$\hat{H}_{\rm S}=\hat{H}_{\rm H}\equiv\hat{H}\ . \tag{23.247}$$

Thus, the matrix element of the operator $\hat{A}_{\rm S}$ in Schrödinger's picture with the time-dependent base $\{|\psi_{\rm S}\rangle\}$ is equal to the matrix element of the operator $\hat{A}_{\rm H}=\mathcal{U}^\dagger\hat{A}_{\rm S}\mathcal{U}$

in Heisenberg's picture with the time-independent base $\{|\psi_{\mathrm{H}}\rangle\}$. In this picture the wavefunctions are independent of time,

$$\boxed{\frac{d}{dt}|\psi_{\mathrm{H}}\rangle = \frac{d}{dt}|\psi_{\mathrm{S}}(0)\rangle = 0}\ , \tag{23.248}$$

but the operators depend *im- and explicitly* on time,

$$\begin{aligned}\frac{d}{dt}\hat{A}_{\mathrm{H}}(t) &= \frac{d}{dt}\left(U(t)^{\dagger}\hat{A}_{\mathrm{S}}(t)\mathcal{U}(t)\right) = \frac{d\mathcal{U}^{\dagger}}{dt}\hat{A}_{\mathrm{S}}(t)\mathcal{U}(t) + \mathcal{U}(t)^{\dagger}\hat{A}_{\mathrm{S}}(t)\frac{d\mathcal{U}}{dt} + \mathcal{U}(t)^{\dagger}\frac{\partial\hat{A}_{\mathrm{S}}(t)}{\partial t}\mathcal{U}(t)\\ &= \frac{\imath}{\hbar}\hat{H}^{\dagger}U(t)^{\dagger}\hat{A}_{\mathrm{S}}\mathcal{U}(t) + \mathcal{U}(t)^{\dagger}\hat{A}_{\mathrm{S}}\frac{-\imath}{\hbar}\hat{H}\mathcal{U}(t) + \mathcal{U}^{\dagger}(t)\frac{\partial\hat{A}_{\mathrm{S}}(t)}{\partial t}\mathcal{U}(t)\ .\end{aligned} \tag{23.249}$$

That is,

$$\boxed{\frac{d}{dt}\hat{A}_{\mathrm{H}}(t) = \frac{\imath}{\hbar}[\hat{H},\hat{A}_{\mathrm{H}}(t)] + \frac{\partial\hat{A}_{\mathrm{H}}(t)}{\partial t}}\ . \tag{23.250}$$

This so-called *Heisenberg equation*, which describes the temporal evolution of an operator acting on time-independent states in the Heisenberg picture, is equivalent to the Schrödinger equation, which expresses the temporal evolution of a quantum state in Schrödinger's picture.

According to equation (23.250), the rate of temporal variation of an operator in the Heisenberg representation is given by the commutator of that operator with the total Hamiltonian of the system. Note that if an operator representing a dynamic variable commutes with the Hamiltonian in the Schrödinger representation, it will also commute with the Hamiltonian in the Heisenberg representation and thus with the complete set of commutating observables,

$$[\hat{H},\hat{A}_{\mathrm{S}}] = 0 \qquad \Longleftrightarrow \qquad [\hat{H},\hat{A}_{\mathrm{H}}] = 0\ . \tag{23.251}$$

We will show this in the Exc. 23.6.7.2. Note that we could interpret Eq. (23.248) as a Schrödinger equation with a Hamiltonian $\tilde{H}_{\mathrm{H}} = 0$. That is, *the Hamiltonian used in the Schrödinger equation differs from the one used in the Heisenberg equation.* We will study this in more detail in Secs. 23.6.4 and 23.6.5.

Example 191 (*Position and momentum operators in the Heisenberg picture*): We know that in Schrödinger's picture (23.240), the operators $\hat{p}_{\mathrm{S}}$ and $\hat{r}_{\mathrm{S}}$ are stationary. Using this fact in derivation (23.249), we can show for example for the momentum operator,

$$\frac{\partial}{\partial t}\hat{p}_{\mathrm{S}} = 0 \qquad \Longrightarrow \qquad \frac{\partial}{\partial t}\hat{p}_{\mathrm{H}} = 0 \qquad \Longrightarrow \qquad \frac{d}{dt}\hat{p}_{\mathrm{H}} = \frac{\imath}{\hbar}[\hat{H},\hat{p}_{\mathrm{H}}]\ .$$

In the Exc. 23.6.7.3 we will use the Heisenberg picture to derive the equations of motion for a particle confined to a potential.

23.6.4 Interaction picture

The *interaction picture* deals with problems where the total Hamiltonian is composed of a time-independent part and a time-dependent part,

$$\hat{H} = \hat{H}_0 + \hat{V}(t) \ . \tag{23.252}$$

Analogously to Eq. (23.244), we define a time evolution operator in terms of the *time-independent* part of the total Hamiltonian,

$$\boxed{|\psi_{\mathrm{I}}(t)\rangle = e^{\imath \hat{H}_0 t/\hbar}|\psi_{\mathrm{S}}(t)\rangle \qquad \text{and} \qquad \hat{A}_{\mathrm{I}}(t) = e^{\imath \hat{H}_0 t/\hbar}\hat{A}_{\mathrm{S}}e^{-\imath \hat{H}_0 t/\hbar}} \ . \tag{23.253}$$

Now we are interested in the temporal dependence of quantum states and operators in the interaction picture. Replacing the inverse function $|\psi_{\mathrm{S}}(t)\rangle = e^{-\imath \hat{H}_0 t/\hbar}|\psi_{\mathrm{I}}(t)\rangle$ in the Schrödinger equation (23.243) we immediately see,

$$\boxed{\hat{V}(t)|\psi_{\mathrm{I}}(t)\rangle = \imath\hbar\frac{\partial}{\partial t}|\psi_{\mathrm{I}}(t)\rangle} \ . \tag{23.254}$$

Apparently, in the interaction picture, only the perturbative term in Hamiltonian controls the temporal evolution. Taking the time derivative of both sides of the equation (23.253) transforming an operator from the Schrödinger to the interaction picture results in,

$$\boxed{\frac{d\hat{A}_{\mathrm{I}}}{dt} = \frac{\imath}{\hbar}[\hat{H}_0, \hat{A}_{\mathrm{I}}] + \frac{\partial \hat{A}_{\mathrm{I}}}{\partial t}} \ . \tag{23.255}$$

Therefore, we see that the time derivative can be expressed in the form of a commutator, resembling the Heisenberg equation (23.250), except that only the unperturbed term of the Hamiltonian appears in the argument of the commutation operator. As already state in Sec. 23.6.3, different Hamiltonians are used in the Schrödinger and in the Heisenberg equation.

Example 192 (*Schrieffer-Wolff transformation*): The *Schrieffer-Wolff transformation* is a unitary transformation used to perturbatively diagonalize the system Hamiltonian to first order in the interaction. As such, the Schrieffer-Wolff transformation is an operator version of second-order perturbation theory. The Schrieffer-Wolff transformation is often used to project out the high energy excitations of a given quantum many-body Hamiltonian in order to obtain an effective low energy model. The Schrieffer-Wolff transformation thus provides a controlled perturbative way to study the strong coupling regime of quantum-many body Hamiltonians.
Consider a quantum system evolving under the time-independent Hamiltonian operator $\hat{H}$ of the form $\hat{H} = \hat{H}_0 + \hat{V}$, where H_0 is a Hamiltonian with known eigenstates $|m\rangle$ and corresponding eigenvalues E_m, and where V is a small perturbation. Moreover, it is assumed without loss of generality that $\hat{V}$ is purely off-diagonal in the eigenbasis of $\hat{H}_0$, i.e.,

$$\langle m|\hat{V}|m\rangle = 0 \tag{23.256}$$

for all m. Indeed, this situation can always be arranged by absorbing the diagonal elements of $\hat{V}$ into $\hat{H}_0$, thus modifying its eigenvalues to,

$$E'_m = E_m + \langle m|\hat{V}|m\rangle \ . \tag{23.257}$$

The Schrieffer-Wolff transformation is a unitary transformation which expresses the Hamiltonian in a basis (the 'dressed' basis) where it is diagonal to first order in the perturbation $\hat{V}$. This unitary transformation is conventionally written as:

$$\hat{H}' = e^{\imath S}\hat{H}e^{-\imath S} \ . \tag{23.258}$$

When $\hat{V}$ is small, the generator S of the transformation will likewise be small. The transformation can then be expanded in S using the Baker-Campbell-Haussdorf formula,

$$\hat{H}' = \hat{H} + [\imath S, \hat{H}] + \tfrac{1}{2}[\imath S, [\imath S, \hat{H}]] + \dots \ . \tag{23.259}$$

In terms of $\hat{H}_0$ and $\hat{V}$, the transformation becomes,

$$\hat{H}' = \hat{H}_0 + \hat{V} + [\imath S, \hat{H}_0] + [\imath S, \hat{V}] + \tfrac{1}{2}[\imath S, [\imath S, \hat{H}_0]] + \tfrac{1}{2}[\imath S, [\imath S, \hat{V}]] + \dots \ . \tag{23.260}$$

The Hamiltonian can be made diagonal to first order in $\hat{V}$ by choosing the generator S such that,

$$[\hat{H}_0, \imath S] = \hat{V} \ . \tag{23.261}$$

This equation always has a definite solution under the assumption that $\hat{V}$ is off-diagonal in the eigenbasis of $\hat{H}_0$. Substituting this choice in the previous transformation yields:

$$\hat{H}' = \hat{H}_0 + \tfrac{1}{2}[\imath S, \hat{V}] + O(\hat{V}^3) \ . \tag{23.262}$$

This expression is the standard form of the Schrieffer-Wolff transformation. Note that all the operators on the right-hand side are now expressed in a new basis 'dressed' by the interaction $\hat{V}$ to first order.
In the general case, the difficult step of the transformation is to find an explicit expression for the generator S. Once this is done, it is straightforward to compute the Schrieffer-Wolff Hamiltonian by computing the commutator $[S, \hat{V}]$. The Hamiltonian can then be projected on any subspace of interest to obtain an effective projected Hamiltonian for that subspace. In order for the transformation to be accurate, the eliminated subspaces must be energetically well separated from the subspace of interest, meaning that the strength of the interaction $\hat{V}$ must be much smaller than the energy difference between the subspaces. This is the same regime of validity as in standard second-order perturbation theory.

23.6.5 Hamiltonian under arbitrary unitary transformation

In the preceding section we have studied particular unitary transformations between the Schrödinger, Heisenberg, and interaction pictures. Let us now have a look at *arbitrary* unitary transformations.

We have seen that the unitary transformation,

$$|\psi_{\mathcal{U}}\rangle = \mathcal{U}^\dagger|\psi\rangle \quad , \quad \hat{A}_{\mathcal{U}} = \mathcal{U}^\dagger \hat{A}\mathcal{U} \ , \tag{23.263}$$

leaves the physics of a system unchanged. The question is now, how the Schrödinger equation,

$$\hat{H}|\psi\rangle = \imath\hbar\frac{d}{dt}|\psi\rangle \tag{23.264}$$

transforms into the new system, that is, what will the Hamiltonian $\hat{H}_{\mathcal{U}}$ look like in the transformed equation,

$$\hat{H}_{\mathcal{U}}|\psi_{\mathcal{U}}\rangle \stackrel{?}{=} \imath\hbar\frac{d}{dt}|\psi_{\mathcal{U}}\rangle \ . \tag{23.265}$$

We calculate,

$$\begin{aligned}\imath\hbar\frac{d}{dt}|\psi_{\mathcal{U}}\rangle &= \imath\hbar\mathcal{U}^\dagger\frac{d}{dt}|\psi\rangle + \imath\hbar\dot{\mathcal{U}}^\dagger|\psi\rangle = (\mathcal{U}^\dagger\hat{H} + \imath\hbar\dot{\mathcal{U}}^\dagger)|\psi\rangle \\ &= (\mathcal{U}^\dagger\hat{H} + \imath\hbar\dot{\mathcal{U}}^\dagger)\mathcal{U}|\psi_{\mathcal{U}}\rangle = (\mathcal{U}^\dagger\hat{H}\mathcal{U} + \imath\hbar\dot{\mathcal{U}}^\dagger\mathcal{U})|\psi_{\mathcal{U}}\rangle = \hat{H}_{\mathcal{U}}|\psi_{\mathcal{U}}\rangle \ .\end{aligned} \tag{23.266}$$

Hence,

$$\boxed{\hat{H}_{\mathcal{U}} = \mathcal{U}^\dagger\hat{H}\mathcal{U} + \imath\hbar\dot{\mathcal{U}}^\dagger\mathcal{U}} \ . \tag{23.267}$$

We will apply this concept in Exc. 23.7.6.2 to a particle in the field of gravity.

Example 193 (*Interaction picture*): The above derivation is general and holds for any unitary transformation. We will now apply it to transform the Hamiltonian $\hat{H} = \hat{H}_0 + \hat{V}(t)$ into the interaction picture via the transformation $\mathcal{U} = e^{-(\imath/\hbar)\hat{H}_0 t}$. From

$$\dot{\mathcal{U}}^\dagger = \frac{\imath}{\hbar}\hat{H}_0 e^{(\imath/\hbar)\hat{H}_0 t} = \frac{\imath}{\hbar}\hat{H}_0\mathcal{U}^\dagger \tag{23.268}$$

we calculate,

$$\begin{aligned}\hat{H}_{\mathcal{U}} &= \mathcal{U}^\dagger\hat{H}\mathcal{U} + \imath\hbar\dot{U}^\dagger\mathcal{U} = \mathcal{U}^\dagger[\hat{H}_0 + \hat{V}(t)]\mathcal{U} + \imath\hbar\frac{\imath}{\hbar}\hat{H}_0 U^\dagger\mathcal{U} \\ &= \mathcal{U}^\dagger[\hat{H}_0 + \hat{V}(t)]\mathcal{U} - \hat{H}_0 = \mathcal{U}^\dagger\hat{V}(t)\mathcal{U} \ ,\end{aligned} \tag{23.269}$$

which confirms the validity of the Schrödinger equation (23.254) in the interaction picture, provided the Hamiltonian is taken to be the perturbation part $\hat{V}(t)$, only. In the Heisenberg picture $\hat{V}(t) = 0$, such that,

$$\hat{H}_{\mathcal{U}} = 0 \ , \tag{23.270}$$

which confirms Eq. (23.248).

23.6.6 Ehrenfest's theorem

For linear operators satisfying $[\hat{A}, \hat{B}] = \imath$ we can give a generalization of the commutation relation:

$$\boxed{[\hat{A}, F(\hat{A}, \hat{B})] = \imath\frac{\delta F(\hat{A}, \hat{B})}{\delta\hat{B}}} \ . \tag{23.271}$$

This can be verified by a Taylor expansion of $F(\hat{A}, \hat{B})$ by $\hat{B}$ around $\hat{B} = 0$, as will be shown in Exc. 23.6.7.4. An immediate consequence of $[\hat{p}, \hat{r}] = -\imath\hbar$ is,

$$[\hat{p}, F(\hat{r})] = -\imath\hbar\frac{\delta F(\hat{r})}{\delta\hat{r}} \ . \tag{23.272}$$

The momentum observable is not singularly defined by the commutation relation, because each unitarily transformed operator satisfies the relation as well. We

can expand a unitarily equivalent momentum as $\tilde{p} = \mathcal{U}p\mathcal{U}^\dagger = e^{\imath F(r)}pe^{-\imath F(r)} = p + \imath[F(r), p] + \frac{1}{2!}[F(r), [F(r), p]] + ...$ using the relation (23.272).

The observables in the Heisenberg picture follow the same equations of motion as the corresponding classical quantities. This *correspondence principle* is called *Ehrenfest theorem*. For example, when working with position and momentum variables $[\hat{r}, \hat{k}] = \imath$ and $\hat{H} = \frac{\hbar^2}{2m}\hat{k}^2 + V(\hat{r})$, we obtain,

$$[\hat{r}, \hat{H}] = \imath\hbar\frac{\delta\hat{H}}{\delta\hat{p}} \qquad \text{and} \qquad [\hat{p}, \hat{H}] = -\imath\hbar\frac{\delta\hat{H}}{\delta\hat{r}} \ , \tag{23.273}$$

and using the Heisenberg equation (23.250),

$$\dot{\hat{r}} = \frac{\delta\hat{H}}{\delta\hat{p}} \qquad \text{and} \qquad \dot{\hat{p}} = -\frac{\delta\hat{H}}{\delta\hat{r}} \ . \tag{23.274}$$

We will demonstrate this in Exc. 23.6.7.5 for the case of a harmonic potential.

In the Schrödinger picture the equation of motion for the eigenvalues of the observables takes the form,

$$\frac{d}{dt}\langle\hat{A}_\mathrm{S}\rangle = \langle\partial_t\psi|\hat{A}_\mathrm{S}|\psi\rangle + \langle\psi|\partial_t\hat{A}_\mathrm{S}|\psi\rangle + \langle\psi|\hat{A}_\mathrm{S}|\partial_t\psi\rangle = \frac{\partial}{\partial t}\langle\hat{A}_\mathrm{S}\rangle + \frac{\imath}{\hbar}\langle[\hat{H}, \hat{A}_\mathrm{S}]\rangle \ . \tag{23.275}$$

The eigenvalues behave as Heisenberg observables in Eq. (23.249), that is, they follow the laws of Hamilton's and Newton's mechanics.

The important result now is that the equations that govern the eigenvalues of the observables are identical in the both pictures, since from the Heisenberg picture we obtain with Eq. (23.249),

$$\frac{d}{dt}\langle\hat{A}_\mathrm{H}\rangle = \frac{\partial}{\partial t}\langle\hat{A}_\mathrm{H}\rangle + \frac{\imath}{\hbar}\langle[\hat{H}, \hat{A}_\mathrm{H}]\rangle \ .$$

23.6.7 Exercises

23.6.7.1 Ex: Coupled two-level atom

Calculate the time evolution of an atom with two levels coupled by a light field using the Hamiltonian,

$$\hat{H} = \begin{pmatrix} 0 & \frac{1}{2}\hbar\Omega \\ \frac{1}{2}\hbar\Omega & -\hbar\Delta \end{pmatrix} \ ,$$

where $\Delta = \omega - \omega_0$ is the detuning between the frequency of the light and the frequency of the transition and Ω the Rabi frequency. **Help:** Determine the matrix of the eigenvalues $\hat{E}$ and the unitary transformation $\mathcal{U}$ given by $\mathcal{U}^\dagger\hat{H}\mathcal{U} = \hat{E}$ and use the formal solution of the Schrödinger equation: $|\psi(t)\rangle = e^{-\imath\hat{H}t/\hbar}|\psi_0\rangle = e^{-\imath\mathcal{U}^\dagger\hat{E}\mathcal{U}t/\hbar}|\psi_0\rangle = \mathcal{U}^\dagger e^{-\imath\hat{E}t/\hbar}\mathcal{U}|\psi_0\rangle$.

23.6.7.2 Ex: Commutator in Schrödinger's and Heisenberg's picture

Show that operators which commute with the Hamiltonian in the Schrödinger picture also do it in the Heisenberg picture. Use the rule $[\hat{H}, \hat{A}\hat{B}] = \hat{A}[\hat{H}, \hat{B}] + [\hat{H}, \hat{A}]\hat{B}$.

23.6.7.3 Ex: Motion in Heisenberg's picture

Consider the Hamiltonian $\hat{H} = \frac{\hat{p}^2}{2m} + \frac{m}{2}\omega^2\hat{r}^2$. Using the relation $[\hat{p}, \hat{r}] = -\imath\hbar$ calculate in the Heisenberg picture the equations of motion for the observables $\hat{p}$, $\hat{r}$, and $\hat{p}\hat{r}$.

23.6.7.4 Ex: Commutator of a function of operators

Prove the relationship (23.271).

23.6.7.5 Ex: Ehrenfest's theorem

Compare the equations of Ehrenfest's theorem with those of Hamilton-Jacobi for a classical particle subject to a time-independent potential. Discuss the classical limit, that is, when the Hamilton-Jacobi equations approach those of Ehrenfest.

23.7 Symmetries in quantum mechanics

We already saw in Sec. 23.5.4 that, beyond observables, there is another category of operators that does not correspond to measurable physical quantities, but is very useful in the quantum formalism. These are the *unitary transformations*. In this section we will encounter some interesting examples.

23.7.1 Translation, rotation and momentum kick

23.7.1.1 Temporal translation operator

The temporal evolution of a system is described by the Schrödinger equation whose formal solution can be written as follows,

$$|\psi(t)\rangle = e^{-\imath\hat{H}t/\hbar}|\psi(0)\rangle \ . \tag{23.276}$$

With this we can define an *evolution operator* or temporal translation,

$$\boxed{\mathcal{U}_{\text{tp}}(\tau) \equiv e^{-\imath\hat{H}t/\hbar} \qquad \text{such that} \qquad \mathcal{U}_{\text{tp}}(\tau)|\psi(t)\rangle = |\psi(t+\tau)\rangle} \ . \tag{23.277}$$

The temporal evolution has already been discussed extensively in Sec. 23.6.

23.7.1.2 Spatial translation operator

In this section we look for a unitary *translation operator*,

$$\mathcal{T}_{\text{tr}}\mathbf{r} \equiv \mathbf{a} + \mathbf{r} \ . \tag{23.278}$$

Before this, we need to derive the following calculation rule for commutators, which will be done in Exc. 23.7.6.1:

$$e^{\hat{A}}\hat{B}e^{-\hat{A}} = \hat{B} + [\hat{A}, \hat{B}] + \tfrac{1}{2!}[\hat{A}, [\hat{A}, \hat{B}]] + \ldots \ . \tag{23.279}$$

Applying this formula to the two operators $\hat{\mathbf{p}}$ and $\hat{\mathbf{r}}$ related by the commutation rule (23.160), we obtain,

$$e^{(\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}\hat{\mathbf{r}}e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}} = \hat{\mathbf{r}} + [(\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}},\hat{\mathbf{r}}] + \tfrac{1}{2!}\cancelto{0}{[(\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}},\mathbf{a}]} + ... = \hat{\mathbf{r}} + \mathbf{a}\ . \tag{23.280}$$

That is, the operator

$$\boxed{\mathcal{U}_{\rm tr}(\mathbf{a}) \equiv e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}} \tag{23.281}$$

performs a spatial translation of the position operator. The operator is unitary,

$$\mathcal{U}_{\rm tr}(\mathbf{a})^{-1} = \mathcal{U}_{\rm tr}(\mathbf{a})^{\dagger}\ , \tag{23.282}$$

and forms a group since $\mathcal{U}_{\rm tr}(\mathbf{a})\mathcal{U}_{\rm tr}(\mathbf{b}) = \mathcal{U}_{\rm tr}(\mathbf{a}+\mathbf{b})$. Summarizing the impact of the translation on the operators of space,

$$\boxed{\mathcal{U}^{\dagger}_{\rm tr}(\mathbf{a})\hat{\mathbf{r}}\mathcal{U}_{\rm tr}(\mathbf{a}) = \hat{\mathbf{r}} + \mathbf{a} \qquad , \qquad \mathcal{U}^{\dagger}_{\rm tr}(\mathbf{a})\hat{\mathbf{p}}\mathcal{U}_{\rm tr}(\mathbf{a}) = \hat{\mathbf{p}}}\ , \tag{23.283}$$

where the second relation is obvious.

To demonstrate how the translation acts on a state, let us calculate,

$$\hat{\mathbf{r}}e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}|\mathbf{r}\rangle = e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}(\hat{\mathbf{r}}+\mathbf{a})|\mathbf{r}\rangle = (\mathbf{r}+\mathbf{a})e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}|\mathbf{r}\rangle\ . \tag{23.284}$$

Hence,

$$\boxed{\mathcal{U}_{\rm tr}(\mathbf{a})|\mathbf{r}\rangle = e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}|\mathbf{r}\rangle = |\mathbf{r}+\mathbf{a}\rangle}\ . \tag{23.285}$$

Therefore, if a particle is in an eigenstate $|\mathbf{r}\rangle$ of the position operator (i.e. located exactly at the position $\mathbf{r}$), then after $\mathcal{U}_{\rm tr}(\mathbf{a})$ acts on it, the particle is at the position $\mathbf{r}+\mathbf{a}$: The translation operator $\mathcal{U}_{\rm tr}(\mathbf{a})$ hence moves particles and fields by the distance $\mathbf{a}$.

Finally, we want to describe, how the translation operator acts on an arbitrary state $|\psi\rangle$ represented in position-space, remembering that the position-space wavefunction is obtained via $\psi(\mathbf{r}) \equiv \langle\mathbf{r}|\psi\rangle$, as already mentioned in Sec. 23.5.7. We get,

$$\psi'(\mathbf{r}) \equiv \mathcal{T}_{\rm tr}\psi(\mathbf{r}) \equiv \langle\mathbf{r}|\mathcal{U}_{\rm tr}(\mathbf{a})|\psi\rangle = \langle\mathcal{U}^{\dagger}_{\rm tr}(\mathbf{a})\mathbf{r}|\psi\rangle = \langle\mathbf{r}-\mathbf{a}|\psi\rangle = \psi(\mathbf{r}-\mathbf{a})\ . \tag{23.286}$$

This relation is easier to remember as $\psi'(\mathbf{r}+\mathbf{a}) = \psi(\mathbf{r})$, which can be read as: *The value of the new wavefunction at the new point equals the value of the old wavefunction at the old point.*

> **Example 194 (*Translation of spatial wavefunctions*):** Here is an example showing that these two descriptions (23.285) and (23.286) are equivalent. The state $|\mathbf{x}\rangle$ corresponds to the wavefunction $\psi(\mathbf{r}) = \delta^3(\mathbf{r}-\mathbf{x})$, while the state $\mathcal{U}_{\rm tr}(\mathbf{a})|\mathbf{x}\rangle = |\mathbf{x}+\mathbf{a}\rangle$ corresponds to the wavefunction $\psi'(\mathbf{r}) = \delta^3(\mathbf{r}-(\mathbf{x}+\mathbf{a}))$. These indeed satisfy $\psi'(\mathbf{r}) = \psi(\mathbf{r}-\mathbf{a})$.

Comparing the expansion of the translation operator,

$$\langle\mathbf{r}|\mathcal{U}_{\rm tr}(\mathbf{a})|\psi\rangle = \langle e^{(\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}\mathbf{r}|\psi\rangle = \left(1 + \frac{\imath}{\hbar}\mathbf{a}\cdot\hat{\mathbf{p}} - \frac{1}{\hbar^2}\frac{(\mathbf{a}\cdot\hat{\mathbf{p}})^2}{2!} + ..\right)\langle\mathbf{r}|\psi\rangle\ , \tag{23.287}$$

with the Taylor expansion of the wavefunction,

$$\langle \mathbf{r}+\mathbf{a}|\psi\rangle = \psi(\mathbf{r}+\mathbf{a}) = \left(1+\mathbf{a}\cdot\nabla+\frac{(\mathbf{a}\cdot\nabla)^2}{2!}+..\right)\psi(\mathbf{r}) \ . \tag{23.288}$$

we obtain

$$\hat{\mathbf{p}}|\mathbf{r}\rangle = \frac{\hbar}{\imath}\nabla|\mathbf{r}\rangle \ . \tag{23.289}$$

Finally, we note that the momentum operator can be defined via the translation operator,

$$\hat{\mathbf{p}} = \imath\hbar\,\nabla_{\mathbf{a}}\mathcal{U}_{\rm tr}(\mathbf{a})|_{\mathbf{a}=\mathbf{0}} \ . \tag{23.290}$$

23.7.1.3 Momentum kick operator

In this section we look for the unitary transformation into a frame moving a constant velocity $\mathbf{v}$,

$$\mathcal{T}_{\rm kc}\mathbf{p} \equiv \mathbf{p}+m\mathbf{v} \ . \tag{23.291}$$

As this transformation corresponds to a 'translation' in momentum space, the form of the unitary transformation operator and the way it acts on operators and states are easy to derive by analogy to the spatial translation operator, simply interchanging the roles of the conjugate operators of space and momentum. The corresponding unitary operator in the so-called *kick operator*,

$$\boxed{\mathcal{U}_{\rm kc}(m\mathbf{v}) = e^{(\imath/\hbar)m\mathbf{v}\cdot\hat{\mathbf{r}}}} \ . \tag{23.292}$$

where $m\mathbf{v} = \mathbf{p} = \hbar\mathbf{k}$ is the gain in momentum due to the kick.

A common situation where such a kick occurs is the photonic recoil that an atom receives upon absorption of a photon. Using the relationship (23.279) derived in Exc. 23.7.6.1 it is easy to verify the following expressions of the left-hand panel,

$$\boxed{\begin{aligned} e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}|\mathbf{r}\rangle &= e^{\imath\mathbf{k}\cdot\mathbf{r}}|\mathbf{r}\rangle \\ e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}|\mathbf{p}\rangle &= |\mathbf{p}+\hbar\mathbf{k}\rangle \\ e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\hat{\mathbf{r}}e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}} &= \hat{\mathbf{r}} \\ e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\hat{\mathbf{p}}e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}} &= \hat{\mathbf{p}}+\hbar\mathbf{k} \\ e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\frac{\hat{\mathbf{p}}^2}{2m}e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}} &= \frac{(\hat{\mathbf{p}}+\hbar\mathbf{k})^2}{2m} \end{aligned}} \ , \quad \boxed{\begin{aligned} e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar}|\mathbf{r}\rangle &= |\mathbf{r}+\mathbf{b}\rangle \\ e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar}|\mathbf{p}\rangle &= e^{-\imath\mathbf{b}\cdot\mathbf{p}/\hbar}|\mathbf{p}\rangle \\ e^{\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar}\hat{\mathbf{r}}e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar} &= \hat{\mathbf{r}}+\mathbf{b} \\ e^{\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar}\hat{\mathbf{p}}e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar} &= \hat{\mathbf{p}} \\ e^{\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar}V(\hat{\mathbf{r}})e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar} &= V(\hat{\mathbf{r}}+\mathbf{b}) \end{aligned}} \tag{23.293}$$

The rule implies $[e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}},\hat{\mathbf{p}}] \neq 0 \neq [e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}},\hat{H}]$. That is, we describe the kick by simply adding the corresponding momentum $\hbar\mathbf{k}$ to the system and adjusting the kinetic energy accordingly.

The right-hand panel of Eq. (23.293) summarizes rules for calculating with the spatial *displacement operator*, $\mathcal{U}_{\rm tr}(\mathbf{b}) = e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar}$, introduced in Sec. 23.7.1. By analogy we find $[e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar},\hat{\mathbf{r}}] \neq 0 \neq [e^{-\imath\mathbf{b}\cdot\hat{\mathbf{p}}/\hbar},\hat{H}]$ when the particle is subject to a potential. The (complex) eigenstates of the translation operator $e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}$ are the momentum states $|\mathbf{p}\rangle$, and the eigenvalues $e^{(-\imath/\hbar)\mathbf{a}\cdot\mathbf{p}}$ are unitary. The (complex) eigenstates of the kick operator $e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}$ are the position states $|\mathbf{r}\rangle$, and the eigenvalues $e^{\imath\mathbf{k}\cdot\mathbf{r}}$ are unitary.

The 'kick' will play a prominent role in the discussion of photonic recoil (see Sec. 24.6.2). Of course the assumption of an infinitely fast transition is an idealization and the ultimate reason for the non-conservation of momentum and energy by the system. In real situations, such as in the case of photonic recoil, the dynamics should be described by a collision process which conserves momentum and energy.

23.7.1.4 Periodic systems, quasi-momentum

Systems with potentials are generally not translationally invariant, since according to Eq. (23.293),

$$e^{(\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}}V(\hat{\mathbf{r}})e^{(-\imath/\hbar)\mathbf{a}\cdot\hat{\mathbf{p}}} = V(\hat{\mathbf{r}}+\mathbf{a}) \neq V(\hat{\mathbf{r}}) \ . \tag{23.294}$$

An exception are precisely those potentials satisfying $V(\hat{\mathbf{r}}+\mathbf{a}) = V(\hat{\mathbf{r}})$, which are called periodic. The (complex) eigenstates $|\mathbf{q}\rangle$ of the translation operator, given by,

$$\mathcal{U}_{\rm tr}(\mathbf{a})|\mathbf{q}\rangle = e^{(-\imath/\hbar)\mathbf{a}\cdot\mathbf{q}}|\mathbf{q}\rangle \ , \tag{23.295}$$

are called *quasi-momenta*. In contrast to the continuous symmetries of homogeneity or isotropy, periodicity and parity represent discrete symmetries. We will study periodic systems state in detail in Chp. 26.

23.7.1.5 Rotation operator

In this section we look for the unitary transformation corresponding to the *rotation operator* [910],

$$\mathcal{T}_{\rm rt}\mathbf{r} \equiv e^{\vec{\alpha}\times}\mathbf{r} \ . \tag{23.296}$$

We calculate,

$$\begin{aligned} e^{\vec{\alpha}\times}\mathbf{r} &= \sum_n \frac{(\vec{\alpha}\times)^n}{n!}\mathbf{r} = \mathbf{r} + \vec{\alpha}\times\mathbf{r} + \tfrac{1}{2}\vec{\alpha}\times(\vec{\alpha}\times\mathbf{r}) + .. \\ &= \hat{\mathbf{e}}_\alpha(\hat{\mathbf{e}}_\alpha\cdot\mathbf{r}) + \hat{\mathbf{e}}_\alpha\times\mathbf{r}\sin\alpha - \hat{\mathbf{e}}_\alpha\times(\hat{\mathbf{e}}_\alpha\times\mathbf{r})\cos\alpha \ , \end{aligned} \tag{23.297}$$

as we will see in Exc. 23.7.6.4. We define the unitary rotational transformation by,

$$\boxed{\mathcal{U}^\dagger_{\rm rt}(\vec{\alpha})\hat{\mathbf{r}}\mathcal{U}_{\rm rt}(\vec{\alpha}) = e^{\vec{\alpha}\times}\hat{\mathbf{r}} \quad , \quad \mathcal{U}_{\rm rt}(\vec{\alpha})|\mathbf{r}\rangle = |e^{\vec{\alpha}\times}\mathbf{r}\rangle} \ . \tag{23.298}$$

To derive the explicit form of the rotation operator, we consider two rotations about the same axis $\vec{\alpha} = \lambda_1\hat{\mathbf{e}}_\alpha + \lambda_2\hat{\mathbf{e}}_\alpha$, such that

$$\mathcal{U}_{\rm rt}(\lambda_1\hat{\mathbf{e}}_\alpha)\mathcal{U}_{\rm rt}(\lambda_2\hat{\mathbf{e}}_\alpha) = \mathcal{U}_{\rm rt}(\lambda_1\hat{\mathbf{e}}_\alpha + \lambda_2\hat{\mathbf{e}}_\alpha) \ . \tag{23.299}$$

Calculating the derivative of this equation by λ_1 and then setting $\lambda_1 = 0$, we have,

$$\begin{aligned} \frac{d\mathcal{U}_{\rm rt}(\lambda_1\hat{\mathbf{e}}_\alpha)}{d\lambda_1}\bigg|_{\lambda_1=0}\mathcal{U}_{\rm rt}(\lambda_2\hat{\mathbf{e}}_\alpha) &= \frac{d\mathcal{U}_{\rm rt}(\lambda_1\hat{\mathbf{e}}_\alpha+\lambda_2\hat{\mathbf{e}}_\alpha)}{d(\lambda_1+\lambda_2)}\bigg|_{\lambda_1=0}\frac{d(\lambda_1+\lambda_2)}{d\lambda_1}\bigg|_{\lambda_1=0} \\ \Longrightarrow \quad \frac{d\lambda_1\hat{\mathbf{e}}_\alpha}{d\lambda_1}\bigg|_{\lambda_1=0}\cdot\nabla_{\vec{\alpha}}U_{\rm rt}(\vec{\alpha})|_{\vec{\alpha}=0}\mathcal{U}_{\rm rt}(\lambda_2\hat{\mathbf{e}}_\alpha) &= \frac{d\mathcal{U}_{\rm rt}(\lambda_2\hat{\mathbf{e}}_\alpha)}{d\lambda_2} \\ \Longrightarrow \quad \hat{\mathbf{e}}_\alpha\cdot\frac{\hat{\mathbf{L}}}{\imath\hbar}\,U_{\rm rt}(\lambda_2\hat{\mathbf{e}}_\alpha) &= \frac{d\mathcal{U}_{\rm rt}(\lambda_2\hat{\mathbf{e}}_\alpha)}{d\lambda_2} \end{aligned} \tag{23.300}$$

where we define the angular momentum operator,

$$\hat{\mathbf{L}} \equiv \imath\hbar\, \nabla_{\vec{\alpha}} \mathcal{U}_{\rm rt}(\vec{\alpha})|_{\vec{\alpha}=0} \ . \tag{23.301}$$

The solution of the last differential equation (23.300) is, with $\lambda_2 \hat{\mathbf{e}}_\alpha = \vec{\alpha}|_{\lambda_1=0}$,

$$\boxed{\mathcal{U}_{\rm rt}(\vec{\alpha}) = e^{(-\imath/\hbar)\hat{\mathbf{L}}\cdot\vec{\alpha}}} \ . \tag{23.302}$$

The explicit form of $\hat{\mathbf{L}}$ follows from its action on a state $|\psi\rangle$ projected into position space. In analogy with the derivation of the result (23.289), comparing the expansion of the operator (23.302),

$$\langle \mathbf{r}|\mathcal{U}_{\rm rt}(\vec{\alpha})|\psi\rangle = \langle e^{(\imath/\hbar)\vec{\alpha}\cdot\hat{\mathbf{L}}}\mathbf{r}|\psi\rangle = \left(1 + \frac{\imath}{\hbar}\vec{\alpha}\cdot\hat{\mathbf{L}} + ..\right)\langle \mathbf{r}|\psi\rangle \ , \tag{23.303}$$

with the Taylor expansion of the wavefunction,

$$\langle e^{\vec{\alpha}\times}\mathbf{r}|\psi\rangle = \psi(\mathbf{r} + \vec{\alpha}\times\mathbf{r} + ..) = [1 + (\vec{\alpha}\times\mathbf{r})\cdot\nabla_{\mathbf{r}} + ..]\,\psi(\mathbf{r}) \ , \tag{23.304}$$

we find,

$$\frac{\imath}{\hbar}\vec{\alpha}\cdot\hat{\mathbf{L}} = (\vec{\alpha}\times\mathbf{r})\cdot\nabla_{\mathbf{r}} = \vec{\alpha}\cdot(\mathbf{r}\times\nabla_{\mathbf{r}}) = \frac{\imath}{\hbar}\vec{\alpha}\cdot(\mathbf{r}\times\hat{\mathbf{p}}) \ , \tag{23.305}$$

that is,

$$\hat{\mathbf{L}} = \hat{\mathbf{r}}\times\hat{\mathbf{p}} \ . \tag{23.306}$$

Therefore, the observable $\hat{\mathbf{L}}$ is the *orbital angular momentum* of the particle producing the rotations.

Inserting the angular momentum expression (23.306) into the rotation operator (23.302) and using the rule (23.279) as well as the commutation relations for position and momentum operators, we can now verify the expression directly. Note also that the rotation transformation acts on the momentum operators and states in the same way as on position operators and states. This is not surprising, as the angular momentum operator is symmetric in $\mathbf{r}$ and $\mathbf{p}$.

23.7.2 Transformation to accelerated and rotating frames

23.7.2.1 Transformation to an accelerated frame

Transformation into a accelerated frame with acceleration $\mathbf{g}$ adds a homogeneous force term to the Hamiltonian. At non-relativistic velocities, the transformation can be performed via a unitary kick into a system instantaneously moving at velocity $\mathbf{g}t$,

$$\boxed{\mathcal{U}_{\rm ac}(\mathbf{g}) = e^{(\imath/\hbar)m\mathbf{g}t\cdot\hat{\mathbf{r}}}} \quad , \quad |\psi_{\rm ac}\rangle = \mathcal{U}_{\rm ac}(\mathbf{g})|\psi\rangle \ . \tag{23.307}$$

This operator removes the force field from the Hamiltonian, since the Schrödinger equation,

$$\imath\hbar\frac{d}{dt}|\psi\rangle = \hat{H}|\psi\rangle \qquad \text{with} \qquad \hat{H} = \frac{\hat{\mathbf{p}}^2}{2m} + m\mathbf{g}\cdot\hat{\mathbf{r}} \ , \tag{23.308}$$

transforms into the Schrödiner equation,

$$\begin{aligned}\imath\hbar\frac{d}{dt}|\psi_{\rm ac}\rangle &= \imath\hbar\frac{d}{dt}\left(e^{(\imath/\hbar)m\mathbf{g}t\cdot\hat{\mathbf{r}}}|\psi\rangle\right) \\ &= \imath\hbar e^{(\imath/\hbar)m\mathbf{g}t\cdot\hat{\mathbf{r}}}\frac{d}{dt}|\psi\rangle + \imath\hbar|\psi\rangle\frac{d}{dt}e^{(\imath/\hbar)m\mathbf{g}t\cdot\hat{\mathbf{r}}} \\ &= e^{(\imath/\hbar)m\mathbf{g}t\cdot\hat{\mathbf{r}}}\left(\frac{\hat{\mathbf{p}}^2}{2m}+m\mathbf{g}\cdot\hat{\mathbf{r}}\right)|\psi\rangle - m\mathbf{g}\cdot\hat{\mathbf{r}}e^{(\imath/\hbar)m\mathbf{g}t\cdot\hat{\mathbf{r}}}|\psi\rangle = \frac{\hat{\mathbf{p}}^2}{2m}|\psi_{\rm ac}\rangle\ .\end{aligned} \tag{23.309}$$

23.7.2.2 Transformation to a rotating frame

Transformation into a frame rotating at angular velocity $\vec{\omega}$ adds ... to the Hamiltonian. At non-relativistic velocities, the transformation can be performed via a unitary rotation transformation into a system rotated by an angle $\vec{\omega}t$,

$$\boxed{\mathcal{U}_{\rm ar}(\vec{\omega}) = e^{(\imath/\hbar)m\vec{\omega}t\cdot\hat{\mathbf{L}}}} \quad , \quad |\psi_{\rm ar}\rangle = \mathcal{U}_{\rm ar}(\vec{\omega})|\psi\rangle\ . \tag{23.310}$$

23.7.3 Composite transformations, Galilei boost

Some transformations are generated by several operators. The Galilei transform of a system into a moving frame, the displacement operator for coherent states (24.130), or the squeezing operator (37.104) are prominent examples. These transformations can be handled using Glauber's formula, which will be introduced below, before we turn our attention to the Galilei transform.

23.7.3.1 Glauber's and Baker-Campbell-Hausdorff's formulas

The *Baker-Campbell-Hausdorff formula* for operators $\hat{A}$ and $\hat{B}$ reads,

$$\ln(e^{\hat{A}}e^{\hat{B}}) = \hat{A}+\hat{B}+\tfrac{1}{2}[\hat{A},\hat{B}]+\tfrac{1}{12}[\hat{A},[\hat{A},\hat{B}]]-\tfrac{1}{12}[\hat{B},[\hat{A},\hat{B}]]+\ldots\ . \tag{23.311}$$

A useful special case called *Glauber's formula* follows when $\hat{A}$ and $\hat{B}$ commute with their commutator, i.e. $[\hat{A},[\hat{A},\hat{B}]]=[\hat{B},[\hat{A},\hat{B}]]=0$,

$$\boxed{e^{[\hat{B},\hat{A}]/2}e^{\hat{A}}e^{\hat{B}} = e^{\hat{A}+\hat{B}} = e^{[\hat{A},\hat{B}]/2}e^{\hat{B}}e^{\hat{A}}}\ . \tag{23.312}$$

Example 195 (*The Baker-Hausdorff formula*): In order to prove the Baker-Hausdorff formula, we consider the operator,

$$\hat{G}(\tau) \equiv e^{\tau(\hat{A}+\hat{B})}e^{-\tau\hat{B}}e^{-\tau\hat{A}}\ .$$

The derivative is,

$$\begin{aligned}\hat{G}'(\tau) &= (\hat{A}+\hat{B})e^{\tau(\hat{A}+\hat{B})}e^{-\tau\hat{B}}e^{-\tau\hat{A}} - e^{\tau(\hat{A}+\hat{B})}\hat{B}e^{-\tau\hat{B}}e^{-\tau\hat{A}} - e^{\tau(\hat{A}+\hat{B})}e^{-\tau\hat{B}}\hat{A}e^{-\tau\hat{A}} \\ &= e^{\tau(\hat{A}+\hat{B})}\left[\hat{A}e^{-\tau\hat{B}} - e^{-\tau\hat{B}}\hat{A}\right]e^{-\tau\hat{A}} = e^{\tau(\hat{A}+\hat{B})}\left[\hat{A} - e^{-\tau\hat{B}}\hat{A}e^{\tau\hat{B}}\right]e^{-\tau\hat{B}}e^{-\tau\hat{A}} \\ &= e^{\tau(\hat{A}+\hat{B})}\left[\hat{A} - \left(\hat{A}+[-\tau\hat{B},\hat{A}]+\tfrac{1}{2!}[-\tau\hat{B},[-\tau\hat{B},\hat{A}]]+..\right)\right]e^{-\tau\hat{B}}e^{-\tau\hat{A}}\ ,\end{aligned}$$

using the formula (23.279). If now $[\hat{A},[\hat{A},\hat{B}]]=0=[\hat{B},[\hat{A},\hat{B}]]$, then,

$$\hat{G}'(\tau) = e^{\tau(\hat{A}+\hat{B})}\tau[\hat{B},\hat{A}]e^{-\tau\hat{B}}e^{-\tau\hat{A}} = -\tau[\hat{A},\hat{B}]e^{\tau(\hat{A}+\hat{B})}e^{-\tau\hat{B}}e^{-\tau\hat{A}} = -\tau[\hat{A},\hat{B}]\hat{G}(\tau)\ .$$

The solution of this differential equation is,

$$\hat{G}(\tau) \equiv e^{-(\tau^2/2)[\hat{A},\hat{B}]}\hat{G}(0) \ .$$

With $\hat{G}(0) = 1$ we obtain at the point $\tau = 1$,

$$e^{\hat{A}+\hat{B}}e^{-\hat{B}}e^{-\hat{A}} = e^{-(1/2)[\hat{A},\hat{B}]} \ .$$

23.7.3.2 Galilei and Lorentz boosts

The *Galilei transform* (or *Galilei boost*) is defined by,

$$\mathcal{T}_G\mathbf{r} = \mathbf{r} + \mathbf{v}t \qquad \text{and} \qquad \mathcal{T}_G\mathbf{p} = \mathbf{p} + m\mathbf{v} \ . \tag{23.313}$$

It describes the transformation of a system into a moving frame. Obviously, the Galilei transform must satisfy $\mathcal{T}_{\mathbf{v}_1}\mathcal{T}_{\mathbf{v}_2} = \mathcal{T}_{\mathbf{v}_1+\mathbf{v}_2}$, while this certainly does not hold for relativistic velocities.

In quantum mechanics we define,

$$\hat{\mathbf{G}} = \hat{\mathbf{p}}t - \hat{\mathbf{r}}m = \imath\hbar\nabla_{\mathbf{v}}\mathcal{U}_G(\mathbf{v})|_{\mathbf{v}=0} \ , \tag{23.314}$$

with the Galilei boost,

$$\boxed{\mathcal{U}_G(\mathbf{v}) = e^{(-\imath/\hbar)\mathbf{v}\cdot\hat{\mathbf{G}}}} \ . \tag{23.315}$$

We can simplify this unitary transform using Glauber's formula (23.312). To this end we first calculate the commutator,

$$[\mathbf{v}\cdot\hat{\mathbf{p}}, \mathbf{v}\cdot\hat{\mathbf{r}}] = -\imath\hbar\mathbf{v}^2 \ , \tag{23.316}$$

which does not depend on $\hat{\mathbf{p}}$ nor $\hat{\mathbf{r}}$, but may contribute a phase factors. With this we can rewrite the expression (23.315),

$$\begin{aligned}
\mathcal{U}_G(\mathbf{v}) &= e^{(-\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}+(\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}} \\
&= e^{(-\imath/\hbar)mt\mathbf{v}^2/2}e^{(\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}}e^{(-\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}} = e^{(\imath/\hbar)mt\mathbf{v}^2/2}e^{(-\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}}e^{(\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}} \\
\mathcal{U}_G^\dagger(\mathbf{v}) &= e^{(\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}-(\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}} \\
&= e^{(-\imath/\hbar)mt\mathbf{v}^2/2}e^{(-\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}}e^{(\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}} = e^{(\imath/\hbar)mt\mathbf{v}^2/2}e^{(\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}}e^{(-\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}} \ .
\end{aligned} \tag{23.317}$$

We apply these expressions to transform the position and momentum operators,

$$\boxed{\begin{aligned}
\mathcal{U}_G^\dagger(\mathbf{v})\hat{\mathbf{r}}\mathcal{U}_G(\mathbf{v}) &= e^{(\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}}\hat{\mathbf{r}}e^{(-\imath/\hbar)\mathbf{v}t\cdot\hat{\mathbf{p}}} = \hat{\mathbf{r}} + \mathbf{v}t \\
\mathcal{U}_G^\dagger(\mathbf{v})\hat{\mathbf{p}}\mathcal{U}_G(\mathbf{v}) &= e^{(-\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}}\hat{\mathbf{p}}e^{(\imath/\hbar)\mathbf{v}m\cdot\hat{\mathbf{r}}} = \hat{\mathbf{p}} + m\mathbf{v}
\end{aligned}} \ , \tag{23.318}$$

and consequently,

$$\begin{aligned}
\mathcal{U}_G^\dagger(\mathbf{v})\frac{\hat{\mathbf{p}}^2}{2m}\mathcal{U}_G(\mathbf{v}) &= \frac{\left[\mathcal{U}_G^\dagger(\mathbf{v})\hat{\mathbf{p}}\mathcal{U}_G(\mathbf{v})\right]^2}{2m} = \frac{(\hat{\mathbf{p}} + m\mathbf{v})^2}{2m} \\
\mathcal{U}_G^\dagger(\mathbf{v})V(\hat{\mathbf{r}})\mathcal{U}_G(\mathbf{v}) &= V(\mathcal{U}_G^\dagger[\mathbf{v})\hat{\mathbf{r}}\mathcal{U}_G(\mathbf{v})] = V(\hat{\mathbf{r}} + \mathbf{v}t) \ .
\end{aligned} \tag{23.319}$$

Setting $m = 0$ the Galilei boost simply reproduces a spatial translation by a vector $\mathbf{v}t$, and setting $t = 0$ the Galilei boost simply becomes the prescription for the momentum kick by an amount $m\mathbf{v}$.

Applying the Galilei boost expressions (23.317) to states, we find,

$$\boxed{\begin{aligned} \mathcal{U}_G(\mathbf{v})|\mathbf{r}\rangle &= e^{(\imath/\hbar)m\mathbf{v}\cdot(\hat{\mathbf{r}}+\mathbf{v}t/2)}|\mathbf{r}+\mathbf{v}t\rangle \\ \mathcal{U}_G(\mathbf{v})|\mathbf{p}\rangle &= e^{-(\imath/\hbar)t\mathbf{v}\cdot(\hat{\mathbf{p}}+m\mathbf{v}/2)}|\mathbf{p}+m\mathbf{v}\rangle \end{aligned}} \ . \tag{23.320}$$

The prefactors do not shift the states, but only contribute irrelevant phase factors.

Finally, knowing the commutator of $\hat{\mathbf{p}}$ and $\hat{\mathbf{r}}$ we derive,

$$[\mathbf{G}\cdot\mathbf{a}, \mathbf{G}\cdot\mathbf{b}] = 0 \ , \tag{23.321}$$

for any vectors $\mathbf{a}$ and $\mathbf{b}$, and with that, using Glauber's formula (23.312), we verify,

$$\mathcal{U}_G(\mathbf{v}_1)\mathcal{U}_G(\mathbf{v}_2) = e^{(-\imath/\hbar)(\mathbf{v}_1+\mathbf{v}_2)\cdot\mathbf{G}-[\mathbf{v}_1\cdot\mathbf{G},\mathbf{v}_2\cdot\mathbf{G}]/2\hbar^2} = \mathcal{U}_G(\mathbf{v}_1+\mathbf{v}_2) \ . \tag{23.322}$$

Obviously, for very high velocities, the Galilei-boost should be replaced by the *Lorentz transform* (or *Lorentz boost*) [473]. Here, we only note, that the additivity of velocities expressed by equation (23.322) does not hold for non-collinear relativistic velocities (see Sec. 17.1.6).

23.7.4 Gauge transformations

We learn in electrodynamics [23], that the motion of a particle carrying the charge q and interacting with an electrical potential $\Phi(\mathbf{r},t)$ and a magnetic vector potential $\mathbf{A}(\mathbf{r},t)$ is governed by the electric and the magnetic field,

$$\vec{\mathcal{E}}(\mathbf{r},t) = -\nabla\Phi - \partial_t\mathbf{A} \qquad \text{and} \qquad \vec{\mathcal{B}}(\mathbf{r},t) = \nabla\times\mathbf{A} \ . \tag{23.323}$$

Also, we know that the fields are invariant under the substitution,

$$\Phi \to \Phi' \equiv \Phi - \partial_t\chi \qquad \text{and} \qquad \mathbf{A} \to \mathbf{A}' \equiv \mathbf{A} + \nabla\chi \ , \tag{23.324}$$

where $\chi(\mathbf{r},t)$ is a scalar field called *gauge field*.

In quantum mechanics the *gauge transform* defined by,

$$\boxed{\mathcal{U}_{\text{gg}}(\chi) = e^{-\imath q\chi(\mathbf{r},t)/\hbar}} \tag{23.325}$$

obviously must keep the Schrödinger equation invariant. However, since the gauge field may depend on time, as shown in Sec. 23.6.5, the Hamiltonian is different in the transformed system. Transforming operators and wave functions as,

$$\hat{H} \to \mathcal{U}_{\text{gg}}\hat{H}\mathcal{U}_{\text{gg}}^{-1} \equiv \hat{H}_{\mathcal{U}} \qquad \text{and} \qquad |\psi\rangle \to \mathcal{U}_{\text{gg}}|\psi\rangle \equiv |\psi_{\mathcal{U}}\rangle \ , \tag{23.326}$$

we calculate for the energy,

$$\begin{aligned} \hat{H}_{\mathcal{U}}|\psi_{\mathcal{U}}\rangle = \mathcal{U}_{\text{gg}}\imath\hbar\tfrac{d}{dt}\mathcal{U}_{\text{gg}}^{-1}|\psi_{\mathcal{U}}\rangle &= \mathcal{U}_{\text{gg}}\imath\hbar\mathcal{U}_{\text{gg}}^{-1}\tfrac{d}{dt}|\psi_{\mathcal{U}}\rangle + \mathcal{U}_{\text{gg}}\imath\hbar\left(\tfrac{-\imath q}{\hbar}\mathcal{U}_{\text{gg}}^{-1}\tfrac{d\chi}{dt}\right)|\psi_{\mathcal{U}}\rangle \\ &= \imath\hbar\left(\tfrac{d}{dt} - \tfrac{\imath q}{\hbar}\tfrac{d\chi}{dt}\right)|\psi_{\mathcal{U}}\rangle \ , \end{aligned} \tag{23.327}$$

[23] See script on *Electrodynamics* (2023).

in accordance with the transformation rule (23.267) for time-dependent unitary transformations. For the momentum, we get analogously,

$$\begin{aligned}\hat{\mathbf{p}}_{\mathcal{U}}|\psi_{\mathcal{U}}\rangle = \mathcal{U}_{\rm gg}(-\imath\hbar\nabla)\mathcal{U}_{\rm gg}^{-1}|\psi_{\mathcal{U}}\rangle &= \mathcal{U}_{\rm gg}(-\imath\hbar)\mathcal{U}_{\rm gg}^{-1}(\nabla|\psi_{\mathcal{U}}\rangle) + \mathcal{U}_{\rm gg}(-\imath\hbar)\left(\tfrac{-\imath q}{\hbar}\mathcal{U}_{\rm gg}^{-1}\nabla\chi\right)|\psi_{\mathcal{U}}\rangle \\ &= (-\imath\hbar)\left[\nabla - \tfrac{\imath q}{\hbar}(\nabla\chi)\right]|\psi_{\mathcal{U}}\rangle\ , \end{aligned} \tag{23.328}$$

This corresponds to the substitutions [24],

$$\boxed{\mathcal{U}_{\rm gg}\imath\hbar\frac{d}{dt}\mathcal{U}_{\rm gg}^{-1} = \imath\hbar\frac{d}{dt} + q\frac{d\chi}{dt} \qquad \text{and} \qquad \mathcal{U}_{\rm gg}\hat{\mathbf{p}}\mathcal{U}_{\rm gg}^{-1} = \hat{\mathbf{p}} - q\nabla\chi}\ . \tag{23.329}$$

This shows that the gauge transformation applies to the *minimal coupling* rule (see Sec. 33.1.2),

$$\hat{H} = \hat{H}_{\rm kin}+q\Phi \overset{\mathcal{U}_{\rm gg}}{\curvearrowright} \hat{H}_{\rm kin}+q\Phi+q\partial_t\chi \quad \text{and} \quad m\hat{\mathbf{v}} = \hat{\mathbf{p}}-q\mathbf{A} \overset{\mathcal{U}_{\rm gg}}{\curvearrowright} \hat{\mathbf{p}}-q\mathbf{A}-q\nabla\chi\ , \tag{23.330}$$

confirming the rules (23.324). That is, the Hamiltonian of a particle carrying the charge q and interacting with an electric potential Φ and a magnetic vector potential $\mathbf{A}$ is,

$$\hat{H} = \tfrac{1}{2m}(\hat{\mathbf{p}} - q\mathbf{A} - q\nabla\chi)^2 + q\Phi + q\partial_t\chi\ . \tag{23.331}$$

23.7.5 Noether's theorem and conservation laws

The fundamental laws of physics are often expressed as symmetries. The knowledge of symmetries allows the characterization of a system and its behavior without the need to know its details. We can often deduce the differential equation of motion from the symmetries. The fundamental symmetries define the fundamental laws of physics. Following *Noether's theorem* each symmetry corresponds to a conserved quantity, that is, a quantities that remains invariant for all time. The invariance of a system under symmetry transformation represents a *conservation law*. For example, the homogeneity of space corresponds to the conservation of linear momentum.

In quantum mechanics, a *symmetry transformation* is defined by,

$$|\psi\rangle \longrightarrow \mathcal{U}|\psi\rangle \qquad \text{and} \qquad \hat{Q} \longrightarrow \mathcal{U}\hat{Q}\mathcal{U}^\dagger\ . \tag{23.332}$$

Therefore, to find a conservation law, i.e., an invariable observable (also called *constant of motion*), we must verify that the observable and the transformed wavefunctions simultaneously satisfy the same fundamental equations (that is, Schrödinger's or Heisenberg's equation) as the original observable and wavefunctions. For example, if the wavefunction $|\psi\rangle$ satisfies the Schrödinger equation, the wave function $\mathcal{U}|\psi\rangle$ must do this too,

$$\hat{H}\mathcal{U}|\psi\rangle \overset{!}{=} \imath\hbar\frac{d}{dt}\mathcal{U}|\psi\rangle = \imath\hbar\frac{d\mathcal{U}}{dt}|\psi\rangle + \imath\hbar\mathcal{U}\frac{d}{dt}|\psi\rangle = \imath\hbar\frac{d\mathcal{U}}{dt}|\psi\rangle + \mathcal{U}\hat{H}|\psi\rangle\ . \tag{23.333}$$

Consequently, we obtain the relation,

$$[\hat{H},\mathcal{U}] = \imath\hbar\dot{\mathcal{U}}\ . \tag{23.334}$$

As shown in (23.275) and (23.276), an operator that commutes with the Hamiltonian does not explicitly depend on time, that is, it is *conserved*.

[24] In quadrivetorial notation $\imath\hbar\partial_\mu \longrightarrow \imath\hbar\partial_\mu + q\partial_\mu\chi$.

23.7.5.1 Temporal homogeneity

Temporal homogeneity means invariance under translation in time by a fixed time interval τ, that is, under the unitary temporal transformation,

$$\mathcal{U}(\tau) \equiv |\psi(\tau)\rangle\langle\psi(0)| = e^{(\imath/\hbar)\hat{E}\tau} \ . \tag{23.335}$$

Since $\frac{d}{dt}e^{(\imath/\hbar)\hat{E}\tau} = 0$, this means $[e^{(\imath/\hbar)\hat{E}\tau}, \hat{H}] = 0$, which implies conservation of energy $[\hat{E}, \hat{H}] = 0$. This will be verified in the Exc. 23.7.6.5.

Example 196 (*Homogeneity of time*): We imagine the following mental experiment or *Gedankenexperiment*: We consider two attractive bodies that move away from each other until they reach the perihelia. At this point, before the bodies reapproach, we change the laws, for example, by modifying the force of attraction. As a consequence, when the bodies arrive at the initial point, the total energy is non-zero. Therefore, the conservation of energy indicates that the laws are invariant.

23.7.5.2 Temporal isotropy

The fundamental laws of classical physics and quantum mechanics are all symmetrical under *time reversal*. That is, they are remain invariant when we change the arrow of time, $t \to -t$.

23.7.5.3 Spatial homogeneity

Spatial homogeneity means invariance under spatial translation, that is, under the unitary translational transformation,

$$\mathcal{U}_{\rm tr}(\mathbf{a}) \equiv \int |\mathbf{r}+\mathbf{a}\rangle\langle\mathbf{r}|d^3r = e^{(-\imath/\hbar)\hat{\mathbf{p}}\cdot\mathbf{a}} \ . \tag{23.336}$$

This is equivalent to momentum conservation $[\hat{\mathbf{p}}, \hat{H}] = 0$ [25].

Example 197 (*Homogeneity of space*): Ehrenfest's theorem says $[\hat{\mathbf{p}}, H] = -\imath\hbar\frac{\partial H}{\partial \hat{\mathbf{p}}}$. Therefore, the commutator is not zero when there is a potential, $\hat{H} = \hat{\mathbf{p}}^2/2m + V(\hat{\mathbf{r}})$. This is obvious, because the potential introduces an energy inhomogeneity to a particle interacting with the potential. However, this does not mean that the space itself is inhomogeneous, because in order to verify the translational invariance of space, we must displace the entire system, that is, the

[25] Imagine that the forces attracting two bodies to each other are not equal: Contrary to Newton's third law, body A attracts body B, more than the body B attracts the body A. In that case after a while the two bodies have different momenta. With the unitary transformation $\mathcal{U}_{\rm tr}(\mathbf{a}) = e^{-\imath\hat{p}\cdot\mathbf{a}/\hbar} \simeq 1 - \imath\epsilon\mathbf{p}\cdot\mathbf{a}/\hbar + ...$ we have,

$$\mathcal{U}_{\rm tr}H|\psi\rangle = \mathcal{U}_{\rm tr}E_\psi|\psi\rangle = E_\psi\mathcal{U}|\psi\rangle = H|\psi(\mathbf{r}+\mathbf{a})\rangle =? = H|\psi(\mathbf{r}\rangle \ .$$

Since, $[H, \hat{p}] = 0$, Heisenberg's equation yields,

$$\frac{\partial}{\partial t}\langle\psi|\hat{p}\cdot\mathbf{a}|\psi\rangle = \frac{1}{\imath\hbar}\langle\psi|[\hat{p}\cdot\mathbf{a}, \hat{H}]|\psi\rangle = 0 \ .$$

particle together with the potential. For example, if the potential is generated by another particle we must consider the Hamiltonian $\hat{H} = \hat{\mathbf{p}}_1^2/2m_1 + \hat{\mathbf{p}}_2^2/2m_2 + V(\hat{\mathbf{r}}_1 - \hat{\mathbf{r}}_2)$.

23.7.5.4 Spatial isotropy

Spatial isotropy means invariance under rotation, that is, under rotational unitary transformation,

$$\mathcal{U}_{\rm rt}(\phi) \equiv e^{(-\imath/\hbar)\hat{\mathbf{L}}\phi} \ . \tag{23.337}$$

This is equivalent to the conservation of angular momentum $[\hat{\mathbf{L}}, \hat{H}] = 0$.

23.7.5.5 Parity conservation

Besides continuous symmetry transformations there exist discrete transformations. Discrete symmetries are important in elementary particle physics. The *parity conservation* means invariance to spatial reflection: $\mathbf{r} \to -\mathbf{r}$. A parity transformation is defined by the mirroring of the wavefunction through a point in space, for example $\mathbf{r} = 0$,

$$\hat{P}|\psi(\mathbf{r})\rangle \equiv |\psi(-\mathbf{r})\rangle \ . \tag{23.338}$$

with

$$\hat{P}^2 = \hat{P} \ . \tag{23.339}$$

We talk about *even* parity when $\hat{P}|\psi(\mathbf{r})\rangle = |\psi(\mathbf{r})\rangle$ and *odd* parity when $\hat{P}|\psi(\mathbf{r})\rangle = -|\psi(\mathbf{r})\rangle$. See Exc. 23.7.6.6.

23.7.5.6 Invariance to the velocity of the inertial system

The *Galilei boost* asks for *Galilei invariance* regarding the transformation,

$$\mathcal{U}_G(\mathbf{v}) \equiv \iint |\mathbf{r} + \mathbf{v}t, \mathbf{p} + m\mathbf{v}\rangle\langle \mathbf{r}, \mathbf{p}| d^3r d^3p \ , \tag{23.340}$$

that is, the equations of motion ruling the dynamics of the inertial system under consideration should not dependent on its velocity $\mathbf{v}$.

23.7.5.7 Charge conservation

Let us consider again the gauge transform (23.324). We know that the Lagrangian density in free space is given in terms of the potentials by,

$$\begin{aligned} \mathcal{L}(x^\mu) &= \tfrac{1}{4\mu_0} F^{\mu\nu}F_{\mu\nu} - A_\mu j^\mu = \tfrac{\varepsilon_0}{2}\vec{\mathcal{E}}^2 - \tfrac{1}{2\mu_0}\vec{\mathcal{B}}^2 - A_\mu j^\mu \\ &= \tfrac{\varepsilon_0}{2}[\nabla\Phi + \partial_t \mathbf{A}]^2 - \tfrac{1}{2\mu_0}[\nabla \times \mathbf{A}]^2 - \Phi\rho + \mathbf{A}\cdot\mathbf{j} \ , \end{aligned} \tag{23.341}$$

and the *action* is simply the four-dimensional integral,

$$S = \int \mathcal{L}(x^\mu) dV dt \ . \tag{23.342}$$

From the Lagrangian formulation, Maxwell's equations can be derived by requiring the action to be minimal, $\delta S = 0$, which yields the Euler-Lagrange equations. As

the field equations do not change under gauge transformation, this implies that the action is also unchanged.

To find the relation with *charge conservation*, we simply have to compare the actions in different gauges. First, we express the Lagrangian transformed into the old gauge,

$$\begin{aligned}\mathcal{L}'(x^\mu) &= \tfrac{\varepsilon_0}{2}\{\nabla[\Phi - \cancel{\partial_t\chi}^{\nearrow}] + \partial_t[\mathbf{A} + \cancel{\nabla\chi}^{\nearrow}]\}^2 - \tfrac{1}{2\mu_0}\{\nabla\times[\mathbf{A} + \cancel{\nabla\chi}^{\nearrow 0}]\}^2 \\ &\quad - [\Phi - \partial_t\chi]\rho + [\mathbf{A} + \nabla\chi]\cdot\mathbf{j} \\ &= \mathcal{L} + (\partial_t\chi)\rho + \nabla\chi\cdot\mathbf{j}\ .\end{aligned} \tag{23.343}$$

With this result, we can calculate the difference between the actions under gauge transformation and recall, that they can not be different:

$$0 \stackrel{!}{=} S' - S = \int[(\partial_t\chi)\rho + \nabla\chi\cdot\mathbf{j}]dVdt = -\int\chi[\partial_t\rho + \nabla\cdot\mathbf{j}]dVdt\ , \tag{23.344}$$

using partial integration [26] and choosing volumes so large, that every charge is inside. This is the *continuity equation* derived from the global *gauge invariance* of the action. The calculation really is nothing more than an application of Noether's theorem from which we could have derived directly the continuity equation, $\partial_\mu j^\mu = 0$.

In summary, the conservation of charge means invariance with respect to gauge transformations,

$$\mathcal{U}_{cl}(\chi) \equiv e^{-\imath q\chi(\mathbf{r},t)/\hbar}\ , \tag{23.345}$$

where χ is the gauge field. We note that q and χ are conjugated observables. Therefore, if $[\chi, \hat{H}] = 0$, then the charge q is a conserved quantity.

Transformations can be combined. For example, we believe that nowadays all laws are invariant with respect to CPT transformation, that is, a combination of *charge conjugation*, *parity inversion*, and *θ-transform*.

23.7.6 Exercises

23.7.6.1 Ex: Calculus with commutator

Derive the rule (23.279) via a Taylor expansion of the operator $\hat{G}(\tau) \equiv e^{\tau\hat{A}}\hat{B}e^{-\tau\hat{A}}$.

23.7.6.2 Ex: Particle in a homogenous gravitational field

a. Consider a particle free to move along the axis of gravity. Derive the time-dependent unitary operator describing the transformation into the particle's rest frame and check, whether the transformation satisfies the expression (23.267).
b. Solve the Schrödinger equation and derive the Heisenberg equations for $\hat{x}$ and $\hat{p}$.
c. Calculate the phase shift due to gravity from the solution of the Schrödinger equation.

[26] Think about the argument, because $\int\partial_t|\chi\rho dt = 0$!

23.7.6.3 Ex: Phase shift in a Ramsey-Bordé interferometer

a. Calculate the time dependence of the dynamical phase accumulated by an atom in the field of gravity as a function of its initial momentum.
b. Derive the phase difference of a particle wavefunction passing through a *Ramsey-Bordé interferometer* [27].
c. Assuming that both free evolution periods of the Ramsey cycle have the same duration τ, generalize the result obtained under (b) allowing for an arbitrary initial velocity.

23.7.6.4 Ex: Rotation operator

Derive the rule $e^{\vec{\alpha}\times}\mathbf{r} = \sum_n \frac{(\vec{\alpha}\times)^n}{n!}\mathbf{r} = \hat{\mathbf{e}}_\alpha(\hat{\mathbf{e}}_\alpha \cdot \mathbf{r}) + \hat{\mathbf{e}}_\alpha \times \mathbf{r}\sin\alpha - \hat{\mathbf{e}}_\alpha \times (\hat{\mathbf{e}}_\alpha \times \mathbf{r})\cos\alpha$.

23.7.6.5 Ex: Constants of motion

Show at the example of energy conservation using the relation (23.334), that energy commutes with the Hamiltonian if $\dot{E} = 0$.

23.7.6.6 Ex: Parity

Show that the eigenfunctions of the Hamiltonian $\hat{H} = -(\hbar/2m)(d^2/dx^2) + V(x)$ have well-defined parity, i.e., parity is a *good quantum number* in cases where the energy is an even function of position, $V(x) = V(-x)$.

Chapter 24

Linear motion / Separable potentials

We have seen in the last chapter that the motion of a particle is ruled by an interplay of kinetic and potential energy and can be characterized by solving the Schrödinger equation. For arbitrary potential landscapes the solution can be difficult to obtain. In contrast, the existence of symmetries can dramatically simplify the task. The present chapter is devoted to, potentials with separable Cartesian dimensions, the subsequent Chp. 25 to potentials with cylindrical or spherical symmetries, and Chp. 26 to periodic potentials. More specifically, we will analyze in the present chapter the translational and vibrational motion of a quantum particle and give special consideration to the rectangular potential and the harmonic oscillator.

24.1 Translational motion

In one dimension the Hamiltonian of a free particle is,

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} \ . \tag{24.1}$$

Therefore, the general solution of the Schrödinger stationary equation,

$$\hat{H}\psi(x) = E\psi(x) \ , \tag{24.2}$$

is,

$$\psi(x) = Ae^{\imath kx} + Be^{-\imath kx} \qquad \text{with} \qquad k = \sqrt{\tfrac{2mE}{\hbar^2}} \ . \tag{24.3}$$

Note that the $e^{\imath kx}$ functions are not quadratically integrable, since $\int_{-\infty}^{\infty} |e^{\imath kx}|^2 dx = \int_{-\infty}^{\infty} dx \to \infty$. On the other side, they do not represent actual physical systems. In practice, we need to consider wave packets or specify a finite volume for the particle. Note also that the spectrum of eigenvalues is continuous. Do the Exc. 24.1.4.1.

24.1.1 Quadratic integrability

To allow for an interpretation as probability density we need to ask for quadratic integrability,

$$\int |\psi|^2 d^3r = 1 \ . \tag{24.4}$$

This means that the wavefunction can not be infinite inside a finite volume. But it can be infinite within an infinitely small volume. Also, since the Schrödinger equation contains the second derivative by position, the wavefunction must be continuous and have a continuous derivative.

24.1.2 Separation of dimensions

Frequently, a 3D potential can be written in the way,

$$V(x,y,z) = V_x(x) + V_y(y) + V_z(z) \ . \tag{24.5}$$

This is the case, for example, for a rectangular well with $V_x(x) = V_y(y) = V_z(z) = V_0/3$ inside the well and $V(x,y,z) = 0$ outside. It also holds for a harmonic potential,

$$V(\mathbf{r}) = \frac{m}{2}\left(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 z^2\right) \ . \tag{24.6}$$

In these cases, the following ansatz for the wavefunction is generally useful,

$$\psi(\mathbf{r}) = \psi_x(x)\psi_y(y)\psi_z(z) \ , \tag{24.7}$$

since inserting the ansatz into the Schrödinger equation,

$$\begin{aligned}&\left[-\frac{\hbar^2}{2m}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}+\frac{d^2}{dz^2}\right)+V_x(x)+V_y(y)+V_z(z)\right]\psi_x(x)\psi_y(y)\psi_z(z) \\ &= E\psi_x(x)\psi_y(y)\psi_z(z) \ ,\end{aligned} \tag{24.8}$$

the equation separates into three independent one-dimensional equations,

$$-\frac{\hbar^2}{2m}\frac{\psi_x''(x)}{\psi_x(x)} + V_x(x) = const. \equiv E_x \ , \tag{24.9}$$

and the same for y and z. Since, $E = E_x + E_y + E_z$ may have the same value for different combinations of E_x, E_y and E_z, multidimensional systems are often degenerate.

24.1.3 Homogeneous force fields, gravity

The behavior of a wavefunction in a homogeneous force field has been studied in Excs. 23.7.6.2 and 23.7.6.3.

24.1.4 Exercises

24.1.4.1 Ex: Trapped particle

Consider the problem of a particle of mass m forced to move in x-direction and completely confined to a box, with walls placed at the positions $x = 0$ and $x = a$.
a. The particle be in the ground state, what is its energy and its wavefunction?
b. Suppose the particle has the following wavefunction:

$$\psi_{\mathrm{I}}(x) = \tfrac{1}{\sqrt{7a}}\left[2\cos\left(\tfrac{\pi}{2a}(6x-a)\right) - 3\imath\sin\left(\tfrac{2\pi}{a}x\right) + \cos\left(\tfrac{\pi}{2a}(2x-a)\right)\right] \ ,$$

what is the probability that a measurement of the energy yields the result $E = \frac{2\pi^2\hbar^2}{ma^2}$?
c. Considering again the ground state of item (a), what is the probability distribution for the momentum of the particle in this state?
d. Still starting from the ground state, suppose we remove (instantaneously) the walls, leaving the particle free ($\hat{H} = \hat{p}^2/2m$). What is the energy of this free particle?
Formulae:

$$\int_0^L e^{\imath Bx} \sin\left(\frac{n\pi x}{L}\right) dx = \frac{n\pi L[1-(-1)^n e^{\imath BL}]}{n^2\pi^2 - B^2L^2} \qquad \text{for} \qquad n = 1, 2, 3, ...$$

$$\int_{-\infty}^{\infty} \frac{x^2}{(1-x^2)^2} \cos^2 \tfrac{\pi x}{2} dx = \tfrac{\pi^2}{4}$$

24.2 Rectangular potentials

The continuity equation (23.123) teaches us that the probability flux of a moving particle cannot make abrupt changes. That is, even if the particle encounters an obstacle represented by a smooth or abrupt variation of the potential depth, the wavefunction and its derivative must remain continuous, unless the potential step is infinitely high.

24.2.1 Box potential

Let us now place the particle into a rectangular potential well, such that the Hamiltonian is,

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + V(x) \qquad \text{with} \qquad V(x) = \begin{cases} 0 & \text{for} \quad x \in [0, L] \\ \infty & \text{for} \quad x \notin [0, L] \end{cases} . \tag{24.10}$$

As the potential barriers are high, the walls are hard, that is, the particle, even being a quantum particle, can not penetrate. The wavefunction and the possible energy values are,

$$\boxed{\psi(x) = \sqrt{\frac{2}{L}} \sin\frac{n\pi x}{L} \qquad \text{and} \qquad E_n = \frac{n^2\hbar^2\pi^2}{2mL^2}} . \tag{24.11}$$

The Exc. 24.2.5.1 asks to demonstrate the result (24.11) illustrated in Fig. 24.1.

Obviously the spectrum of eigenvalues is now discrete. They can be enumerated by an integer n called *quantum number*. Note that the energy levels are not equidistant.

Example 198 (*Localization energy*): There is a minimal *energy* $E_1 = \frac{\hbar^2\pi^2}{2mL^2}$ which is called *zero point energy* or *localization energy*. This energy can be understood as a consequence of Heisenberg's *uncertainty principle*. We can make the following gross estimation of the zero point energy. Obviously, the particle is localized with an uncertainty lower than $\Delta x < L$. Hence, $\Delta p > \hbar/\Delta x > \hbar/L$. The average kinetic energy is,

$$\frac{\langle p^2\rangle}{2m} = \frac{\langle p\rangle^2 + \Delta p^2}{2m} = \frac{\Delta p^2}{2m} > \frac{\hbar^2}{2mL^2} .$$

The fact that the numerical value is different from the value calculated by the formula (24.11) comes from the particular geometry of the box potential.

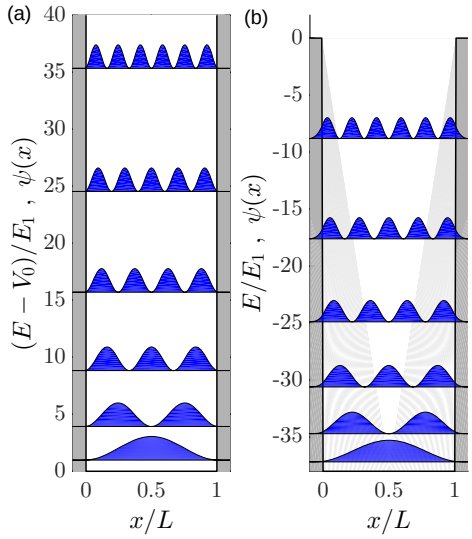

Figure 24.1: (code) (a) Wavefunctions and energies in the box potential. (b) The rectangular potential well with the reference energy set to the height of the well.

24.2.2 Multidimensional box potential

In a multidimensional well there can be degeneracy if the well exhibits symmetries. In the case of a 2D quadratic well $L_x = L_y$, the eigenenergies are doubly degenerate, since $E_{n_x,n_y} = E_{n_y,n_x}$. In the case of a 3D cubic well $L_x = L_y = L_z$, the eigenenergies are 6-fold degenerate, because $E_{n_x,n_y,n_z} = E_{n_y,n_z,n_x} = E_{n_z,n_x,n_y} = E_{n_z,n_y,n_x} = E_{n_y,n_x,n_z} = E_{n_x,n_z,n_y}$. The states and energies of the 2D well are calculated in Exc. 24.2.5.2.

24.2.3 Potentials with several sections of constant depths

To find the global wavefunction in potentials with several sections of constant depths, we solve Schrödinger's equations separately for each section labeled by $a = 1, 2, ..,$

$$\left(-\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + V_a\right)\psi_a(x) = E\psi_a(x) \ . \tag{24.12}$$

The general solution for a section a with potential energy V_a is,

$$\boxed{\psi_a(x) = A_a e^{\imath k_a x} + B_a e^{-\imath k_a x}} \ , \tag{24.13}$$

where $k_a = \frac{1}{\hbar}\sqrt{2m(E - V_a)}$. If $E > V_a$, the wave is propagating. k_a is the Broglie wavevector of the wave. If $E < V_a$, the wave is evanescent. That is, the wave decays within a distance $\kappa_a = -\imath k_a$.

If the particle is confined, that is, if $E < V(x \to \pm\infty)$, the possible energy levels are quantized and the spectrum is discrete.

For every transition between two sections $a = 1$ and $a = 2$ we require the boundary conditions,

$$\psi_1(x) = \psi_2(x) \qquad \text{and} \qquad \psi_1'(x) = \psi_2'(x) \ . \tag{24.14}$$

Together with the normalization, $1 = \int_{-\infty}^{\infty} |\psi|^2 dx$, these conditions are sufficient to determine the wavefunction unambiguously.

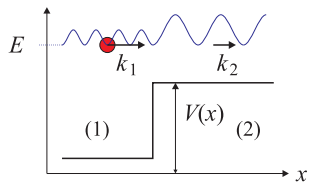

Figure 24.2: Scheme of a potential with several sections of constant depths.

24.2.4 Potential well

Consider a particle with energy E and a potential well of finite depth such that $V(x) = V_0 < 0$ for $-L/2 > x > L/2$ and $V(x) = 0$ otherwise, as illustrated in Fig. 24.3(a). The particle be confined, $E < 0$.

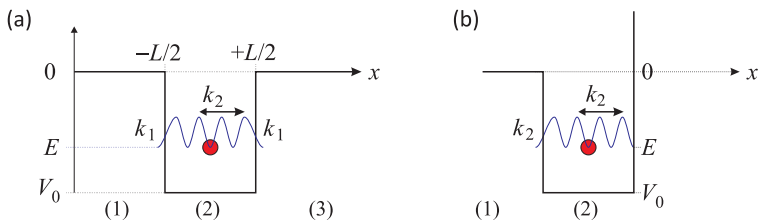

Figure 24.3: (a) Scheme of a two-sided and (b) one-sided potential well.

The wavevectors are

$$k_1 = k_3 = \tfrac{1}{\hbar}\sqrt{2mE} = \imath\tfrac{1}{\hbar}\sqrt{2m|E|} = \imath\kappa_1 \qquad \text{and} \qquad k_2 = \tfrac{1}{\hbar}\sqrt{2m(E - V_0)} \ . \tag{24.15}$$

with $\kappa_1 \in \mathbb{R}^+$. The boundary conditions yield,

$$\begin{aligned} A_1 e^{-\imath k_1 L/2} + B_1 e^{\imath k_1 L/2} &= A_2 e^{-\imath k_2 L/2} + B_2 e^{\imath k_2 L/2} \\ -\imath k_1 A_1 e^{-\imath k_1 L/2} + \imath k_1 B_1 e^{\imath k_1 L/2} &= -\imath k_2 A_2 e^{-\imath k_2 L/2} + \imath k_2 B_2 e^{\imath k_2 L/2} \\ A_2 e^{\imath k_2 L/2} + B_2 e^{-\imath k_2 L/2} &= A_3 e^{\imath k_1 L/2} + B_3 e^{-\imath k_1 L/2} \\ \imath k_2 A_2 e^{\imath k_2 L/2} - \imath k_2 B_2 e^{-\imath k_2 L/2} &= \imath k_1 A_3 e^{\imath k_1 L/2} - \imath k_1 B_3 e^{-\imath k_1 L/2} \ . \end{aligned} \tag{24.16}$$

For confined particles, $E < 0$, the problem is totally symmetric. In addition, the wavefunction must disappear for $x \to \pm\infty$. Therefore, we can simplify,

$$A_1 = 0 = B_3 \qquad \text{and} \qquad A_3 = B_1 \ . \tag{24.17}$$

The first two equations (24.16) now give,

$$B_1 e^{\imath k_1 L/2} = A_2 e^{-\imath k_2 L/2} + B_2 e^{\imath k_2 L/2} = \frac{k_2}{k_1}\left(-A_2 e^{-\imath k_2 L/2} + B_2 e^{\imath k_2 L/2}\right) . \tag{24.18}$$

We now consider the quotient B_2/A_2. Using the right part of equation (24.18),

$$\frac{B_2}{A_2} = \frac{e^{-\imath k_2 L/2}(k_2 + k_1)}{e^{\imath k_2 L/2}(k_2 - k_1)} = \frac{e^{-\imath k_2 L}(k_2 + \imath\kappa_1)^2}{k_2^2 + \kappa_1^2} . \tag{24.19}$$

Since the amplitudes are real, the imaginary part of the quotient (24.19) should disappear, which is the case when,

$$0 = \mathfrak{Im}\, e^{-\imath k_2 L}(k_2 + \imath\kappa_1)^2 = 2\kappa_1 k_2 \cos k_2 L + (\kappa_1^2 - k_2^2)\sin k_2 L \tag{24.20}$$
$$\Longrightarrow \tan k_2 L = \frac{2\kappa_1 k_2}{-\kappa_1^2 + k_2^2} .$$

In order to construct graphically the values of the momenta k_2 of the particle associated with the allowed energy levels, we introduce a constant $\beta \equiv \hbar/(L\sqrt{2m|V_0|})$. Hence,

$$\tan k_2 L = \tan \frac{1}{\beta}\sqrt{1 - |E/V_0|} = \frac{2\sqrt{|E/V_0|}\sqrt{1 - |E/V_0|}}{1 - 2|E/V_0|} = \frac{2\kappa_1 k_2}{-\kappa_1^2 + k_2^2} . \tag{24.21}$$

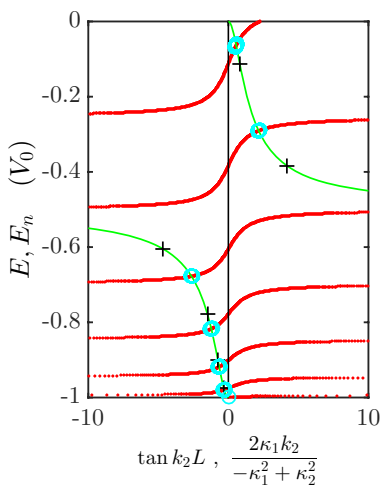

Figure 24.4: (code) Graphical solution for a finite bilateral potential well. The red dotted curves represent the tangents (left side of the equation (24.21)), the solid green curves the hyperbolas (right side of the equation), the circles in cyan are the eigenenergies. When $0 < E - V_0 \ll E$, they converge to the eigenenergies of the infinitely deep well (black crosses and vertical black line).

At the bottom of deep potentials, that is, when $0 < E - V_0 \ll E$, or equivalently, $E \simeq V_0$, we have $k_2 \ll \kappa_1$ and hence, $\tan k_2 L \to 0 \Longrightarrow k_2 L = n\pi$. The energies are

then,

$$E - V_0 = \frac{\hbar^2}{k_2^2} 2m = \frac{\hbar^2 \pi^2}{2mL^2} n^2 \ . \tag{24.22}$$

Apply the notions obtained in this section to solve Excs. 24.2.5.3 and 24.2.5.4.

24.2.5 Exercises

24.2.5.1 Ex: Particle in a box

Obtain the wavefunctions and associated energy levels of a particle confined in a box, where $V(x) = 0$ for $0 \leq x \leq l$ and $V(x) = \infty$ outside.

24.2.5.2 Ex: Particle in a two-dimensional box

Obtain the wavefunctions and associated energy levels of a particle trapped in a two-dimensional box inside which the particle is confined to a rectangular surface with dimensions L_1 in x-direction and L_2 in y-direction, $V(x, y) = 0$ for $0 \leq x \leq L_1$ and $0 \leq y \leq L_2$ and $V(x, y) = \infty$ else.

24.2.5.3 Ex: Particle in a well

Obtain the energies of the bound states of a particle in the potential well in which $V(x) = \infty$ for $x < 0$, $V(x) = -V_0$ for $0 \leq x \leq L/2$ and $V(x) = 0$ to $x > L/2$. Compare the obtained values with those of the symmetrical well discussed in Sec. 24.2.4 and the well with infinitely high walls discussed in Sec. 24.2.1.

24.2.5.4 Ex: Least bound states and localization energy

Calculate, based on the discussion in Sec. 24.2.4, the minimum required potential depth V_0 of a three-dimensional finite rectangular well potential of size L to have a bound state capable of trapping an ^{87}Rb atom. Assuming a trap volume of $L = 10\,\text{nm}$, how deep should the trap be?

24.3 Potential barrier

The linear momentum of a particle described by $\psi(x, t) = Ae^{\imath kx}$ is,

$$\langle \psi | \hat{p} | \psi \rangle = \langle \psi | \frac{\hbar}{\imath} \frac{d}{dx} | \psi \rangle = \hbar k \ . \tag{24.23}$$

Therefore, this particle propagates towards $+\infty$. On the contrary, the particle $Be^{-\imath kx}$ propagates towards $-\infty$. Thus, the two solutions (24.13) of the Schrödinger equation (24.12) correspond to propagating particle waves. From here on we will use the letter A (B) to denote the amplitudes of waves propagating in direction ∞ ($-\infty$).

In locations where the potential changes abruptly, the particle can be partially reflected.

24.3.1 $\mathcal{T}$-scattering matrix

As we have already shown in the previous section, we can write the transformation of the amplitudes due to a potential step at position L as,

$$\begin{aligned} A_2 e^{\imath k_2 L} + B_2 e^{-\imath k_2 L} &= A_1 e^{\imath k_1 L} + B_1 e^{-\imath k_1 L} \\ \imath k_2 A_2 e^{\imath k_2 L} - \imath k_2 B_2 e^{-\imath k_2 L} &= \imath k_1 A_1 e^{\imath k_1 L} - \imath k_1 B_1 e^{-\imath k_1 L} \ . \end{aligned} \tag{24.24}$$

We can summarize these two equations in a matrix formalism,

$$\boxed{\begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = \mathcal{T} \begin{pmatrix} A_1 \\ B_1 \end{pmatrix}} \ , \tag{24.25}$$

with the *scattering matrix* $\mathcal{T}$ for a particle with energy E (see Fig. 24.2),

$$\begin{aligned} \mathcal{T} &= \tfrac{1}{2} \begin{pmatrix} \left(1 + \frac{k_1}{k_2}\right) e^{\imath(k_1 - k_2)L} & \left(1 - \frac{k_1}{k_2}\right) e^{\imath(-k_1 - k_2)L} \\ \left(1 - \frac{k_1}{k_2}\right) e^{\imath(k_1 + k_2)L} & \left(1 + \frac{k_1}{k_2}\right) e^{\imath(-k_1 + k_2)L} \end{pmatrix} \\ &= \tfrac{1}{2} \begin{pmatrix} e^{-\imath k_2 L} & 0 \\ 0 & e^{\imath k_2 L} \end{pmatrix} \begin{pmatrix} 1 + \frac{k_1}{k_2} & 1 - \frac{k_1}{k_2} \\ 1 - \frac{k_1}{k_2} & 1 + \frac{k_1}{k_2} \end{pmatrix} \begin{pmatrix} e^{\imath k_1 L} & 0 \\ 0 & e^{-\imath k_1 L} \end{pmatrix} \ . \end{aligned} \tag{24.26}$$

If there are more zones with different depths, we may concatenate the scattering matrices. Denoting by $\mathcal{T}_{m \to n}$ the scattering matrix describing a transition at position $L_{m,n}$ of a potential of the depth V_m to another potential V_n, we write,

$$\mathcal{T} = \mathcal{T}_{2 \to 3} \mathcal{T}_{1 \to 2} \ . \tag{24.27}$$

24.3.2 $\mathcal{S}$-scattering matrix

Another common definition is the *scattering matrix* $\mathcal{S}$,

$$\boxed{\begin{pmatrix} A_2 \\ B_1 \end{pmatrix} = \mathcal{S} \begin{pmatrix} B_2 \\ A_1 \end{pmatrix}} \ . \tag{24.28}$$

To see how the scattering matrices are interconnected, we start with

$$\begin{pmatrix} A_2 \\ B_2 \end{pmatrix} = \mathcal{T} \begin{pmatrix} A_1 \\ B_1 \end{pmatrix} = \begin{pmatrix} \mathcal{T}_{11} A_1 + \mathcal{T}_{12} B_1 \\ \mathcal{T}_{21} A_1 + \mathcal{T}_{22} B_1 \end{pmatrix} \ , \tag{24.29}$$

Multiplying the first line with $\mathcal{T}_{22}$ and the second with $-\mathcal{T}_{12}$ and adding them,

$$\mathcal{T}_{22} A_2 - \mathcal{T}_{12} B_2 = \left(\mathcal{T}_{11} \mathcal{T}_{22} - \mathcal{T}_{12} \mathcal{T}_{21}\right) A_1 \ . \tag{24.30}$$

This equation resolved by A_2 along with the second equation (24.29) resolved by B_1 give,

$$\begin{pmatrix} A_2 \\ B_1 \end{pmatrix} = \mathcal{S} \begin{pmatrix} B_2 \\ A_1 \end{pmatrix} = \begin{pmatrix} \mathcal{T}_{12}/\mathcal{T}_{22} & \mathcal{T}_{11} - \mathcal{T}_{12}\mathcal{T}_{21}/\mathcal{T}_{22} \\ 1/\mathcal{T}_{22} & -\mathcal{T}_{21}/\mathcal{T}_{22} \end{pmatrix} \begin{pmatrix} B_2 \\ A_1 \end{pmatrix} \ . \tag{24.31}$$

The matrix $\mathcal{S}$ describes the causality of scattering process more adequately: The amplitude A_2 in region (2) results from the superposition of a wave B_2 being reflected by the barrier and a wave A_1 being transmitted by the barrier. The amplitude B_1 in region (1) results from the superposition of a wave A_1 being reflected by the barrier and a wave B_2 being transmitted by the barrier. Therefore, the matrix $\mathcal{S}$ is more appropriate for the description of the quantum reflection, as we will discuss in the next section. However, it has the disadvantage that it can not be concatenated in the same way as the $\mathcal{T}$ matrices.

Unlike the $\mathcal{T}$ matrix the $\mathcal{S}$ matrix is *unitary*, since

$$\det \mathcal{S} = \mathcal{S}_{11}\mathcal{S}_{22} - \mathcal{S}_{12}\mathcal{S}_{21} = -\frac{\mathcal{T}_{11}}{\mathcal{T}_{22}} = -e^{2\imath k_1 L} \ . \tag{24.32}$$

Also, it is possible to show,

$$\mathcal{S}^\dagger \mathcal{S} = \begin{pmatrix} \mathcal{S}_{11}^* & \mathcal{S}_{21}^* \\ \mathcal{S}_{12}^* & \mathcal{S}_{22}^* \end{pmatrix} \begin{pmatrix} \mathcal{S}_{11} & \mathcal{S}_{12} \\ \mathcal{S}_{21} & \mathcal{S}_{22} \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \ . \tag{24.33}$$

24.3.3 Quantum reflection at a potential step

The *quantum reflection* is a non-classical property of the motion of a particle. An example is the *reflection* of a quantum particle by an *attractive* potential. To study this effect, we consider a plane wave $e^{\imath k_1 x}$ propagating in region (1) ($E_1 > V_1$) encountering a potential step up or down at position $x = 0$ leading to another region (2). Using the S matrix formalism introduced in the previous section,

$$\mathcal{S} = \frac{1}{k_1 + k_2} \begin{pmatrix} k_2 - k_1 & 2k_1 \\ 2k_2 & k_1 - k_2 \end{pmatrix} \ , \tag{24.34}$$

we find that one part of the wave is reflected into the region (1), another is transmitted into the region (2),

$$\begin{aligned} \begin{pmatrix} A_2 \\ B_1 \end{pmatrix} = \mathcal{S} \begin{pmatrix} 0 \\ 1 \end{pmatrix} &= \begin{pmatrix} \mathcal{T}_{11} - \mathcal{T}_{12}\mathcal{T}_{21}/\mathcal{T}_{22} \\ -\mathcal{T}_{21}/\mathcal{T}_{22} \end{pmatrix} = \begin{pmatrix} \frac{(1+k_1/k_2)^2 - (1-k_1/k_2)^2}{2(1+k_1/k_2)} \\ -\frac{1-k_1/k_2}{1+k_1/k_2} \end{pmatrix} \\ &= \frac{1}{k_1 + k_2} \begin{pmatrix} 2k_1 \\ k_1 - k_2 \end{pmatrix} \ . \end{aligned} \tag{24.35}$$

We use $B_2 = 0$, since no wave comes from the side of region (2), and $A_1 = 1$, because it simplifies the formulas and does not affect the generality of the results. The interesting results are:

- Even when $E_2 < V_2$, the particle enters the classically prohibited region: $\psi_2(x) \propto e^{-\kappa_2 x}$ with $\kappa_2 = \frac{1}{\hbar}\sqrt{2m(V_2 - E_2)}$, i.e. the transmission is non-zero, $|A_2| > 0$.
- Even with $E_2 > V_2$, the particle has a probability of being reflected at the step, $|B_1| > 0$.

Example 199 (*Contrast of a partially reflected wave*): Defining $K_\pm \equiv \frac{1}{2}\left(\max|\psi_1|^2 \pm \min|\psi_1|^2\right)$, the *contrast* of the wavefunction in region (1) is given

by K_-/K_+. Writing the function as $\psi_1 = e^{\imath k_1 x} + B_1 e^{-\imath k_1 x}$ it is easy to show, that

$$|B_1| = \frac{\sqrt{K_+ + K_-} - \sqrt{K_+ - K_-}}{\sqrt{K_+ + K_-} + \sqrt{K_+ - K_-}} \simeq \frac{K_-}{2K_+} \ . \tag{24.36}$$

This formula can be understood as an analogue of *Fresnel formula* for matter waves [1].

In Exc. 24.3.7.1 we calculate the behavior of a Broglie wave passing through a potential step and entering a classically forbidden region. In Exc. 24.3.7.2 we investigate a model describing the collision between attracting or repelling particles via a partial reflection at a potential step.

24.3.4 Continuity of probability flow

The continuity equation (23.123) requires that the *probability flux* be preserved in stationary situations,

$$0 = \frac{dj}{dx} = \frac{d}{dx}\frac{\hbar}{2m\imath}\left[\psi^*\left(\frac{d}{dx}\psi\right) - \left(\frac{d}{dx}\psi^*\right)\psi\right] \ . \tag{24.37}$$

Applying this to a potential step separating the regions $n = 1, 2$, we find,

$$\begin{aligned} j_n &= \frac{\hbar}{2m\imath}\left[\psi^*\frac{d}{dx}\psi - \psi\frac{d}{dx}\psi^*\right] \\ &= \frac{\hbar}{2m\imath}\left[(A_n^* e^{-\imath k_n x} + B_n^* e^{\imath k_n x})(\imath k_n A_n e^{\imath k_n x} - \imath k_n B_n e^{-\imath k_n x})\right. \\ &\quad \left. - (A_n e^{\imath k_n x} + B_n e^{-\imath k_n x})(-\imath k_n A_n^* e^{-\imath k_n x} + \imath k B_n^* e^{\imath k x})\right] \\ &= \frac{\hbar k_n}{m}(|A_n|^2 - |B_n|^2) \ . \end{aligned} \tag{24.38}$$

Hence, $j_1 = j_2$ implies $k_1|A_1|^2 - k_1|B_1|^2 = k_2|A_2|^2 - k_2|B_2|^2$. Assuming that the particle comes from side 1 and $B_2 = 0$, we have,

$$1 = |B_1|^2 + \tfrac{k_2}{k_1}|A_2|^2 = R + T \ , \tag{24.39}$$

defining the *transmission* T and the *reflection* R as,

$$T \equiv \tfrac{k_2}{k_1}|\mathcal{S}_{12}|^2 = \tfrac{k_2}{k_1}|A_2|^2 \qquad \text{and} \qquad R \equiv |\mathcal{S}_{22}|^2 = |B_1|^2 \ . \tag{24.40}$$

24.3.5 Tunneling and quantum reflection at a potential well

Particles thrown with a kinetic energy E against potential barriers can cross them even if $V_0 > E$ or be reflected even when $V_0 < E$, as illustrated in Fig. 24.5(a). This can be verified by considering a particle propagating from $x = -\infty$ towards $x = +\infty$ through a potential well located at $x \in [0, a]$. We determine the concatenation $\mathcal{T} = \mathcal{T}_{2\to 3}\mathcal{T}_{1\to 2}$. Then we find the $\mathcal{S}$ matrix that corresponds to the $\mathcal{T}$ matrix and solve the

[1] In this sense light reflection at an optical interface (with typical losses of 4% for glass) can be interpreted as quantum reflection of light

problem in the same way as in the previous section. For example, we can calculate the transmission and reflection probabilities. The formula is derived in Exc. 24.3.7.3,

$$\boxed{R = 1 - T = \left(1 + \frac{16E/V_0(1 - E/V_0)}{(e^{\kappa L} - e^{-\kappa L})^2}\right)^{-1}} \ , \tag{24.41}$$

and sketched in Fig. 24.5(b). The phenomenon is called *tunneling*. Do the Exc. 24.3.7.4.

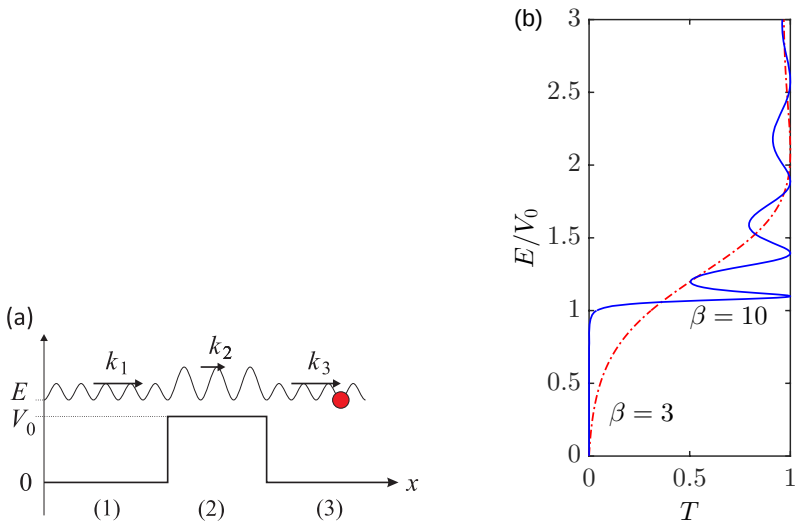

Figure 24.5: (code) (a) Tunnel effect and quantum transmission and reflection at a potential barrier. (b) Coefficients of transmission and reflection (horizontal) through the shown potential barrier as a function of the energy normalized to the height of the barrier E/V_0. The dashed red curve corresponds to a low barrier, $\beta \equiv \frac{1}{\hbar}L\sqrt{2mV_0} = 3$, the blue solid curve corresponds to a deep barrier $\beta = 10$.

24.3.6 The delta-potential

In quantum mechanics the δ-potential can be used to simulate situations, where a particle is free to move in two regions of space with a barrier in between. For example, an electron can move almost freely in a conducting material, but when two conducting surfaces are put close together, the interface between them acts as a barrier for the electron that can be approximated by a δ-potential. The δ-potential is a limiting case of the finite potential well when we decrease its width while maintained the product of its width and its depth constant. Here, for simplicity, we only consider a one-dimensional potential well, but the analysis can be expanded to more dimensions.

The time-independent Schrödinger equation for the wavefunction $\psi(x)$ of a particle in one dimension is,

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + \alpha\delta(x)\psi(x) = E\psi(x) \ , \tag{24.42}$$

The potential is called a δ-potential well if α is negative and a δ-potential barrier if α is positive.

The potential splits the space in two parts ($x < 0$ and $x > 0$). In each of these parts the potential energy is zero, and the Schrödinger equation reduces to,

$$\frac{d^2\psi}{dx^2} = -\frac{2mE}{\hbar^2}\psi \ . \tag{24.43}$$

The solutions of this differential equation are linear combinations of $e^{\imath kx}$ and $e^{-\imath kx}$, where the wavenumber k is related to the energy by $k = \frac{\sqrt{2mE}}{\hbar}$. In general, due to the presence of the δ-potential in the origin, the coefficients of the solution need not be the same in both half-spaces:

$$\psi(x) = \begin{cases} \psi_1(x) = A_1 e^{\imath kx} + B_1 e^{-\imath kx} & \text{for } x < 0 \\ \psi_2(x) = A_2 e^{\imath kx} + B_2 e^{-\imath kx} & \text{for } x > 0 \end{cases} , \tag{24.44}$$

where, in the case of positive energies (real k), $e^{\imath kx}$ represents a wave traveling to the right, and $e^{-\imath kx}$ one traveling to the left. One obtains a relation between the coefficients by imposing that the wavefunction be continuous at the origin,

$$\psi(0) = \psi_1(0) = \psi_2(0) = A_1 + B_1 = A_2 + B_2 \ . \tag{24.45}$$

A second relation can be found by studying the derivative of the wavefunction. Normally, we could also impose differentiability at the origin, but this is not possible because of the δ-potential. However, if we integrate the Schrödinger equation around $x = 0$ over an interval $[-\epsilon, +\epsilon]$:

$$-\frac{\hbar^2}{2m}\int_{-\epsilon}^{+\epsilon} \psi''(x)dx + \int_{-\epsilon}^{+\epsilon} V(x)\psi(x)dx = E\int_{-\epsilon}^{+\epsilon} \psi(x)dx \ . \tag{24.46}$$

In the limit $\epsilon \to 0$ the right-hand side of this equation vanishes,

$$-\frac{\hbar^2}{2m}[\psi_2'(0) - \psi_1'(0)] + \alpha\psi(0) = 0 \ . \tag{24.47}$$

Substituting the definition of ψ into this expression, we obtain,

$$-\frac{\hbar^2}{2m}\imath k(A_1 - B_1 - A_2 + B_2) + \alpha(A_1 + B_1) = 0 \ . \tag{24.48}$$

The boundary conditions thus give the following restrictions on the coefficients,

$$\boxed{\begin{aligned} A_1 + B_1 - A_2 - B_2 &= 0 \\ A_1 - B_1 - A_2 + B_2 &= \frac{2m\alpha}{\imath k\hbar^2}(A_1 + B_1) \end{aligned}} \ . \tag{24.49}$$

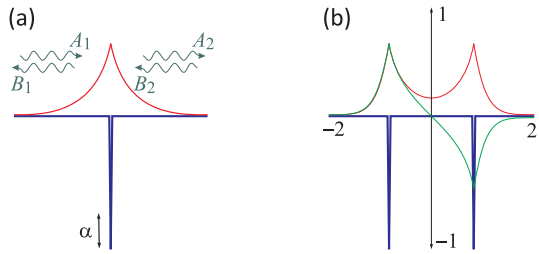

Figure 24.6: (a) The δ-potential (green) and the bound state wavefunction (blue). (b) Double δ-potential (green).

24.3.6.1 Bound states

The bound state wavefunction solution to the δ-function potential is continuous everywhere, but its derivative is not defined at $x = 0$.

In any one-dimensional attractive potential there will be a bound state. To find its energy, note that for negative energies, $E < 0$, the wavenumber $k = \imath\sqrt{2m|E|}/\hbar = \imath\kappa$ is imaginary and the wavefunctions are exponentially increasing or decreasing functions of x (see above). Requiring that the wavefunctions do not diverge at infinity eliminates half of the terms: $A_2 = B_1 = 0$. The wavefunction is then an evanescent wave,

$$\psi(x) = \begin{cases} \psi_1(x) = A_1 e^{\kappa x} & \text{for } x < 0 \\ \psi_2(x) = B_2 e^{-\kappa x} & \text{for } x > 0 \end{cases} . \tag{24.50}$$

From the boundary conditions and normalization conditions, it follows that,

$$A_1 = B_2 = \sqrt{\kappa} \qquad \text{and} \qquad \kappa = -\frac{m\alpha}{\hbar^2} , \tag{24.51}$$

from which follows that α must be negative, that is the bound state only exists for the well, and not for the barrier. The Fourier transform of this wavefunction is a Lorentzian function. The energy of the bound state is then,

$$E_\mathrm{b} = -\frac{\hbar^2\kappa^2}{2m} = -\frac{m\alpha^2}{2\hbar^2} . \tag{24.52}$$

The δ-potential well and its wavefunction are exhibited in Fig. 24.6(a).

24.3.6.2 Scattering

For positive energies, the wavefunctions are oscillating functions of x. That is, the particle is free to move in either half-space: $x < 0$ or $x > 0$, but it may be scattered at the δ-potential. The quantum case can be studied in the following situation: a particle incident on the barrier from the left side (A_1) may be reflected (B_1) or transmitted (A_2). To find the amplitudes for reflection and transmission for incidence from the left, we set in the equations (24.49) $A_1 = 1$ (incoming particle), $B_1 = r$ (reflection), $B_2 = 0$ (no incoming particle from the right), and $A_2 = t$ (transmission), and solve

for r and t,

$$t = \frac{1}{1 - \dfrac{m\alpha}{\imath\hbar^2 k}} \quad , \quad r = \frac{1}{\dfrac{\imath\hbar^2 k}{m\alpha} - 1} \, . \tag{24.53}$$

Due to the mirror symmetry of the model, the amplitudes for incidence from the right are the same as those from the left. The result is that there is a non-zero probability,

$$R = |r|^2 = \frac{1}{1 + \dfrac{\hbar^4 k^2}{m^2\alpha^2}} = \frac{1}{1 + \dfrac{2\hbar^2 E}{m\alpha^2}} \, . \tag{24.54}$$

for the particle to be reflected. This does not depend on the sign of α, that is, a barrier has the same probability of reflecting the particle as a well. This is a significant difference from classical mechanics, where the reflection probability would be 1 for the barrier (the particle simply bounces back), and 0 for the well (the particle passes through the well undisturbed). The probability for transmission is,

$$T = |t|^2 = 1 - R = \frac{1}{1 + \dfrac{m^2\alpha^2}{\hbar^4 k^2}} = \frac{1}{1 + \dfrac{m\alpha^2}{2\hbar^2 E}} \, . \tag{24.55}$$

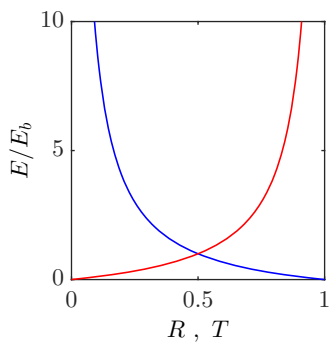

Figure 24.7: (code) Transmission (red) and reflection (blue) probability of a δ-potential well. The energy $E > 0$ is in units of $E_\mathrm{b} = m\alpha^2/2\hbar^2$.

An application example regards the interfaces between two conducting materials. In the bulk of the materials, the motion of the electrons is quasi-free and can be described by the kinetic term in the above Hamiltonian with an effective mass m. Often, the surfaces of such materials are covered with oxide layers or are not ideal for other reasons. This thin, non-conducting layer may then be modeled by a local δ-function potential. Electrons may then tunnel from one material to the other giving rise to a current.

Example 200 (*Double delta-potential*): The δ-function model is actually a one-dimensional version of the hydrogen atom. The model becomes particularly useful when applied to the hydrogen molecule ion, as shown in the following.

The double-well δ-function models a diatomic hydrogen molecule by the corresponding Schrödinger equation:

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2}(x) + V(x)\psi(x) = E\psi(x) \ ,$$

where the potential is now:

$$V(x) = -q\lambda\left[\delta\left(x+\tfrac{R}{2}\right) + \delta\left(x-\tfrac{R}{2}\right)\right]$$

where $0 < R < \infty$ is the 'internuclear' distance with δ-function (negative) peaks located at $x = \pm R/2$ (shown in brown in the diagram). Keeping in mind the relationship of this model with its three-dimensional molecular counterpart, we use atomic units and set $\hbar = m = 1$. Here $0 < \lambda < 1$ is a formally adjustable parameter. From the single well case, we can infer the 'ansatz' for the solution to be:

$$\psi(x) = Ae^{-d\left|x+\frac{R}{2}\right|} + Be^{-d\left|x-\frac{R}{2}\right|} \ .$$

Matching of the wavefunction at the δ-function peaks yields the determinant:

$$\begin{vmatrix} q-d & qe^{-dR} \\ q\lambda e^{-dR} & q\lambda - d \end{vmatrix} = 0 \quad \text{where} \quad E = -\frac{d^2}{2} \ .$$

Thus, d is found to be governed by the pseudo-quadratic equation:

$$d_\pm(\lambda) = \tfrac{1}{2}q(\lambda+1) \pm \tfrac{1}{2}\left\{q^2(1+\lambda)^2 - 4\lambda q^2[1-e^{-2d_\pm(\lambda)R}]\right\}^{1/2} \ ,$$

which has two solutions $d = d_\pm$. For the case of equal charges (symmetric homonuclear case), $\lambda = 1$ and the pseudo-quadratic reduces to:

$$d_\pm = q[1 \pm e^{-d_\pm R}] \ .$$

The '+' case corresponds to a wave function symmetric about the midpoint (shown in red in the diagram) where $A = B$ and is called gerade. Correspondingly, the '-' case is the wavefunction that is anti-symmetric about the midpoint where $A = -B$ is called ungerade (shown in green in the diagram). They represent an approximation of the two lowest discrete energy states of the three-dimensional H_2^+ and are useful in its analysis. Analytical solutions for the energy eigenvalues for the case of symmetric charges are given by:

$$d_\pm = q + W(\pm qRe^{-qR})/R \ ,$$

where W is the standard Lambert function. Note that the lowest energy corresponds to the symmetric solution d_+. In the case of unequal charges, and for that matter the three-dimensional molecular problem, the solutions are given by a generalization of the Lambert function (see section on generalization of Lambert function and references herein).

One of the most interesting cases is when $qR \leq 1$, which results in $d_- = 0$. Thus, one has a non-trivial bound state solution with $E = 0$. For these specific parameters, there are many interesting properties that occur, one of which is the unusual effect that the transmission coefficient is unity at zero energy.

24.3.7 Exercises

24.3.7.1 Ex: Tunneling

A rubidium-87 atom moves in free space (region 0) with velocity $v = 1\,\mathrm{cm/s}$ (see diagram). Suddenly it encounters a gap with depth $V_1 = -k_\mathrm{B} \cdot 1\,\mu\mathrm{K}$.
a. What is the particle's Broglie wavelength in region 1?
b. Now the atom encounters a barrier of height $V_2 = -V_1$. What is the probability that the particle will enter region 2?
c. What is the probability of finding the particle inside region 2 up to a depth of $x_2 = 10\,\mathrm{nm}$?

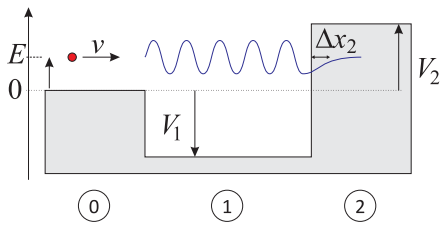

Figure 24.8: Particle in a potential landscape.

24.3.7.2 Ex: Collisions

A *collision* between attractive or repulsive particles can be described by the Schrödinger equation as a one-dimensional scattering,

$$-\frac{\hbar^2}{2m}\psi''(x) + \alpha\delta(x)\psi(x) = E\psi(x) \ .$$

The energy spectrum may be a discrete spectrum of bound states and a continuum of free states.
a. Calculate the transmission coefficient for the case of a particle with energy E thrown against the potential energy barrier $V(x) = \alpha\delta(x)$. Does the result change for the case when $V(x) = -\alpha\delta(x)$, with $\alpha > 0$?
b. For this last potential, find the energy of the bound state and its corresponding wavefunction.

24.3.7.3 Ex: Energy barrier

Consider a particle with energy E thrown (in the direction $\hat{\mathbf{e}}_x$) against a potential energy barrier of finite height and width, such that $V(x) = 0$ for $x < 0$ or $x > L$ and $V(x) = V_0$ for $0 \le x \le L$.
a. Obtain the reflection and transmission coefficients R and T for the case $E > V_0$. Discuss the result.
b. Do the same for the case $E < V_0$.

24.3.7.4 Ex: Wavepacket reflected at a potential barrier

Simulate the reflection of a Gaussian wavepacket at a potential barrier for various kinetic energies using the Julia programming language.

24.4 Numerical approaches for arbitrary potentials

In practice, many potentials are not box-shaped or harmonic, which renders an analytic treatment difficult or impossible. To some extend approximation methods can be used, as will be discussed in Sec. 27.5, but many problems can only be solved numerically. In Sec. 24.4.1 we will first show at the example of arbitrary one-dimensional potentials, how the Schrödinger equation can be solved numerically and how this allows one to determine the eigenenergies of bound states. In Sec. 24.4.2 we will introduce the very efficient Fourier grid method for calculating bound state energies and wavefunctions.

24.4.1 Calculation of free and bound states wavefunctions

Numerical routines or packages are available for solving ordinary differential equations (ODE). Generally it is advantageous to convert the one-dimensional second-order Schrödinger equation into two first-order differential equations via,

$$\varphi'(x) = \frac{2m}{\hbar^2}[E - V(x)]\psi(x) \qquad \text{and} \qquad \psi'(x) = \varphi(x) \ . \tag{24.56}$$

For free states, $E > V(x)$, we just solve equation (24.56) specifying the kinetic energy of the particle. The magenta curve in Fig 24.9(a) is an example of a collisional wavefunction in a Morse-type interatomic potential.

For bound states, we must additional satisfy the eigenvalue problem, since only specific discrete eigenenergies E are permitted. A possible procedure consists in guessing an eigenvalue E, calculating the associated wavefunction $\psi(x)$ using an ODE solver, check whether it diverges for $x \to \pm\infty$, and vary E until $\psi(x)$ no longer diverges. Then we repeat the procedure for are bound state energies, until we got them all. The red curve in Fig 24.9(a) shows the wavefunction of a vibrational state in a Morse-type potential obtained by solving the Schrödinger equation and adjusting the energy until the function stops diverging in the classically forbidden range. In this example the iteration process was stopped when the wavefunction diverged at around $R \approx 19a_{\mathrm{B}}$. In Exc. 24.4.4.1 we will practice this technique at the example of Hermite's differential equation, and in Exc. 24.4.4.2 we will study the case of a potential whose depth linearly increases with the distance from origin.

24.4.2 The Fourier grid method for bound states

The objective of the *Fourier grid method* is to analytically solve the 1D Schrödinger equation with an arbitrary potential $V(r)$ on a grid of $2N+1$ equally spaced spatial points r_i, where $i = 0, \pm 1, ..., \pm N$. That is, we assume the potential $V(r_i)$ to be given at these points. Skaling by the spatial coordinate r by $r/L = x/2\pi$, we get for the

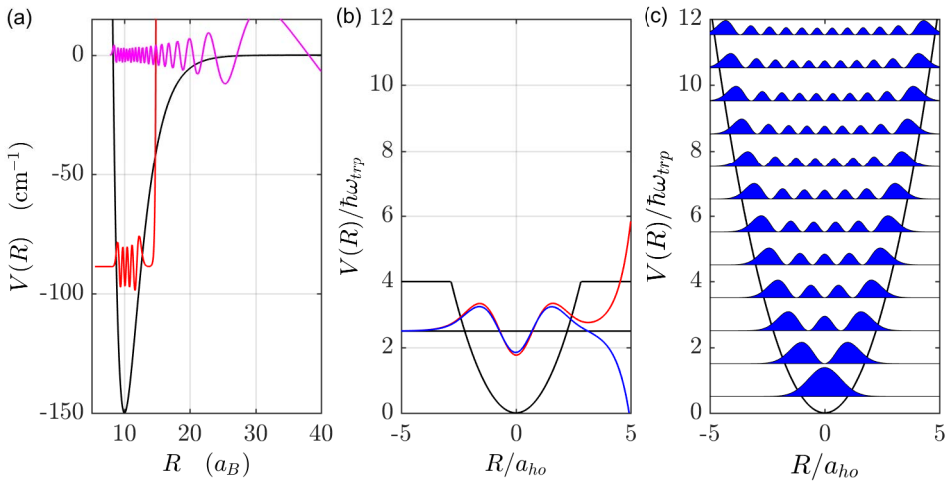

Figure 24.9: (code) (a) Free particle (magenta) and bound state wavefunction (red) calculated using a MATLAB ODE solver. (b) Bound state wavefunction of the harmonic oscillator calculated using a MATLAB ODE solver. For the red curve the eigenvalue has been slightly overestimated and for the blue curve underestimated. (c) Calculation of the harmonic oscillator energies and wave functions using the Fourier grid method.

dimensionless coordinate x the Schrödinger equation,

$$\left[-\frac{h^2}{2mL^2}\frac{d^2}{dx^2}+V(x)\right]\psi(x)=E\psi(x)\ , \tag{24.57}$$

with the grid given by,

$$x_i \equiv \frac{2\pi i}{2N+1}\ . \tag{24.58}$$

The main difficulty for numerically solving such eigenvalue equations is obviously the derivative. Numerical differentiation schemes can be cast into the following general form [642],

$$f'(x_i)=\sum_{j=-N}^{N} D_{ij} f(x_j)\ , \tag{24.59}$$

that is, they can be expressed as a multiplication of the discretized wavefunction represented as a vector $f(x_j)$ and a matrix D_{ij}. These schemes are usually based on interpolation polynomials and are the more accurate, the higher the order of these polynomials is chosen to be.

Example 201 (*Newton's derivation matrix*): For example the Newton method, which represents the lowest order interpolation polynomial, consists

in approximating the differentiation matrix by,

$$D_{ij}f(x_j) \simeq \frac{1}{\Delta x}\begin{pmatrix} \ddots & \ddots & & & \\ & -1 & 1 & & \\ & & -1 & \ddots & \\ & & & \ddots & \end{pmatrix}\begin{pmatrix} \vdots \\ f_{j-1} \\ f_j \\ \vdots \end{pmatrix} = \begin{pmatrix} \vdots \\ \frac{f_j - f_{j-1}}{\Delta x} \\ \frac{f_{j+1} - f_j}{\Delta x} \\ \vdots \end{pmatrix} \simeq \begin{pmatrix} \vdots \\ f'_{j-1} \\ f'_j \\ \vdots \end{pmatrix} .$$

Instead of using interpolation polynomials, one may consider over-all approximation of a function $f(x)$ by a Fourier series of N-th order, i.e. to assume (see (18.104)),

$$f(x) = \sum_{k=-\infty}^{\infty} c_k e^{\imath kx} \simeq \sum_{k=-N}^{N} c_k e^{\imath kx} . \tag{24.60}$$

The highest harmonics of the Fourier expansion N is set by the distance between two grid points. The expansion coefficients are,

$$c_k = \frac{1}{2\pi}\int_0^{2\pi} f(x)e^{-\imath kx}dx \longrightarrow \frac{1}{2\pi}\sum_{j=-N}^{N} f(x_j)e^{-\imath kx_j}\Delta x = \frac{1}{2N+1}\sum_{j=-N}^{N} f(x_j)e^{-\imath kx_j} . \tag{24.61}$$

Now, substituting x by the discrete variable x_i, we take the derivative $f'(x_i)$ of the function (24.60), insert the expansion coefficients (24.61), and compare the resulting expression to the linear combination (24.59) of the functional values $f(x_j)$,

$$\begin{aligned} f'(x_i) &= \sum_{k=-N}^{N} \imath k c_k e^{\imath kx_i} = \frac{\imath}{2N+1}\sum_{k=-N}^{N} k \sum_{j=-N}^{N} f(x_j)e^{\imath k(x_i - x_j)} \\ &= \frac{2}{2N+1}\sum_{k=1}^{N} k \sum_{j=-N}^{N} f(x_j)\sin k(x_j - x_i) \equiv \sum_{j=-N}^{N} D_{ij}f(x_j) . \end{aligned} \tag{24.62}$$

From this we see, that the matrix elements D_{ij} are given by,

$$D_{ij} = \frac{2}{2N+1}\sum_{k=1}^{N} k\sin k(x_j - x_i) = \frac{2}{2N+1}\sum_{k=1}^{N} k\sin\frac{2\pi k(i-j)}{2N+1} . \tag{24.63}$$

The sum can be evaluated analytically, as shown in Exc. 24.4.4.3 [878],

$$D_{ii} = 0 \qquad \text{and} \qquad D_{i\neq j} = \frac{(-1)^{i-j}}{2\sin\frac{x_i - x_j}{2}} = \frac{(-1)^{i-j}}{2\sin\frac{\pi(i-j)}{2N+1}} . \tag{24.64}$$

We may proceed similarly for the second derivative,

$$\begin{aligned} f''(x_i) &= -\sum_{k=-N}^{N} k^2 c_k e^{\imath kx_i} = \frac{-1}{2N+1}\sum_{k=-N}^{N} k^2 \sum_{j=-N}^{N} f(x_j)e^{\imath k(x_i - x_j)} \\ &= \frac{-2}{2N+1}\sum_{k=1}^{N} k^2 \sum_{j=-N}^{N} f(x_j)\cos k(x_j - x_i) \equiv \sum_{j=-N}^{N} (D^2)_{ij}f(x_j) , \end{aligned} \tag{24.65}$$

yielding,

$$(D^2)_{ij} = \frac{-2}{2N+1}\sum_{k=1}^{N} k^2 \cos k(x_j - x_i) = \frac{-2}{2N+1}\sum_{k=1}^{N} k^2 \cos\frac{2\pi k(i-j)}{2N+1} \ . \tag{24.66}$$

Again, the sum can be evaluated analytically, as shown in Exc. 24.4.4.3 [878],

$$\boxed{(D^2)_{ii} = -\frac{N^2+2}{12} \qquad \text{and} \qquad (D^2)_{i\neq j} = -\frac{(-1)^{i-j}}{2\sin^2\frac{\pi(i-j)}{2N+1}}} \ . \tag{24.67}$$

With this scheme of differentiation, the set of difference equations representing the problem (24.67) is readily found to be [616, 279, 878],

$$\boxed{\hat{H}\psi = E\psi \qquad \text{with} \qquad \hat{H}_{ij} = -\frac{h^2}{2mL^2}(D^2)_{ij} + V(x_j)\delta_{ij}} \ . \tag{24.68}$$

This eigenvalue problem can easily be solved on a computer, see Fig 24.9(b).

24.4.2.1 Mapping coordinate grids to potentials

To properly describe the wavefunction of a particle it obviously takes a minimum number of points per de Broglie wavelength. Now, if the particle moves in a potential characterized by shallow and deep areas, the de Broglie wavelength suffers large variations. Numerical procedures evaluating the wavefunction on a grid of points then benefit from a flexible distribution of the points along the propagation axis: Where the potential is shallow less points are needed, while in deeper areas the grid is more dense.

The general procedure consists in rescaling the Schrödinger equation

$$\left[-\frac{\hbar^2}{2m}\frac{d^2}{dr^2} + V(r)\right]\psi(r) = E\psi(r) \tag{24.69}$$

by transforming the r-axis into an x-axis according to [529],

$$\boxed{r = f(x) \quad , \quad dr = J(x)dx \quad , \quad V_x(x) = V(r) \quad , \quad \psi_x(x) = \psi(r)} \ . \tag{24.70}$$

The function $f^{-1}(r)$ must now be designed as a function of the local potential depth such as to produce less grid points x in shallow areas of the potential. Applying the transform we find,

$$\left[-\frac{\hbar^2}{2m}\left(\frac{1}{J(x)^2}\frac{d^2}{dx^2} - \frac{J'(x)}{J(x)^3}\frac{d}{dx}\right) + V_x(x)\right]\psi_x(x) = E\psi_x(x) \ . \tag{24.71}$$

Introducing a new wavefunction via,

$$\boxed{\psi_x(x) = J^{-1/2}(x)\phi(x)} \tag{24.72}$$

we get,

$$\left[-\frac{\hbar^2}{2mJ^2}\frac{d^2}{dx^2} + \frac{\hbar^2 J'}{mJ^3}\frac{d}{dx} + V_x + \frac{\hbar^2}{2m}\left(\frac{1}{2}\frac{J''}{J^3} - \frac{5}{4}\frac{J'^2}{J^4}\right)\right]\phi = E\phi \ , \tag{24.73}$$

or introducing an effective potential,

$$\bar{V}_x \equiv V_x + \frac{\hbar^2}{2m}\left(\frac{7}{4}\frac{J'^2}{J^4} - \frac{1}{2}\frac{J''}{J^3}\right) , \tag{24.74}$$

we get,

$$\boxed{\left[-\frac{\hbar^2}{4m}\left(\frac{1}{J(x)^2}\frac{d^2}{dx^2} + \frac{d^2}{dx^2}\frac{1}{J(x)^2}\right) + \bar{V}_x(x)\right]\phi(x) = E\phi(x)} . \tag{24.75}$$

Finally, we apply the Fourier grid method to the mapped coordinate grid in the same way as in (24.68), however with the modified matrices,

$$\boxed{\begin{array}{lcl} (D^2)_{ii} & = & -\frac{N^2+2}{12}\frac{1}{J_i^2} \quad \text{and} \quad (D^2)_{i\neq j} = -\frac{(-1)^{i-j}}{2\sin^2\frac{\pi(i-j)}{N}}\left(\frac{1}{2J_i^2} + \frac{1}{2J_j^2}\right) \\ \bar{V}(x_j) & = & V(x_j) + \frac{1}{2m}\left(\frac{7}{4}\frac{J'^2}{J^4} - \frac{1}{2}\frac{J''}{J^3}\right) \end{array}} , \tag{24.76}$$

where $J(x) = f'(x)$, $J'(x)$ and $J'(x)$ are calculated numerically on the grid x_j.

In practice, to adapt the mapped grid to the rapidity of the de Broglie wave oscillations, we define an equidistant grid x and set,

$$x = f^{-1}(r) \equiv \frac{1}{\pi}\int_{r_i}^{r} k(r')dr' \quad \text{with} \quad k(R) = \sqrt{\tfrac{2m}{\hbar^2}[0 - V(r)]} . \tag{24.77}$$

Inverting this function we obtain the desired mapped grid,

$$r = f(x) . \tag{24.78}$$

Do the Exc. 24.4.4.4.

24.4.3 Steepest descent ot the ground state

The softwares 'Maple' or 'Mathematics' are useful for analytical calculations, that is, multiplying matrices or determining eigenvalues. For numerical calculations the softwares 'Matlab' or 'Python' are more adapted. For example, the time evolution of a Schrödinger equation,

$$|\psi(t)\rangle = e^{-\imath\hat{H}t/\hbar}|\psi(0)\rangle , \tag{24.79}$$

can be calculated in a single command line using the Matlab `expm` function.

When the system varies temporally, $\hat{H}(t)$, we may divide time into small units dt and propagate the wavefunction as,

$$|\psi(t+dt)\rangle = e^{-\imath\hat{H}(t)dt/\hbar}|\psi(t)\rangle \simeq |\psi(t)\rangle\left(1 - \imath\frac{\hat{H}(t)}{\hbar}dt\right) , \tag{24.80}$$

continuously reinserting the solution into the equation. This *Newton method* does not converge quickly (dt should be chosen small enough, when $\hat{H}(t)$ varies rapidly), but there are other more sophisticated methods like the *Runge-Kutta method*.

A variation of this method is called *steepest descent method*. This method is similar to the Newton Eq. (24.80), but replaces the time dt with an imaginary time.

Thus, the coherent temporal evolution of the Schrödinger equation is replaced by a dissipative evolution. The loss of energy automatically takes the system to the ground state. However, in order to preserve the normalization of the wavefunction, it must be renormalized at each iteration step,

$$|\psi(t+dt)\rangle \to \frac{|\psi(t+dt)\rangle}{\sqrt{\langle\psi(t+dt)|\psi(t+dt)\rangle}} \ . \tag{24.81}$$

The method also applies to more complicated equations than the Schrödinger equation, for example, the *Gross-Pitaevskii equation*. We will deepen this technique in Sec. 50.3.3.

As an example Fig. 24.10 shows the splitting of a quantum mechanical function (in this case a Bose-Einstein condensate with repulsive interatomic interactions) in the ground state of a quartic double-well potential calculated from the steepest descent method. In Exc. 24.4.4.5, using the Fourier grid method, we study the splitting of bound state energy levels due to tunneling in a *double-well potential*.

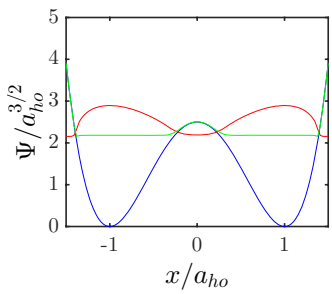

Figure 24.10: (code) Condensate wavefunction (red) in a double-well potential (blue) numerically calculated using the steepest descent method. Also shown is the chemical potential (green).

Another numerical method often used in quantum mechanics is the method called the quantum *Monte Carlo simulation* of the wavefunction [661]. This method simulates trajectories of quantum systems treating intrinsic quantum noise as random processes disrupting the uniformity of the trajectory. The advantage of this method is that it also applies to dissipative systems.

24.4.4 Exercises

24.4.4.1 Ex: Numerical resolution of the Hermite differential equation

Solve the Hermite differential equation (24.102) numerically for $n = 8$, e.g. using the `ode45` ordinary differential equation solver of Matlab, or similar. Plot the wavefunction of the 8-th vibrational level of a harmonic oscillator.

24.4.4.2 Ex: Numerical resolution of the Schrödinger equation

Paramagnetic atoms, such as rubidium, can be confined in quadrupolar magnetic traps, which are characterized by a linear increase of the magnetic field in any

direction of space. Let us consider one dimension of such a potential, given by $V(x) = \mu_{\rm B}\partial_x B\,|x| - V_0$ wherever $V(x)$ is negative and $V(x) = 0$ else. Here $\mu_{\rm B}$ is the Bohr magneton. Be $\partial_x B = 200\,{\rm G/cm}$ the magnetic field gradient and $V_0 = h\ 15\,{\rm kHz}$ the potential depth.
a. Calculate the energy and wavefunction of the lowest bound state of this potential by numerical integration of the stationary Schrödinger equation using Matlab or another software.
b. Obtain all bound state energies and wavefunctions using the Fourier grid method.

24.4.4.3 Ex: The Fourier grid method

Derive (a) the formula (24.64) and (b) the formula (24.67) for $N \gg 1$ using the formula (1.352) from [376].

24.4.4.4 Ex: Derivation of the Fourier grid method from the FFT

The Fast Fourier Transform (FFT) is defined by,

$$\begin{aligned} H_n &= \sum_{k=0}^{N-1} e^{-2\pi\imath nk/N} h_k \\ &= \sum_{k=0}^{N-1} e^{-2\pi\imath nk/(N/2)} h_{2k} + e^{-2\pi\imath k/N} \sum_{k=0}^{N/2-1} e^{-2\pi\imath nk/(N/2)} h_{2k+1} = even + odd\ . \end{aligned}$$

the inverse transform is,

$$h_k = \frac{1}{N} \sum\nolimits_{k=0}^{N-1} e^{2\pi\imath nk/N} H_n\ .$$

The sinus transform of a real vector s_k is,

$$S_n = \frac{2}{N} \sum\nolimits_{k=1}^{N-1} s_k \sin \pi nk/N\ .$$

Calculate the inverse transform of the matrix $T_{rs} = k_r^2 \delta_{rs}$.

24.4.4.5 Ex: Infinite rectangular double-well potential

a. Consider the rectangular double-well potential sketched in Fig. 24.11 and calculate the energy levels according to the procedure taught in Sec. 24.3.5.
b. For the same type of potential as in (a) prepare a numerical calculation of the wavefunctions, e.g. using the Fourier grid method introduced in Sec. 35.2.5, for ^{87}Rb using the following dimensions of the potential: $V_0 = h \times 15\,{\rm MHz}$, $L = 40\,{\rm nm}$, and $b = 3\,{\rm nm}$.

24.5 Harmonic oscillator

Many systems oscillate. Common examples are vibrations of atoms bound in a molecule or in a crystalline lattice, of particles trapped in applied electric or magnetic

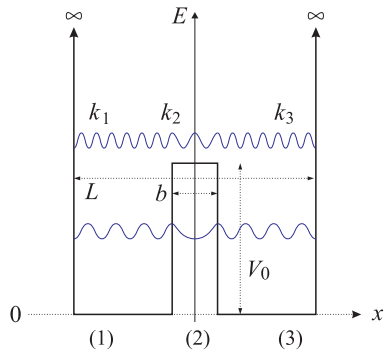

Figure 24.11: Scheme of the rectangular double-well potential.

fields, or light in an electromagnetic mode. Most periodic movements are approximately harmonic for small amplitude vibrations and can be treated in a way that we will detail now.

We start with the unidimensional *harmonic oscillator* (OH),

$$\left[\frac{-\hbar^2}{2m}\frac{d^2}{dx^2} + V(x) - E\right]\psi(x) = 0 \qquad \text{where} \qquad V(x) = \frac{m}{2}\omega^2 x^2 \ . \tag{24.82}$$

24.5.1 Factorization of the Hamiltonian and Fock states

Respecting the fact that the operators $\hat{p}$ and $\hat{x}$ do not commute, $\frac{\imath}{\hbar}[\hat{p},\hat{x}] = 1$, we can rewrite the Hamiltonian of the harmonic oscillator in the following way,

$$\begin{aligned}\hat{H} &= -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{m}{2}\omega^2\hat{x}^2 = \hbar\omega\left[\left(\sqrt{\tfrac{m\omega}{2\hbar}}\hat{x} - \imath\sqrt{\tfrac{1}{2m\hbar\omega}}\hat{p}\right)\left(\sqrt{\tfrac{m\omega}{2\hbar}}\hat{x} + \imath\sqrt{\tfrac{1}{2m\hbar\omega}}\hat{p}\right) + \tfrac{1}{2}\right] \\ &= \hbar\omega\left(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}\right) \ ,\end{aligned} \tag{24.83}$$

with the abbreviation

$$\hat{a} \equiv \sqrt{\frac{m\omega}{2\hbar}}\hat{x} + \imath\sqrt{\frac{1}{2m\hbar\omega}}\hat{p} \tag{24.84}$$

and its Hermitian transposition $\hat{a}^\dagger$. Now let's try to find out the properties of the operators $\hat{a}^\dagger$ and $\hat{a}$. First of all, the commutator is,

$$\begin{aligned}[\hat{a},\hat{a}^\dagger] &= \left[\sqrt{\frac{m\omega}{2\hbar}}\hat{x} + \imath\sqrt{\frac{1}{2m\hbar\omega}}\hat{p}, \sqrt{\frac{m\omega}{2\hbar}}\hat{x} - \imath\sqrt{\frac{1}{2m\hbar\omega}}\hat{p}\right] = \frac{\imath}{2\hbar}\left[\hat{x}+\hat{p}, \hat{x}-\hat{p}\right] \\ &= \tfrac{\imath}{\hbar}\left[\hat{p},\hat{x}\right] = 1 \ .\end{aligned} \tag{24.85}$$

Knowing $\hat{H}|\psi\rangle = E|\psi\rangle$ is it clear that $\hat{a}^\dagger\hat{a}$ is an observable with the eigenvalue $n \equiv \frac{E}{\hbar\omega} - \frac{1}{2}$,

$$\hat{a}^\dagger\hat{a}|\psi\rangle = \left(\tfrac{E}{\hbar\omega} - \tfrac{1}{2}\right)|\psi\rangle \equiv n|\psi\rangle \implies |\psi\rangle = |n\rangle \ . \tag{24.86}$$

Now, we show that the states $\hat{a}|\psi\rangle$ are eigenstates of the operator defined as $\hat{n} \equiv \hat{a}^\dagger \hat{a}$, since,

$$\begin{aligned}
\hat{a}^\dagger \hat{a}\hat{a}|\psi\rangle &= (\hat{a}\hat{a}^\dagger - [\hat{a}, \hat{a}^\dagger])\hat{a}|\psi\rangle = (\hat{a}\hat{a}^\dagger\hat{a} - \hat{a})|\psi\rangle = \hat{a}(\hat{a}^\dagger\hat{a} - 1)|\psi\rangle = (n-1)\hat{a}|\psi\rangle \\
&\Longrightarrow \hat{a}|\psi\rangle \propto |n-1\rangle \equiv C|n-1\rangle \\
&\Longrightarrow n = \langle n|\hat{a}^\dagger\hat{a}|n\rangle = C^2\langle n-1|n-1\rangle \\
&\Longrightarrow C = \sqrt{n}\ . \qquad (24.87)
\end{aligned}$$

We note that the quantum number of the new $|n-1\rangle$ is decreased by 1. Similarly, we show for the state $\hat{a}^\dagger|\psi\rangle$,

$$\begin{aligned}
\hat{a}^\dagger\hat{a}\hat{a}^\dagger|\psi\rangle &= \hat{a}^\dagger([\hat{a}, \hat{a}^\dagger] + \hat{a}^\dagger\hat{a})|\psi\rangle = \hat{a}^\dagger(1 + \hat{a}^\dagger\hat{a})|\psi\rangle = (n+1)\hat{a}^\dagger|\psi\rangle \\
&\Longrightarrow \hat{a}^\dagger|\psi\rangle \propto |n+1\rangle \equiv C|n+1\rangle \\
&\Longrightarrow n+1 = \langle n|\hat{a}^\dagger\hat{a} + [\hat{a}, \hat{a}^\dagger]|n\rangle = C^2\langle n+1|n+1\rangle \\
&\Longrightarrow C = \sqrt{n+1}\ . \qquad (24.88)
\end{aligned}$$

Therefore, this new state is also an eigenvector $|n+1\rangle$, with a quantum number increased by one unit. $\hat{a}^\dagger$ and $\hat{a}$ are creation and annihilation operators of an energy packet,

$$\boxed{\hat{a}^\dagger|n\rangle = \sqrt{n+1}|n+1\rangle \qquad \text{and} \qquad \hat{a}|n\rangle = \sqrt{n}|n-1\rangle}\ . \qquad (24.89)$$

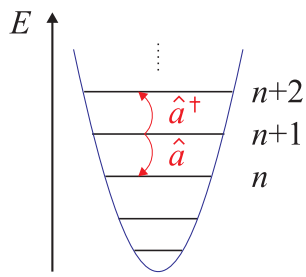

Figure 24.12: Equidistant ladder of vibrational levels showing the actions of the creation and the annihilation operator.

The matrix representation of the field operators is,

$$\hat{a}^\dagger = \sum_n \sqrt{n+1}|n+1\rangle\langle n| \qquad \text{and} \qquad \hat{a} = \sum_n \sqrt{n}|n-1\rangle\langle n|\ , \qquad (24.90)$$

from which we deduce,

$$\hat{n} = \hat{a}^\dagger\hat{a} = \sum_n n|n\rangle\langle n| \qquad \text{and} \qquad \hat{H} = \hbar\omega\left(\hat{n} + \tfrac{1}{2}\right)\ . \qquad (24.91)$$

Now it is clear, that $\hat{n}$ can be understood as a number operator [2]. The energy spectrum of the harmonic oscillator is equidistant,

$$\boxed{E_n = \hbar\omega\left(n + \tfrac{1}{2}\right)}\ . \qquad (24.92)$$

[2] Also, we can define phase operators by $\widehat{\exp}(\mp\imath\phi) = \sum_n |n \mp 1\rangle\langle n|$.

The state with n quanta can be created from the vacuum,

$$|n\rangle = \frac{\hat{a}^\dagger}{\sqrt{n}}|n-1\rangle = \frac{\hat{a}^{\dagger n}}{\sqrt{n!}}|0\rangle \ . \tag{24.93}$$

The state $|n\rangle$ is called *number state* or *Fock state*.

24.5.1.1 Uncertainty in Fock states

We consider an OH of mass m and angular frequency ω prepared in the stationary state $|n\rangle$ which is an eigenstate of the Hamiltonian $\hat{H}$ with eigenvalue $(n+\frac{1}{2})\hbar\omega$. Defining the characteristic size of the OH, $a_{\rm ho} = \sqrt{\hbar/m\omega}$, the annihilation and creation operators can be written,

$$\hat{a} = \frac{1}{\sqrt{2}}\left(\frac{\hat{x}}{a_{\rm ho}} + \imath\frac{a_{\rm ho}}{\hbar}\hat{p}\right) \qquad \text{and} \qquad \hat{a}^\dagger = \frac{1}{\sqrt{2}}\left(\frac{\hat{x}}{a_{\rm ho}} - \imath\frac{a_{\rm ho}}{\hbar}\hat{p}\right) \ . \tag{24.94}$$

Therefore, the position and momentum operators are,

$$\sqrt{2}\frac{1}{a_{\rm ho}}\hat{x} = \hat{a} + \hat{a}^\dagger \qquad \text{and} \qquad \sqrt{2}\imath\frac{a_{\rm ho}}{\hbar}\hat{p} = \hat{a} - \hat{a}^\dagger \ . \tag{24.95}$$

The mean squared deviations of the position $\hat{x}$ and the momentum $\hat{p}$ are,

$$\begin{aligned}
\Delta x^2 &= \langle n|\hat{x}^2|n\rangle = \frac{a_{\rm ho}^2}{2}\langle n|\hat{a}\hat{a} + \hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a} + \hat{a}^\dagger\hat{a}^\dagger|n\rangle = \frac{a_{\rm ho}^2}{2}\langle n|2\hat{n}+1|n\rangle \\
&= \frac{a_{\rm ho}^2}{2}(2n+1) \qquad\qquad (24.96)\\
\Delta p^2 &= \langle n|\hat{p}^2|n\rangle = \frac{-\hbar^2}{2a_{\rm ho}^2}\langle n|\hat{a}\hat{a} - \hat{a}\hat{a}^\dagger - \hat{a}^\dagger\hat{a} + \hat{a}^\dagger\hat{a}^\dagger|n\rangle = \frac{-\hbar^2}{2a_{\rm ho}^2}\langle n| -2\hat{n}-1|n\rangle \\
&= \frac{\hbar^2}{2a_{\rm ho}^2}(2n+1) \ .
\end{aligned}$$

From the results of the previous item we obtain the uncertainty relation $\Delta x\Delta p$ for the OH in the state $|n\rangle$,

$$\Delta p\Delta x = \tfrac{\hbar}{2}(2n+1) \ . \tag{24.97}$$

Example 202 (*Localization energy*): The non-vanishing energy of the fundamental state of the harmonic oscillator, $E_0 = \hbar\omega/2$, is an immediate consequence of the Heisenberg principle $\Delta x\Delta p \geq \hbar$, because in analogy with example 198 we calculate,

$$\frac{\langle p^2\rangle}{2m} = \frac{\Delta p^2}{2m} > \frac{\hbar^2}{2m\Delta x^2} > \frac{\hbar^2}{2ma_{\rm ho}^2} = \frac{\hbar\omega}{2} \ .$$

In the case of an electromagnetic field this energy is called *vacuum fluctuation*.

24.5.2 Harmonic oscillator in spatial representation

To simplify the Schrödinger equation in spatial representation,

$$\left[-\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{m}{2}\omega^2x^2\right]\psi(x) = \hbar\omega(n+\tfrac{1}{2})\psi(x) \ , \tag{24.98}$$

we use the scale $\tilde{x} \equiv x/a_{\rm ho}$, where $a_{\rm ho} = \sqrt{\hbar/m\omega}$ is the spatial extent of the ground state. Therefore,

$$\frac{2}{\hbar\omega}\left[-\frac{\hbar^2}{2m}\frac{d^2}{d(a_{\rm ho}\tilde{x})^2} + \frac{m}{2}\omega^2(a_{\rm ho}\tilde{x})^2\right]\tilde{\psi}(\tilde{x}) = \frac{2}{\hbar\omega}\left[-\frac{\hbar\omega}{2}\frac{d^2}{d\tilde{x}^2} + \frac{\hbar\omega}{2}\tilde{x}^2\right]\tilde{\psi}(\tilde{x})$$
$$= \left[-\frac{d^2}{d\tilde{x}^2} + \tilde{x}^2\right]\tilde{\psi}(\tilde{x}) = (2n+1)\tilde{\psi}(\tilde{x}) \ .$$

Now we start looking for asymptotic solutions. For $\tilde{x} \to \pm\infty$, that is, when the particle enters the classically forbidden region, we can neglect the total energy of the particle,

$$\left[-\frac{d^2}{d\tilde{x}^2} + \tilde{x}^2\right]\tilde{\psi}_\infty(\tilde{x}) \simeq 0 \ . \tag{24.99}$$

The solution of this equation is $\tilde{\psi}_\infty(\tilde{x}) = Ce^{-\tilde{x}^2/2}$, since

$$\left[-\frac{d^2}{d\tilde{x}^2} + \tilde{x}^2\right]e^{-\tilde{x}^2/2} = -\frac{d}{d\tilde{x}}(-\tilde{x})e^{-\tilde{x}^2/2} + \tilde{x}^2e^{-\tilde{x}^2/2} \tag{24.100}$$
$$= -\tilde{x}^2e^{-\tilde{x}^2/2} + e^{-\tilde{x}^2/2} + \tilde{x}^2e^{-\tilde{x}^2/2} = e^{-\tilde{x}^2/2} \simeq 0 \ .$$

This motivates the ansatz $\tilde{\psi}(\tilde{x}) \equiv e^{-\tilde{x}^2/2}H(\tilde{x})$ for the complete differential equation (24.98),

$$\left[-\frac{d^2}{d\tilde{x}^2} + \tilde{x}^2\right]e^{-\tilde{x}^2/2}H(\tilde{x}) = -e^{-\tilde{x}^2/2}\frac{d^2H(\tilde{x})}{d\tilde{x}^2} - 2\frac{de^{-\tilde{x}^2/2}}{d\tilde{x}}\frac{dH(\tilde{x})}{d\tilde{x}} - \frac{d^2e^{-\tilde{x}^2/2}}{d\tilde{x}^2}H(\tilde{x}) + \tilde{x}^2e^{-\tilde{x}^2/2}H(\tilde{x})$$
$$= -e^{-\tilde{x}^2/2}\frac{d^2H(\tilde{x})}{d\tilde{x}^2} - 2(-x)e^{-\tilde{x}^2/2}\frac{dH(\tilde{x})}{d\tilde{x}} + \left[-\tilde{x}^2e^{-\tilde{x}^2/2} + e^{-\tilde{x}^2/2}\right]H(\tilde{x}) + \tilde{x}^2e^{-\tilde{x}^2/2}H(\tilde{x})$$
$$\equiv (2n+1)e^{-\tilde{x}^2/2}H(\tilde{x}) \ . \tag{24.101}$$

Thus, the functions $H(\tilde{x})$ must satisfy the differential equation,

$$H''(\tilde{x}) = 2\tilde{x}H'(\tilde{x}) - 2nH(\tilde{x}) \ . \tag{24.102}$$

We can verify that the Hermite polynomials defined by,

$$H_n(\tilde{x}) = (-1)^n e^{\tilde{x}^2}\frac{d^n}{d\tilde{x}^n}e^{-\tilde{x}^2} \ , \tag{24.103}$$

transform the differential equation into a recursion formula,

$$H_{n+1}(\tilde{x}) = 2\tilde{x}H_n(\tilde{x}) - 2nH_{n-1}(\tilde{x}) \ , \tag{24.104}$$

which allows us to easily calculate the polynomials,

$$H_0(\tilde{x}) = 1 \quad , \quad H_1(\tilde{x}) = 2x \quad , \quad H_2(\tilde{x}) = 4x^2 - 2 \quad , \quad ... \tag{24.105}$$

In summary, the eigenfunction of a harmonic oscillator in the state of excitation n is,

$$\boxed{\langle x|n\rangle = \psi_n(x) = C_n e^{-x^2/2a_{\rm ho}^2}H_n(x/a_{\rm ho})} \ , \tag{24.106}$$

where the constant C_n is determined by the normalization condition (28.24), $\langle\psi_m|\psi_n\rangle = \delta_{m,n}$,

$$C_n = \frac{1}{\sqrt{a_{\rm ho}\sqrt{\pi}2^n n!}} \ . \tag{24.107}$$

The Hermite functions, H_n, are found in mathematical tables, see Sec. 28.3. The spatial and momentum wavefunctions for the vibrational ground state are,

$$\langle x|0\rangle = \frac{1}{\pi^{1/4}\sqrt{a_{\rm ho}}}e^{-x^2/2a_{\rm ho}^2} \quad \text{and} \quad \langle p|0\rangle = \frac{1}{\pi^{1/4}}\sqrt{\frac{a_{\rm ho}}{\hbar}}e^{-a_{\rm ho}^2p^2/2\hbar^2} \ . \tag{24.108}$$

Here we will only show the graphical representation of $|\psi|^2$ in Fig. 24.13. The Exc. 24.5.6.1 asks to evaluate HO in a classically forbidden region and in Exc. 24.5.6.2 we will calculate the spectrum of a semi-harmonic HO.

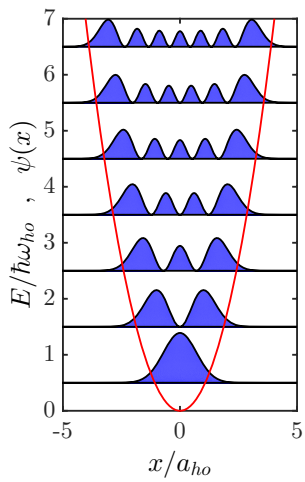

Figure 24.13: (code) Wavefunctions and energies for a harmonic potential.

24.5.3 Properties of the harmonic oscillator

We note that there are regions where $\psi(\tilde{x}) \neq 0$ even though $V(x) > E$. This effect is purely quantum. Classically, we can not find a particle in regions where its energy is below the potential.

We also note that for high quantum numbers, $n \to \infty$, we expect to recover the classical predictions, i.e.,

$$\lim_{n\to\infty} |\psi(x)|^2 = P_E(x) \ , \tag{24.109}$$

where P_E is the probability density of finding the oscillating particle at position x. The probability of finding the particle in a range dx close to the location x is easily calculated,

$$E = \frac{m}{2}v^2 + \frac{m}{2}\omega^2x^2 \tag{24.110}$$

$$\Rightarrow \qquad P_E(x)dx = \frac{t(x+dx)-t(x)}{T} = \frac{dx}{vT} = \frac{dx}{T}\frac{1}{\sqrt{2E/m-\omega^2x^2}} \ .$$

We see that for high energy values the wavefunction approaches the classical expectation.

We already mentioned that there exist solutions only for certain energies $E_n = \hbar\omega(2n+1)$. Consequently, the energy levels are equidistant, $E_{n+1} - E_n = \hbar\omega$, as if there were a box into which we add, one after the other, particles with the energy $\hbar\omega$ until we have accumulated n portions of energy. These particles are called *phonons* in the case of vibrations of massive particles, and *photons* in the case of a radiation field.

The fact that the energy distribution is the same as the one proposed by Planck for the black-body radiation suggests the use of the harmonic oscillator to describe the second quantization.

24.5.4 Time evolution of the unperturbed harmonic oscillator

Here we study the temporal evolution of a population distribution in a harmonic oscillator. The formal solution of the Schrödinger equation is,

$$|\psi(t)\rangle = e^{-\imath\hat{H}t/\hbar}|\psi(0)\rangle \ . \tag{24.111}$$

As the Hamiltonian is diagonal in the basis $|n\rangle$,

$$\hat{H} = \hbar\omega(\hat{n} + \tfrac{1}{2}) \ . \tag{24.112}$$

we can write,

$$e^{-\imath\hat{H}t/\hbar} = \sum_n |n\rangle e^{-\imath\omega t(n+1/2)}\langle n| \ . \tag{24.113}$$

If the initial state is $|\psi(0)\rangle = \sum_m c_m|m\rangle$, the final state and the eigenvalue of any observable will be,

$$|\psi(t)\rangle = \sum_n |n\rangle e^{-\imath\omega t(n+1/2)}\langle n|\psi(0)\rangle = \sum_n e^{-\imath\omega t(n+1/2)}c_n|n\rangle \tag{24.114}$$

$$\langle\psi(t)|\hat{A}|\psi(t)\rangle = \sum_m \langle m|e^{\imath\omega t(m+1/2)}c_m^*|\hat{A}|\sum_n e^{-\imath\omega t(n+1/2)}c_n|n\rangle = \sum_{m,n} c_m^* c_n e^{\imath\omega t(m-n)}\langle m|\hat{A}|n\rangle \ .$$

If the oscillator is initially in an eigenstate, $|\psi(0)\rangle = |k\rangle$, we obtain,

$$|\psi(t)\rangle = e^{-\imath\omega t(k+1/2)}|k\rangle \qquad \text{and} \qquad \langle\psi(t)|\hat{A}|\psi(t)\rangle = \langle k|\hat{A}|k\rangle \ , \tag{24.115}$$

that is, the *state remains stationary*. Motion needs non-diagonal elements of $\hat{A}$.

Another observation is that the populations do not change, even in the case of an initial superposition, since,

$$P_k(t) = |\langle k|\psi(t)\rangle|^2 = |e^{-\imath\omega t(k+1/2)}c_k|^2 = |c_k|^2 \ . \tag{24.116}$$

We conclude that

- movement of an observable $\hat{A}$ is possible, but only due to *variations of the phase factors*;

- to carry out transitions between the vibrational states is necessary to *perturb the oscillator*, e.g. by applying fields of electromagnetic radiation.

Example 203 (*Motion of a harmonic oscillator*): We now consider some specific examples. If the studied observable is the Hamiltonian and the initial state an arbitrary superposition, then

$$\langle\psi(t)|\hat{H}|\psi(t)\rangle = \hbar\omega\sum_{m,n} c_m^* c_n e^{\imath\omega t(m-n)}\langle m|\hat{n}+\tfrac{1}{2}|n\rangle = \hbar\omega\sum_n |c_n|^2(n+\tfrac{1}{2}) \ .$$

That is, the total energy of the oscillator is the sum of the energies of the states weighted with the populations of those states. In the case of the position operator,

$$\begin{aligned}\langle\psi(t)|\hat{x}|\psi(t)\rangle &= \tfrac{a_{\rm ho}}{\sqrt{2}}\sum_{m,n} c_m^* c_n e^{\imath\omega t(m-n)}\langle m|\hat{a}+\hat{a}^\dagger|n\rangle \\ &= \tfrac{a_{\rm ho}}{\sqrt{2}}\sum_n \left(c_{n-1}^* c_n e^{-\imath\omega t}\sqrt{n} + c_{n+1}^* c_n e^{\imath\omega t}\sqrt{n+1}\right) \\ &\overset{m,n\to\infty}{\longrightarrow} a_{\rm ho}\sqrt{2}\sum_n \sqrt{n}|c_n|^2\cos\omega t \ .\end{aligned}$$

That is, *the particle can only oscillate, if there are populations in consecutive states*. If this is not the case, $\langle\psi(t)|\hat{x}|\psi(t)\rangle = 0$. The oscillation frequency is always ω, independent of the energy of the particle. We will study this in Excs. 24.5.6.3, leaving the discussion of the temporal evolution of perturbed oscillators to later sections.

24.5.5 Multidimensional harmonic oscillator

The 3D harmonic potential is given by

$$V_{\rm ho}(\mathbf{r}) = \frac{m}{2}\omega_x^2 x^2 + \frac{m}{2}\omega_y^2 y^2 + \frac{m}{2}\omega_z^2 z^2 \ . \tag{24.117}$$

Making the ansatz

$$\psi(\mathbf{r}) = \psi_x(x)\psi_y(y)\psi_z(z) \ , \tag{24.118}$$

we can separate the spatial directions and obtain a one-dimensional equation for each coordinate, such that the coordinates can be considered separately. Each function $\psi_k(x_k)$ is of the form (24.106) and the energies are,

$$E_k = \hbar\omega_k(n_k+\tfrac{1}{2}) \ , \tag{24.119}$$

where $k = x, y, z$.

24.5.6 Exercises

24.5.6.1 Ex: Ground state of a harmonic oscillator

Equating the ground state energy of quantum HO to that of its classical analog, obtain the maximum elongation $x_{\rm m}$. Now, knowing that the ground state wavefunction is proportional to the Gaussian $\psi_0 \propto e^{-x^2/2x_{\rm m}^2}$, obtain the expression for the probability of finding the HO outside the classical limits and estimate its value.

24.5.6.2 Ex: Particle in a semi-harmonic well

Find the energy levels of a particle in a potential energy well of the form $V(x) = \infty$ for $x < 0$ and $V(x) = \frac{m\omega^2 x^2}{2}$ for $x > 0$. What is the parity of the allowed states?

24.5.6.3 Ex: Vibration of a harmonic oscillator

Consider a HO of mass m and angular frequency ω. At time $t = 0$ the oscillator's state is $|\psi(0)\rangle = \sum_n c_n |n\rangle$, where $|n\rangle$ are the stationary states of the HO with energy $(n + 1/2)\hbar\omega$.
a. What is the probability P for measuring, at an arbitrary time $t > 0$, an energy of the HO higher than $2\hbar\omega$? For the case when $P = 0$, what are the non-zero coefficients c_n?
b. From now on, we assume that only c_0 and c_1 are nonzero. Write down the normalization condition for $|\psi(0)\rangle$ and the mean value $\langle \hat{H} \rangle$ of energy in terms of c_0 and c_1. With the additional requirement $\langle \hat{H} \rangle = \hbar\omega$, calculate $|c_0|^2$ and $|c_1|^2$.
c. Given that the normalized state vector $|\psi(0)\rangle$ is defined to less than an overall phase factor, we determine this factor by choosing the real and positive coefficients c_0 and $c_1 = |c_1| e^{\imath\theta}$. Assuming $\langle \hat{H} \rangle = \hbar\omega$ and $\langle \hat{x} \rangle = \frac{1}{2}\sqrt{\hbar/m\omega}$, calculate θ.
d. With $|\psi(0)\rangle$ determined (according to the previous item), write down $|\psi(t)\rangle$ for $t > 0$ and calculate the value θ at this time t. Deduce the average value $\langle \hat{x} \rangle(t)$ of the position at time t.

24.6 Superposition states of a harmonic oscillator

As any other quantum system, a harmonic oscillator does not need to be in a particular vibrational eigenstate. In fact, it is much more common to encounter them in superpositions of many states. In a system in thermal equilibrium, the energetic distribution of occupied states reflects the temperature of the system.

24.6.1 Coherent states

The most common superposition for a harmonic oscillation is a Poissonian probability distribution of occupied vibrational (Fock) states. This state, called coherent or Glauber state, has particular features that we will discuss in the following sections.

24.6.1.1 Displacement operator

We now consider the so-called *displacement operator*,

$$\mathcal{D}(\alpha) \equiv e^{\alpha \hat{a}^\dagger - \alpha^* \hat{a}} \ , \tag{24.120}$$

which acts on the phase space of a harmonic oscillator spanned by the operators $\hat{a}$ and $\hat{a}^\dagger$, that is, $\hat{x} \propto \mathfrak{Re}\, \hat{a}$ and $\hat{p} \propto \mathfrak{Im}\, \hat{a}$, and try to discovers its features.

$\mathcal{D}(\alpha)$ is a unitary operator, since using Glauber's formula (23.312) we get,

$$\begin{aligned}\mathcal{D}^\dagger(\alpha)\mathcal{D}(\alpha) &= e^{\alpha^*\hat{a}-\alpha\hat{a}^\dagger}e^{\alpha\hat{a}^\dagger-\alpha^*\hat{a}} = e^{\alpha^*\hat{a}-\alpha\hat{a}^\dagger+\alpha\hat{a}^\dagger-\alpha^*\hat{a}+[\alpha^*\hat{a}-\alpha\hat{a}^\dagger,\alpha\hat{a}^\dagger-\alpha^*\hat{a}]/2} \\ &= e^{[\alpha^*\hat{a}-\alpha\hat{a}^\dagger,\alpha\hat{a}^\dagger-\alpha^*\hat{a}]/2} = e^{[\alpha^*\hat{a},\alpha\hat{a}^\dagger]/2+[-\alpha\hat{a}^\dagger,\alpha\hat{a}^\dagger]/2+[\alpha^*\hat{a},-\alpha^*\hat{a}]/2+[-\alpha\hat{a}^\dagger,-\alpha^*\hat{a}]/2} \\ &= e^{|\alpha|^2[\hat{a},\hat{a}^\dagger]/2+|\alpha|^2[\hat{a}^\dagger,\hat{a}]/2} = e^0 = \hat{1}\ .\end{aligned} \tag{24.121}$$

We can rewrite the displacement operator using Glauber's formula:

$$\begin{aligned}\mathcal{D}(\alpha) &= e^{\alpha\hat{a}^\dagger-\alpha^*\hat{a}} = e^{\alpha\hat{a}^\dagger}e^{-\alpha^*\hat{a}}e^{-[\alpha\hat{a}^\dagger,-\alpha^*\hat{a}]/2} = e^{\alpha\hat{a}^\dagger}e^{-\alpha^*\hat{a}}e^{|\alpha|^2[\hat{a}^\dagger,\hat{a}]/2} \\ &= e^{\alpha\hat{a}^\dagger}e^{-\alpha^*\hat{a}}e^{-|\alpha|^2/2}\ .\end{aligned} \tag{24.122}$$

The state resulting from the action of the operator $\mathcal{D}(\alpha)$ onto the ground state of the HO is,

$$\begin{aligned}|\alpha\rangle \equiv \mathcal{D}(\alpha)|0\rangle &= e^{-|\alpha|^2/2}e^{\alpha\hat{a}^\dagger}e^{-\alpha^*\hat{a}}|0\rangle = e^{-|\alpha|^2/2}\sum_{n=0}^{\infty}\frac{(\alpha\hat{a}^\dagger)^n}{n!}|0\rangle \\ &= e^{-|\alpha|^2/2}\left(1+\alpha\hat{a}^\dagger+\frac{(\alpha\hat{a}^\dagger)^2}{2!}+..\right)|0\rangle \\ &= e^{-|\alpha|^2/2}\left(|0\rangle+\frac{\alpha}{1!}\sqrt{1}|1\rangle+\frac{\alpha^2}{2!}\sqrt{2!}|2\rangle+..\right)\ ,\end{aligned} \tag{24.123}$$

that is, the state $|\alpha\rangle$ is a superposition distributed according to the *Poisson distribution*,

$$\boxed{|\alpha\rangle = e^{-|\alpha|^2/2}\sum_{n=0}^{\infty}\frac{\alpha^n}{\sqrt{n!}}|n\rangle}\ . \tag{24.124}$$

Applying the step-down operator $\hat{a}$ onto the state $|\alpha\rangle$, we find,

$$\begin{aligned}\hat{a}|\alpha\rangle &= e^{-|\alpha|^2/2}\sum_{n=0}^{\infty}\frac{\alpha^n}{\sqrt{n!}}\hat{a}|n\rangle = e^{-|\alpha|^2/2}\sum_{n=0}^{\infty}\frac{\alpha^n}{\sqrt{n!}}\sqrt{n}|n-1\rangle \\ &= e^{-|\alpha|^2/2}\sum_{n=0}^{\infty}\frac{\alpha^n}{\sqrt{(n-1)!}}|n-1\rangle\ ,\end{aligned} \tag{24.125}$$

that is,

$$\boxed{\hat{a}|\alpha\rangle = \alpha|\alpha\rangle}\ . \tag{24.126}$$

We can also write,

$$\langle\alpha|\hat{a}^\dagger = (\hat{a}|\alpha\rangle)^\dagger = (\alpha|\alpha\rangle)^\dagger = \langle\alpha|\alpha^*\ . \tag{24.127}$$

The state $|\alpha\rangle$ is called *coherent state* or *Glauber state* [3]. We note that, in spite of its appearance, the equation (24.126) is not an eigenvalue equation, since $\hat{a}$ is not observable.

Using the formula (23.279), we verify immediately,

[3] We can also define a *Bargmann state* as the eigenstate corresponding to the step-up operator using the notation $\hat{a}^\dagger||\alpha\rangle = \alpha||\alpha\rangle$.

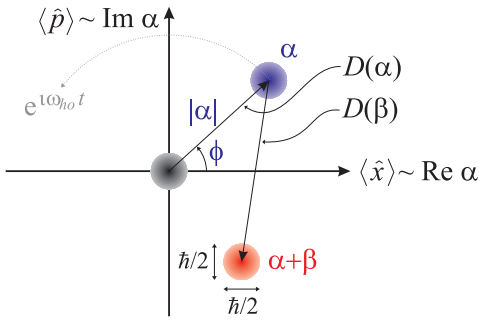

Figure 24.14: Illustration of the action of displacement operators $\mathcal{D}(\alpha)$ and $\mathcal{D}(\beta)$ on Glauber states in the phase space spanned by $\alpha = \mathfrak{Re}\,\alpha + \imath\,\mathfrak{Im}\,\alpha = |\alpha|e^{\imath\phi}$. The uncertainty of Glauber states Δx and Δp is represented by a finite distribution of the amplitude α in the phase space.

$$\mathcal{D}^\dagger(\alpha)\hat{a}\mathcal{D}(\alpha) = \hat{a} + \alpha \ . \tag{24.128}$$

Furthermore, the product of two displacement operators is, apart from a phase factor, another displacement operator satisfying,

$$\boxed{\mathcal{D}(\alpha)\mathcal{D}(\beta) = e^{(\alpha\beta^* - \alpha^*\beta)/2}\mathcal{D}(\alpha+\beta)} \ , \tag{24.129}$$

as will be verified in Exc. 24.6.6.1. When acting on an eigenket, the phase factor $e^{(\alpha\beta^* - \alpha^*\beta)/2}$ appears in each term of the resulting state, which makes it physically irrelevant.

24.6.1.2 Rotation operator

Another interesting operator is the *rotation operator* defined by,

$$\mathcal{R}(\varphi) \equiv e^{\imath\varphi\hat{a}^\dagger\hat{a}} \ . \tag{24.130}$$

Its properties are easily derived,

$$\mathcal{R}(\varphi)|n\rangle = e^{\imath\varphi n}|n\rangle \qquad \text{and} \qquad \mathcal{R}(\varphi)|\alpha\rangle = |e^{\imath\varphi}\alpha\rangle \ . \tag{24.131}$$

With the abbreviation $\hat{A} \equiv \imath\varphi\hat{a}^\dagger\hat{a}$, we can show,

$$\begin{aligned}\mathcal{R}^\dagger(\varphi)\hat{a}\mathcal{R}(\varphi) &= e^{\hat{A}}\hat{a}e^{-\hat{A}} = \hat{a} + [\hat{A},\hat{a}] + \tfrac{1}{2!}\Big[\hat{A},[\hat{A},\hat{a}]\Big] + \tfrac{1}{3!}\Big[\hat{A},\Big[\hat{A},[\hat{A},\hat{a}]\Big]\Big] + \ldots \\ &= \hat{a} + \imath\varphi\hat{a} + \tfrac{(\imath\varphi)^2}{2!}\hat{a} + \tfrac{(\imath\varphi)^3}{3!}\hat{a} + \ldots = e^{\imath\varphi}\hat{a} \ .\end{aligned} \tag{24.132}$$

In other words, the phase factor $e^{\imath\varphi}$ is the eigenvalue of the operator $\hat{a}\mathcal{R}(\varphi)$,

$$\mathcal{R}^\dagger(\varphi)\hat{a}\mathcal{R}(\varphi) = e^{\imath\varphi}\hat{a} \ . \tag{24.133}$$

Note also that,

$$\mathcal{R}(\varphi)\mathcal{D}(\alpha) \neq \mathcal{D}(\alpha)\mathcal{R}(\varphi) \ . \tag{24.134}$$

Do the Exc. 24.6.6.2.

Example 204 (*Operators acting on harmonic oscillators*): Other operators acting on single harmonic oscillator modes are the Kerr operator $\mathcal{K}$ studied in Exc. 37.3.5.15 and the squeezing operator $\mathcal{S}$ studied in Sec. 37.4.1. Tab. 24.1 lists the most common operators. Operators can also be designed to simultaneously manipulate different modes, thus establishing a coupling between them. Examples are the beam splitter $\mathcal{B}$ or the two-mode squeezer $\mathcal{S}_2$ studied in Sec. 37.5 or the Schrieffer-Wolff transform coupling a light mode and a collective atomic spin and studied in Exc. 46.2.4.12.

Table 24.1: List of basic transformation for harmonic oscillators.

unitary operation	action on field operators	action on field states
$\mathcal{D}(\beta) = e^{\beta\hat{a}^\dagger - \beta^*\hat{a}}$	$\mathcal{D}^\dagger\hat{a}\mathcal{D} = \hat{a} + \beta$	$\mathcal{D}\lvert n\rangle = \frac{1}{\sqrt{n!}}(\hat{a}^\dagger - \alpha^*)^n\lvert\alpha\rangle$ $\mathcal{D}\lvert\alpha\rangle = e^{(\alpha^*\beta - \alpha\beta^*)/2}\lvert\alpha+\beta\rangle$
$\mathcal{R}(\varphi) = e^{\imath\varphi\hat{a}^\dagger\hat{a}}$	$\mathcal{R}^\dagger\hat{a}\mathcal{R} = e^{\imath\varphi}\hat{a}$	$\mathcal{R}\lvert n\rangle = e^{\imath\varphi n}\lvert n\rangle$ $\mathcal{R}\lvert\alpha\rangle = e^{\imath\varphi\alpha}\lvert\alpha\rangle$
$\mathcal{S}(\xi) = e^{\xi^*\hat{a}^2/2 - \xi\hat{a}^{\dagger 2}/2}$	$\mathcal{S}^\dagger\hat{a}\mathcal{S} = \hat{a}\cosh r - \hat{a}^\dagger e^{\imath\varphi}\sinh r$	$\mathcal{S}\hat{a}\mathcal{S}^\dagger\lvert\alpha,\xi\rangle = (\alpha\cosh r + \alpha^* e^{\imath\varphi}\sinh r)\lvert\alpha,\xi\rangle$
$\mathcal{K}(\tau) = e^{\imath\tau\hat{a}^{\dagger 2}\hat{a}^2/2}$	$\mathcal{K}^\dagger\hat{a}\mathcal{K} = e^{\imath\tau\hat{n}}\hat{a}$	$\mathcal{K}\lvert n\rangle = e^{(\imath\tau/2)n(n-1)}\lvert n\rangle$ $\mathcal{K}\lvert\alpha\rangle = e^{\imath(\tau/2)\alpha^2\hat{a}^{\dagger 2}}\lvert\alpha\rangle$
$\mathcal{B}(\theta) = e^{\theta(\hat{a}^\dagger\hat{b} - \hat{a}\hat{b}^\dagger)}$	$\mathcal{B}^\dagger\binom{\hat{a}}{\hat{b}}\mathcal{B} = \binom{\hat{a}}{\hat{b}}\cos\theta + \binom{\hat{b}}{-\hat{a}}\sin\theta$	
$\mathcal{S}_2(\theta) = e^{\xi^*\hat{a}\hat{b}/2 - \hat{a}^\dagger\hat{b}^\dagger/2}$		

24.6.1.3 Uncertainty in Glauber states

Consider a HO prepared in a state $|\alpha\rangle$. The eigenvalues of the observables $\hat{x} \equiv \frac{a_{\text{ho}}}{\sqrt{2}}(\hat{a}^\dagger + \hat{a})$ and $\hat{p} \equiv \frac{\imath\hbar}{a_{\text{ho}}\sqrt{2}}(\hat{a}^\dagger - \hat{a})$ are,

$$\begin{aligned} \tfrac{\sqrt{2}}{a_{\text{ho}}}\langle\alpha|\hat{x}|\alpha\rangle &= \langle\alpha|\hat{a} + \hat{a}^\dagger|\alpha\rangle = \alpha + \alpha^* \\ \tfrac{\imath a_{\text{ho}}\sqrt{2}}{\hbar}\langle\alpha|\hat{p}|\alpha\rangle &= \langle\alpha|\hat{a} - \hat{a}^\dagger|\alpha\rangle = \alpha - \alpha^* . \end{aligned} \tag{24.135}$$

With this the eigenvalues of the quadratures become,

$$\begin{aligned} \tfrac{2}{a_{\text{ho}}^2}\langle\alpha|\hat{x}^2|\alpha\rangle &= \langle\alpha|(\hat{a} + \hat{a}^\dagger)^2|\alpha\rangle = \langle\alpha|\hat{a}\hat{a} + 1 + 2\hat{a}^\dagger\hat{a} + \hat{a}^\dagger\hat{a}^\dagger|\alpha\rangle \\ &= \alpha^2 + 1 + 2|\alpha|^2 + \alpha^{*2} = 1 + (\alpha + \alpha^*)^2 = 1 + \tfrac{2}{a_{\text{ho}}^2}\langle\alpha|\hat{x}|\alpha\rangle^2 \\ \tfrac{-a_{\text{ho}}^2 2}{\hbar^2}\langle\alpha|\hat{p}^2|\alpha\rangle &= \langle\alpha|(\hat{a} - \hat{a}^\dagger)^2|\alpha\rangle = \langle\alpha|\hat{a}\hat{a} - 1 - 2\hat{a}^\dagger\hat{a} + \hat{a}^\dagger\hat{a}^\dagger|\alpha\rangle \\ &= \alpha^2 - 1 - 2|\alpha|^2 + \alpha^{*2} = -1 + (\alpha - \alpha^*)^2 = -1 - \tfrac{2a_{\text{ho}}^2}{\hbar^2}\langle\alpha|\hat{p}|\alpha\rangle^2 . \end{aligned} \tag{24.136}$$

The uncertainties defined in (23.178) become,

$$\begin{aligned} \Delta x^2 &= \langle\alpha|\hat{x}^2|\alpha\rangle - \langle\alpha|\hat{x}|\alpha\rangle^2 = \tfrac{a_{\text{ho}}^2}{2} \\ \Delta p^2 &= \langle\alpha|\hat{p}^2|\alpha\rangle - \langle\alpha|\hat{p}|\alpha\rangle^2 = \tfrac{\hbar^2}{2a_{\text{ho}}^2} . \end{aligned} \tag{24.137}$$

And finally, we find the Heisenberg relation,

$$\Delta p\Delta x = \tfrac{\hbar}{2} . \tag{24.138}$$

Comparing with the uncertainty relation (24.97) derived for Fock states, we conclude that the uncertainty is always *smallest* for Glauber states. In this sense, the Glauber states are the ones which are closest to classical states characterized by the absence of uncertainty.

Example 205 (*Quantum fluctuations*): We have seen that the displacement operator (24.120) can be used to generate any coherent state $\hat{a}$ from the vacuum state, which we will now call $\delta\hat{a}$,

$$\delta\hat{a} \equiv \mathcal{D}(\alpha)\hat{a}\mathcal{D}(\alpha)^\dagger = \hat{a} - \langle\hat{a}\rangle \ . \tag{24.139}$$

The uncertainty of the vacuum state is, obviously, the same,

$$\Delta(\delta\hat{a})^2 = \langle\delta\hat{a}^2\rangle - \langle\delta\hat{a}\rangle^2 = \langle(\hat{a}-\alpha)^2\rangle - \langle\hat{a}-\alpha\rangle^2 = \langle\hat{a}^2\rangle - \alpha^2 = \Delta\hat{a}^2 \ . \tag{24.140}$$

The procedure of separating quantum noise from an operator can be applied to other quantities than harmonic oscillators.

24.6.1.4 Orthogonality and completeness of Glauber states

Glauber are not orthogonal, since,

$$|\langle\alpha|\beta\rangle|^2 = e^{-|\alpha-\beta|^2} \ . \tag{24.141}$$

We leave the demonstration for Exc. 24.6.6.3, but we note here already that for $|\alpha - \beta| \gg 0$ the states are approximately orthogonal. The reason for this is, that the respective population distributions through the Fock states, $|\langle n|\alpha\rangle|^2$ and $|\langle n|\beta\rangle|^2$, do not overlap and hence do not interfere. Some more useful relationships are studied in Exc. 24.6.6.4. In Exc. 24.6.6.5 we show that the coherent state basis is not only complete,

$$\tfrac{1}{\pi}\int |\alpha\rangle\langle\alpha| d^2\alpha = \mathbb{I} \ , \tag{24.142}$$

but it is overcomplete. The state $|\alpha\rangle + |-\alpha\rangle$ is sometimes called *Schrödinger cat state*. In Exc. 24.6.6.6 we will show why such states are very difficult to detect.

24.6.2 Kicking a harmonic oscillator

Let us now study the dynamics of a harmonic oscillator subject to a *kick* or a dislocation or both in the same time. For this we need to remember the Galilei boost introduced in Sec. 23.7.3 and the unitary transformations corresponding to a spatial displacement (23.281) and to a kick (23.292),

$$\mathcal{U}_{\rm tr}(b) = e^{(-\imath/\hbar)b\hat{p}} \qquad \text{and} \qquad \mathcal{U}_{\rm kc}(k) = e^{\imath k\hat{x}} \ , \tag{24.143}$$

where we restrict to one dimension. The crucial point is that for a harmonic oscillator we know how to expand the operators $\hat{x}$ and $\hat{p}$ into linear combinations of the field operators $\hat{a}$ and $\hat{a}^\dagger$, which allows us to apply the whole formalism developed in the last sections to these transformation operators.

24.6.2.1 Transitions between vibrational states via momentum kick and dislocation

With the formalism developed in the last sections the displacement operator (24.123) can be decomposed in a combination of a spatial displacement and a kick operator (24.143). We can see this by simply substituting the field operators $\hat{a}$ and $\hat{a}^\dagger$ by linear combinations of position and momentum operators using (24.94),

$$\begin{aligned}\alpha\hat{a}^\dagger - \alpha^*\hat{a} &= \frac{\alpha}{\sqrt{2}}\left(\frac{\hat{x}}{a_{\rm ho}} - \imath\frac{a_{\rm ho}\hat{p}}{\hbar}\right) - \frac{\alpha^*}{\sqrt{2}}\left(\frac{\hat{x}}{a_{\rm ho}} + \imath\frac{a_{\rm ho}\hat{p}}{\hbar}\right) \\ &= -\imath\frac{\sqrt{2}a_{\rm ho}\mathfrak{Re}\,\alpha}{\hbar}\,\hat{p} + \imath\frac{\sqrt{2}\mathfrak{Im}\,\alpha}{a_{\rm ho}}\,\hat{x}\ .\end{aligned} \tag{24.144}$$

Using Glauber's rule,

$$\mathcal{D}(\alpha) = e^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}} = e^{\imath\,\mathfrak{Re}\,\alpha\mathfrak{Im}\,\alpha}e^{(-\imath a_{\rm ho}\sqrt{2}/\hbar)\mathfrak{Re}\,\alpha\,\hat{p}}e^{(\imath\sqrt{2}/a_{\rm ho})\mathfrak{Im}\,\alpha\,\hat{x}}\ . \tag{24.145}$$

Hence, similarly to the Galilei boost in time and space, the displacement operator $D(\alpha)$ transforms the state of a harmonic oscillator, for example the ground state, $|\alpha\rangle = D(\alpha)|0\rangle$, by kicking its momentum by an amount,

$$\hbar k = \frac{\hbar\sqrt{2}}{a_{\rm ho}}\mathfrak{Im}\,\alpha\ , \tag{24.146}$$

and/or displacing its position suddenly by an amount,

$$b = \sqrt{2}a_{\rm ho}\mathfrak{Re}\,\alpha\ , \tag{24.147}$$

such that,

$$\alpha = \frac{b}{\sqrt{2}a_{\rm ho}} + \imath\frac{ka_{\rm ho}}{\sqrt{2}}\ . \tag{24.148}$$

The real and imaginary parts of α decide which contribution predominates, the kick or the dislocation,

$$\boxed{\mathcal{D}(\alpha) = e^{\imath\,\mathfrak{Re}\,\alpha\mathfrak{Im}\,\alpha}\,\mathcal{U}_{\rm tr}(\sqrt{2}a_{\rm ho}\mathfrak{Re}\,\alpha)\,\mathcal{U}_{\rm kc}(\tfrac{\hbar\sqrt{2}}{a_{\rm ho}}\mathfrak{Im}\,\alpha)}\ . \tag{24.149}$$

For example, if α is imaginary the operation describes a pure momentum kick by an amount $\hbar k$, which puts the harmonic oscillator into a coherent state with the mean occupation number,

$$n = |\alpha|^2 = |\mathfrak{Im}\,\alpha|^2 = \tfrac{1}{2}k^2a_{\rm ho}^2\ , \tag{24.150}$$

On the other hand, if α is real the operation describes a pure dislocation by an amount b, which puts the harmonic oscillator into a coherent state with the mean occupation number,

$$n = |\alpha|^2 = |\mathfrak{Re}\,\alpha|^2 = \frac{b^2}{2a_{\rm ho}^2}\ . \tag{24.151}$$

Now, let us focus on the kick operator and study how it acts on Fock states,

$$\begin{aligned}\langle n|e^{\imath k\hat{x}}|0\rangle = \langle n|\alpha\rangle &= \langle n|e^{-|\alpha|^2/2}\sum_{m=0}^{\infty}\frac{\alpha^m}{\sqrt{m!}}|m\rangle \\ &= e^{-|\alpha|^2/2}\frac{\alpha^n}{\sqrt{n!}} = e^{-|ka_{\rm ho}|^2/4}\frac{(\imath k a_{\rm ho})^n}{\sqrt{2^n n!}} \ ,\end{aligned} \tag{24.152}$$

using (24.148). This formula tells us that for small α, transitions may only occur to the vibrational states $|0\rangle$ and $|1\rangle$, since,

$$\langle n|e^{\imath k\hat{x}}|0\rangle \stackrel{ka_{\rm ho}\to 0}{\longrightarrow} \frac{\alpha^n}{\sqrt{n!}} \simeq \delta_{n,0} + \alpha\delta_{n,1} \ . \tag{24.153}$$

On the other hand for very large α, the exponential in (24.152) pulls the transition rate to a particular vibrational state $|n\rangle$ to zero, but this is simply due to the fact that the population is redistributed over many states, since,

$$\sum_n |\langle n|e^{\imath k\hat{x}}|0\rangle|^2 = e^{-(ka_{\rm ho})^2/2}\sum_{n=0}^{\infty}\frac{|\alpha|^{2n}}{n!} = e^{-(ka_{\rm ho})^2/2}e^{|\alpha|^2} = 1 \ . \tag{24.154}$$

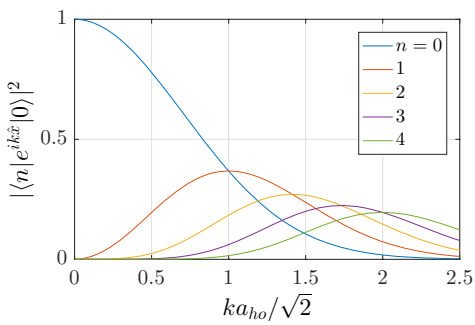

Figure 24.15: (code) Transition matrix element $|\langle n|e^{\imath k\hat{x}}|0\rangle|^2$ as a function of $ka_{\rm ho}$. The curves are Poisson distributions of photon numbers in coherent states.

For small momentum kicks we may approximate the transition matrix elements by,

$$\begin{aligned}\langle m|e^{\imath k\hat{x}}|n\rangle &\simeq \langle m|1 + \imath k\tfrac{a_{\rm ho}}{\sqrt{2}}(\hat{a}+\hat{a}^\dagger)|n\rangle \\ &= \delta_{m,n} + \tfrac{\imath k a_{\rm ho}}{\sqrt{2}}(\sqrt{n}\delta_{m,n-1} + \sqrt{n+1}\delta_{m,n+1}) \ ,\end{aligned} \tag{24.155}$$

such that,

$$\sum_{m\neq n}|\langle m|e^{\imath k\hat{x}}|n\rangle|^2 \simeq k^2 a_{\rm ho}^2(n+\tfrac{1}{2}) \ . \tag{24.156}$$

Formula (24.156) tell us that the probability for a transition between vibrational states depends on the parameter $ka_{\rm ho}$, which we will discuss in the next section. For small $ka_{\rm ho}$ it gets increasingly more difficult for the system to leave the original

vibrational state $|n\rangle$ and to form a coherent state. After a momentum kick, the population is coherently distributed over several vibrational states in a way to fulfill momentum and energy conservation. Let us consider, for simplicity, an initial state $|0\rangle$. If the kick is weak or the trap strong (i.e. if $|\alpha| < 1$), the atom will stay in $|0\rangle$ with a high probability amplitude and go to $|1\rangle$ only with a small probability amplitude. We will derive in Exc. 24.6.6.7 the general expression for the transition matrix element for arbitrary values of α [4],

$$\boxed{\langle m|e^{\imath k\hat{x}}|n\rangle = e^{|\alpha|^2/2}\sum_{k=0}^{n}\sqrt{\binom{n}{k}\binom{m}{k}}\langle n-k|\alpha\rangle\langle m-k|\alpha\rangle} \ . \tag{24.157}$$

The formula satisfies,

$$\sum_m |\langle m|e^{\imath k\hat{x}}|n\rangle|^2 = \sum_m \langle n|e^{\imath kx}|m\rangle\langle m|e^{-\imath kx}|n\rangle = \langle n|e^{\imath kx}e^{-\imath kx}|n\rangle = 1 \ . \tag{24.158}$$

Kicking a harmonic oscillator initially in state $|0\rangle$ we obtain for the expectation value of position and momentum,

$$\boxed{\begin{aligned} \langle\alpha|\hat{p}|\alpha\rangle &= \langle 0|D(\alpha)^\dagger\hat{p}D(\alpha)|0\rangle = \langle 0|e^{\imath k\hat{x}}\hat{p}e^{-\imath k\hat{x}}|0\rangle = \langle 0|\hat{p}|0\rangle + \hbar k \\ \langle\alpha|\hat{x}|\alpha\rangle &= \langle 0|\hat{x}|0\rangle \end{aligned}} \ .$$

24.6.2.2 Lamb-Dicke regime

We already introduced $|\alpha|$ as the amplitude (24.151) of the coherent vibrational state created by kicking a harmonic oscillator. Defined as,

$$\boxed{\eta \equiv |\alpha| = \tfrac{1}{\sqrt{2}}ka_{\text{ho}}} \qquad \text{with} \qquad a_{\text{ho}} \equiv \sqrt{\frac{\hbar}{m\omega_{\text{ho}}}} \ . \tag{24.159}$$

the so-called *Lamb-Dicke parameter* measures the *degree of confinement* of a particle in a harmonic trap with respect to the momentum kick. We say that we are in the *Lamb-Dicke regime*, when $\eta < 1$, that is when the particle is localized to a volume smaller than the wavelength, $2\pi x_0 \ll \lambda = 2\pi/k$, corresponding to the momentum change.

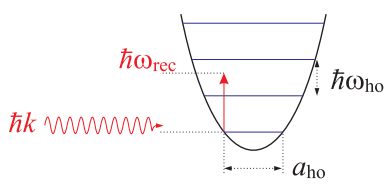

Figure 24.16: Illustration of the Lamb-Dicke parameter.

[4] See also 37.3.3.

We can also rewrite the Lamb-Dicke parameter in terms of the trap's secular frequency, $\omega_{\rm ho}$, and the recoil-shift,

$$\boxed{\eta = \sqrt{\frac{\omega_{\rm rec}}{\omega_{\rm ho}}}} \qquad \text{with} \qquad \omega_{\rm rec} \equiv \frac{\hbar k^2}{2m} \ , \tag{24.160}$$

where we understand the recoil-energy $\hbar\omega_{\rm rec}$ as the kinetic energy gained through the recoil acceleration. In this form the Lamb-Dicke parameter tells us that, in the Lamb-Dicke regime, the energy of the momentum kick is not sufficient to efficiently excite vibrational states,

$$(2n+1)\hbar k^2/m \ll \omega_{\rm ho} \ . \tag{24.161}$$

That is, cold particles in low vibrational states n can not accommodate the recoil shift within the vibrational spectrum of the trap. Consequently, the recoil cannot be transferred to the particle itself, but must be absorbed by the entire trap. This is the case of the *strong binding regime* in ion traps, which is analogous to the *Mößbauer effect* discussed later in Sec. 43.3.3.

Finally, the Lamb-Dicke parameter can be rewritten in terms of the *inverse Doppler modulation index*,

$$\boxed{\eta = \frac{k v_{\rm max}}{2\omega_{\rm ho}}} \qquad \text{with} \qquad \frac{m}{2} v_{\rm max}^2 = \hbar\omega_{\rm ho} \ . \tag{24.162}$$

Accelerated by the momentum kick, the atom will execute harmonic oscillations with frequency $\omega_{\rm ho}$ and with the maximum velocity-excursions $v_{\rm max}$. Hence, any quantity depending on the atomic velocity, e.g. the Doppler-shift of light scattered from the atom, will be modulated. We will see in Sec. 43.3.3 that the modulation generates a spectrum of frequency sidebands which, in case of small $\eta < 1$, are restricted to first-order sidebands located at $\pm\omega_{\rm ho}$ of the light frequency. Do the Exc. 24.6.6.8.

Example 206 (*Absorption of recoil by a molecular dimer*): To be able to discuss the validity of energy and momentum conservation in a kicked system, let us consider a molecule made of two atoms with masses m_1 and m_2 bound by a force obeying Hooke's law. Then we kick atom 1 via the momentum shift operator $e^{\imath k\hat{x}_1}$ (e.g. during a photon absorption process with the associated recoil) and analyze the motional dynamics of the whole system [5]. (We restrict ourselves to one dimension.)

The first step is to write down the Hamiltonian,

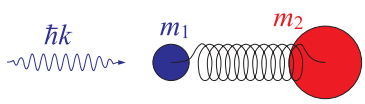

Figure 24.17: Illustration of a heteronuclear dimer kicked by photonic recoil.

$$\hat{H} = -\frac{\hbar^2}{2m_1}\frac{d^2}{dx_1^2} - \frac{\hbar^2}{2m_2}\frac{d^2}{dx_2^2} + \frac{\mu}{2}\omega_{\rm ho}^2(x_1-x_2)^2 \ ,$$

[5] The selective kicking is realistic if we image both atoms being of different species with different transitions responding differently to incident radiation.

We transform in the center-of-mass system via,

$$M \equiv m_1 + m_2 \quad \text{and} \quad \frac{1}{\mu} \equiv \frac{1}{m_1} + \frac{1}{m_2}$$
$$R = \frac{m_1 x_1 + m_2 x_2}{M} \quad \text{and} \quad r = x_1 - x_2 \ .$$

Applying the separation ansatz $\psi(x_1, x_2) = \Theta(R)\phi(r)$ to the Schrödinger equation,

$$\left[-\frac{\hbar^2}{2m_1}\frac{d^2}{dx_1^2} - \frac{\hbar^2}{2m_2}\frac{d^2}{dx_2^2} + \frac{\mu}{2}\omega_{\text{ho}}^2(\hat{x}_1 - \hat{x}_2)^2 \right] \psi(x_1, x_2) = E_{\text{tot}}\psi(x_1, x_2) \ ,$$

we calculate for $i = 1, 2$,

$$\frac{d}{dx_i} = \frac{dR}{dx_i}\frac{d}{dR} + \frac{dr}{dx_i}\frac{d}{dr} = \frac{m_i}{M}\frac{d}{dR} \pm \frac{d}{dr}$$
$$\frac{d^2}{dx_i^2} = \frac{m_i^2}{M^2}\frac{d^2}{dR^2} \pm 2\frac{m_i}{M}\frac{d}{dR}\frac{d}{dr} + \frac{d^2}{dr^2}$$
$$-\frac{\hbar^2}{2m_1}\frac{d^2}{dx_1^2} - \frac{\hbar^2}{2m_2}\frac{d^2}{dx_2^2} = -\frac{\hbar^2}{2M}\frac{d^2}{dR^2} - \frac{\hbar^2}{2\mu}\frac{d^2}{dr^2} \ .$$

Hence, we get,

$$-\frac{\hbar^2}{2M}\frac{d^2}{dR^2}\Theta(R) = (E_{\text{tot}} - E)\Theta(R) \quad , \quad \left[-\frac{\hbar^2}{2\mu}\frac{d^2}{dr^2} + \frac{\mu}{2}\omega_{\text{ho}}^2 \hat{r}^2 \right] \phi(r) = E\phi(r) \ ,$$

with the vibrational energy E and the energy of the center-of-mass motion $E_{\text{tot}} - E$.

Now, we analyze the kick operator $e^{\imath k \hat{x}_1}$ with $\hat{x}_1 = \hat{R} - \frac{m_2}{M}\hat{r}$. We find that, because of $[\hat{R}, \hat{r}] = 0$,

$$e^{\imath k \hat{x}_1} = e^{\imath k \hat{R}} e^{-\imath k \frac{m_2}{M}\hat{r}} \ .$$

This means that the kick operator simultaneously acts on both: the center-of-mass receives a recoil accelerating it by an amount $p_{\text{cm}} = \hbar k$, and the vibrational relative motion receives a kick of an amount $p_{\text{rel}} = \hbar k m_2/M$ following the dynamics described in Sec. 24.6.2.

Obviously, the total system conserves momentum, which is imparted to the center-of-mass motion. Whether the kick also excites the relative motion depends on mass ratio. In the limit $m_1 \ll m_2$ we find $p_{\text{rel}} = \hbar k$, while in the limit $m_1 \gg m_2$ we get $p_{\text{rel}} \to 0$. In terms of the Lamb-Dicke parameter, we find,

$$\eta = \frac{p_{\text{rel}} a_{\text{ho}}}{\hbar\sqrt{2}} = \frac{k m_2}{M\sqrt{2}}\sqrt{\frac{\hbar}{\mu\omega_{\text{ho}}}} = \frac{k m_2}{m_1 + m_2}\sqrt{\frac{\hbar}{2\omega_{\text{ho}}}\left(\frac{1}{m_1} + \frac{1}{m_2}\right)} \ .$$

Hence, in the limit $m_1 \ll m_2$ we expect a much larger Lamb-Dicke parameter than for $m_1 \gg m_2$. In particular, considering the limit $m_2 \to \infty$, we recover the formula (24.160) holding for an atom confined in a harmonic potential,

$$\eta \overset{m_2 \to \infty}{\longrightarrow} \sqrt{\frac{\hbar k^2}{\omega_{\text{ho}} 2 m_1}} = \sqrt{\frac{\omega_{\text{rec}}}{\omega_{\text{ho}}}} \ .$$

We find that the energy transferred to the relative motion quadratically decreases with the Lamb-Dicke parameter for $\eta < 1$ and quadratically increases for $\eta > 1$,

$$E_{\text{rel}} = \frac{p_{\text{rel}}^2}{2\mu} = \frac{1}{2\mu}\frac{2\hbar^2\eta^2}{a_{\text{ho}}^2} = \hbar\omega_{\text{ho}}\eta^2 \ .$$

24.6.3 Shaking a harmonic oscillator

As we mentioned below the formulae (23.293), the transformation in momentum space is not a realistic concept for a *kick*. In practice, a kick will always be the results of a collision, which is understood here as a scattering of a free (massive or massless) particle at our harmonically trapped particle. And the scattering process will take a finite amount of time, e.g. the duration of a radiative π-pulse required to excite an atomic transition.

More realistic is to expose the harmonic oscillator to periodic forcing,

$$\boxed{\hat{H}(t) = \hat{H}^{(0)} + \hat{H}^{(1)} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{m}{2}\omega_{\rm ho}^2\hat{x}^2 + \frac{\hbar\Omega}{2}(\hat{a}e^{\imath\nu t} + \hat{a}^\dagger e^{-\imath\nu t})} \ . \tag{24.163}$$

To study its time evolution we calculate,

$$|\psi(t)\rangle = e^{-(\imath/\hbar)\hat{H}t}\sum_n a_n|n\rangle \overset{a_n=\delta_{n,0}}{\longrightarrow} e^{-(\imath/\hbar)\hat{H}t}|0\rangle \ , \tag{24.164}$$

when the oscillator is initially in the state $|0\rangle$. We rewrite the time evolution propagator as,

$$e^{-(\imath/\hbar)\hat{H}t} = e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)-(\imath\Omega t/2)(\hat{a}e^{\imath\nu t}+\hat{a}^\dagger e^{-\imath\nu t})} \ . \tag{24.165}$$

To simplify the propagator, we first have a closer look at the terms $\hat{a}e^{\imath\omega_{\rm ho}t}$ and $\hat{a}^\dagger e^{-\imath\omega_{\rm ho}t}$, which we evaluate through their action on the complete system of unperturbed eigenfunctions,

$$\begin{aligned} e^{-(\imath/\hbar)\hat{H}^{(0)}t}\hat{a}e^{(\imath/\hbar)\hat{H}^{(0)}t}|n\rangle &= e^{-(\imath/\hbar)\hat{H}^{(0)}t}\hat{a}e^{(\imath/\hbar)E_n^{(0)}t}|n\rangle \\ &= e^{-(\imath/\hbar)E_{n-1}^{(0)}t}e^{(\imath/\hbar)E_n^{(0)}t}\hat{a}|n\rangle = e^{\imath\omega_{\rm ho}t}\hat{a}|n\rangle \ . \end{aligned} \tag{24.166}$$

Hence, defining the detuning $\Delta \equiv \nu - \omega_{\rm ho}$,

$$\begin{array}{rcccl} \hat{a}e^{\imath\nu t} &=& e^{\imath\omega_{\rm ho}t}\hat{a}e^{\imath\Delta t} &=& e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)}\hat{a}e^{\imath\Delta t}e^{\imath\omega_{\rm ho}t(\hat{n}+1/2)} \\ \hat{a}^\dagger e^{-\imath\nu t} &=& e^{-\imath\omega_{\rm ho}t}\hat{a}^\dagger e^{-\imath\Delta t} &=& e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)}\hat{a}^\dagger e^{-\imath\Delta t}e^{\imath\omega_{\rm ho}t(\hat{n}+1/2)} \\ \hat{n} &=& && e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)}\hat{n}e^{\imath\omega_{\rm ho}t(\hat{n}+1/2)} \end{array} \ . \tag{24.167}$$

Substituting these expression into the propagator (24.165) we get,

$$e^{-(\imath/\hbar)\hat{H}t} = e^{e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)}\left[-\imath\omega_{\rm ho}t(\hat{n}+1/2)-(\imath\Omega t/2)\hat{a}e^{\imath\Delta t}-(\imath\Omega t/2)\hat{a}^\dagger e^{-\imath\Delta t}\right]e^{\imath\omega_{\rm ho}t(\hat{n}+1/2)}} \ . \tag{24.168}$$

Now, making use of the relationship,

$$e^{e^{-\hat{A}}\hat{B}e^{\hat{A}}} = \sum_n \frac{(e^{-\hat{A}}\hat{B}e^{\hat{A}})^n}{n!} = \sum_n \frac{e^{-\hat{A}}\hat{B}^n e^{\hat{A}}}{n!} = e^{-\hat{A}}e^{\hat{B}}e^{\hat{A}} \ , \tag{24.169}$$

which is easy to show by expansion of $e^{\hat{B}}$, we find [6],

$$e^{-(\imath/\hbar)\hat{H}t} = e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)}e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)-(\imath\Omega t/2)(\hat{a}e^{\imath\Delta t}+\hat{a}^\dagger e^{-\imath\Delta t})}e^{\imath\omega_{\rm ho}t(\hat{n}+1/2)} \ . \tag{24.170}$$

[6] Note, that this formula can not be simplified using Glauber's formula, because $[\hat{n},[\hat{n},\hat{a}]] \neq 0$. Note also, that the unitary transformation corresponds to a transformation into Dirac's interaction picture, which will be studied in the context of quantized radiation fields in Sec. 40.2.

In particular, for $\Delta = 0$,

$$\boxed{\langle n|e^{-(\imath/\hbar)\hat{H}t}|0\rangle = e^{-n\imath\omega_{\rm ho}t}\langle n|e^{-\imath\omega_{\rm ho}t(\hat{n}+1/2)-(\imath\Omega t/2)(\hat{a}+\hat{a}^\dagger)}|0\rangle} \ . \tag{24.171}$$

The dynamics is illustrated in Fig. 24.18. Again, we notice that the state generated

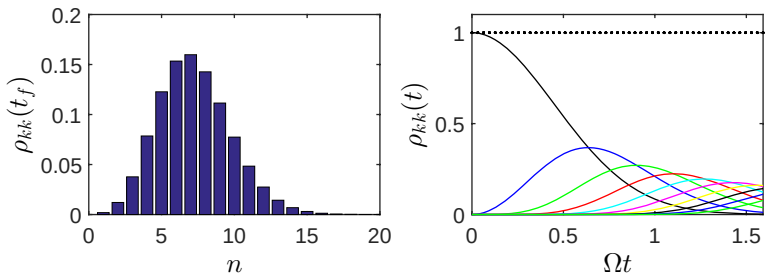

Figure 24.18: (code) (a) Populations of the vibrational states after a given interaction time. (b) Time evolution of the lowest populations.

is a coherent state. In Exc. 24.6.6.9 we will study how to generalize the problem to non-resonant excitation, $\Delta \neq 0$.

24.6.4 Forcing a harmonic oscillator

In Secs. 24.6.2 and 24.6.3 we studied two ways of exciting a harmonic oscillator. We found that the energy and momentum imparted to a harmonic oscillator upon excitation are determined by conservation laws. On the other hand, the excitation probability depends on the shape of the perturbation: While an abrupt kick *always* results in an excitation, a monochromatic excitation needs to satisfy a *resonance condition*. We will study this in more detail in Sec.27.4.2.

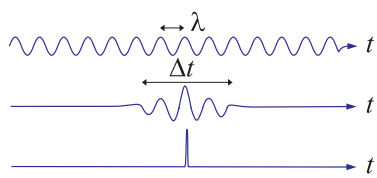

Figure 24.19: Illustration of possible shapes of an excitation field.

The transfer of momentum is the result of a (generally) constant force applied for a certain amount of time,

$$\hbar k = \int_{-\infty}^{\infty} mg\ \Theta_{[0,\Delta t]}(t)\ dt \ , \tag{24.172}$$

where g denotes the acceleration. That is, we expect that a harmonic oscillator,

$$\boxed{\hat{H}(t) = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{m}{2}\omega_{\rm ho}^2\hat{x}^2 - mg\hat{x}\ \Theta_{[0,\Delta t]}(t)} \ , \tag{24.173}$$

forced for a period of time Δt should have suffered a kick.

24.6.4.1 Displaced harmonic oscillator

To begin with, we will derive the dynamics of a harmonic oscillator suddenly exposed to a homogeneous constant force $F(t) = mg\ \Theta_{[0,\infty]}(t)$. It is easy to see, that the above perturbed Hamiltonian can be cast into the form,

$$\hat{H}(t) = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{m}{2}\omega_{\rm ho}^2\left(\hat{x} - \frac{g}{\omega_{\rm ho}^2}\right)^2 - \frac{mg^2}{2\omega_{\rm ho}^2}\ , \tag{24.174}$$

where the last constant term plays no role in the dynamics. That is, as we know from classical physics, the essential impact of a homogeneous force (e.g. gravity) on a harmonic oscillator consists in displacing its equilibrium position. Knowing the eigenvalues and -states of the unperturbed Hamiltonian, the obvious solution of the perturbed eigenvalue problem is,

$$\begin{aligned} \hat{H}|\psi_n^{(1)}\rangle &= E_n^{(1)}|\psi_n^{(1)}\rangle \\ \text{with}\quad E_n^{(1)} &= E_n - \frac{mg^2}{2\omega_{\rm ho}^2} \\ \text{and}\quad \langle x|\psi_n^{(1)}\rangle &= \psi_n^{(1)}(x) = \psi_n(x - \tfrac{g}{\omega_{\rm ho}^2}) = \langle x - \tfrac{g}{\omega_{\rm ho}^2}|n\rangle\ . \end{aligned} \tag{24.175}$$

Using the properties (23.281) and (23.283) we may write,

$$\langle x - \tfrac{g}{\omega_{\rm ho}^2}|n\rangle = \langle x|U_{\rm tr}^\dagger(-\tfrac{g}{\omega_{\rm ho}^2})|n\rangle = \langle x|e^{-(\imath/\hbar)(g/\omega_{\rm ho}^2)\hat{p}}|n\rangle\ , \tag{24.176}$$

and using the representation (24.95) of the momentum operator by the field operators and introducing the abbreviation $\beta \equiv \frac{g}{\omega_{\rm ho}^2 a_{\rm ho}\sqrt{2}}$ we can rewrite,

$$\langle x - \tfrac{g}{\omega_{\rm ho}^2}|n\rangle = e^{-\beta(\hat{a}-\hat{a}^\dagger)}\langle x|n\rangle\ . \tag{24.177}$$

Note, that the transition from (24.173) to (24.175) can also be obtained by a redefinition of the field operators according to,

$$\hat{b} \equiv \hat{a} - \tfrac{mga_{\rm ho}}{\hbar\omega_{\rm ho}\sqrt{2}}\ , \tag{24.178}$$

since,

$$\hat{H} = \hbar\omega_{\rm ho}(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}) - \tfrac{mga_{\rm ho}}{\sqrt{2}}(\hat{a} + \hat{a}^\dagger) = \hbar\omega_{\rm ho}(\hat{b}^\dagger\hat{b} + \tfrac{1}{2}) - \tfrac{mg^2}{2\omega_{\rm ho}^2} \tag{24.179}$$

and $\hat{a} - \hat{a}^\dagger = \hat{b} - \hat{b}^\dagger$.

The temporal evolution is given by the time-dependent Schrödinger equation. Since the jump is finite, the solution must be well behaved at time $t = 0$,

$$\begin{aligned} \langle x|\psi_n^{(1)}(t)\rangle &= \langle x|e^{-(\imath/\hbar)\hat{H}t}|\psi_n^{(1)}(0)\rangle \\ &= \langle x|e^{-(\imath/\hbar)\hat{H}t}e^{-\beta(\hat{a}-\hat{a}^\dagger)}|n\rangle \\ &= \langle x|e^{-(\imath/\hbar)\hat{H}t}e^{-\beta(\hat{a}-\hat{a}^\dagger)}e^{(\imath/\hbar)\hat{H}t}e^{-(\imath/\hbar)\hat{H}t}|n\rangle\ . \end{aligned} \tag{24.180}$$

To simplify the first three exponential functions, we use the relationships (24.169) and (24.166) [7],

$$e^{-(\imath/\hbar)\hat{H}t}e^{-\beta(\hat{a}-\hat{a}^\dagger)}e^{(\imath/\hbar)\hat{H}t} = e^{-\beta e^{-(\imath/\hbar)\hat{H}t}(\hat{a}-\hat{a}^\dagger)e^{(\imath/\hbar)\hat{H}t}} = e^{-\beta\left(e^{\imath\omega_{\rm ho}t}\hat{a}-e^{-\imath\omega_{\rm ho}t}\hat{a}^\dagger\right)} , \tag{24.181}$$

and write the temporal solution,

$$\begin{aligned}\psi_n^{(1)}(x,t) &= e^{-\beta(\hat{a}e^{\imath\omega_{\rm ho}t}-\hat{a}^\dagger e^{-\imath\omega_{\rm ho}t})}e^{-(\imath/\hbar)\hat{H}t}\psi_n(x) \\ &= e^{-\beta(\hat{a}-\hat{a}^\dagger)\cos\omega_{\rm ho}t-\imath\beta(\hat{a}+\hat{a}^\dagger)\sin\omega_{\rm ho}t}e^{-(\imath/\hbar)E_n^{(0)}t}\psi_n(x) \ .\end{aligned} \tag{24.182}$$

Using Glauber's formula (23.312) we find,

$$\begin{aligned}&\psi_n^{(1)}(x,t) = e^{-\imath\beta(\hat{a}+\hat{a}^\dagger)\sin\omega_{\rm ho}t}e^{-\beta(\hat{a}-\hat{a}^\dagger)\cos\omega_{\rm ho}t}e^{\imath\beta^2\sin\omega_{\rm ho}t\cos\omega_{\rm ho}t}e^{-(\imath/\hbar)E_n^{(0)}t}\psi_n(x) \\ &= e^{-\imath(mg/\hbar\omega_{\rm ho})\hat{x}\sin\omega_{\rm ho}t}e^{-(\imath/\hbar)(g/\omega_{\rm ho}^2)\hat{p}\cos\omega_{\rm ho}t}e^{\imath\beta^2\sin\omega_{\rm ho}t\cos\omega_{\rm ho}t}e^{-(\imath/\hbar)E_n^{(0)}t}\psi_n(x) \\ &= e^{-\imath\beta(\hat{a}+\hat{a}^\dagger)\sin\omega_{\rm ho}t}e^{\imath\beta^2\sin\omega_{\rm ho}t\cos\omega_{\rm ho}t}e^{-(\imath/\hbar)E_n^{(0)}t}\psi_n(x-b\cos\omega_{\rm ho}t) \ .\end{aligned} \tag{24.183}$$

Finally,

$$\boxed{|\psi_n^{(1)}(x,t)|^2 = |\psi_n(x-\bar{x}(t))|^2 \qquad \text{where} \qquad \bar{x}(t) \equiv \tfrac{g}{\omega_{\rm ho}^2}\cos\omega_{\rm ho}t} \ . \tag{24.184}$$

This means that the spatial distribution of $\psi_n^{(1)}$ around $\bar{x}(t)$ is the same as of ψ_n around $\bar{x}=0$. The entire distribution oscillates without deformation. The momentum distribution follows from the Fourier transform,

$$\begin{aligned}\phi_n^{(1)}(p,t) &= \frac{1}{\sqrt{2\pi\hbar}}\int dx e^{-(\imath/\hbar)px}\psi_n^{(1)}(x,t) \\ &= \frac{1}{\sqrt{2\pi\hbar}}\int du\ e^{-(\imath/\hbar)pu}e^{-(\imath/\hbar)um\omega_{\rm ho}\frac{g}{\omega_{\rm ho}^2}\sin\omega_{\rm ho}t}e^{\imath\gamma(p,t)}\psi_n \\ &= e^{\imath\gamma(p,t)}\phi_n(p+m\omega_{\rm ho}\tfrac{g}{\omega_{\rm ho}^2}\sin\omega_{\rm ho}t) \ ,\end{aligned} \tag{24.185}$$

where the abbreviation $\gamma=\gamma^*$ contains all unitary transformations of (24.183), that do not depend on x. We obtain,

$$\boxed{|\phi_n^{(1)}(p,t)|^2 = |\phi_n(p-\bar{p}(t))|^2 \qquad \text{where} \qquad \bar{p}(t) \equiv -m\tfrac{g}{\omega_{\rm ho}}\sin\omega_{\rm ho}t} \ . \tag{24.186}$$

24.6.4.2 Discussion of the kick dynamics

For the acceleration of the harmonic oscillator to resemble a 'kick', the time during which the perturbation is active must be much smaller than a trap oscillation period, $\omega_{\rm ho}\Delta t \ll 1$. In this case, we may expand the oscillatory motion (24.184) and (24.186),

$$\bar{x} = \frac{g}{\omega_{\rm ho}^2} \qquad \text{and} \qquad \bar{p} = -mg\Delta t \equiv -\hbar k \ , \tag{24.187}$$

[7] We can use (24.166), because the shifted harmonic oscillator has, except from a constant offset the same eigenenergies.

which is consistent with the initial request (24.172). It is also clear that, for a given force mg, the maximum momentum that can be transmitted is limited, $\hbar k < mg/\omega_{\rm ho}$.

As long as the kick-approximation $\omega_{\rm ho}\Delta t \ll 1$ holds, we may simply describe the dynamics during the application of the force, via a time-dependent kick operator,

$$e^{\imath k(t)\hat{x}} = \mathcal{D}(\alpha(t)) \ , \tag{24.188}$$

where the acquired momentum increases linearly with time according to $k(t) = k\frac{\max(\min(t,\Delta t),0)}{\Delta t}$. I.e. the populations of the vibrational states evolve like (24.152) into a coherent state with increasing amplitude $|\alpha(t)|^2$. At the end of the kick, on a much slower time-scale $\omega_{\rm ho}^{-1}$, the wavefunctions will start to oscillate all in phase, according to (24.184).

The time-dependence of the states $|\alpha(t)\rangle$, as shown in Exc. 24.6.6.10 is given by,

$$\begin{aligned}|\alpha(t)\rangle &= e^{-(\imath/\hbar)\hat{H}t}|\alpha(0)\rangle = \sum_n e^{-(\imath/\hbar)E_n t}e^{-|\alpha(0)|^2/2}\frac{\alpha(0)^n}{\sqrt{n!}}|n\rangle \\ &= e^{-\imath\omega_{\rm ho}t/2}\sum_n e^{-|\alpha(0)|^2/2}\frac{(\alpha(0)e^{-\imath\omega_{\rm ho}t})^n}{\sqrt{n!}}|n\rangle = e^{-\imath\omega_{\rm ho}t/2}|\alpha(0)e^{-\imath\omega_{\rm ho}t}\rangle \ .\end{aligned} \tag{24.189}$$

With (24.166) we find,

$$\begin{aligned}\hat{x}(t) &= e^{-(\imath/\hbar)\hat{H}t}\hat{x}(0)e^{(\imath/\hbar)\hat{H}t} = \hat{x}(0)\cos\omega_{\rm ho}t + \tfrac{\hat{p}(0)}{m\omega_{\rm ho}}\sin\omega_{\rm ho}t \qquad \text{and} \\ \hat{p}(t) &= e^{-(\imath/\hbar)\hat{H}t}\hat{p}(0)e^{(\imath/\hbar)\hat{H}t} = m\omega_{\rm ho}\hat{x}(0)\sin\omega_{\rm ho}t + \hat{p}(0)\cos\omega_{\rm ho}t \ ,\end{aligned} \tag{24.190}$$

or with (24.189),

$$\boxed{\begin{aligned}\langle\alpha(t)|\hat{x}|\alpha(t)\rangle &= \langle\alpha(0)|\hat{x}|\alpha(0)\rangle\cos\omega_{\rm ho}t + \tfrac{1}{m\omega_{\rm ho}}\langle\alpha(0)|\hat{p}|\alpha(0)\rangle\sin\omega_{\rm ho}t \\ \langle\alpha(t)|\hat{p}|\alpha(t)\rangle &= m\omega_{\rm ho}\langle\alpha(0)|\hat{x}|\alpha(0)\rangle\sin\omega_{\rm ho}t + \langle\alpha(0)|\hat{p}|\alpha(0)\rangle\cos\omega_{\rm ho}t\end{aligned}} \ . \tag{24.191}$$

We note, that the position and momentum wavefunctions $\langle x|n\rangle$ and $\langle p|n\rangle$ of the excited vibrational states are complicated Hermite polynomials, but we don't have to write them down explicitly to get to the last result. We will derive some further properties in Exc. 24.6.6.11.

24.6.4.3 Simulation of the displacement of a harmonic oscillator

The Hamiltonian of a harmonic oscillator subject to an external force can be cast into the form,

$$\begin{aligned}\hat{H}(t) &= -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{m}{2}\omega_{\rm ho}^2\hat{x}^2 + mg\hat{x} = \hbar\omega_{\rm ho}(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}) + mg\tfrac{a_{\rm ho}}{\sqrt{2}}(\hat{a} + \hat{a}^\dagger) \\ &= \begin{pmatrix} \ddots & \ddots & & 0 \\ \ddots & (n+\frac{1}{2})\hbar\omega_{\rm ho} & mg\frac{a_{\rm ho}}{\sqrt{2}}\sqrt{n+1} & \\ & mg\frac{a_{\rm ho}}{\sqrt{2}}\sqrt{n+1} & (n+\frac{3}{2})\hbar\omega_{\rm ho} & \ddots \\ 0 & & \ddots & \ddots \end{pmatrix} \ .\end{aligned} \tag{24.192}$$

The temporal evolution of the state is given by,

$$|\psi(t)\rangle = e^{-(\imath/\hbar)\hat{H}t}|\psi(0)\rangle = e^{-(\imath/\hbar)\hat{H}t}\sum_n a_n|n\rangle \overset{a_n=\delta_{n,0}}{\longrightarrow} e^{-(\imath/\hbar)\hat{H}t}|0\rangle \ , \tag{24.193}$$

when the oscillator is initially in the state $|0\rangle$. Note that, without perturbation, $|\psi(t)\rangle = \sum_n e^{-\imath\omega_{\rm ho}(\hat{n}+1/2)t}a_n|n\rangle$.

Various quantities now are interesting to plot as a function of time. Firstly, we calculate the populations $|\langle n|\psi(t)\rangle|^2$ of the various states and the total energy from,

$$\boxed{\begin{aligned} \langle n|\psi(t)\rangle &= \langle n|e^{-(\imath/\hbar)\hat{H}t}\sum_m a_m|m\rangle \\ E_{\rm tot}(t) &= \sum_n \hbar\omega_{\rm ho}(n+\tfrac{1}{2})|\langle n|\psi(t)\rangle|^2 \end{aligned}} \ . \tag{24.194}$$

Secondly, we get for the temporal evolution of the spatial wavefunction,

$$\langle x|\psi(t)\rangle = \sum_n \langle x|n\rangle\langle n|\psi(t)\rangle = \sum_n \langle x|n\rangle\langle n|e^{-(\imath/\hbar)\hat{H}t}\sum_m a_m|m\rangle \ , \tag{24.195}$$

where $|\langle x|n\rangle\langle n|\psi(t)\rangle|^2$ is the spatial representation of the wavefunction of the n-th eigenstate derived in (24.106),

$$\langle x|n\rangle = \frac{e^{-x^2/2a_{\rm ho}^2}H_n(x/a_{\rm ho})}{\sqrt{a_{\rm ho}\sqrt{\pi}2^n n!}} \ , \tag{24.196}$$

weighed with instantaneous population (24.194) of this state. We thus obtain for the total wavefunction,

$$\boxed{\langle x|\psi(t)\rangle = \sum_n \frac{e^{-x^2/2a_{\rm ho}^2}H_n(x/a_{\rm ho})}{\sqrt{a_{\rm ho}\sqrt{\pi}2^n n!}}\langle n|e^{-(\imath/\hbar)\hat{H}t}|n\rangle} \ . \tag{24.197}$$

Furthermore, we may calculate the expectation values of the position and the momentum of the harmonic oscillator from the total wavefunction $\langle x|\psi(t)\rangle$,

$$\begin{aligned} \langle\psi(t)|\hat{x}|\psi(t)\rangle &= \int \langle\psi(t)|\hat{x}|x\rangle\langle x|\psi(t)\rangle dx = \int x|\psi(x,t)|^2 dx \\ \langle\psi(t)|\hat{p}|\psi(t)\rangle &= \int \langle\psi(t)|\hat{p}|p\rangle\langle p|\psi(t)\rangle dp = \int p|\phi(p,t)|^2 dp \ , \end{aligned} \tag{24.198}$$

where $\phi(p,t)$ is the Fourier transform of $\psi(x,t)$ according to (23.212). In practice, it is however easier to calculate them from the populations $\langle n|\psi(t)\rangle$,

$$\boxed{\begin{aligned} \langle\psi(t)|\hat{x}|\psi(t)\rangle &= \tfrac{a_{\rm ho}}{\sqrt{2}}\sum_n \langle\psi(t)|\hat{a}+\hat{a}^\dagger|n\rangle\langle n|\psi(t)\rangle \\ \langle\psi(t)|\hat{p}|\psi(t)\rangle &= \tfrac{\hbar}{\imath a_{\rm ho}\sqrt{2}}\sum_n \langle\psi(t)|\hat{a}-\hat{a}^\dagger|n\rangle\langle n|\psi(t)\rangle \end{aligned}} \ . \tag{24.199}$$

The temporal evolution of the forced harmonic oscillator defined by (24.193) can be numerically propagated. In cases where the force varies in time, the propagation can be done iteratively by subdividing time in intervals $t_k - t_{k-1}$ for $k \in \mathbb{N}$ sufficiently small that the force can be considered constant within them,

$$|\psi(t_k)\rangle = e^{-(\imath/\hbar)\hat{H}(t_k - t_{k-1})}|\psi(t_{k-1})\rangle \ . \tag{24.200}$$

The results of such a simulation are illustrated in Fig. 24.20.

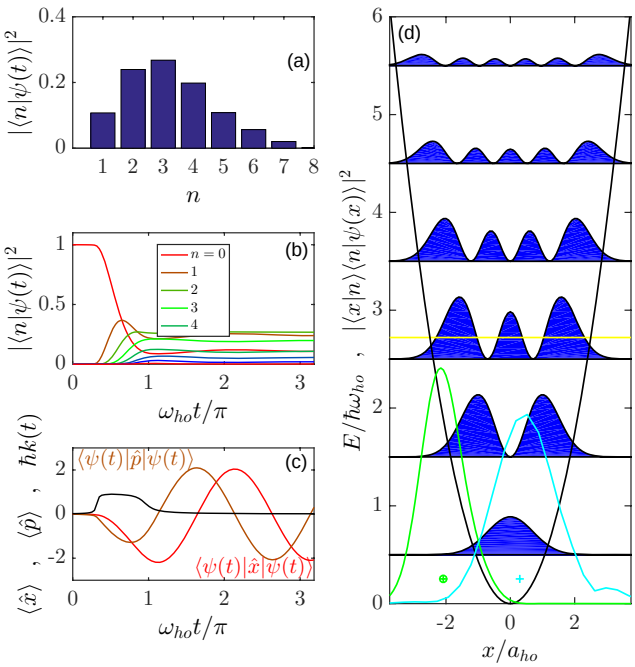

Figure 24.20: (code) Evolution of a harmonic oscillator subject to time-dependent forcing. (a) Histogram of the final population of the vibrational states. (b) Time evolution of the vibrational state populations. (c) Time evolution of the applied force (black) and of the expectation values of position (red) and momentum (brown). (d) Spatial wavefunctions $\langle n|\psi(x)\rangle|^2$ (Hermite polynomials) (blue) of the lowest vibrational states of the harmonic potential (black). The green Gaussian is the coherent sum of the spatial wavefunctions $|\sum_n \langle n|\psi(x)\rangle|^2$, and the cyan Gaussian the coherent sum of the momentum wavefunctions $|\sum_n \langle n|\psi(p)\rangle|^2$. The horizontal yellow line is the total energy of the system. You may also run a movie of the simulation clicking on (watch movie)! Furthermore, a presentation about the topic of recoil on trapped atoms is available at (watch talk)!

24.6.5 Quantization of the electromagnetic field

The quantization of light (also called *second quantization*) triggered by Max Planck's treatments of black-body radiation in 1905 resolved the problem of the ultraviolet

divergence and explained the photoelectric effect. Twenty years later the quantization of the atom by Niels Bohr (also called *first quantization*) explained the internal structure of the atom.

The operator for the electric field of a laser mode is given by,

$$\hat{\mathcal{E}} = \imath\mathcal{E}_1[\hat{a}e^{\imath\mathbf{k}\cdot\mathbf{r}-\imath\omega t} - \hat{a}^\dagger e^{-\imath\mathbf{k}\cdot\mathbf{r}+\imath\omega t}] \ , \tag{24.201}$$

where $\mathcal{E}_1 = \sqrt{\hbar\omega/2\varepsilon_0 V}$ is the electric field generated by a single photon in the mode volume V. Exc. 24.6.6.12 asks to calculate the eigenvalues $\langle\hat{\mathcal{E}}\rangle$ and $\Delta\hat{\mathcal{E}}$.

It is sometimes convenient to represent the light field by its quadratures. With the definition $\hat{a} \equiv \hat{x}_1 + \imath\hat{x}_2$, where $\hat{x}_{1,2}$ are non-commuting observables ($[\hat{x}_1, \hat{x}_2] = \imath/2$), we can write the field as,

$$\hat{\mathcal{E}} = -2\mathcal{E}_1[\hat{x}_1 \sin(\mathbf{k}\cdot\mathbf{r} - \omega t) + \hat{x}_2 \cos(\mathbf{k}\cdot\mathbf{r} - \omega t)] \ . \tag{24.202}$$

Heisenberg's uncertainty relations requires,

$$\Delta x_1 \Delta x_2 \geq \tfrac{1}{4} \ . \tag{24.203}$$

For coherent states, $\Delta x_1 = \Delta x_2 = \frac{1}{2}$.

24.6.6 Exercises

24.6.6.1 Ex: Sum of displacements operators

Prove formula (24.129). Find a geometric interpretation of the phase factor $(\alpha\beta^* - \alpha^*\beta)/2$ in the complex plane of Glauber states.

24.6.6.2 Ex: Rotation operator

Calculate $\mathcal{D}^\dagger(\alpha)\mathcal{R}(\varphi)\mathcal{D}(\alpha)$ and $\mathcal{R}^\dagger(\varphi)\mathcal{D}(\alpha)\mathcal{R}(\varphi)$ where $\mathcal{R}(\varphi) = e^{\imath\varphi\hat{a}^\dagger\hat{a}}$ and $\mathcal{D}(\alpha) = e^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}}$.

24.6.6.3 Ex: Harmonic oscillator and coherent states

a. Verify whether the Glauber states of a harmonic oscillator are orthogonal.
b. Show that $\langle\alpha|\hat{n}|\alpha\rangle = |\alpha|^2$, $\langle\alpha|\hat{n}^2|\alpha\rangle = |\alpha|^4 + |\alpha|^2$, and $\Delta\hat{n} = |\alpha|$.
c. Now calculate the energy uncertainty $\Delta\hat{H}$ for a Glauber state.
d. What is the population of the state $|n\rangle$ of a harmonic oscillator in a Glauber state?

24.6.6.4 Ex: Annihilation operator acting on Fock and Glauber states

Show that the annihilation operator $\hat{a}$ does not reduce the photon number of a Glauber state in contrast to a Fock state.

24.6.6.5 Ex: Completeness of coherent states

a. Show,

$$\tfrac{1}{\pi}\int |\alpha\rangle\langle\alpha| d^2\alpha = \sum_{n=0}^{\infty} |n\rangle\langle n| = \mathbb{I}\ .$$

b. Show that coherent states can be expanded in terms of other coherent states and that, consequently, the coherent state basis is overcomplete.

24.6.6.6 Ex: Schrödinger cat state

Calculate the probability of finding n photons in Schrödinger's cat state $|\psi\rangle = 2^{-1/2}(|\alpha\rangle \pm |-\alpha\rangle)$.

24.6.6.7 Ex: Transition elements for arbitrary Lamb-Dicke parameters

Calculate the general expression for $\langle m|e^{\imath k\hat{x}}|n\rangle$ with the abbreviation $\alpha \equiv \imath k a_{\rm ho}/\sqrt{2}$ for arbitrary values of the Lamb-Dicke parameter using the following results of the discussion of the displacement operator $\mathcal{D}(\alpha) = e^{\alpha\hat{a}^\dagger - \alpha^*\hat{a}} = e^{-|\alpha|^2/2} e^{\alpha\hat{a}^\dagger} e^{-\alpha^*\hat{a}}$ for Glauber states. The relations

$$|n\rangle = \frac{(\hat{a}^\dagger)^n}{\sqrt{n!}}|0\rangle \qquad \text{and} \qquad \langle n|\alpha\rangle = e^{-|\alpha|^2/2}\frac{\alpha^n}{\sqrt{n!}}$$

describe the relation between Fock and Glauber states. Furthermore,

$$\mathcal{D}(-\alpha) = \mathcal{D}^\dagger(\alpha) \qquad \text{and} \qquad \mathcal{D}^\dagger(\alpha)\hat{a}^\dagger\mathcal{D}(\alpha) = \hat{a}^\dagger + \alpha^*\ .$$

24.6.6.8 Ex: Lamb-Dicke regime

A rubidium atom is trapped in an isotropic harmonic trap with secular frequency $\omega_{\rm ho} = (2\pi)\ 1\,\text{kHz}$. Determine whether, driven on its D_2 line, it is within the Lamb-Dicke regime.

24.6.6.9 Ex: Resonantly excited harmonic oscillator

Write down the Hamiltonian of a harmonic oscillator subject to an oscillating homogenous force, and numerically simulate the evolution of the vibrational states starting from the ground state.

24.6.6.10 Ex: Shifted harmonic oscillator

Consider a HO of mass m, angular frequency ω, and electric charge q immersed in a uniform electric field oriented parallel to the axis $\hat{\mathbf{e}}_x$ of the oscillator.
a. Get the energies of the stationary states of the HO and show how to get the corresponding eigenstates.
b. Calculate the expectation values $\langle x\rangle$ and $\langle p\rangle$ for the displaced oscillator now using Glauber states (or arbitrary superpositions of states) and taking advantage of the

formulas (24.95), (24.128), and (23.279).
c. Now, the electric field is suddenly turned off. Calculate the time evolution of the oscillator.

24.6.6.11 Ex: Spatial wavefunction of a particle in a coherent state

a. Derive the following relations for the harmonic oscillator having received a recoil momentum,

$$\langle\psi_n^{(1)}|\hat{x}|\psi_n^{(1)}\rangle = 0 \qquad \text{and} \qquad \langle\psi_n^{(1)}|\hat{p}|\psi_n^{(1)}\rangle = \hbar k \ .$$

b. Calculate the temporal evolution of the oscillator after having received the recoil via,

$$\langle x|e^{-\imath\hat{H}t/\hbar}e^{-\imath k\hat{x}}|n\rangle \ .$$

c. Calculate the spatial wavefunction of a particle in a coherent state,

$$\langle x|\alpha\rangle = \sum_n e^{-|\alpha|^2/2}\frac{\alpha^n}{\sqrt{n!}}\langle x|n\rangle \ .$$

24.6.6.12 Ex: Electric field amplitude and fluctuation

Calculate $\langle\hat{\mathcal{E}}\rangle$ and $\Delta\hat{\mathcal{E}}$ for a coherent state.

24.6.6.13 Ex: Beam splitting a Fock state

A beam splitter is a device dividing an input mode (e.g. a laser beam) into two output modes 1 and 2. Assuming that a beam splitter sends every single photon with equal probability to one of the two output modes and that the input mode be a Fock state, what would be the photon statistics in the output mode? **Help:** Create the total output state $|n_1, n_2\rangle$ from vacuum by successive application of the photon creation operator $\hat{a}_1^\dagger + \hat{a}_2^\dagger$.

24.6.6.14 Ex: Wavefunction of a harmonic oscillator in a Glauber state

Derive the wavefunction for a harmonic oscillator in a coherent state using the exponential generating function of Hermite polynomials,

$$e^{2xt-t^2} = \sum_{n=0}^{\infty}\frac{t^n}{n!}H_n(x) \ .$$

Chapter 25

Rotations / Central potentials

Rotations are, on the same rights as translations, symmetry operations in space. They are of fundamental importance for the discussion of composite particles, such as atoms because they help us to formulate appropriate boundary conditions facilitating the solution of the three-dimensional Schrödinger equation.

25.1 Particle in a central potential

Many potentials do not have Cartesian symmetry, but fortunately, many problems have *some* kind of symmetry, cylindrical, spherical or periodic. Those with cylindrical or spherical symmetry can be solved by separating the curvilinear coordinates, as we will show in the following. Particularly important are spherical potentials caused by central forces, for example, the Coulomb force between the proton and the electron in the hydrogen atom.

25.1.1 Transformation to relative coordinates

The hydrogen atom represents a *two-body problem*. We consider the two masses $m_{1,2}$ of a proton and an electron separated by a distance $\mathbf{r}$ and interacting through a potential $V(\mathbf{r})$. The Hamiltonian is

$$\hat{H} = \frac{-\hbar^2}{2m_1}\nabla_{r1}^2 + \frac{-\hbar^2}{2m_2}\nabla_{r2}^2 + V(\mathbf{r}_1 - \mathbf{r}_2) \ , \tag{25.1}$$

where $\mathbf{r}_{1,2}$ are the positions of the proton and the electron. With the ansatz $\Xi(t, \mathbf{r}_1, \mathbf{r}_2) = \Xi(\mathbf{r}_1, \mathbf{r}_2)e^{-\imath E_{\text{tot}}t/\hbar}$, the time-dependent Schrödinger equation

$$\hat{H}\Xi(t, \mathbf{r}_1, \mathbf{r}_2) = \imath\hbar\frac{d}{dt}\Xi(t, \mathbf{r}_1, \mathbf{r}_2) \ , \tag{25.2}$$

becomes stationary,

$$\left[\frac{-\hbar^2}{2m_1}\nabla_{r_1}^2 + \frac{-\hbar^2}{2m_2}\nabla_{r_2}^2 + V(\mathbf{r}_1 - \mathbf{r}_2)\right]\Xi(\mathbf{r}_1, \mathbf{r}_2) = E_{\text{tot}}\Xi(\mathbf{r}_1, \mathbf{r}_2) \ . \tag{25.3}$$

Now we transform into the center-of-mass system making for the total wavefunction the ansatz $\Xi(\mathbf{r}_1, \mathbf{r}_2) = e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\Psi(\mathbf{r})$ with $\mathbf{R} \equiv \frac{m_1}{M}\mathbf{r}_1 + \frac{m_2}{M}\mathbf{r}_2$ and $\mathbf{r} \equiv \mathbf{r}_1 - \mathbf{r}_2$ and introducing the abbreviation $M = m_1 + m_2$. This corresponds to a product of a plane

wave, describing the linear motion of the center of the masses, and a radial wave function, which describes the relative motion of the atom. The kinetic energy of one mass is:

$$\begin{aligned}
&\frac{-\hbar^2}{2m_1}\nabla_{r_1}^2 e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\Psi(\mathbf{r}) \qquad (25.4)\\
&= \frac{-\hbar^2}{2m_1}\left[e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\nabla_{r_1}^2\Psi(\mathbf{r}) + 2(-\tfrac{\imath m_1\mathbf{P}}{\hbar M})e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\nabla_{r_1}\Psi(\mathbf{r}) + \Psi(\mathbf{r})(-\tfrac{\imath m_1}{\hbar^2 M}\mathbf{P})^2 e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\right]\\
&= e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\left[\frac{-\hbar^2}{2m_1}\nabla_{r_1}^2\Psi(\mathbf{r}) + \frac{\imath\hbar\mathbf{P}}{M}\nabla_{r_1}\Psi(\mathbf{r}) - \frac{m_1\mathbf{P}^2}{2M^2}\Psi(\mathbf{r})\right] .
\end{aligned}$$

Hence, for two atoms,

$$\begin{aligned}
&E_{\text{tot}}\Xi(\mathbf{r}_1,\mathbf{r}_2) - V(\mathbf{r})\Xi(\mathbf{r}_1,\mathbf{r}_2) \qquad (25.5)\\
&= e^{-\imath\mathbf{P}\cdot\mathbf{R}/\hbar}\left[\frac{-\hbar^2}{2m_1}\nabla_{r_1}^2\Psi(\mathbf{r}) + \frac{-\hbar^2}{2m_2}\nabla_{r_2}^2\Psi(\mathbf{r}) + \frac{\imath\hbar\mathbf{P}}{M}(\nabla_{r_1}+\nabla_{r_2})\Psi(\mathbf{r}) + \frac{\mathbf{P}^2}{2M}\Psi(\mathbf{r})\right] .
\end{aligned}$$

Using $\nabla_{r_1} = -\nabla_{r_2} = \nabla_r$, we see that the third term cancels, such that,

$$\frac{P^2}{2M}\Psi(\mathbf{r}) + \frac{-\hbar^2}{2m_1}\nabla_r^2\Psi(\mathbf{r}) + \frac{-\hbar^2}{2m_2}\nabla_r^2\Psi(\mathbf{r}) + V(\mathbf{r})\Psi(\mathbf{r}) = E_{\text{tot}}\Psi(\mathbf{r}) . \qquad (25.6)$$

Subtracting the energy of the center-of-mass motion with $E = E_{\text{tot}} - \frac{P^2}{2M}$ and introducing the abbreviation $m^{-1} = m_1^{-1} + m_2^{-1}$, we finally get,

$$\boxed{\left[\frac{-\hbar^2}{2m}\nabla_r^2 + V(\mathbf{r})\right]\Psi(\mathbf{r}) = E\Psi(\mathbf{r})} . \qquad (25.7)$$

25.1.2 Particle in a cylindrical potential

The equation (25.7) is three-dimensional because $\Psi(\mathbf{r})$ is a *scalar field* and the momentum operator in Cartesian coordinates is given by,

$$\nabla_r^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} . \qquad (25.8)$$

However, in some situations, the symmetry of the system allows to reduce dimensionality similarly to the cases of the box potential and the three-dimensional harmonic oscillator. Let us now discuss the cases of cylindrical and spherical symmetry.

Electrons in magnetic fields are subject to the Lorentz force, which keeps them in a rotating motion. We can rewrite the momentum operator in cylindrical coordinates,

$$x = \rho\cos\varphi \quad , \quad y = \rho\sin\varphi \quad , \quad z = z , \qquad (25.9)$$

as

$$\nabla_r^2 = \frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial}{\partial\rho} + \frac{1}{\rho^2}\frac{\partial^2}{\partial\varphi^2} + \frac{\partial^2}{\partial z^2} . \qquad (25.10)$$

Now, with the assumption that the potential only depends on ρ, $V(\mathbf{r}) = V(\rho)$, we can try the ansatz,

$$\Psi(\mathbf{r}) = R(\rho)\xi(\varphi)\zeta(z) , \qquad (25.11)$$

and obtain,

$$\frac{1}{R(\rho)}\left[-\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial}{\partial\rho}+V(\rho)\right)\right]R(\rho)-\frac{\hbar^2}{2m}\frac{1}{\zeta(z)}\frac{\partial^2}{\partial z^2}\zeta(z)-\frac{\hbar^2}{2m\rho^2}\frac{1}{\xi(\varphi)}\frac{\partial^2}{\partial\varphi^2}\xi(\varphi)=E\,. \tag{25.12}$$

First, we separate the axial motion,

$$-\frac{\zeta''}{\zeta}=const\equiv\frac{2mE_z}{\hbar^2}\equiv k_z^2\,, \tag{25.13}$$

the solution of this equation being a superposition of two plane waves counterpropagating along the axis z, $\zeta(z)=Ae^{\imath k_z z}+Be^{-\imath k_z z}$. Now, we separate the azimuthal motion,

$$\frac{\rho^2}{R(\rho)}\frac{\partial R^2(\rho)}{\partial\rho^2}+\frac{\rho}{R(\rho)}\frac{\partial R(\rho)}{\partial\rho}+\frac{2m\rho^2}{\hbar^2}[E-V(\rho)]-\rho^2k_z^2=-\frac{\xi''}{\xi}=const\equiv m_\varphi^2\,. \tag{25.14}$$

The solution of the right-hand part of the equation is $\xi(\varphi)=Ce^{\imath m_\varphi\varphi}+De^{-\imath m_\varphi\varphi}$. Finally, we have the radial equation,

$$\frac{1}{R(\rho)}\frac{\partial R(\rho)^2}{\partial\rho^2}+\frac{1}{\rho R(\rho)}\frac{\partial R(\rho)}{\partial\rho}-\frac{2m}{\hbar^2}[E-V(\rho)]-k_z^2-\frac{m_\varphi^2}{\rho^2}=0\,, \tag{25.15}$$

with the effective potential $V_{\text{eff}}=V(\rho)+\frac{\hbar^2m_\varphi^2}{2m\rho^2}$. For a homogeneous potential, $V(\rho)=V_0$, the solution will be a superposition of Bessel functions.

Example 207 (*Rigid rotor in cylindrical coordinates*): As an example, we disregard the potential, $V(\rho)=0$, and we consider for the particle an orbit with constant radius, $\rho=const$ such that $R(\rho)=\delta(\rho-\rho_0)$. In this case, we only need to treat the orbital motion described by the right part of Eq. (25.14). For the solution of this equation, $\xi(\varphi)=Ae^{\imath m_\varphi\varphi}$, to be well-defined, we need $\xi(\varphi)=\xi(\varphi+2\pi)$. This implies,

$$m_\varphi=0,\pm1,\pm2,..$$

and

$$E_\varphi=\frac{\hbar^2m_\varphi^2}{2m\rho^2}\,.$$

The allowed energies $E_{m_\varphi}=E_\varphi$ can be obtained by letting the Hamiltonian

$$\hat{H}=-\frac{\hbar^2}{2I}\frac{\partial^2}{\partial\varphi^2}\,,$$

with the moment of inertia $I=m\rho^2$ actuate on the azimuthal wavefunction $\xi(\varphi)$. We now define the operator,

$$\hat{l}_z=\frac{\hbar}{\imath}\frac{\partial}{\partial\varphi}\,.$$

This operator acts on the wavefunction ξ as follows,

$$\hat{l}_z\xi(\varphi)=\hbar m_\varphi\xi(\varphi)\,.$$

It is easy to show that wavefunctions with different values m_l are orthogonal. Note: 1. The state $m_\varphi=0$ has zero energy. That is, it has no zero-point energy, which is due to the absence of a confining potential. 2. The particle is delocalized within a ring of radius r: $\Delta l_z\Delta\sin\varphi\geq\frac{\hbar}{2}|\langle\cos\varphi\rangle|$.

25.1.3 Hamiltonian in spherical coordinates

We can rewrite the momentum operator in spherical coordinates,

$$x = r\sin\vartheta\cos\varphi \quad , \quad y = r\sin\vartheta\sin\varphi \quad , \quad z = r\cos\vartheta \ , \tag{25.16}$$

as [1],

$$\nabla_r^2 = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + \frac{1}{r^2}\frac{\hat{\mathbf{L}}^2}{\hbar^2} \quad \text{where} \quad \frac{\hat{\mathbf{L}}^2}{\hbar^2} \equiv \frac{1}{\sin\vartheta}\frac{\partial}{\partial\vartheta}\left(\sin\vartheta\frac{\partial}{\partial\vartheta}\right) + \frac{1}{\sin^2\vartheta}\frac{\partial^2}{\partial\varphi^2} \ , \tag{25.17}$$

is an abbreviation called *Legendre operator*. For an isotropic potential, $V(\mathbf{r}) = V(r)$, we can try the ansatz,

$$\Psi(\mathbf{r}) = R(r)Y(\vartheta,\varphi) \tag{25.18}$$

to solve the Schrödinger equation (23.168),

$$\frac{r^2}{R(r)}\left[-\frac{\hbar^2}{2m}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + V(r) - E\right]R(r) = \frac{-1}{2m}\frac{\hat{\mathbf{L}}^2 Y(\vartheta,\varphi)}{Y(\vartheta,\varphi)} = const \equiv -\frac{\hbar^2}{2m}\ell(\ell{+}1) \ , \tag{25.19}$$

where we choose a separation constant, $\ell(\ell+1)$, the significance of which we shall soon learn. Considering only the angular part,

$$\boxed{\hat{\mathbf{L}}^2 Y(\vartheta,\varphi) = \hbar^2\ell(\ell+1)Y(\vartheta,\varphi)} \ , \tag{25.20}$$

and making another separation ansatz,

$$Y(\vartheta,\varphi) = \Theta(\vartheta)\Phi(\varphi) \ , \tag{25.21}$$

we obtain,

$$\sin^2\vartheta\left(\frac{1}{\Theta(\vartheta)}\frac{1}{\sin\vartheta}\frac{\partial}{\partial\vartheta}\sin\vartheta\frac{\partial}{\partial\vartheta}\Theta(\vartheta) + \ell(\ell+1)\right) = -\frac{1}{\Phi(\varphi)}\frac{\partial^2}{\partial\varphi^2}\Phi(\varphi) = const \equiv m^2 \ , \tag{25.22}$$

where we choose a separation constant, m^2. Introducing another abbreviation,

$$\hat{L}_z \equiv \frac{\hbar}{\imath}\frac{\partial}{\partial\varphi} \ , \tag{25.23}$$

the azimuthal equation takes the form

$$\boxed{\hat{L}_z\Phi(\varphi) = \hbar m\Phi(\varphi)} \ . \tag{25.24}$$

As in the case of the cylindrical potential, the solution of the *azimuthal equation* is, using the normalization,

$$\Phi(\varphi) = \tfrac{1}{\sqrt{2\pi}}e^{\imath m\varphi} \ , \tag{25.25}$$

with the *magnetic quantum number* $m = 0, \pm1, \pm2, ...$

[1] We may also write: $\mathbf{p}^2 = (\hat{\mathbf{e}}_r\cdot\mathbf{p})^2 + (\hat{\mathbf{e}}_r\times\mathbf{p})^2 = p_r^2 + \frac{\mathbf{L}^2}{r^2}$, where p_r^2 is the radial part of the Laplace operator and $\frac{\mathbf{L}^2}{r^2}$ the angular part.

The *polar equation*,

$$\frac{1}{\Theta(\vartheta)}\frac{1}{\sin\vartheta}\frac{\partial}{\partial\vartheta}\sin\vartheta\frac{\partial}{\partial\vartheta}\Theta(\vartheta)+\ell(\ell+1)=\frac{m^2}{\sin^2\vartheta}\ , \tag{25.26}$$

is called Legendre's differential equation and can be solved by a power series in $\cos^k\vartheta$. For $m=0$, the solutions are the *Legendre polynomials*, $P_\ell(\cos\vartheta)$ with

$$P_\ell(z)=\frac{1}{2^\ell\ell!}\frac{d^\ell}{dz^\ell}[(z^2-1)^\ell]\ . \tag{25.27}$$

The first polynomials are,

$$P_0(z)=1\quad,\quad P_1(z)=z\quad,\quad P_2(z)=\tfrac{1}{2}(3z^2-1)\quad,\quad P_3(z)=\tfrac{1}{2}(5z^3-3z)\ . \tag{25.28}$$

For $m>0$, the solutions are the associated polynomials,

$$P_\ell^m(z)=(-1)^m(1-z^2)^{m/2}\frac{d^m}{dz^m}P_\ell(z)=\frac{(-1)^m}{2^\ell\ell!}(1-z^2)^{m/2}\frac{d^{\ell+m}}{dz^{\ell+m}}[(z^2-1)^\ell] \tag{25.29}$$

$$P_\ell^{-m}(z)=(-1)^m\frac{(\ell-m)!}{(\ell+m)!}P_\ell^m(z)\ .$$

The polar function must still be normalized,

$$\Theta_\ell^m(\vartheta)=P_\ell^m(\cos\vartheta)\sqrt{\frac{2\ell+1}{2}\frac{(\ell-m)!}{(\ell+m)!}}\ . \tag{25.30}$$

The functions $Y_{\ell m}(\vartheta,\varphi)$ are the *spherical harmonics*. They form an orthonormal system,

$$\int_0^\pi\int_0^{2\pi}Y^*_{\ell' m'}(\vartheta,\varphi)Y_{\ell m}(\vartheta,\varphi)\sin\vartheta d\vartheta d\varphi=\delta_{\ell'\ell}\delta_{m'm}\ . \tag{25.31}$$

Finite solutions only exist when the *angular momentum quantum number* is $\ell=0,1,..$ and for $|m|\le\ell$.

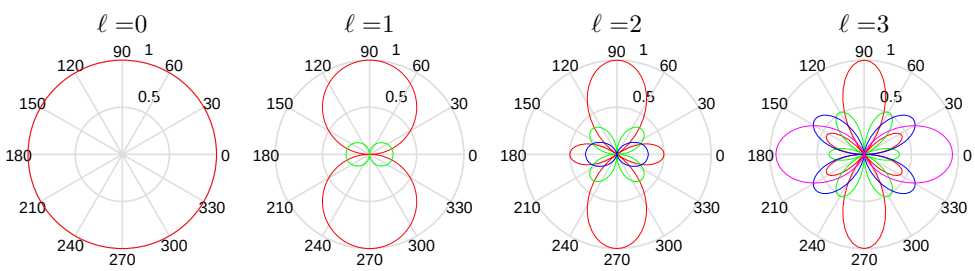

Figure 25.1: (code) Angular wavefunctions. Shown are the Legendre polynomials $P_\ell^m(\cos\vartheta)$ for $\ell=0,1,2,3$ and $m=0,..,\ell$. Red: $m=0$, green: $|m|=1$, blue: $|m|=2$, and magenta: $|m|=3$.

The solutions of the angular part of the Schrödinger equation for the hydrogen atom are finally,

$$\boxed{Y_{\ell m}(\vartheta,\varphi) = \frac{1}{\sqrt{2\pi}}\, P_\ell^m(\cos\vartheta)\sqrt{\frac{2\ell+1}{2}\frac{(\ell-m)!}{(\ell+m)!}}\; e^{\imath m\varphi}} \; . \tag{25.32}$$

The spherical harmonics are simultaneously eigenfunctions of the operators $\mathbf{L}^2$, as can be seen from Eq. (25.20), and of the operator L_z according to Eq. (25.24). The quantities represented by the quantum operators $\hat{H}, \hat{\mathbf{L}}^2, \hat{L}_z$ are conserved in the hydrogen system. The conservation of the angular momentum is due to the spherical symmetry of the Coulomb potential.

We will verify the parity of the spherical harmonics in Exc. 25.1.5.1.

25.1.4 Separation of radial motion

In Sec. 25.1.3 we derived, after having separated the motion of the center-of-mass (that is, of the heavy nucleus) and the angular coordinates, the radial equation (25.19) describing the radial component of the electronic motion,

$$\frac{1}{R(r)}\left[-\frac{\hbar^2}{2m}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) + V(r) - E\right] R(r) = -\frac{\hat{\mathbf{L}}^2}{2mr^2} \; , \tag{25.33}$$

Now, we make the substitution $R(r) = u(r)/r$ and the radial equation becomes,

$$\boxed{\left[-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial r^2} + \frac{\hat{\mathbf{L}}^2}{2mr^2} + V(r)\right] u(r) = E u(r)} \; . \tag{25.34}$$

This equation is very similar to a one-dimensional Schrödinger equation, but there is an additional potential term called *centrifugal potential*,

$$V_\ell(r) \equiv \frac{\hat{\mathbf{L}}^2}{2mr^2} \; . \tag{25.35}$$

For example, for the potential of an electron orbiting a proton, we have,

$$\left[-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial r^2} - \frac{Ze^2}{4\pi\varepsilon_0 r} + \frac{\hbar^2\ell(\ell+1)}{2mr^2} - E\right] u_{E\ell}(r) = 0 \; . \tag{25.36}$$

We will discuss this equation intensely in the context of the hydrogen atom.

In Exc. 25.1.5.2 we derive the radial Gross-Pitaevskii equation for a Bose-Einstein condensate trapped in a spherical potential. In the Exc. 25.1.5.3 we will study particles inside a central potential of zero depth, in the Excs. 25.1.5.4 and 25.1.5.5 we consider 3D spherical box potentials and in Exc. 25.1.5.6 a spherical harmonic potential.

Example 208 (*Rigid rotor in spherical coordinates*): We continue the discussion of the rigid rotor, now in spherical coordinates. In the case that the orbit of the particle is fixed to a radius R, we can neglect the kinetic energy due

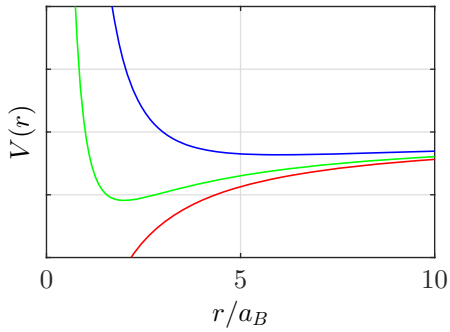

Figure 25.2: (code) Sum of a Coulomb potential and centrifugal potential for $\ell = 0$ (lower curve), $\ell = 1$ (center curve), and $\ell = 2$ (upper curve).

to the radial motion and the potential, both being constant. In this case the radial Schrödinger equation is,

$$\left[\frac{\hbar^2 \ell(\ell+1)}{2mr^2}\right] u_{E\ell} = E_\ell u_{E\ell} \ .$$

The energies of the *rigid rotor* are

$$E_\ell = \frac{\hbar^2 \ell(\ell+1)}{2I} \ ,$$

with the *momentum of inertia* $I = mR^2$.

25.1.5 Exercises

25.1.5.1 Ex: Parity of the spherical harmonic functions

We consider the parity transformation $\mathbf{P}$ with $(x, y, z) \xrightarrow{\mathbf{P}} (-x, -y, -z)$. Use spherical coordinates to show that $Y_{\ell m} \xrightarrow{\mathbf{P}} (-1)^\ell Y_{\ell m}$, and therefore that a spherical surface function has even parity when ℓ is even, and odd parity, when ℓ is odd.

25.1.5.2 Ex: Bose-Einstein condensate in an isotropic potential

The time-dependent Gross-Pitaevskii equation describing the wavefunction of a Bose-Einstein condensate reads,

$$\imath\hbar \frac{\partial \psi(\mathbf{r}, t)}{\partial t} = \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{\text{trp}}(r) + g|\psi(\mathbf{r}, t)|^2\right) \psi(\mathbf{r}, t) \ ,$$

where the factor g depends on the force of the interatomic interaction and V_{trp} is the potential trapping the atoms. Derive the stationary Gross-Pitaevskii equation via the transform $\psi(\mathbf{r}, t) = \psi(\mathbf{r}) e^{-\imath\mu t/\hbar}$, where the constant μ is called the chemical potential. For $V(\mathbf{r}) = V(r)$ the wavefunction will have radial symmetry, $\psi(\mathbf{r}) = \frac{\phi(r)}{r}$. Rewrite the Gross-Pitaevskii equation for the function ϕ.

25.1.5.3 Ex: Motion of a free particle in spherical coordinates

Obtain the eigenfunctions of a free particle as the limiting case of its motion in a central force field with $V(r) \to 0$. Compare the derived eigenfunctions – associated with the complete set of observables $\hat{H}$, $\hat{L}^2$, and $\hat{L}_z$ – to those described by plane waves – associated with the motion characterized by the observables $\hat{p}_x$, $\hat{p}_y$, $\hat{p}_z$, and $\hat{H} = \hat{\mathbf{P}}^2/2m$ –, which also constitute a complete set of observables.

25.1.5.4 Ex: Particle in a spherical box

Find the energy levels and wavefunctions of a particle confined in a spherical box described by potential energy, $V(r) = 0$ for $r < a$ and $V(r) = \infty$ for $r \geq a$ considering the angular momentum $\ell = 0$.

25.1.5.5 Ex: Finite spherical 3D potential well

a. Derive the possible energy levels and associated wavefunctions for a particle trapped in a spherical 3D potential well of depth V_0 and radius a. Note that this problem is analogous to *Mie scattering* of scalar waves.
b. Discuss the case of a well surrounded by infinitely high walls.

25.1.5.6 Ex: Particle in a spherical harmonic potential

A quantum particle of mass m is subject to a potential

$$V = \tfrac{1}{2} m\omega^2 (x^2 + y^2 + z^2) \ .$$

a. Obtain the energy levels of this particle. That is, determine the eigenvalues of

$$-\frac{\hbar^2}{2m}\nabla^2\psi + V\psi = E\psi \ .$$

b. Consider the fundamental level and the first two excited levels. Set up a table showing for each of these three levels the energy value, the degeneracy, and the respective states in terms of the quantum numbers.
c. Using

$$\nabla^2\psi = \left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right) - \frac{L^2}{\hbar^2 r^2}\right]\psi$$

and remembering $\hat{\mathbf{L}}^2 Y_{\ell m}(\theta,\phi) = \hbar^2\ell(\ell+1)Y_{\ell m}$, write down the differential equation of item (a) for the radial part of the wavefunction (it is not necessary to solve it). Identify in this equation the effective potential $V_{\text{eff}}(r)$.
d. Solve the differential equation of the previous item for the case where $\ell = 0$ and determine the corresponding eigenvalue. To do this, allow for a solution of the type $e^{-\alpha r^2}$ and determine α.

25.2 Quantum treatment of hydrogen

According to Rutherford's and Bohr's planetary atomic model we may imagine an atom as a very heavy nucleus having a positive electric charge surrounded by a very

light negatively charged charge electronic cloud. Since the nucleus is very small compared to the electronic cloud, we treat it as an entity with mass M and charge Ze, where Z is the number of protons and corresponds to the order of the element in the periodic system.

The canonical procedure for calculating all properties of an atom is to establish its Hamiltonian, that is, to determine the kinetic energies of all components and all interaction energies between them, and to solve the Schrödinger equation. For each component we write the kinetic energy,

$$T_{\rm ncl} = \frac{P^2}{2M} \qquad \text{and} \qquad T_{ele} = \sum_{i=1}^{Z} \frac{p_i^2}{2m} \ . \tag{25.37}$$

Here, $(\mathbf{R}, \mathbf{P})$ are the nuclear coordinates and $(\mathbf{r}_i, \mathbf{p}_i)$ those of the electrons. The energies that corresponds to the interactions, that is, Coulombian attraction or repulsion, between the components of the atom are,

$$V_{\rm ncl:ele} = -\sum_{i=1}^{Z} \frac{Ze^2}{4\pi\varepsilon_0|\mathbf{R}-\mathbf{r}_i|} \qquad \text{and} \qquad V_{\rm ele:ele} = \sum_{i\neq j=1}^{Z} \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_i-\mathbf{r}_j|} \ . \tag{25.38}$$

There are also interactions due to the spin of the particles, which we will deal with later.

Obviously, the solution to this many-body problem is very complicated. For this reason, we will in this chapter, based on the Schrödinger equation, calculate the complete spectrum of the simplest possible atom, hydrogen. This atom consists of a proton and an electron, only.

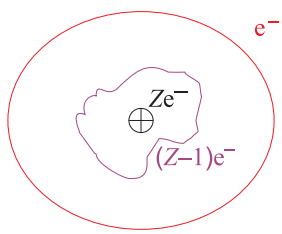

Figure 25.3: The hydrogen model applies to other atoms having a single valence electron occupying a sufficiently large space, that it sees the nucleus together with rest of the electrons shielding the nucleus as a single positive charge.

25.2.1 Bohr's model

Let us now turn our attention to the radial part of the Schrödinger equation describing a particle in a radial potential. We expect that the quantum solutions for the hydrogen atom are similar to the predictions of Bohr's model. Following this model, the orbit is stable when the attraction force is equal to the centrifugal force. But in addition, Bohr postulated, that only certain energies are allowed. For the hydrogen atom he found,

$$E_n = -\frac{1}{2}\frac{Ze^2}{4\pi\varepsilon_0}\frac{1}{r_n} = -\frac{Z^2\hbar^2}{2ma_{\rm B}^2}\frac{1}{n^2} = -\frac{Z^2e^2}{4\pi\varepsilon_0}\frac{1}{2a_{\rm B}n^2} = -\frac{Z^2}{n^2}\ 13.6\,{\rm eV} \ , \tag{25.39}$$

with the *Bohr radius*

$$a_{\mathrm{B}} \equiv 4\pi\varepsilon_0 \frac{\hbar^2}{me^2} \ . \tag{25.40}$$

With this equation he was able to explain the spectral observations. Electrons can only jump from one level to another, while emitting or absorbing a photon. The series observed in the hydrogen spectrum $(E_n - E_m)/\hbar$ are the Lyman $(m = 1)$, the Balmer $(m = 2)$, the Paschen $(m = 3)$ an the Brackett series $(m = 4)$.

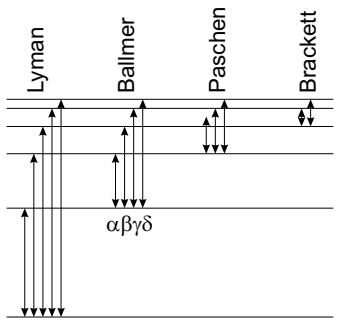

Figure 25.4: The hydrogen transitions.

The discussion of the hydrogen atom within quantum mechanics can start from the radial Schrödinger equation (25.36) with the Coulomb attraction potential,

$$\left[-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial r^2} - \frac{Ze^2}{4\pi\varepsilon_0 r} + \frac{\hbar^2\ell(\ell+1)}{2mr^2} - E\right] u_{E\ell}(r) = 0 \ . \tag{25.41}$$

In order to facilitate comparison with Bohr's classical model, let us express the energy in terms of Bohr's energy, $E \equiv E_n = E_1/n^2$, and write the radius in units of a_{B}, that is, $\tilde{r} \equiv Zr/a_{\mathrm{B}}$. This yields,

$$u''_{n\ell}(\tilde{r}) + \left(-\frac{\ell(\ell+1)}{\tilde{r}^2} + \frac{2}{\tilde{r}} - \frac{1}{n^2}\right) u_{n\ell}(\tilde{r}) = 0 \ . \tag{25.42}$$

To ensure that for large radii, $r \to \infty$, the solution is finite, we need an asymptotic behavior like $u_{n\ell}(\tilde{r} \to \infty) = e^{-\tilde{r}/n}$. To ensure that for small radii, $r \to 0$, the solution is finite, we need $u_{n\ell}(\tilde{r} \to 0) = \tilde{r}^{\ell+1}$. We derive the asymptotic solutions in Exc. 25.2.3.1. The resulting differential equation only has solutions for an integer and positive *main quantum number* n and when $\ell = 0, 1, .., n-1$. That is, in the relation $E = E_1/n^2$ the parameter n is integer and positive, such that energy levels remain degenerate in ℓ and m. This means that Bohr's postulate of discrete (i.e. quantized) energy levels is valid (uff!)

Substituting the ansatz,

$$u_{n\ell}(\tilde{r}) = D_{n\ell}\tilde{r}^{\ell+1}e^{-\tilde{r}/n}L(\tilde{r}) \ , \tag{25.43}$$

it's easy to show (see Exc. 25.2.3.2), that the differential equation (25.42) reduces to,

$$\tilde{r}L''(\tilde{r}) + 2\left[(\ell+1) - \tfrac{1}{n}\tilde{r}\right]L'(\tilde{r}) + 2\left[1 - \tfrac{1}{n}(\ell+1)\right]L(\tilde{r}) = 0 \ . \tag{25.44}$$

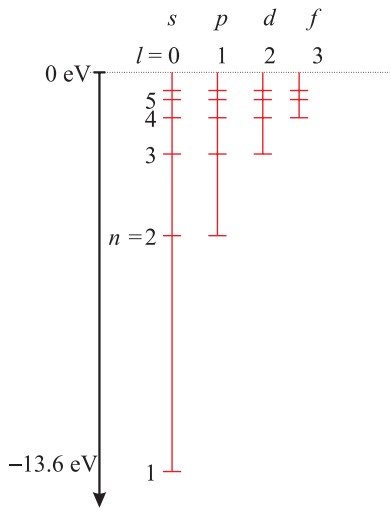

Figure 25.5: Level scheme.

Still with the abbreviation $\rho \equiv 2\tilde{r}/n = 2Zr/na_{\rm B}$ the ansatz

$$u_{n\ell}(\rho) = D_{n\ell}\rho^{\ell+1}e^{-\rho/2}L(\rho) \ , \tag{25.45}$$

leads to the differential equation [2]

$$\rho L''(\rho) + [2(\ell+1) - \rho]\, L'(\rho) + [n - \ell - 1]L(\rho) = 0 \ . \tag{25.46}$$

The solutions of this differential equation, $L^{(2\ell+1)}_{n-\ell-1}(\rho)$, are the *Laguerre polynomials*. These polynomials are listed in mathematical tables. Using the properties of these polynomials it is possible to show that the radial functions are orthogonal and can be normalized (see Exc. 25.2.3.3). Fig. 25.6 shows the curves for the lowest orbitals.

Finally, we can write the complete solutions of the Schrödinger equation $\hat{H}\psi = E\psi$,

$$\boxed{\psi_{n\ell m}(r,\theta,\phi) = \frac{u_{n\ell}(r)}{r}Y_{\ell m}(\theta,\phi) \qquad \text{and} \qquad E_n = -\frac{\hbar^2}{2ma_{\rm B}^2}\frac{Z^2}{n^2}} \ , \tag{25.47}$$

where $n = 1, 2, 3, ..$ and $\ell = 0, 1, .., n-1$ and $m = -\ell, -\ell+1, .., \ell$. Of course, each energy level n is,

$$\sum_{\ell=0}^{n-1}(2\ell+1) = n^2 \tag{25.48}$$

[2] *Laguerre's associated differential equation* is,

$$\rho\partial_\rho^2 L_\nu^{(\alpha)} + (\alpha+1-\rho)\partial_\rho L_\nu^{(\alpha)} + \nu L_\nu^{(\alpha)} = 0 \ .$$

The Laguerre polynomials are generated by

$$L_\nu^{(\alpha)}(\rho) = \frac{e^\rho\rho^{-\alpha}}{\alpha!}\frac{d^\nu}{d\rho^\nu}\left(e^{-\rho}\rho^{\nu+\alpha}\right) \ .$$

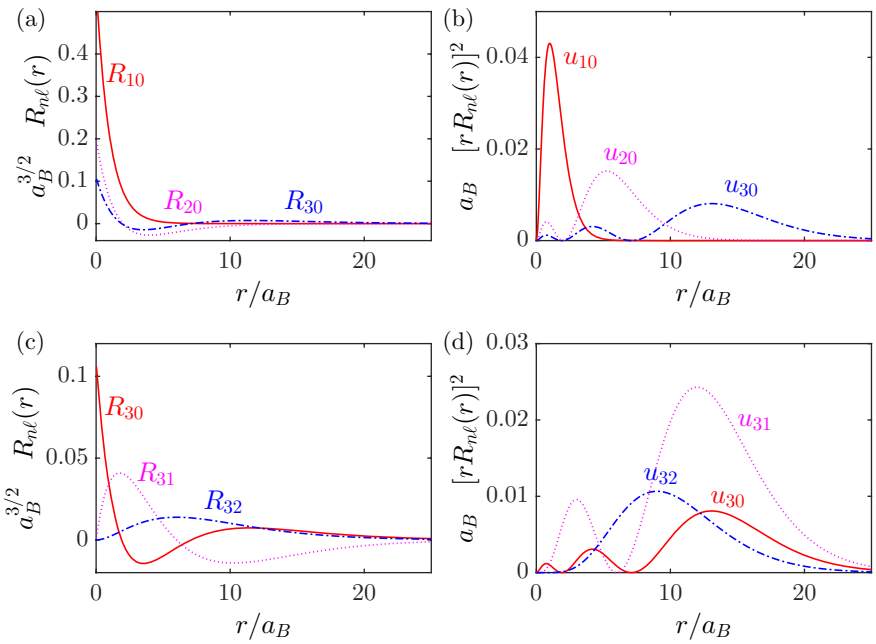

Figure 25.6: (code) (a,c) Radial wavefunctions $R_{n\ell}(r)$ and (b,d) square of the radial wavefunctions $u_{n\ell}(r)$ for various quantum numbers n and ℓ.

times degenerate.

From the normalization condition,

$$\begin{aligned} 1 &= \int_{\mathbb{R}^3} |\psi_{n\ell m}(r,\theta,\phi)|^2 d^3r \\ &= \int_0^\infty |u_{n\ell}(r)|^2 dr \int_{\mathbb{R}^2} |Y_{\ell m}(\theta,\phi)|^2 \sin\theta d\theta d\phi = \int_0^\infty |u_{n\ell}(r)|^2 dr \ , \end{aligned} \tag{25.49}$$

we obtain the constants,

$$D_{n\ell} = \sqrt{\left(\frac{2Z}{na_{\mathrm{B}}}\right)^3 \frac{(n-\ell-1)!}{2n(n+\ell)!}} \ , \tag{25.50}$$

and the radial wavefunctions finally read,

$$R_{n\ell}(r) = D_{n\ell} \left(\frac{2\tilde{r}}{n}\right)^\ell e^{-\tilde{r}/n} L_{n-\ell-1}^{(2\ell+1)}(\tfrac{2\tilde{r}}{n}) = D_{n\ell}\rho^\ell e^{-\rho/2} L_{n-\ell-1}^{(2\ell+1)}(\rho) \ , \tag{25.51}$$

using the previously introduced abbreviations.

Here is a list of the first wavefunctions of the hydrogen atom,

$$
\begin{aligned}
\psi_{100} &= \tfrac{1}{\sqrt{\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} e^{-\tilde{r}} \\
\psi_{200} &= \tfrac{1}{4\sqrt{2\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} (2-\tilde{r})e^{-\tilde{r}/2} \\
\psi_{210} &= \tfrac{1}{4\sqrt{2\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} \tilde{r}e^{-\tilde{r}/2}\cos\theta \\
\psi_{21\pm1} &= \tfrac{1}{8\sqrt{\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} \tilde{r}e^{-\tilde{r}/2}\sin\theta e^{\pm\imath\varphi} \\
\psi_{300} &= \tfrac{1}{81\sqrt{3\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} (27-18\tilde{r}+2\tilde{r}^2)e^{-\tilde{r}/3} \\
\psi_{31\pm1} &= \tfrac{\sqrt{2}}{81\sqrt{3\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} (6-\tilde{r})\tilde{r}e^{-\tilde{r}/3}\sin\theta e^{\pm\imath\varphi} \\
\psi_{320} &= \tfrac{1}{81\sqrt{6\pi}}\left(\tfrac{Z}{a_{\mathrm{B}}}\right)^{3/2} \tilde{r}^2e^{-\tilde{r}/3}(3\cos^2\theta-1)\ ,
\end{aligned}
\tag{25.52}
$$

where we use the abbreviation $\tilde{r} \equiv Zr/a_{\mathrm{B}}$. Using these wavefunctions we can now calculate important eigenvalues such as, for example,

$$
\begin{aligned}
\langle 1\rangle_{n\ell m} &= 1 \\
\langle \delta^{(3)}(\tilde{r})\rangle_{n\ell m} &= \frac{\delta_{\ell,0}}{\pi n^3} \\
\langle \tilde{r}\rangle_{n\ell m} &= n^2\left[1+\frac{1}{2}\left(1-\frac{\ell(\ell+1)}{n^2}\right)\right] \\
\langle \tilde{r}^2\rangle_{n\ell m} &= n^4\left[1+\frac{3}{2}\left(1-\frac{\ell(\ell+1)-\frac{1}{3}}{n^2}\right)\right] \\
\langle \tilde{r}^3\rangle_{n\ell m} &= n^6\left[\frac{35}{8}-\frac{35}{8n^2}-\frac{15}{4n^2}(\ell+2)(\ell-1)+\frac{3}{8n^4}(\ell+2)(\ell+1)\ell(\ell-1)\right] \\
\langle \tilde{r}^4\rangle_{n\ell m} &= n^8\left[\frac{63}{8}+\frac{35}{8n^2}(2\ell^2+2\ell-3)+\frac{5}{8n^4}5\ell(\ell+1)(3\ell^2+3\ell-10)+\frac{12}{n^8}\right] \\
\left\langle\frac{1}{\tilde{r}}\right\rangle_{n\ell m} &= \frac{1}{n^2} \\
\left\langle\frac{1}{\tilde{r}^2}\right\rangle_{n\ell m} &= \frac{1}{n^3(\ell+\frac{1}{2})} \\
\left\langle\frac{1}{\tilde{r}^3}\right\rangle_{n\ell m} &= \frac{n}{n^4\ell(\ell+\frac{1}{2})(\ell+1)} \\
\left\langle\frac{1}{\tilde{r}^4}\right\rangle_{n\ell m} &= \frac{\frac{3}{2}n^2-\frac{1}{2}\ell(\ell+1)}{n^5(\ell+\frac{3}{2})(\ell+1)(\ell+\frac{1}{2})\ell(\ell-\frac{1}{2})}\ .
\end{aligned}
\tag{25.53}
$$

These results will become important later. In Exc. 25.2.3.4 we will calculate the eigenvalue $\langle r\rangle$ for several orbitals $|\psi_{n\ell m}\rangle$.

25.2.2 The virial theorem

Originally derived for classical mechanics, the *virial theorem* also holds for quantum mechanics, as shown for the first time by *Fock*. We evaluate the commutator between the Hamiltonian

$$\hat{H} = \hat{\mathbf{p}}^2/2m + V(\hat{\mathbf{r}}) \ , \tag{25.54}$$

and the product of the position operator $\hat{\mathbf{r}}$ with the momentum operator $\hat{\mathbf{p}} = -\imath\hbar\nabla$ of the particle:

$$[\hat{H}, \hat{\mathbf{r}} \cdot \hat{\mathbf{p}}] = [\hat{H}, \hat{\mathbf{r}}] \cdot \hat{\mathbf{p}} + \hat{\mathbf{r}} \cdot [\hat{H}, \hat{\mathbf{p}}] = -\imath\hbar \frac{\hat{\mathbf{p}}^2}{m} + \imath\hbar\hat{\mathbf{r}} \cdot \nabla V \ , \tag{25.55}$$

using the theorems of Ehrenfest. Therefore, we find for the operator $\hat{Q} = \hat{\mathbf{r}} \cdot \hat{\mathbf{p}}$ the commutator,

$$\frac{\imath}{\hbar}[\hat{H}, \hat{Q}] = 2E_{\text{kin}} - \hat{\mathbf{r}} \cdot \nabla V \ . \tag{25.56}$$

The left side of this equation is precisely $-d\hat{Q}/dt$, following the Heisenberg equation of motion. The eigenvalue $\langle d\hat{Q}/dt\rangle$ of the temporal derivative vanishes in steady state, therefore we obtain the virial theorem,

$$2\langle E_{\text{kin}}\rangle = \langle \hat{\mathbf{r}} \cdot \nabla V\rangle \ . \tag{25.57}$$

Example 209 (*Virial theorem applied to a central potential*): For example, for a central potential $V(r) \propto r^s$ we obtain,

$$2\langle E_{\text{kin}}\rangle = \langle \hat{\mathbf{r}} \cdot \hat{\mathbf{e}}_r \frac{\partial V}{\partial r}\rangle = \langle r \frac{\partial V}{\partial r}\rangle = s\langle V\rangle \ .$$

In Exc. 25.2.3.5 we calculate the eigenvalues $\langle r^{-1}\rangle$ and $\langle p^2\rangle$ and we verify the virial theorem. Finally, in Exc. 25.2.3.6 we calculate transition matrix elements between different orbitals.

25.2.3 Exercises

25.2.3.1 Ex: Asymptotes of Laguerre's polynomials

Derive the asymptotic solutions of equation (25.42).

25.2.3.2 Ex: Laguerre equation

Show that the equation (25.42) transforms with the ansatz (25.43) into equation (25.44).

25.2.3.3 Ex: Laguerre functions

Using the orthogonality relation of associated Laguerre polynomials,

$$\int_0^\infty \rho^\alpha e^{-\rho} L_n^{(\alpha)}(\rho) L_m^{(\alpha)}(\rho) d\rho = \frac{\Gamma(n+\alpha+1)}{n!}\delta_{n,m}$$

$$\int_0^\infty \rho^{\alpha+1} e^{-\rho} L_n^{(\alpha)} \rho^2 d\rho = \frac{(n+\alpha)!}{n!}(2n+\alpha+1) \ ,$$

and the recursion formula,

$$nL_n^{(\alpha+1)}(\rho) = (n-\rho)L_{n-1}^{(\alpha+1)}(\rho r) + (n+\alpha)L_{n-1}^{(\alpha)}(\rho)$$
$$\rho L_n^{(\alpha+1)}(\rho) = (n+\alpha)L_{n-1}^{(\alpha)}(\rho) - (n-\rho)L_n^{(\alpha)}(\rho) \ ,$$

a. calculate the normalization constant $D_{n,l}$ for a hydrogen-like atom with atomic number Z;
b. calculate the mean value

$$\langle r\rangle_{nlm} = \frac{n^2 a_{\rm B}}{Z}\left[1+\frac{1}{2}\left(1-\frac{\ell(\ell+1)}{n^2}\right)\right] \ ;$$

c. calculate the mean value

$$\left\langle \frac{1}{r}\right\rangle_{n\ell m} = \frac{Z}{n^2 a_{\rm B}} \ .$$

25.2.3.4 Ex: Orbital radii in Bohr's model

Using the results of 25.2.3.3, obtain the expectation values $\langle r\rangle$ for the states ψ_{100}, ψ_{210} and ψ_{320} of the hydrogen atom. Compare the results with those of Bohr's model.

25.2.3.5 Ex: The virial theorem and Bohr's model

Calculate, for the state ψ_{320} of the hydrogen atom, the expectation values $\langle\frac{1}{r}\rangle$, $\langle\frac{\mathbf{L}^2}{r^2}\rangle$, and $\langle\mathbf{p}^2\rangle$.
From the results, obtain the expectation values for the kinetic and potential energies, $\langle T\rangle$ and $\langle V\rangle$, and show that, consistent with the virial theorem, $\langle T\rangle = -(1/2)\langle V\rangle$. Compare the results with Bohr's model.

25.2.3.6 Ex: Transition matrix elements

Using the following (non-normalized) wavefunctions of hydrogen, $\psi_{100}(\mathbf{r}) = e^{-\tilde{r}}$, $\psi_{210}(\mathbf{r}) = \tilde{r}e^{-\tilde{r}/2}\cos\theta$ and $\psi_{21\pm1}(\mathbf{r}) = \tilde{r}e^{-\tilde{r}/2}\sin\theta e^{\pm\imath\phi}$, calculate the matrix elements (a) $\langle\psi_{100}|\tilde{z}|\psi_{210}\rangle$, (b) $\langle\psi_{100}|\tilde{z}|\psi_{211}\rangle$, (c) $\langle\psi_{100}|\tilde{x}-\imath\tilde{y}|\psi_{210}\rangle$, and (d) $\langle\psi_{100}|\tilde{x}-\imath\tilde{y}|\psi_{211}\rangle$ using the formulae:

$$\int_0^\infty x^4 e^{-3x/2}dx = \tfrac{256}{81} \quad , \quad \int_0^\pi \sin^3 x dx = \tfrac{4}{3} \ ,$$
$$\int_0^\pi \cos x \sin^2 x dx = 0 \quad , \quad \int_0^\pi \cos^2 x \sin x dx = \tfrac{2}{3} \ .$$

Try to interpret the results.

25.3 Angular momentum

25.3.1 The orbital angular momentum operator

The definition of *orbital angular momentum* is adopted from classical mechanics:

$$\hat{\mathbf{L}} = \hat{\mathbf{r}} \times \hat{\mathbf{p}} = -\imath\hbar\hat{\mathbf{r}} \times \hat{\nabla} = -\imath\hbar \begin{vmatrix} \hat{\mathbf{e}}_x & \hat{\mathbf{e}}_y & \hat{\mathbf{e}}_z \\ x & y & z \\ \partial_x & \partial_y & \partial_z \end{vmatrix} . \tag{25.58}$$

To better understand the properties of the angular momentum operator in quantum mechanics we will derive in the Excs. 25.3.4.1 and 25.3.4.2 some of its properties.

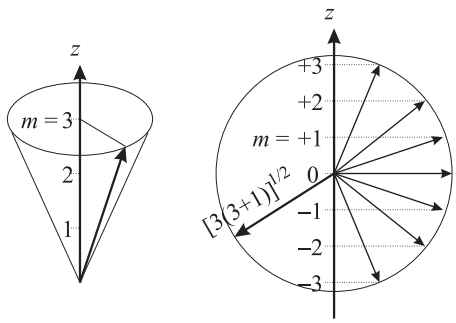

Figure 25.7: Illustration of angular momentum in quantum mechanics.

25.3.1.1 Constants of motion

The preceding chapter dealt with the resolution of the radial and angular equations for the case of a radial potential. The radial equation allowed to calculate the eigenenergies of the Hamiltonian $\hat{H}$,

$$\hat{H}|\psi\rangle = E_{n\ell}|\psi\rangle \ . \tag{25.59}$$

We also found the common eigenvalues and eigenfunctions of operators $\hat{\mathbf{L}}^2$ and $\hat{L}_z$ [see Eqs. (25.20) and (25.24)]. We now use the notation $|\ell, m\rangle \equiv Y_{\ell m}(\theta, \phi)$ for the eigenfunctions,

$$\hat{\mathbf{L}}^2|\ell, m\rangle = \hbar^2\ell(\ell+1)|\ell, m\rangle \qquad \text{and} \qquad \hat{L}_z|\ell, m\rangle = \hbar m|\ell, m\rangle \ . \tag{25.60}$$

With this we have,

$$\begin{aligned} [\hat{H}, \hat{\mathbf{L}}^2]|\psi\rangle &= \hat{H}\hbar^2\ell(\ell+1)|\psi\rangle - \hat{\mathbf{L}}^2 E|\psi\rangle = 0 \\ \text{and} \qquad [\hat{H}, \hat{L}_z]|\psi\rangle &= \hat{H}\hbar m|\psi\rangle - \hat{L}_z E|\psi\rangle = 0 \ . \end{aligned} \tag{25.61}$$

Therefore, the operators $\hat{\mathbf{L}}^2$ and $\hat{L}_z$ are constants of motion,

$$[\hat{H}, \hat{L}_z] = 0 = [\hat{H}, \hat{\mathbf{L}}^2] \ . \tag{25.62}$$

Exc. 25.3.4.3 asks to show explicitly, at the example of an isotropic three-dimensional harmonic oscillator, that $\hat{\mathbf{L}}^2$ and $\hat{L}_z$ are constants of motion.

25.3.2 SU(2) algebra of angular momentum and spin

So far, we have solved the angular eigenvalue equation in the spatial representation for an orbital angular momentum, $\hat{\mathbf{L}} = \hat{\mathbf{r}} \times \hat{\mathbf{p}}$. But it is not clear, whether *every* angular momentum has this representation, which is derived from classical notions. Using the orbital angular momentum expression (25.58) it is easy to verify,

$$\hat{\mathbf{L}} \times \hat{\mathbf{L}} = \imath\hbar\hat{\mathbf{L}} \ . \tag{25.63}$$

However, it is not clear a priori, whether *any* quantity $\hat{\mathbf{J}}$ satisfying

$$\boxed{\hat{\mathbf{J}} \times \hat{\mathbf{J}} = \imath\hbar\hat{\mathbf{J}}} \qquad \text{or equivalently} \qquad [\hat{J}_m, \hat{J}_n] = \imath\hbar\epsilon_{kmn}\hat{J}_k \tag{25.64}$$

using the Levi-Civita symbol, can be represented like (25.58). In fact, we will see that the electron has an intrinsic spin with no orbiting charges, and cannot be represented as an orbital angular momentum. What needs to be done now is to show that (25.64) generates a consistent algebra even in cases beyond the representation (25.58).

Since $\hat{\mathbf{J}}^2$ and $\hat{J}_z$ commute (we show this from Eq. (25.64) in Exc. 25.3.4.4), they have common eigenfunctions $|j, m\rangle$. We can write the eigenvalues as,

$$\hat{\mathbf{J}}^2|j, m\rangle = \hbar^2 j(j+1)|j, m\rangle \qquad \text{and} \qquad \hat{J}_z|j, m\rangle = \hbar m|j, m\rangle \ , \tag{25.65}$$

where, for now, we only know that m is real and $j \geq 0$. But since $\langle j, m|\hat{\mathbf{J}}^2|j, m\rangle \geq \langle j, m|\hat{J}_z^2|j, m\rangle$, it is clear that $j(j+1) \geq m^2$.

25.3.2.1 Rising and lowering operator

Now we introduce the *rising operator* $\hat{J}_+$ and the *lowering operator* $\hat{J}_-$ via

$$\hat{J}_\pm \equiv \hat{J}_x \pm \imath\hat{J}_y \qquad \text{such that} \qquad \hat{J}_- = \hat{J}_+^\dagger \ . \tag{25.66}$$

It is easy to check the following relationships

$$[\hat{J}_z, \hat{J}_\pm] = \pm\hbar\hat{J}_\pm \qquad \text{and} \qquad [\hat{\mathbf{J}}^2, \hat{J}_\pm] = 0 \qquad \text{and} \qquad \hat{J}_\mp\hat{J}_\pm = \hat{\mathbf{J}}^2 - \hat{J}_z^2 \mp \hbar\hat{J}_z \ . \tag{25.67}$$

With this we find

$$\begin{aligned} &\hat{J}_z\hat{J}_\pm|j, m\rangle = ([\hat{J}_z, \hat{J}_\pm] + \hat{J}_\pm J_z)|j, m\rangle = \hbar(m \pm 1)\hat{J}_\pm|j, m\rangle \\ \text{and} \quad &\hat{\mathbf{J}}^2 J_\pm|j, m\rangle = \hat{J}_\pm\hat{\mathbf{J}}^2|j, m\rangle = \hbar^2 j(j+1)\hat{J}_\pm|j, m\rangle \ . \end{aligned} \tag{25.68}$$

That is, $\hat{J}_\pm|j, m\rangle$ is a eigenstate of $\hat{\mathbf{J}}^2$ and $\hat{J}_z$ with the eigenvalues j and $m \pm 1$, respectively, if $J_\pm|j, m\rangle \neq 0$. Hence,

$$\hat{J}_+|j, m\rangle \propto |j, m+1\rangle \ . \tag{25.69}$$

In order not to violate the condition $m^2 \leq j(j+1)$, we need to fix $\hat{J}_\pm|j, \pm j\rangle = 0$. Therefore, for a specified j, the m can have only one of the $2j+1$ possible values $m = -j, -j+1, .., j$. Since $2j+1$ is an integer, j can only have values $j = 0, \frac{1}{2}, 1, \frac{3}{2}, ...$ Thus, the eigenvalue equation of the observables $\hat{\mathbf{J}}^2$, $\hat{\mathbf{J}}$ is solved, since we could have chosen instead of $\hat{J}_z$ any one of the components of $\hat{\mathbf{J}}$, knowing that the others do not commute with the chosen one.

All spin components $\hat{J}_z$ and the scalar $\hat{\mathbf{J}}^2$ can only have discrete eigenvalues. The smallest unit is $\hbar/2$. With the normalization $\langle j,m|j',m'\rangle = \delta_{j,j'}\delta_{m,m'}$ we have,

$$\langle j,m|\hat{J}_\mp\hat{J}_\pm|j,m\rangle = \langle j,m|(\hat{\mathbf{J}}^2 - \hat{J}_z^2 \mp \hbar\hat{J}_z)|j,m\rangle = \hbar^2[j(j+1) - m(m\pm 1)] \ , \quad (25.70)$$

and

$$\boxed{\hat{J}_\pm|j,m\rangle = \hbar\sqrt{j(j+1)-m(m\pm 1)}|j,m\pm 1\rangle} \ . \quad (25.71)$$

In Exc. 25.3.4.5 we calculate the uncertainty of the angular momentum components, in Exc. 25.3.4.6 we write the operator $\hat{J}_x$ in a matrix form, and in Excs. 25.3.4.7 and 25.3.4.8 we calculate projections of the spin of the electron in different directions of the quantization axis.

25.3.3 The electron spin

Every angular momentum $\hat{\mathbf{J}}$ generates a *magnetic dipole moment* $\vec{\mu}_j \propto \hat{\mathbf{J}}$, which interacts with external magnetic fields, $V(\vec{\mathcal{B}}) = \vec{\mu}_j \cdot \vec{\mathcal{B}}$. *Inhomogeneous* magnetic fields exert forces on dipole moments, $\mathbf{F} = -\nabla(\vec{\mu}_j \cdot \vec{\mathcal{B}})$, which are detected by the *Stern-Gerlach experiment*. This experiment reveals not only the quantization of angular momentum, but also the presence of semi-integral values for the magnetic quantum number.

In 1925 Uhlenbeck and Goudsmit proposed that the electron could have an intrinsic angular momentum with the quantum number $s = 1/2$. This angular momentum, called *spin*, would not correspond to any orbiting mass or charge distribution within the classical radius of the electron of the type $\mathbf{L} = \mathbf{r} \times \mathbf{p}$. The spin is a purely quantum phenomenon because it disappears when $\hbar \to 0$. It is believed nowadays that the electron is actually point-like with no detectable deviation from Coulomb's law at any distance. The spin of the electron does not follow from the Schrödinger equation, but can be included, ad hoc. On the other hand, it is interesting that it is a necessary consequence of the stringent relativistic derivation of quantum mechanics by *Paul Dirac*.

To characterize the spin, we can use the whole SU(2) formalism of the quantum mechanics of angular momentum:

$$\hat{\mathbf{S}} \times \hat{\mathbf{S}} = \imath\hbar\hat{\mathbf{S}} \ , \quad (25.72)$$

and

$$\hat{\mathbf{S}}^2|\tfrac{1}{2},\pm\tfrac{1}{2}\rangle = \hbar^2\tfrac{3}{4}|\tfrac{1}{2},\pm\tfrac{1}{2}\rangle \quad , \quad \hat{S}_z|\tfrac{1}{2},\pm\tfrac{1}{2}\rangle = \pm\tfrac{\hbar}{2}|\tfrac{1}{2},\pm\tfrac{1}{2}\rangle \quad , \quad (25.73)$$
$$\hat{S}_\pm = \hbar\hat{\sigma}_\pm = \hbar|\tfrac{1}{2},\pm\tfrac{1}{2}\rangle\langle|\tfrac{1}{2},\mp\tfrac{1}{2}| \ .$$

The operators $\hat{\sigma}_\pm$ are the *Pauli spin matrices* defined in (23.154) for the basis chosen as,

$$|\tfrac{1}{2},+\tfrac{1}{2}\rangle = \begin{pmatrix}1\\0\end{pmatrix} \quad \text{and} \quad |\tfrac{1}{2},-\tfrac{1}{2}\rangle = \begin{pmatrix}0\\1\end{pmatrix} \ . \quad (25.74)$$

25.3.4 Exercises

25.3.4.1 Ex: Properties of the angular orbital momentum

Show that $\hat{\mathbf{L}} \times \hat{\mathbf{L}} = \imath\hbar\hat{\mathbf{L}}$ and $[\hat{L}_x, \hat{L}_y] = \imath\hbar\hat{L}_z$.

25.3.4.2 Ex: Levi-Civita tensor

a. Demonstrate $[\hat{L}_k, \hat{r}_m] = \imath\hbar\hat{r}_n\epsilon_{kmn}$ where the Levi-Civita tensor is defined by $\epsilon_{kmn} = 1$ when (kmn) is an even permutation of (123), $\epsilon_{kmn} = -1$ for an odd permutation, and $\epsilon_{kmn} = 0$ when two of the indices are equal.
b. Verify $\hat{J}_m\hat{J}_n = \frac{1}{4}\delta_{mn} + \frac{\imath}{2}\epsilon_{kmn}\hat{J}_k$.

25.3.4.3 Ex: Angular orbital momentum of a harmonic oscillator

Show for an isotropic three-dimensional harmonic oscillator: $[\hat{H}, \hat{\mathbf{L}}^2] = [\hat{H}, \hat{L}_z] = 0$. Make explicit calculations, that is, show

$$\left[\tfrac{\hat{p}^2}{2m}, \hat{L}_z\right] = 0 = \left[\frac{m}{2}\omega^2\hat{r}^2, \hat{L}_z\right] \qquad \text{and} \qquad \left[\tfrac{\hat{p}^2}{2m}, \hat{\mathbf{L}}^2\right] = 0 = \left[\frac{m}{2}\omega^2\hat{r}^2, \hat{\mathbf{L}}^2\right] \ .$$

25.3.4.4 Ex: Commutation of the absolute value and the components of the orbital angular momentum

Show $[\hat{\mathbf{J}}^2, \hat{\mathbf{J}}] = 0$.

25.3.4.5 Ex: Uncertainty of angular momentum components

Show that if $\hat{J}_z$ is precise, then $\hat{J}_x$ and $\hat{J}_y$ are imprecise.

25.3.4.6 Ex: Matrix representation of the components of the angular momentum

Calculate the matrix elements of $\hat{J}_x$ and $\hat{J}_x^2$ in the basis where $\hat{J}_z$ is observable. Give the general formula and examples for $j = \frac{1}{2}$ and $j = 1$.

25.3.4.7 Ex: Spin-1/2-particle in a magnetic field

Consider a spin-1/2-particle whose magnetic moment is $\vec{\mu} = \gamma\mathbf{S}$ (where γ is a constant). We can describe the quantum state of this particle in terms of the space generated by the eigenvectors $|+\rangle$ and $|-\rangle$ of the operator $\hat{S}_z$, which measures the spin projection in z-direction:

$$\hat{S}_z|+\rangle = \tfrac{\hbar}{2}|+\rangle \qquad , \qquad \hat{S}_z|-\rangle = -\tfrac{\hbar}{2}|-\rangle$$

Initially $(t = 0)$ the particle is in the state $\psi(t = 0)\rangle = |+\rangle$ and is subject to a uniform magnetic field $\vec{\mathcal{B}} = \mathcal{B}\hat{\mathbf{e}}_y$, so that:

$$\hat{H} = -\vec{\mu}\cdot\vec{\mathcal{B}} = -\gamma\mathcal{B}\hat{S}_y \ .$$

a. What are the possible measurements of the spin projection on the y-axis?
b. Find the eigenvectors of $\hat{S}_y$.
c. Get $|\psi(t)\rangle$ at $t > 0$ in terms of the eigenvectors $|+\rangle$ and $|-\rangle$ defined above.
d. Obtain the mean expectation values of the observables $\hat{S}_x$, $\hat{S}_y$ and $\hat{S}_z$ as a function of time.

25.3.4.8 Ex: Spin expectation value for a two-level system

Consider an arbitrary state of a two-level system $|\vartheta,\varphi\rangle = \cos\frac{\vartheta}{2}|+\rangle + e^{\imath\varphi}\sin\frac{\vartheta}{2}|-\rangle$ and calculate the expectation values of the ladder operators $\hat{S}_\pm$ and of the spin operator $\hat{\mathbf{S}}$. Also calculate the expectation values of $\hat{S}_\pm^2$, $\hat{S}_\pm\hat{S}_\mp$, $\hat{S}_\alpha^2$ with $\alpha = x, y, z$. Finally, calculate the uncertainties of $\hat{s}_\alpha$ and check the uncertainty relation.

25.4 Coupling of angular momenta

25.4.1 Singlet and triplet states with two electrons

In this section we first consider the spin states of two electrons, which can be combined into two groups with well-defined total spin. With this we can understand the energy spectrum of helium, which is very much dominated by Pauli's principle and quantum statistics. The introduced concepts can be extended to atoms with many electrons.

Angular momentum is an important quantum number in the treatment of the internal structure of atoms. The two electrons in the helium electronic shell each contribute a spin of $s = \frac{1}{2}$, which couple to a total angular momentum. Let us consider, for simplicity, two free electrons. The state of the two-particle system is an element of the product space of the two Hilbert spaces in which the individual electrons are described. We will now apply the formalism of Sec. 23.5.8 explicitly to a pair of electrons. The states that the two electrons can occupy are:

$$|\gamma_1\rangle = \begin{pmatrix}1\\0\end{pmatrix}\otimes\begin{pmatrix}1\\0\end{pmatrix} = \begin{pmatrix}1\\0\\0\\0\end{pmatrix} \equiv |\uparrow\uparrow\rangle \quad , \tag{25.75}$$

$$|\gamma_2\rangle = |\uparrow\downarrow\rangle \quad , \quad |\gamma_3\rangle = |\downarrow\uparrow\rangle \quad , \quad |\gamma_4\rangle = |\downarrow\downarrow\rangle \ .$$

The Pauli matrices act on the spin of the individual electrons. They can be extended to the product Hilbert space as follows,

$$\begin{aligned}
\tfrac{\hbar}{2}\hat{\sigma}_x\otimes\mathbb{I}_2 &= \tfrac{\hbar}{2}\begin{pmatrix}0 & \mathbb{I}_2\\ \mathbb{I}_2 & 0\end{pmatrix} \quad , \quad \tfrac{\hbar}{2}\mathbb{I}_2\otimes\hat{\sigma}_x = \tfrac{\hbar}{2}\begin{pmatrix}\hat{\sigma}_x & 0\\ 0 & \hat{\sigma}_x\end{pmatrix} \\
\tfrac{\hbar}{2}\hat{\sigma}_y\otimes\mathbb{I}_2 &= \tfrac{\hbar}{2}\begin{pmatrix}0 & \imath\mathbb{I}_2\\ -\imath\mathbb{I}_2 & 0\end{pmatrix} \quad , \quad \tfrac{\hbar}{2}\mathbb{I}_2\otimes\hat{\sigma}_y = \tfrac{\hbar}{2}\begin{pmatrix}\hat{\sigma}_y & 0\\ 0 & \hat{\sigma}_y\end{pmatrix} \\
\tfrac{\hbar}{2}\hat{\sigma}_z\otimes\mathbb{I}_2 &= \tfrac{\hbar}{2}\begin{pmatrix}-\mathbb{I}_2 & 0\\ 0 & \mathbb{I}_2\end{pmatrix} \quad , \quad \tfrac{\hbar}{2}\mathbb{I}_2\otimes\hat{\sigma}_z = \tfrac{\hbar}{2}\begin{pmatrix}\hat{\sigma}_z & 0\\ 0 & \hat{\sigma}_z\end{pmatrix} \ .
\end{aligned} \tag{25.76}$$

With these operators we can now build other operators. We first consider the three

components of the total angular momentum,

$$\hat{S}_k = \tfrac{\hbar}{2}(\hat{\sigma}_k \otimes \mathbb{I}_2 + \mathbb{I}_2 \otimes \hat{\sigma}_k) \qquad \text{such that} \tag{25.77}$$

$$\hat{S}_x = \tfrac{\hbar}{2}\begin{pmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 \end{pmatrix} \quad , \quad \hat{S}_y = \tfrac{\imath\hbar}{2}\begin{pmatrix} 0 & 1 & 1 & 0 \\ -1 & 0 & 0 & 1 \\ -1 & 0 & 0 & 1 \\ 0 & -1 & -1 & 0 \end{pmatrix} \quad , \quad \hat{S}_z = \hbar\begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} .$$

The operator for the square of the absolute value of the total angular momentum is calculated as follows:

$$\hat{\mathbf{S}}^2 = \hat{S}_x^2 + \hat{S}_y^2 + \hat{S}_z^2 = \hbar^2 \begin{pmatrix} 2 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 2 \end{pmatrix} . \tag{25.78}$$

Now, we look for the eigenvalues of the total angular momentum. The equation for the eigenvalues of $\hat{S}_z$,

$$\hat{S}_z|\gamma_k\rangle = M_S|\gamma_k\rangle \ , \tag{25.79}$$

is already diagonal in the introduced basis $\{\gamma_k\}$ with the eigenvalues,

$$M_S = -\hbar, 0, 0, \hbar \ . \tag{25.80}$$

For $\hat{\mathbf{S}}^2$ the situation is more interesting: The states $|\gamma_1\rangle$ and $|\gamma_4\rangle$ *are* eigenstates of $\mathbf{S}^2$ for the eigenvalue $2\hbar^2$, but the states $|\gamma_2\rangle$ and $|\gamma_3\rangle$ are *not* eigenstates. On the other hand, we know that the linear combination of two eigenstates with the same eigenvalue is also a eigenstate. Therefore, the states

$$|\tilde{\gamma}_1\rangle \equiv |\gamma_1\rangle \quad , \quad |\tilde{\gamma}_4\rangle \equiv |\gamma_4\rangle \quad , \quad |\tilde{\gamma}_a\rangle \equiv \tfrac{1}{\sqrt{2}}(|\gamma_2\rangle - |\gamma_3\rangle) \quad , \quad |\tilde{\gamma}_s\rangle \equiv \tfrac{1}{\sqrt{2}}(|\gamma_2\rangle + |\gamma_3\rangle) \ , \tag{25.81}$$

are *still* eigenstates of $\hat{S}_z$, but they *also* are eigenstates of $\hat{\mathbf{S}}^2$, since we can easily verify,

$$\hat{\mathbf{S}}^2|\gamma_s\rangle = 2\hbar^2|\gamma_s\rangle \qquad \text{and} \qquad \hat{\mathbf{S}}^2|\gamma_a\rangle = 0\hbar^2|\gamma_a\rangle \ , \tag{25.82}$$

using the matrices (25.77). In summary, for the eigenvalue $\langle\hat{\mathbf{S}}^2\rangle = 2\hbar^2$ there exist the following three states:

$$\left.\begin{array}{ll} |\gamma_1\rangle & M_s = 1 \\ |\gamma_4\rangle & M_s = -1 \\ |\gamma_s\rangle & M_s = 0 \end{array}\right\} \qquad \text{triplet} \ , \ S = 1 \tag{25.83}$$

For $\langle\mathbf{S}^2\rangle = 0$ there is only one state:

$$|\gamma_a\rangle \quad M_s = 0 \qquad \text{singlet} \ , \ S = 0 \ . \tag{25.84}$$

By exchanging the two electrons, the vectors $|\gamma_1\rangle$ and $|\gamma_4\rangle$ retain their shape, while the mixed vectors change their shape: $\gamma_2 \leftrightarrow \gamma_3$. Under particle exchange $|\gamma_a\rangle$ reverses

its sign, that is, it is antisymmetric, while $|\gamma_1\rangle$, $|\gamma_4\rangle$ and $|\gamma_c\rangle$ conserve their signs, that is, they are symmetrical.

In summary, the triplet states have the quantum number of the total angular momentum (with the expected value for $\hat{\mathbf{S}}^2$ of $\hbar^2 S(S+1) = 2\hbar^2$), and they are symmetrical about the exchange of particles. The singlet state has the quantum number of the total angular momentum $S = 0$, and it is antisymmetric about the exchange of particles. The transition from the original basis $\{|\gamma_1\rangle, |\gamma_2\rangle, |\gamma_3\rangle, |\gamma_4\rangle\}$ to the new basis $\{|\tilde{\gamma}_1\rangle, |\tilde{\gamma}_s\rangle, |\tilde{\gamma}_a\rangle, |\tilde{\gamma}_4\rangle\}$ described by Eqs. (25.81) is done by a unitary transformation,

$$|\tilde{\gamma}\rangle = \mathcal{U}_{\mathrm{CGC}}|\gamma\rangle \qquad \text{with} \qquad \mathcal{U}_{\mathrm{CGC}} = \begin{pmatrix} 1 & & & \\ & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{2}} & \\ & \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} & \\ & & & 1 \end{pmatrix} , \tag{25.85}$$

whose components are known as Clebsch-Gordan coefficients. A similar treatment can be done with bosons, as will be discussed in Sec. 34.1.

25.4.2 Coupling two spins

We now consider a perturbation of the system which, for some reason, only affects the first spin. In the absence of the second atom we would have,

$$\hat{H}_1 = \begin{pmatrix} 0 & \Omega^* \\ \Omega & 0 \end{pmatrix} . \tag{25.86}$$

Including the second atom,

$$\hat{H} = \hat{H}_1 \otimes \mathbb{I} = \begin{pmatrix} & & \Omega^* & \\ & & & \Omega^* \\ \Omega & & & \\ & \Omega & & \end{pmatrix} . \tag{25.87}$$

In this case, the perturbation Hamiltonian does not commute with the total angular momentum,

$$[\hat{\mathbf{S}}^2, \hat{H}] \neq 0 . \tag{25.88}$$

Another type of perturbation affects both spin symmetrically (e.g., Dicke superradiance with two atoms in the same radiative mode or two counterpropagating modes in a ring cavity). The interaction Hamiltonian is now the sum of the individual perturbations,

$$\hat{H} = \hat{H}_1 \otimes \mathbb{I} + \mathbb{I} \otimes \hat{H}_1 = \begin{pmatrix} & \Omega^* & \Omega^* & \\ \Omega & & & \Omega^* \\ \Omega & & & \Omega^* \\ & \Omega & \Omega & \end{pmatrix} . \tag{25.89}$$

This Hamiltonian commutes with the total angular momentum,

$$[\hat{\mathbf{S}}^2, \hat{H}] = 0 . \tag{25.90}$$

S now is a good quantum number. Singlet states do not couple with triplets. This is the idea behind Dicke's superradiance. The absolute value of the total angular momentum is conserved. The quantum number S is called *Dicke cooperativity* [256]. In Exc. 48.5.7.1 we will discuss the coupling of two counterpropagating modes in a ring cavity. In Sec. 46.1 we will discuss Dicke states.

Example 210 (*Two atoms interacting through their dipole moments*): As an example of a system exhibiting coupling of the type described in (25.89) we consider two two-level atoms $j = 1, 2$. As long as the atoms do not interact, the Hamiltonian will be,

$$\hat{H} = \hbar\omega_0 \hat{S}_z \ , \tag{25.91}$$

with $\hat{S}_z$ given by (25.77). Now, if the atoms interact via their dipole moments with an electromagnetic field assumed to be the same for both atoms,

$$\begin{aligned}\hat{H}_{int} = &- \tfrac{q}{m}\mathbf{A}(\mathbf{r}_1)\cdot(p_x\hat{\mathbf{e}}_x\hat{\sigma}_x\otimes\mathbb{I} + p_y\hat{\mathbf{e}}_y\hat{\sigma}_y\otimes\mathbb{I}) \\ &- \tfrac{q}{m}\mathbf{A}(\mathbf{r}_2)\cdot(p_x\hat{\mathbf{e}}_x\mathbb{I}\otimes\hat{\sigma}_x + p_y\hat{\mathbf{e}}_y\mathbb{I}\otimes\hat{\sigma}_y) \ ,\end{aligned} \tag{25.92}$$

with $\mathbf{r}_1 \simeq \mathbf{r}_2$. By the rules (25.76) we find in matrix notation a Hamiltonian equivalent to (25.89). Using the abbreviations $\Omega_x \equiv \frac{q}{m}A_x p_x$, $\Omega_y \equiv \frac{q}{m}A_y p_y$, $\Omega_\pm \equiv \Omega_x \pm \imath\Omega_y$, and $\Omega \equiv \sqrt{\Omega_x^2 + \Omega_y^2}$,

$$\hat{H} = \begin{pmatrix} 0 & \Omega_- & \Omega_- & 0 \\ \Omega_+ & 0 & 0 & \Omega_- \\ \Omega_+ & 0 & 0 & \Omega_- \\ 0 & \Omega_+ & \Omega_+ & 0 \end{pmatrix} \ . \tag{25.93}$$

Using symbolic algebra software we find the eigenvector and eigenvalue matrices,

$$\mathcal{U} = \begin{pmatrix} \frac{\Omega_-}{\Omega_+} & -\frac{\Omega_-}{\Omega_+} & 0 & \frac{\Omega_-}{\Omega_+} \\ -\sqrt{\frac{\Omega_-}{\Omega_+}} & 0 & -1 & \sqrt{\frac{\Omega_-}{\Omega_+}} \\ -\sqrt{\frac{\Omega_-}{\Omega_+}} & 0 & 1 & \sqrt{\frac{\Omega_-}{\Omega_+}} \\ 1 & 1 & 0 & 1 \end{pmatrix} \quad \text{and} \quad \hat{E} = \begin{pmatrix} -2\Omega & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2\Omega \end{pmatrix} \ . \tag{25.94}$$

Now, we get for the evolution of the various states,

$$\mathcal{U}e^{\imath\hat{E}t}\mathcal{U}^{-1}\begin{pmatrix} 0 \\ 1 \\ 1 \\ 0 \end{pmatrix} = \begin{pmatrix} -\sqrt{\frac{-\Omega_-}{\Omega_+}}\sin 2\Omega t \\ \cos 2\Omega t \\ \cos 2\Omega t \\ \sqrt{\frac{\Omega_+}{-\Omega_-}}\sin 2\Omega t \end{pmatrix} \quad \text{and} \quad \mathcal{U}e^{\imath\hat{E}t}\mathcal{U}^{-1}\begin{pmatrix} 0 \\ 1 \\ -1 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \\ -1 \\ 0 \end{pmatrix} \ . \tag{25.95}$$

That is, the Hamiltonian (25.92) does not mix antisymmetric singlet states and symmetric triplet states.

25.4.3 Decoupled and coupled bases

Electrically charged orbiting particles produce a magnetic field. This field can influence the motion of other particles. In the same way, the spin of an electron can influence its own orbital motion. That is, angular momenta can couple and interact in a complicated way. Even to describe the behavior of an atom as simple as hydrogen in

an external field, we need to construct the eigenstates of the total angular momentum resulting from a coupling of the electron's intrinsic spin and its orbital motion.

On the other side, we have hitherto considered predominantly hydrogen and hydrogen-like atoms, that is, atoms with a nucleus and a single (valence) electron. But in fact atoms can have more than 100 electrons, which complicates the exact description. In atoms with many electrons, one of the most common coupling schemes is when the angular momenta of all electrons couple to a *total angular momentum*, $\hat{\mathbf{L}} = \sum_k \hat{\mathbf{l}}_k$, which then couples to the *total spin*, $\hat{\mathbf{S}} = \sum_k \hat{\mathbf{s}}_k$, to form the complete total angular momentum, $\hat{\mathbf{J}} = \hat{\mathbf{L}} + \hat{\mathbf{S}}$. We generally assign total momenta to capital letters.

Adopting an unbiased notation we study some properties of the total angular momentum, $\hat{\mathbf{J}} \equiv \hat{\mathbf{j}}_1 + \hat{\mathbf{j}}_2$. In Exc. 25.4.5.1 we find that the addition of angular momenta produces a quantity which is also an angular momentum, but not the subtraction.

The angular momenta of two particles or two angular momenta of different origins in a single particle represent independent degrees of freedom, $[\mathbf{j}_1, \mathbf{j}_2] = 0$. Without interaction between angular momenta the Hilbert spaces are orthogonal:

$$\mathcal{H}_1 \otimes \mathcal{H}_2 = \begin{pmatrix} \mathcal{H}_1 & 0 \\ 0 & \mathcal{H}_2 \end{pmatrix} . \tag{25.96}$$

The eigenfunctions act on a space of dimension, $\dim \mathcal{H}_1 \cdot \dim \mathcal{H}_2$:

$$|j_1, m_{j1}; j_2, m_{j2}\rangle . \tag{25.97}$$

That is, there is a complete set of commuting operators $\{\hat{\mathbf{j}}_1^2, \hat{j}_{1z}, \hat{\mathbf{j}}_2^2, \hat{j}_{2z}\}$. Therefore, we can specify quantum numbers j_1, j_2, m_{j1}, and m_{j2} simultaneously. On the other hand, the group $\{\hat{\mathbf{j}}_1^2, \hat{\mathbf{j}}_2^2, \hat{\mathbf{J}}^2, \hat{J}_z\}$ also represents a complete set of commuting operators, as shown in Exc. 25.4.5.2. It has the basis

$$|(j_1, j_2)J, M_J\rangle . \tag{25.98}$$

To describe the two angular momenta simultaneously, we must opt between the decoupled picture $|j_1, m_{j1}; j_2, m_{j1}\rangle$ and the coupled picture $|(j_1, j_2)J, M_J\rangle$. For now, the choice of the picture makes no difference, but we will see later that there may be an energy associated with the coupling [3]. In this case, as we will show, the choice of the coupled base is more natural, because generally the energy commutes like $[\hat{H}, \hat{\mathbf{J}}^2] = 0 = [\hat{H}, \hat{J}_z]$ and $[\hat{H}, \hat{\mathbf{j}}_1^2] = 0 = [\hat{H}, \hat{\mathbf{j}}_2^2]$, but $[\hat{H}, \hat{j}_{1z}] \neq 0 \neq [\hat{H}, \hat{j}_{2z}]$.

Example 211 (*Coupled basis*): For example, using the Hamiltonian (25.94) it is easy to see that,

$$[\hat{H}, (\hat{\sigma}_x \otimes \mathbb{I})^2 + (\hat{\sigma}_y \otimes \mathbb{I})^2 + (\hat{\sigma}_z \otimes \mathbb{I})^2] = 0 = [\hat{H}, (\mathbb{I} \otimes \hat{\sigma}_x)^2 + (\mathbb{I} \otimes \hat{\sigma}_y)^2 + (\mathbb{I} \otimes \hat{\sigma}_z)^2]$$
$$[\hat{H}, \hat{\sigma}_z \otimes \mathbb{I}] \neq 0 \neq [\hat{H}, \mathbb{I} \otimes \hat{\sigma}_z] .$$

[3] That is, the Hamiltonian of the system does not contain terms of type $\hat{\mathbf{j}}_1 \cdot \hat{\mathbf{j}}_2$, but may have terms proportional to $\hat{\mathbf{j}}_1 + \hat{\mathbf{j}}_2$.

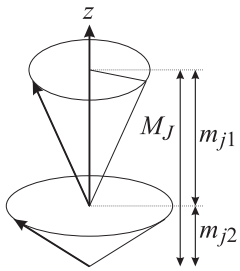

Figure 25.8: Illustration of the coupling of two angular momenta.

25.4.3.1 Allowed values of total angular momentum

As long as we do not specify an interaction energy between the spins or between spins and external fields, all states are energetically degenerate. In the decoupled image the degeneracy is easily calculated,

$$\# = \sum_{m_{j1}=-j_1}^{j_1} \sum_{m_{j2}=-j_2}^{j_2} 1 = (2j_1+1)(2j_2+1) \ . \tag{25.99}$$

Now, we want to find the possible values of J and M_J in the coupled picture. The values of M_J follow immediately from $\hat{\mathbf{j}}_1 + \hat{\mathbf{j}}_2 = \hat{\mathbf{J}}$,

$$M_J = m_{j1} + m_{j2} \ . \tag{25.100}$$

With $|m_{j1}| \leq j_1$ and $|m_{j2}| \leq j_2$ the values of M_J are limited to

$$|M_J| \leq j_1 + j_2 \ . \tag{25.101}$$

We often know the two angular momenta j_1 and j_2 and all their projections in the decoupled base,

$$|m_{j1}| \leq j_1 \qquad \text{and} \qquad |m_{j2}| \leq j_2 \ . \tag{25.102}$$

To find the quantum numbers in the coupled base, we arrange the states ordering them by their total magnetic quantum number M_J. We can, without loosing generality, concentrate on the situation $j_1 \geq j_2$. The following table reproduces the possible combinations. The x-symbols represent Clebsch-Gordan coefficients:

m_{j1}	$+m_{j2} =$	J / M_J	J / J	J / $J-1$	$J-1$ / $J-1$	J / $J-2$	$J-1$ / $J-2$	$J-2$ / $J-2$		J / $-J+1$	$J-1$ / $-J+1$	J / $-J$
j_1	j_2		x									
j_1	j_2-1			x	x							
j_1-1	j_2			x	x							
j_1	j_2-2					x	x	x				
j_1-1	j_2-1					x	x	x				
j_1-2	j_2					x	x	x				
									$\ddots$			
$-j_1+1$	$-j_2$									x	x	
$-j_1$	j_2+1									x	x	
$-j_1$	$-j_2$											x

The possible values for J are all those allowing for $J \geq |M_J| = |m_{j1} + m_{j2}|$, that is,

$$|j_1 - j_2| \leq J \leq j_1 + j_2 \ . \tag{25.103}$$

Each value of J has the degeneracy $2J+1$. Therefore, as will be verified in Exc. 25.4.5.3, the total degeneracy is,

$$\sum_{J=|j_1-j_2|}^{j_1+j_2} 2J+1 = (2j_1+1)(2j_2+1) \ . \tag{25.104}$$

Example 212 (*Spin states in the presence of* $\mathbf{L}\cdot\mathbf{S}$ *coupling*): As an example we consider two electrons occupying the $(5p)^2$ orbital. That is, both electrons have $s_i = \frac{1}{2}$ and $\ell_i = 1$. As illustrated in Fig. 25.9, the coupling first gives $S = s_1 + s_2 = 0, 1$ and $L = \ell_1 + \ell_2 = 0, 1, 2$. Then we determine the possible values of the total angular momentum $J = L + S = 0, 1, 2$ depending on the values of L and S.

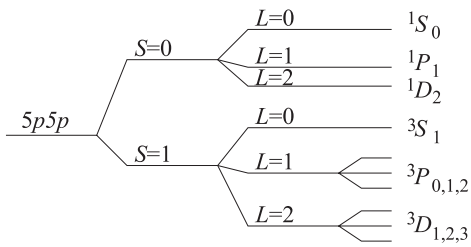

Figure 25.9: Possible spin states of two electrons occupying the $(5p)^2$ orbital. Spin-orbit coupling $\mathbf{L}\cdot\mathbf{S}$ leads to a splitting of the energy levels.

25.4.4 Clebsch-Gordan coefficients

Let us now describe how to add *two* angular momenta, $\hat{\mathbf{j}}_1$ and $\hat{\mathbf{j}}_2$. Since they act on different degrees of freedom,

$$[\vec{\alpha}_1 \cdot \hat{\mathbf{j}}_1, \vec{\alpha}_2 \cdot \hat{\mathbf{j}}_2] = 0 \tag{25.105}$$

for arbitrary vectors $\vec{\alpha}_1$ and $\vec{\alpha}_2$. We have a system of common eigenvectors, $|\eta, j_1, j_2, m_1, m_2\rangle$, where η are the eigenvalues of other observables commuting with $\hat{\mathbf{j}}_1$ and $\hat{\mathbf{j}}_2$. These eigenvectors give the values $\hbar^2 j_1(j_1+1)$ and $\hbar^2 j_2(j_2+1)$ for the observables $\hat{\mathbf{j}}_1^2$ and $\hat{\mathbf{j}}_2^2$, as well as $\hbar m_1$ and $\hbar m_2$ for the observables j_{z1} and j_{z2}. The number of states is $(2j_1+1)(2j_2+1)$. Now we want to construct the eigenstates of the total angular momentum $\hat{\mathbf{J}} = \hat{\mathbf{j}}_1 + \hat{\mathbf{j}}_2$. Since

$$[\hat{\mathbf{J}}, \hat{\mathbf{j}}_1^2] = 0 = [\hat{\mathbf{J}}, \hat{\mathbf{j}}_2^2] \ , \tag{25.106}$$

there exist common eigenstates $|j_1, j_2, J, M\rangle$ for the set of observables $\hat{\mathbf{j}}_1^2$, $\hat{\mathbf{j}}_2^2$, $\hat{\mathbf{M}}^2$ and $\hat{M}_z$. These eigenstates are linear combinations of the individual states,

$$\begin{aligned} |(j_1, j_2)J, M\rangle &= \sum_{m_1,m_2} |j_1, j_2, m_1, m_2\rangle\langle j_1, j_2, m_1, m_2|(j_1, j_2)J, M\rangle \\ &= \sum_{m_1,m_2} |j_1, j_2, m_1, m_2\rangle \left(\begin{array}{cc|c} j_1 & j_2 & J \\ m_1 & m_2 & M \end{array}\right) . \end{aligned} \tag{25.107}$$

The matrix coefficient is called *Clebsch-Gordan coefficient*. The Clebsch-Gordans disappear when the conditions [4]

$$|j_1 - j_2| \leq J \leq j_1 + j_2 \qquad \text{and} \qquad M = -j_1 - j_2, -j_1 - j_2 + 1, .., j_1 + j_2 \tag{25.108}$$

are not satisfied.

The unitary transformation matrices between decoupled and coupled bases,

$$|(j_1, j_2)J, M\rangle = \mathcal{U}_{\text{CGC}}|j_1, m_1; j_2, m_2\rangle \ , \tag{25.109}$$

are listed in tables of the Clebsch-Gordan coefficients.

Example 213 (*Clebsch-Gordans for the coupling of two spins* $\frac{1}{2}$): For example, for the system consisting of two $\frac{1}{2}$ spins we have,

$$\begin{pmatrix} |(\frac{1}{2}, \frac{1}{2})1, +1\rangle \\ |(\frac{1}{2}, \frac{1}{2})1, 0\rangle \\ |(\frac{1}{2}, \frac{1}{2})0, 0\rangle \\ |(\frac{1}{2}, \frac{1}{2})1, -1\rangle \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \sqrt{\frac{1}{2}} & \sqrt{\frac{1}{2}} & 0 \\ 0 & \sqrt{\frac{1}{2}} & -\sqrt{\frac{1}{2}} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} |\frac{1}{2}, +\frac{1}{2}; \frac{1}{2}, +\frac{1}{2}\rangle \\ |\frac{1}{2}, -\frac{1}{2}; \frac{1}{2}, +\frac{1}{2}\rangle \\ |\frac{1}{2}, +\frac{1}{2}; \frac{1}{2}, -\frac{1}{2}\rangle \\ |\frac{1}{2}, -\frac{1}{2}; \frac{1}{2}, -\frac{1}{2}\rangle \end{pmatrix} .$$

In the Excs. 25.4.5.4 and 25.4.5.5 we write all possible states of two angular momenta in decoupled and coupled bases. In Excs. 25.4.5.6, 25.4.5.7, we derive the matrix representation of two spins in the decoupled and the coupled base. In 25.4.5.8, and 25.4.5.9 we practice the transformation between decoupled and coupled bases, and in Exc. 25.4.5.10 we verify a rule guaranteeing the unitarity of the Clebsch-Gordan transformation. Finally in 25.4.5.11, 25.4.5.12, and 25.4.5.13 we study $\mathbf{L} \cdot \mathbf{S}$-coupling.

25.4.4.1 Coupling of three angular moments

Three angular momenta can be coupled in three different configurations: First j_1 with j_2, then the total spin $(j_1, j_2)j_{12}$ with the third one j_3. We use the notation $|[(j_1, j_2)j_{12}, j_3]J\rangle$ or $|[(j_1, j_3)j_{13}, j_2]J\rangle$ or $|[(j_2, j_3)j_{23}, j_1]J\rangle$. The recoupling of three spins

$$\begin{array}{ccccc} \mathbf{j}_1 & + & \mathbf{j}_2 & = & \mathbf{j}_{12} \\ + & & & & + \\ \mathbf{j}_3 & & & & \mathbf{j}_3 \\ = & & & & = \\ \mathbf{j}_{13} & + & \mathbf{j}_2 & = & \mathbf{J} \end{array} \tag{25.110}$$

[4] The Clebsch-Gordans are related to the $(3j)$ de Wigner symbols.

is described by $\{6j\} = \begin{Bmatrix} j_1 & j_3 & j_{13} \\ J & j_{12} & j_2 \end{Bmatrix}$-symbols, for example,

$$|[(j_1, j_2)j_{12}, j_3]J\rangle = \sum_{j_{13}} \{6j\} |[(j_1, j_3)j_{13}, j_2]J\rangle \ . \tag{25.111}$$

25.4.4.2 Notation for atomic states with LS-coupling

In an atom, the spins of the electrons often couple to a total spin, $\mathbf{S} = \sum_k \mathbf{s}_k$, and separately the orbital angular momenta to a total orbital angular momentum, $\mathbf{L} = \sum_k \mathbf{l}_k$. These two total spins now couple to a total angular momentum, $\mathbf{J} = \mathbf{L}+\mathbf{S}$. When this **LS**-*coupling* happens, the following notation is used to characterize the electronic states in atoms:

$$^{2S+1}L_J \ . \tag{25.112}$$

For historical reasons the orbital angular momentum quantum number $L = 0, 1, 2, 3, ...$ is generally labeled by letters $L = S, P, D, F, ...$

25.4.4.3 jj-coupling

There is also the case that for each electron its spin couples to its own orbital angular momentum, $\mathbf{j}_k = \mathbf{l}_k + \mathbf{s}_k$, before coupling to the total angular momenta of other electrons, $\mathbf{J} = \sum_k \mathbf{j}_k$. This is called **jj**-*coupling*. In the case of two electrons the recoupling of the four involved spins

$$\begin{array}{ccccc} \mathbf{l}_1 & + & \mathbf{l}_2 & = & \mathbf{L} \\ + & & + & & + \\ \mathbf{s}_1 & + & \mathbf{s}_2 & = & \mathbf{S} \\ = & & = & & = \\ \mathbf{j}_1 & + & \mathbf{j}_2 & = & \mathbf{J} \end{array} \tag{25.113}$$

is described by $\{9j\} = \begin{Bmatrix} l_1 & l_2 & L \\ s_1 & s_2 & S \\ j_1 & j_2 & J \end{Bmatrix}$-symbols,

$$|[(l_1, s_1)j_1, (l_2, s_2)j_2]J\rangle = \sum_{L,S} \{9j\} |[(l_1, l_2)L, (s_1, s_2)S]J\rangle \ . \tag{25.114}$$

25.4.5 Exercises

25.4.5.1 Ex: Addition/subtraction of angular momenta

Show that $\hat{\mathbf{j}}_1 + \hat{\mathbf{j}}_2$ is an angular momentum, but not $\hat{\mathbf{j}}_1 - \hat{\mathbf{j}}_2$.

25.4.5.2 Ex: CSCO for coupled angular momenta

Be $\hat{\mathbf{J}} = \hat{\mathbf{j}}_1 + \hat{\mathbf{j}}_2$. Show that $\{\hat{\mathbf{j}}_1^2, \hat{\mathbf{j}}_2^2, \hat{\mathbf{J}}^2, \hat{J}_z\}$ is a CSCO; that is, show that
a. $\hat{\mathbf{J}}^2$ commutes with $\hat{\mathbf{j}}_1^2$ and $\hat{\mathbf{j}}_2^2$;
b. $\hat{\mathbf{J}}^2$ does not commute with $\hat{j}_{1z}$ or $\hat{j}_{2z}$ and that we can not specify m_{j1} or m_{j2} together with J.

25.4.5.3 Ex: Multiplicity of coupled angular momenta

Verify $\# = (2j_1 + 1)(2j_2 + 1)$ within the coupled representation.

25.4.5.4 Ex: Possible states of two (de-)coupled angular momenta

Find all possible states with the angular momenta $j_1 = 1$ and $j_2 = 1/2$ in decoupled and coupled pictures.

25.4.5.5 Ex: Fine and hyperfine structure of the rubidium atom ^{85}Rb

1. The rubidium atom ^{85}Rb has one valence electron. In the first excited state this electron has the orbital angular momentum, $L = 1$. What are the possible states?
2. In the fundamental state of this atom the total electronic angular momentum J couples with the spin of the nucleus, $I = 5/2$, to form the total angular momentum $\mathbf{F} = \mathbf{J} + \mathbf{I}$. Determine the possible values for the angular momentum F and the magnetic quantum number m_F.

25.4.5.6 Ex: Expansion of the hyperfine structure of the rubidium atom ^{87}Rb

Determine for the states $S_{1/2}$ and $P_{3/2}$ of an atom with nuclear spin $I = 3/2$ and hyperfine coupling $\hat{\mathbf{J}} \cdot \hat{\mathbf{I}}$ how the eigenstates of the coupled base expand into the decoupled base. Do not consider external magnetic fields.

25.4.5.7 Ex: Transition amplitudes between Zeeman sub-states

a. We consider the atom of ^{87}Rb having the nuclear angular momentum $I = 3/2$. What are the possible hyperfine states F resulting from a coupling of I with the total electronic state angular momentum of the ground state $^2S_{1/2}$? What are the possible Zeeman sub-states of F?
b. What are the possible hyperfine states F' resulting from a coupling of I with the total electronic angular momentum of the excited state $^2P_{3/2}$, $F' = 2$? What are the possible Zeeman sub-states of F'?
c. A transition between a ground hyperfine state and an excited hyperfine state can be described by a coupling of the total angular momentum F with the angular momentum of the photon κ forming the angular momentum of the excited state F'. To see this, we now consider the levels $F = 1$ and $F' = 2$. Expand the coupled angular momentum $|(F, \kappa)F', m_{F'}\rangle = |(1, 1)2, m_{F'}\rangle$ on a decoupled basis for every possible value $m_{F'}$. Use the table in Fig. 25.10 to determine the Clebsch-Gordan coefficients.
Note: The Clebsch-Gordans only compare the oscillator strengths of transitions between Zeeman sub-states of a given set (F, F'). In order to compare the oscillator strengths to other transitions (F, F') it is necessary to calculate $6j$-coefficients.

25.4.5.8 Ex: Gymnastics of angular momentum operators

Consider the problem of adding angular momenta $j_1 = 1$ and $j_2 = 1/2$:
a. What are the possible values of M and J, in which $\hat{J}^2|J, M\rangle = J(J + 1)\hbar^2|J, M\rangle$ and $J_z|j, m\rangle = M\hbar|J, M\rangle$?

b. What are the degeneracy $g_{j_1,j_2}(m)$?
c. Find the base states $\{|J,M\rangle\}$, which are common to the operators $\mathbf{j}_1^2$, $\mathbf{j}_2^2$, $\mathbf{J}$, J_z, expanded in the base $\{|j_1,m_1\rangle \otimes |j_2,m_2\rangle\}$ of the eigenstates of $\mathbf{j}_1^2$, $\mathbf{j}_2^2$, j_{1z}, j_{2z}.

25.4.5.9 Ex: (Un-)coupled bases of the spherical harmonics

Expand the triplet state ^3P_J of strontium in a decoupled basis and write down the transformation matrix between the bases.

25.4.5.10 Ex: Properties of Clebsch-Gordan coefficients

Given the momenta j_1 and j_2, and C_{m_1,m_2} denoting the Clebsch-Gordan coefficients, prove that $\sum_{m_1,m_2} |C_{m_1,m_2}|^2 = 1$.

25.4.5.11 Ex: Spin-orbit coupling

a. Show that the operator $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$ associated with the spin-orbit coupling, satisfies the relation $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}} = \hat{L}_z \hat{S}_z + (\hat{L}_+ \hat{S}_- + \hat{L}_- \hat{S}_+)/2$.
Obtain the matrix representation of the operator $\mathbf{L} \cdot \mathbf{S}$, considering the bases:
b. $\{|m_L\rangle \otimes |m_S\rangle\}$ of the eigenstates which are common to the operators $\hat{\mathbf{L}}^2$, $\hat{\mathbf{S}}^2$, $\hat{L}_z$, $\hat{S}_z$;
c. $\{|J,M\rangle\}$, which is associated with the operators $\hat{\mathbf{L}}^2$, $\hat{\mathbf{S}}^2$, $\hat{\mathbf{J}}^2$, $\hat{J}_z$.
d. Give the explicit matrices for the case $L = 1$ and $S = \frac{1}{2}$ in the representations (b) and (c) and verify that the two representations yield the same eigenvalue spectrum.

25.4.5.12 Ex: Expansion of the spin-orbit coupling

Consider the problem of adding the orbital angular momentum ℓ and a spin 1/2. Obtain the $2\ell + 1$ states $|\ell + 1/2, m_j\rangle$, in addition to the 2ℓ states $|\ell - 1/2, m_j\rangle$ (which constitute a common basis for the operators $\mathbf{l}_1^2$, $\mathbf{s}_2^2$, $\mathbf{j}^2$, j_z), expanded in the base $|m_1, m_2\rangle$ of the eigenstates of the operators $\mathbf{l}^2$, $\mathbf{s}^2$, l_z, s_z. You can simplify the procedure by deriving two recurrence relationships from which the desired states follow [5].

25.4.5.13 Ex: External product of two spins

Derive the matrix representation of the spin-orbit coupling operator $\mathbf{L} \cdot \mathbf{S}$ for $L = 1$ and $S = 1/2$ from the definition of the outer product.

25.4.5.14 Ex: Coupling three spins

Express the states of three coupled $\frac{1}{2}$ spins in the uncoupled basis using the Clebsch-Gordan coefficients. Proceed by first coupling two spins and then coupling the result to the third spin. Compare the dimensions of the Hilbert spaces in both basis and discuss your findings.

Chapter 26

Periodic systems

Many physical systems treat quantum particles in periodic potential. Examples are electrons in crystals or cold atoms in optical lattices. The periodicity gives rise to a wealth of new phenomena, such as Bragg scattering, the formation of energy bands, Mott insulators, or Bloch oscillations. Various theoretical approaches have been developed leading to a deep understanding of the features of crystals, metals, and optical lattices for atomic gases.

In the following sections we will mainly focus on the Bloch model, which is based on introducing periodic boundary conditions to the Schrödinger equation. In the Secs. 26.1 we will give a brief introduction into the Bloch model for electrons in solids, where the periodicity is imposed by the crystalline structure of the material. We will, however, not go into details leaving a comprehensive treatment to specialized textbooks [34, 520]. Then, in Sec. 26.2, we will dig deeper into the symmetries imposed by periodic potentials. In order to keep the formalism simple, we will concentrate on one-dimensional geometries and mostly on sinusoidal potentials. Such potentials are realized, for example, by optical lattices formed by counterpropagating laser beams, which under certain circumstances are capable of trapping atomic gases. The physical realization of these lattices, which can be realized with nearly perfect periodicity, have permitted the experimental observation of phenomena which had been elusive in solid state physics. For this situation we will develop a powerful formalism capable of computing energy spectra and quantum transport phenomena.

26.1 The Bloch model for electrons

The motion of an electron inside a crystal is ruled by a spatially periodic potential $V(\mathbf{r})$ originating from the positively charged crystal atoms and the mean field produced by the quasi-free electrons,

$$V(\mathbf{r}) = V(\mathbf{r} + \mathbf{R}) \ , \tag{26.1}$$

where $\mathbf{R}$ is a vector connecting two arbitrarily chosen atoms of the lattice. With the Hamiltonian

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{r}) \tag{26.2}$$

we can write the Schrödinger equation,

$$\hat{H}\psi(\mathbf{r}) = E\psi(\mathbf{r}) \ . \tag{26.3}$$

Since V and ∇ are invariant under translations $U_{\rm tr}(\mathbf{R})\psi(\mathbf{r}) \equiv \psi(\mathbf{r}+\mathbf{R})$ by a fixed distance $\mathbf{R}$, where the translation operator has been defined in Eq. (23.281), we have,

$$\hat{H}U_{\rm tr}(\mathbf{R})\psi(\mathbf{r}) = EU_{\rm tr}(\mathbf{R})\psi(\mathbf{r}) \ . \tag{26.4}$$

That is, for a non-degenerate eigenvalue [1],

$$\psi(\mathbf{r}+\mathbf{R}) = f(\mathbf{R})\psi(\mathbf{r}) \ . \tag{26.5}$$

This relation holds for all vectors $\mathbf{R}$ of the lattice, such that,

$$f(\mathbf{R}_1+\mathbf{R}_2)\psi(\mathbf{r}) = \psi(\mathbf{r}+\mathbf{R}_1+\mathbf{R}_2) = f(\mathbf{R}_1)\psi(\mathbf{r}+\mathbf{R}_2) = f(\mathbf{R}_1)f(\mathbf{R}_2)\psi(\mathbf{r}) \ . \tag{26.6}$$

The relationship $f(\mathbf{R}_1+\mathbf{R}_2) = f(\mathbf{R}_1)f(\mathbf{R}_2)$ is satisfied by the ansatz $f(\mathbf{R}) \equiv e^{\imath\mathbf{k}\cdot\mathbf{R}}$, where $\mathbf{k}$ is an arbitrary vector of reciprocal space. We get the famous *Bloch theorem*,

$$\boxed{\psi_{\mathbf{k}}(\mathbf{r}+\mathbf{R}) = e^{\imath\mathbf{k}\cdot\mathbf{R}}\psi_{\mathbf{k}}(\mathbf{r})} \ , \tag{26.7}$$

which represents a necessary condition for any eigenfunction $\psi_{\mathbf{k}}$ of the Schrödinger equation with periodic potential. Bloch's theorem simply postulates that, apart from a phase factor, the wavefunction has the same periodicity as the potential.

The *Bloch function*,

$$\boxed{\psi_{\mathbf{k}}(\mathbf{r}) \equiv u_{\mathbf{k}}(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} \qquad \text{with} \qquad u_{\mathbf{k}}(\mathbf{r}+\mathbf{R}) = u_{\mathbf{k}}(\mathbf{r})} \ , \tag{26.8}$$

automatically satisfies Bloch's theorem. That is, the wave function of the electron ψ is a plane wave $e^{\imath\mathbf{k}\cdot\mathbf{r}}$ modulated by a function $u_{\mathbf{k}}$ having the same periodicity as the lattice [530]. Although the vector of the electronic wave is arbitrary, it is possible (and useful) to restrict its value to the first *Brillouin zone* defined by $\mathbf{k} \in [-\pi/\mathbf{a}, \pi/\mathbf{a}]$, where $\mathbf{a}$ is an elementary vector of the lattice. The reason is that we can reduce a wavevector $\mathbf{k}$ in a wavefunction trespassing the first Brillouin zone by an appropriate vector $\mathbf{G}$ of the *reciprocal lattice*,

$$\mathbf{k}' = \mathbf{k} + \mathbf{G} \ , \tag{26.9}$$

yielding,

$$\psi_{\mathbf{k}}(\mathbf{r}) = u_{\mathbf{k}}(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} = u_{\mathbf{k}}(\mathbf{r})e^{-\imath\mathbf{G}\cdot\mathbf{r}}e^{\imath\mathbf{k}'\cdot\mathbf{r}} \ . \tag{26.10}$$

We now define another function $u_{\mathbf{k}'}(\mathbf{r}) \equiv u_{\mathbf{k}}(\mathbf{r})e^{-\imath\mathbf{G}\cdot\mathbf{r}}$, which also satisfies the requirement (26.8), knowing that $\mathbf{G}\cdot\mathbf{R} = n2\pi$, we see,

$$u_{\mathbf{k}'}(\mathbf{r}+\mathbf{R}) = u_{\mathbf{k}}(\mathbf{r}+\mathbf{R})e^{-\imath\mathbf{G}\cdot(\mathbf{r}+\mathbf{R})} = u_{\mathbf{k}}(\mathbf{r})e^{-\imath\mathbf{G}\cdot\mathbf{r}} = u_{\mathbf{k}'}(\mathbf{r}) \ . \tag{26.11}$$

Hence,

$$\psi_{\mathbf{k}}(\mathbf{r}) = u_{\mathbf{k}'}(\mathbf{r})e^{\imath\mathbf{k}'\cdot\mathbf{r}} = \psi_{\mathbf{k}+\mathbf{G}}(\mathbf{r}) \ . \tag{26.12}$$

[1] This also holds true for degenerate eigenvalues if we choose suitable basis of eigenvectors.

26.1.1 Tight binding approximation for quasi-bound electrons

We now assume that the behavior of the electron near an atom is not influenced a lot by atoms further away, so that it is pretty much localized. It is then sensible to expand its wavefunction into states $w(\mathbf{r})$ localized near atoms,

$$\psi_{\mathbf{k}}(\mathbf{r}) = \sum_{j\in\text{lattice}} c_j(\mathbf{k}) w(\mathbf{r}-\mathbf{R}_j) \ . \tag{26.13}$$

In other words, the electron is exposed to a potential $V_{\text{at}}(\mathbf{r}-\mathbf{R}_j)$ in the vicinity of the atom itself located at the position $\mathbf{R}_j$, and it is described by the eigenfunction $w(\mathbf{r}-\mathbf{R}_j)$ with energy E_0,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V_{\text{at}}(\mathbf{r}-\mathbf{R}_j)\right] w(\mathbf{r}-\mathbf{R}_j) = E_0 w(\mathbf{r}-\mathbf{R}_j) \ . \tag{26.14}$$

Even so, the function $\psi_{\mathbf{k}}(\mathbf{r})$ must satisfy Bloch's theorem. This is the case when $c_j(\mathbf{k}) = e^{\imath\mathbf{k}\cdot\mathbf{R}_j}$ and therefore,

$$\boxed{\psi_{\mathbf{k}}(\mathbf{r}) = \frac{1}{\sqrt{N}} \sum_{j\in\text{lattice}} e^{\imath\mathbf{k}\cdot\mathbf{R}_j} w(\mathbf{r}-\mathbf{R}_j)} \ . \tag{26.15}$$

The functions $w(\mathbf{r}-\mathbf{R}_j)$ are called *Wannier functions*. Only, if the spatial extend of $w(\mathbf{r})$ is smaller than the lattice spacing, the electron becomes completely bound to a particular atom.

Example 214 (*Ansatz for a quasi-bound electron wavefunction*): The ansatz (26.15) satisfies Bloch's theorem because,

$$\begin{aligned}\psi_{\mathbf{k}}(\mathbf{r}+\mathbf{R}_j) &= \sum_i e^{\imath\mathbf{k}\cdot\mathbf{R}_i} w(\mathbf{r}-(\mathbf{R}_i-\mathbf{R}_j)) \\ &= e^{\imath\mathbf{k}\cdot\mathbf{R}_j} \sum_i e^{\imath\mathbf{k}\cdot(\mathbf{R}_i-\mathbf{R}_j)} w(\mathbf{r}-(\mathbf{R}_i-\mathbf{R}_j)) = e^{\imath\mathbf{k}\cdot\mathbf{R}_j}\psi_{\mathbf{k}}(\mathbf{r}) \ .\end{aligned}$$

We now calculate the energy $E(\mathbf{k})$ of an electron with the wavevector $\mathbf{k}$ inserting the function $\psi_{\mathbf{k}}(\mathbf{r})$ of (26.15) in the Schrödinger equation (26.3) and obtain,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V(\mathbf{r})\right] \sum_j e^{\imath\mathbf{k}\cdot\mathbf{R}_j} w(\mathbf{r}-\mathbf{R}_j) = E(\mathbf{k}) \sum_j e^{\imath\mathbf{k}\cdot\mathbf{R}_j} w(\mathbf{r}-\mathbf{R}_j) \ . \tag{26.16}$$

$V(\mathbf{r})$ is the potential energy of the electron illustrated in Fig. 26.1 together with the energy $V_{\text{at}}(\mathbf{r}-\mathbf{R}_j)$ of a free electron.

Substituting the kinetic energy term of (26.16) by the kinetic energy of (26.14), we calculate,

$$\sum_j e^{\imath\mathbf{k}\cdot\mathbf{R}_j} [-V_{\text{at}}(\mathbf{r}-\mathbf{R}_j) + E_0 + V(\mathbf{r}) - E(\mathbf{k})] w(\mathbf{r}-\mathbf{R}_j) = 0 \ . \tag{26.17}$$

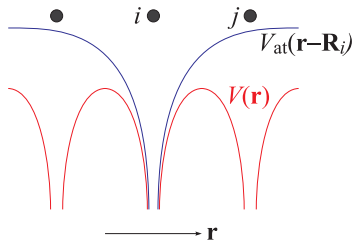

Figure 26.1: Potential energy $V(\mathbf{r})$ of a crystal electron (red) and potential energy $V_{\rm at}(\mathbf{r}-\mathbf{R}_j)$ of the electron of a free atom (blue).

Now, multiplying this equation with $\psi^*_{\mathbf{k}}(\mathbf{r}) = \sum_i e^{-\imath \mathbf{k}\cdot\mathbf{R}_i} w^*(\mathbf{r}-\mathbf{R}_i)$ and integrating over the volume of the crystal, we obtain,

$$[E(\mathbf{k}) - E_0] \sum_{i,j} e^{\imath \mathbf{k}\cdot(\mathbf{R}_j-\mathbf{R}_i)} \int w^*(\mathbf{r}-\mathbf{R}_i) w(\mathbf{r}-\mathbf{R}_j) d^3r \tag{26.18}$$
$$= \sum_{i,j} e^{\imath \mathbf{k}\cdot(\mathbf{R}_j-\mathbf{R}_i)} \int w^*(\mathbf{r}-\mathbf{R}_i)[V(\mathbf{r}) - V_{\rm at}(\mathbf{r}-\mathbf{R}_j)] w(\mathbf{r}-\mathbf{R}_j) d^3r \ .$$

The Wannier functions $w^*(\mathbf{r}-\mathbf{R}_i)$ and $w(\mathbf{r}-\mathbf{R}_j)$ overlap only a little, even for adjacent atoms. That is, they are nearly orthogonal, such that we can neglect the terms $i \neq j$ on the left side. The sum then corresponds to the number N of sites in the lattice. On the right side, we can not neglect the terms involving other sites, because even if the wavefunctions of adjacent sites overlap little, the contribution of the potential difference $|V(\mathbf{r}) - V_{\rm at}(\mathbf{r}-\mathbf{R}_j)|$ is much lower for $\mathbf{r} = \mathbf{R}_j$ than for $\mathbf{r} = \mathbf{R}_i$. On the other hand, as the wavefunctions $w(\mathbf{r}-\mathbf{R}_j)$ disappear quickly when $|\mathbf{r}-\mathbf{R}_j| > |\mathbf{R}_m - \mathbf{R}_j|$, we can focus on adjacent sites (called $\mathbf{R}_m$),

$$N[E(\mathbf{k}) - E_0] = N \int w^*(\mathbf{r}-\mathbf{R}_j)[V(\mathbf{r}) - V_{\rm at}(\mathbf{r}-\mathbf{R}_j)] w(\mathbf{r}-\mathbf{R}_j) d^3r \tag{26.19}$$
$$+ N \sum_{m=\text{adjacent}} e^{\imath \mathbf{k}\cdot(\mathbf{R}_j-\mathbf{R}_m)} \int w^*(\mathbf{r}-\mathbf{R}_m)[V(\mathbf{r}) - V_{\rm at}(\mathbf{r}-\mathbf{R}_j)] w(\mathbf{r}-\mathbf{R}_j) d^3r \ .$$

Example 215 (*Eigenenergies for s orbitals*): Now we further suppose that the eigenfunction $w(\mathbf{r})$ exhibits radial symmetry corresponding to an s orbital. We obtain for the eigenvalues from the Schrödinger equation,

$$E(\mathbf{k}) = E_0 - \alpha - \mathbf{G}amma \sum_{m \text{ adjacent of } j} e^{\imath \mathbf{k}\cdot(\mathbf{R}_j-\mathbf{R}_m)} \tag{26.20}$$

$$\text{with} \quad \alpha = \int w^*(\mathbf{r}-\mathbf{R}_j)[V_{\rm at}(\mathbf{r}-\mathbf{R}_j) - V(\mathbf{r})] w(\mathbf{r}-\mathbf{R}_j) d^3r$$

$$\text{and} \quad \mathbf{G}amma = \int w^*(\mathbf{r}-\mathbf{R}_m)[V_{\rm at}(\mathbf{r}-\mathbf{R}_j) - V(\mathbf{r})] w(\mathbf{r}-\mathbf{R}_j) d^3r \ .$$

The interpretation is as follows: The combination of the atoms in a lattice produces an energy displacement α. In addition, it generates a spitting into a continuous band of energies as a function of reduced wavevector $\mathbf{k}$.

26.1.1.1 Wannier functions

Wannier functions have been defined in (26.15) as a new basis of states localized near atoms in which the electronic wavefunction can be expanded. The transformation (26.15) can be inverted,

$$\boxed{w(\mathbf{r}-\mathbf{R}_j) = \frac{1}{\sqrt{N}}\sum_{\mathbf{k}} e^{-\imath\mathbf{k}\cdot\mathbf{R}_j}\psi_{\mathbf{k}}(\mathbf{r})} = \frac{V}{(2\pi)^d}\int_{BZ} e^{-\imath\mathbf{k}\cdot\mathbf{R}_j}\psi_{\mathbf{k}}(\mathbf{r})d^3k \ , \tag{26.21}$$

which can be checked quickly for one dimension ($R_j = ja$) by inserting the expression into one another,

$$\tfrac{1}{\sqrt{N}}\sum_j e^{\imath kja}w_j(z) = \tfrac{1}{N}\sum_{k'}\sum_j e^{\imath(k-k')ja}\psi_k(z) = \sum_{k'}\delta_{k,k'}\psi_k(z) = \psi_k(z) \ . \tag{26.22}$$

According to (26.21), Wannier functions of an isolated band are defined in terms of Bloch functions (26.8) of the same band. $\mathbf{R}_j$ are lattice points and V the volume of a unit cell. Wannier functions about different lattice points are orthonormal, as will be verified in Exc. 26.1.5.1.

Example 216 (*Wannier function in one dimension*): For example, in one dimension $\psi_k(z) = N^{-1/2}u_0(z)e^{\imath kz}$ for N atoms on a line of lattice constant a, so that $z_j = ja$,

$$w(z-z_n) = \frac{1}{\sqrt{N}}\sum_{k\in[-a/2,a/2]} e^{-\imath kz_j}\psi_k(z) = \frac{1}{N}\sum_k e^{\imath k(z-ja)}u_0(z)$$

$$\longrightarrow \frac{a}{2\pi}\int_{-\pi/a}^{\pi/a} e^{\imath k(z-ja)}u_0(z)dk \simeq \frac{a}{2\pi}u_0(z)\left.\frac{e^{\imath k(z-ja)}}{\imath(z-ja)}\right|_{-\pi/a}^{\pi/a} = u_0(z)\frac{\sin\frac{\pi}{a}(z-z_j)}{\frac{\pi}{a}(z-z_j)} \ .$$

26.1.2 Approximation for quasi-free electrons

Here we assume an essentially homogeneous potential acting on the free electrons and consider the impact of the periodic lattice as a small perturbation. The periodic potential can be decomposed into a Fourier series by the vectors $\mathbf{G}$ of the reciprocal lattice,

$$V(\mathbf{r}) = \sum_{\mathbf{G}} U_{\mathbf{G}}e^{\imath\mathbf{G}\cdot\mathbf{r}} \ . \tag{26.23}$$

Consequently, we can make for Bloch functions (26.10) the following periodic ansatz,

$$\psi_{\mathbf{k}}(\mathbf{r}) = u_{\mathbf{k}}(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} \qquad \text{with} \qquad u_{\mathbf{k}}(\mathbf{r}) = \tfrac{1}{\sqrt{V_c}}\sum_{\mathbf{G}} u_{\mathbf{G}}(\mathbf{k})e^{\imath\mathbf{G}\cdot\mathbf{r}} \ , \tag{26.24}$$

where V_c is the volume of the crystal.

Without periodic potential, the eigenfunctions would be those of a free particle,

$$\psi_{\mathbf{k}}(\mathbf{r}) = \tfrac{1}{V_c}e^{\imath\mathbf{k}\cdot\mathbf{r}} \tag{26.25}$$

with the eigenenergies

$$E_0(\mathbf{k}) = V_0 + \frac{\hbar^2 k^2}{2m} \ . \tag{26.26}$$

Inserting the functions (26.23) and (26.24) in the Schrödinger equation, we obtain,

$$\left[-\tfrac{\hbar^2}{2m}\nabla^2 + \sum_{\mathbf{G}''} U_{\mathbf{G}''} e^{\imath \mathbf{G}''\cdot\mathbf{r}}\right] \tfrac{1}{\sqrt{V_c}} e^{\imath\mathbf{k}\cdot\mathbf{r}} \sum_{\mathbf{G}'} u_{\mathbf{G}'}(\mathbf{k}) e^{\imath\mathbf{G}'\cdot\mathbf{r}} = E(\mathbf{k}) \tfrac{1}{\sqrt{V_c}} e^{\imath\mathbf{k}\cdot\mathbf{r}} \sum_{\mathbf{G}} u_{\mathbf{G}'}(\mathbf{k}) e^{\imath\mathbf{G}'\cdot\mathbf{r}} \ , \tag{26.27}$$

that is,

$$\begin{aligned} &\tfrac{1}{\sqrt{V_c}} \sum_{\mathbf{G}'} \left[-\tfrac{\hbar^2}{2m}(\mathbf{k}+\mathbf{G}')^2 - E(\mathbf{k})\right] u_{\mathbf{G}'}(\mathbf{k}) e^{\imath(\mathbf{k}+\mathbf{G}')\cdot\mathbf{r}} \\ &\quad + \tfrac{1}{\sqrt{V_c}} \sum_{\mathbf{G}''} U_{\mathbf{G}''} e^{\imath\mathbf{G}''\cdot\mathbf{r}} \sum_{\mathbf{G}'} u_{\mathbf{G}'}(\mathbf{k}) e^{\imath(\mathbf{k}+\mathbf{G}')\cdot\mathbf{r}} = 0 \ . \end{aligned} \tag{26.28}$$

Now multiplying with $\frac{1}{\sqrt{V_c}} e^{\imath(\mathbf{k}+\mathbf{G})\cdot\mathbf{r}}$ and integrating over the volume of the crystal (knowing $\frac{1}{V_c}\int_{V_c} e^{\imath\mathbf{G}\cdot\mathbf{r}} dV = \delta_{\mathbf{G},0}$), we obtain,

$$\left[\tfrac{\hbar^2}{2m}(\mathbf{k}+\mathbf{G})^2 - E(\mathbf{k})\right] u_{\mathbf{G}}(\mathbf{k}) + \sum_{\mathbf{G}'} U_{\mathbf{G}-\mathbf{G}'} u_{\mathbf{G}'}(\mathbf{k}) = 0 \ , \tag{26.29}$$

for any value of $\mathbf{G}$.

To estimate the dependence of the Fourier components $u_{\mathbf{G}}(\mathbf{k})$ for $\mathbf{G} \neq 0$ we insert the unperturbed eigenenergies into the equation (26.29) only considering, in the sum over $\mathbf{G}'$, the terms of the first perturbative order, that is, those containing U_0 or $u_0(\mathbf{k})$,

$$\begin{aligned} &\frac{\hbar^2}{2m}[(\mathbf{k}+\mathbf{G})^2 - k^2] u_{\mathbf{G}}(\mathbf{k}) - U_0 u_{\mathbf{G}}(\mathbf{k}) + U_0 u_{\mathbf{G}}(\mathbf{k}) + U_{\mathbf{G}} u_0(\mathbf{k}) = 0 \\ &\Longrightarrow \quad u_{\mathbf{G}}(\mathbf{k}) = \frac{U_{\mathbf{G}} u_0(\mathbf{k})}{\frac{\hbar^2}{2m}[k^2 - (\mathbf{k}+\mathbf{G})^2]} \ . \end{aligned} \tag{26.30}$$

Since the Fourier coefficients $U_{\mathbf{G}}$ have, for $\mathbf{G} \neq 0$, small values, the function $u_{\mathbf{G}}(\mathbf{k})$ is not negligible only for $k^2 \simeq (\mathbf{k}+\mathbf{G})^2$ that is,

$$-2\mathbf{k}\cdot\mathbf{G} \simeq |\mathbf{G}|^2 \ . \tag{26.31}$$

We now want to find out the meaning of this condition ...

For the coefficients $u_0(\mathbf{k})$ and $u_{\mathbf{G}}(\mathbf{k})$ we obtain,

$$\begin{aligned} &\left[\tfrac{\hbar^2}{2m}k^2 - E(\mathbf{k})\right] u_0(\mathbf{k}) + U_0 u_0(\mathbf{k}) + U_{-\mathbf{G}}(\mathbf{k}) u_{\mathbf{G}}(\mathbf{k}) = 0 \\ &\left[\tfrac{\hbar^2}{2m}k^2 - E(\mathbf{k})\right] u_{\mathbf{G}}(\mathbf{k}) + U_{\mathbf{G}} u_0(\mathbf{k}) + U_0(\mathbf{k}) u_{\mathbf{G}}(\mathbf{k}) = 0 \ . \end{aligned} \tag{26.32}$$

From this follows,

$$\left[\tfrac{\hbar^2}{2m}k^2 + U_0 - E(\mathbf{k})\right]^2 = U_{\mathbf{G}} U_{-\mathbf{G}} = 0 \ . \tag{26.33}$$

Since the potential $U(\mathbf{r})$ is real, $U_{-\mathbf{G}} = U^*_{\mathbf{G}}$. Therefore, introducing the eigenenergies $E_0(\mathbf{k})$ of free electrons (26.26),

$$E(\mathbf{k}) = E_0(\mathbf{k}) \pm |U_{\mathbf{G}}| \ . \tag{26.34}$$

Under the influence of the periodic perturbation potential we find at the surfaces of a Brillouin zone an energy splitting developing a forbidden gap in the spectrum. We can understand this observation as follows: In the crystal all electronic waves with wavevectors ending on a surface of a Brillouin zone are reflected by Bragg reflection. In the example of a one-dimensional lattice we understand that the superposition of an incident wave ($k = n\pi/a$) with the reflected one ($k = -n\pi/a$) produces a standing electronic probability density wave ρ being proportional to $\rho_1 \propto \cos^2 n\pi/a$ or $\rho_2 \propto \sin^2 n\pi/a$. The charge density ρ_1 is maximal at the location of the atom in this site, which corresponds to an increased interaction energy; the density ρ_2 is minimal at the location of the atom. This explains the splitting.

The Bloch model can explain many properties of metals, semiconductors and insulators.

26.1.3 The Kronig-Penney model

The *Kronig-Penney model* describes the band structure of a lattice. Let us assume a periodic potential of rectangular wells with valleys of widths a and peaks of widths b,

$$V(x) = U_0 \theta_{\mathrm{mod}(x,a+b)\in[a,a+b]} \ . \tag{26.35}$$

Inserting into the Schrödinger equation the plane wave ansatz $\psi = Ae^{\imath Kx} + Be^{-\imath Kx}$ for the wavefunction in the valley, $0 < x < a$, and $\psi = Ce^{Qx} + De^{-Qx}$ in the peak, $-b < x < 0$, we obtain $\varepsilon = \hbar^2 K^2/2m$ and $U_0 - \varepsilon = \hbar^2 Q^2/2m$. Choosing the constants A, B, C, D such that ψ and $\dot{\psi}$ are continuous in $x = 0, a$, we derive, using the periodicity of the Bloch wave $\psi(a < x < a + b) = \psi(-b < x < 0)e^{\imath k(a+b)}$,

$$\begin{pmatrix} 1 & 1 & -1 & -1 \\ \imath K & -\imath K & -Q & Q \\ e^{\imath Ka} & e^{-\imath Ka} & -e^{-Qb+\imath k(a+b)} & -e^{Qb+\imath k(a+b)} \\ \imath K e^{\imath Ka} & -\imath K e^{-\imath Ka} & -Qe^{-Qb+\imath k(a+b)} & Qe^{Qb+\imath k(a+b)} \end{pmatrix} \begin{pmatrix} A \\ B \\ C \\ D \end{pmatrix} = 0 \ . \tag{26.36}$$

The determinant of the matrix must be zero, or,

$$\frac{Q^2 - K^2}{2QK} \sinh Qb \sin Ka + \cosh Qb \cos Ka = \cos k(a + b) \ . \tag{26.37}$$

For δ-shaped peaks, we let $b = 0$ and $U_0 = \infty$ such that $Q^2 ba/2 = P$, this simplifies to,

$$\frac{P}{Ka} \sin Ka + \cos Ka = \cos ka \ . \tag{26.38}$$

The dispersion relation for light is different. According to [629],

$$-\frac{\sqrt{\varepsilon} + \sqrt{\varepsilon}^{-1}}{2} \sin(\sqrt{\varepsilon}\omega a/c) \sin(\omega a/c) + \cos(\sqrt{\varepsilon}\omega a/c) \cos(\omega a/c) = \cos ka \ . \tag{26.39}$$

For $\varepsilon = 1$ the equation simplifies to $ka = 2\omega a/c$.

26.1.3.1 Photonic density of states

The *photonic density of states* in free space in three dimensions is evaluated from [933],

$$dN = 2\left(\frac{L}{2\pi}\right)^3 \int d^3k = 2\left(\frac{L}{2\pi}\right)^3 k^2 dk \int d\phi d\cos\theta = \frac{L^3\omega^2}{\pi^2 c^3} d\omega \equiv D(\omega)d\omega \ . \quad (26.40)$$

In one dimension,

$$dN = 2\frac{L}{2\pi}dk = \frac{L}{\pi c}d\omega \ . \quad (26.41)$$

The density is normalized $\int_0^{\pi c/L} D(\omega)d\omega = 1$ and the total energy, if all states are populated, is $E \equiv \int_0^{\pi c/L} \omega D(\omega)d\omega = \pi c/L$. However, this applies only if $\omega = ck$. If the dispersion relation is more complicated, for example, inside a cavity or a forbidden photonic band, $\omega = \omega(k)$, we must generalize,

$$D(\omega) = \frac{L}{\pi}\frac{dk}{d\omega} \ . \quad (26.42)$$

Assuming that the dispersion relation is given by the Kronig-Penney model, we obtain gaps in the density-of-states for those values of ω which do not belong to any k.

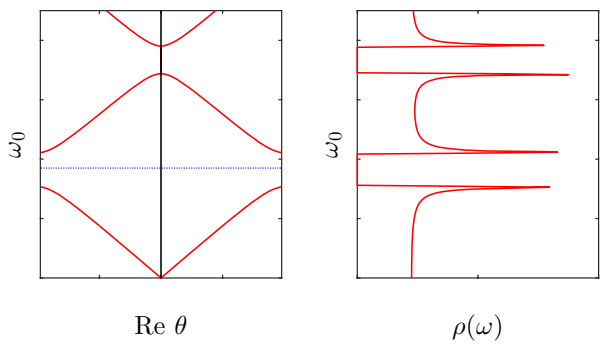

Figure 26.2: (code) Dispersion ratio and state density for a one-dimensional optical lattice.

26.1.4 Bloch oscillations

A *Bloch oscillation* is a phenomenon in solid state physics. It is the oscillation of a particle (e.g., an electron) confined to a periodic potential (e.g. a crystal), when a constant force (e.g., generated by a continuous electric field) acts on it. This phenomenon is very difficult to observe in solid crystals because, due to electron scattering by defects of the lattice [213, 720], the coherent evolution is limited to a small fraction of the Brillouin zone. However, Bloch oscillations were observed in semiconducting superlattices, in ultrathin *Josephson junctions*, and with cold atoms in optical lattices [414, 619].

Let us first show a simple treatment for electrons subject to a constant electric field $\mathcal{E}$. The one-dimensional equation of motion is,

$$\hbar \frac{dk}{dt} = -e\mathcal{E} \ , \tag{26.43}$$

with the solution,

$$k(t) = k(0) - \frac{e\mathcal{E}}{\hbar} t \ . \tag{26.44}$$

The velocity v of the electron is given by,

$$v(k) = \frac{1}{\hbar} \frac{d\mathcal{E}}{dk} \ , \tag{26.45}$$

where $\mathcal{E}(k)$ denotes the *dispersion relation* for a given energy band. We now assume that it has the following form (tight-binding limit),

$$\mathcal{E} = A \cos ak \ , \tag{26.46}$$

where a is the lattice parameter and A a constant. Then, $v(k)$ is given by,

$$v(k) = -\frac{Aa}{\hbar} \sin ak \ , \tag{26.47}$$

and the position of the electron by,

$$x(t) = \int v(k(t))dt = -\frac{A}{e\mathcal{E}} \cos\left(\frac{ae\mathcal{E}}{\hbar} t\right) \ . \tag{26.48}$$

This shows, that the electron is oscillating in real space. The oscillation frequency, called *Bloch frequency* is given by,

$$\omega_{\text{blo}} = \frac{ae|\mathcal{E}|}{\hbar} \ . \tag{26.49}$$

We will provide a deeper discussion in Sec. 26.2.2.

26.1.5 Exercises

26.1.5.1 Ex: Orthonomality of Wannier functions

Verify the orthonomality of Wannier functions.

26.1.5.2 Ex: Effective mass of particles in a lattice

The *effective mass* of particles in a lattice is defined as,

$$\frac{1}{m^*} = \frac{1}{\hbar^2} \frac{d^2 E(k)}{dk^2} \ .$$

Calculate the effective mass of a rubidium atom in a far-detuned optical standing wave.

26.2 One-dimensional optical lattices

In Chp. 24 we studied the motion of particles in free space and inside a potential and learned how to characterize it by states in position space $|z\rangle$, in momentum space $|k\rangle$, or by its energy $|E\rangle$. In free space the energy spectrum is *continuous*, while confined in a potential it is *discrete*, so that it can be labeled by integer numbers $|n\rangle$.

However, between the two opposite cases, totally free and totally confined, there exist more complex potential landscapes, e.g. double-well potentials or periodic potentials. The energy spectra of such potentials can be partially discrete and partially continuous. Generally, low-energy states are almost bound, while high-energy states are almost free. Periodic potentials are paradigmatic examples, as their symmetry allows us to introduce a powerful mathematical formalism based on the Bloch wave expansion [2]

Periodic potentials for quantum particles can be realized artificially. A prominent example are *optical lattices* formed by the interference patterns of intersecting laser beams. Tuned sufficiently far away from atomic resonances the periodically structured light field exerts optical forces on the atoms which can be derived from potentials being proportional to the local light intensity. As these forces are relatively weak, the kinetic energy of the atoms must be very low (typically μK) to allow for their impact to be relevant. In many cases, the depth of the optical lattice only allows for a small number of localized quantum states, so that the quantum nature of the atomic motion becomes highly relevant. Famous examples are the Bloch oscillations and the Mott insulating states.

We are not yet prepared to understand, how these potential arise from the light-atom interaction, as this topic will only be treated in the Secs. 43.2 and in Chp. 48.8.2. However, this is not necessary to understand many of the features of the atomic dynamics in optical lattices. We will thus simply impose a known periodic potential to a cold atomic cloud and study its energetic band structure and the atomic motion. Various three-dimensional crystalline geometries have been realized and studied [485, 396, 99]. In the following, we will mainly focus on one-dimensional lattices, leaving a discussion of phenomena specific to three-dimensional lattices to future sections.

In this section we will elaborate and deepen the formalism of the description of atomic motion in periodic potentials, first recalling the notions of unitary spatial translation, Bloch waves, and Wannier functions, and then applying them to understand the phenomena of localization, Bloch oscillation, and tunneling.

26.2.1 Translations and accelerations in periodic potentials

26.2.1.1 Free particles

In Sec. 23.7.1 we studied the behavior of systems under unitary transformation, in particular, translations and momentum kicks. Spatial translation by a distance a in one dimension along the z-axis was described by the operator $\mathcal{U}_{\mathrm{tr}}(a)$, which acts on

[2] This is somewhat similar to the way in which the second-quantization formalism turned the harmonic trap into an epitome for confining potentials.

position and momentum states,

$$\boxed{\mathcal{U}_{\rm tr}(a) \equiv e^{-\imath \hat{k} a} \quad , \quad \mathcal{U}_{\rm tr}(a)|z\rangle = |z+a\rangle \quad , \quad \mathcal{U}_{\rm tr}(a)|k\rangle = e^{-\imath k a}|k\rangle} \ . \tag{26.50}$$

Obviously, the free particle states $|k\rangle$ are the eigenstates of $\mathcal{U}_{\rm tr}(a)$. Due to the fact that the operator $U_{\rm tr}(a)$ commutes with the free particle Hamiltonian,

$$[\mathcal{U}_{\rm tr}, \hat{H}] = 0 \quad \text{with} \quad \hat{H} = \frac{\hbar^2 \hat{k}^2}{2m} \ , \tag{26.51}$$

the free particle states $|k\rangle$ are also eigenstates of the free particle Hamiltonian.

In Sec. 23.5.7 we showed, how the wavefunctions in position space $\psi(z) \equiv \langle z|\psi\rangle$ and in momentum space $\phi(k) \equiv \langle k|\psi\rangle$ are related via the Fourier theorem [3],

$$e^{\imath k z} = \tfrac{1}{\sqrt{2\pi}} \langle z|k\rangle \ , \tag{26.52}$$

yielding,

$$|z\rangle = \tfrac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} |k\rangle e^{-\imath k z} dk \quad , \quad |k\rangle = \tfrac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} |z\rangle e^{\imath k z} dz \ , \tag{26.53}$$

which allows us to expand any arbitrary state like,

$$|\psi\rangle = \int_{-\infty}^{\infty} |z\rangle \psi(z) dz = \int_{-\infty}^{\infty} |k\rangle \phi(k) dk \ . \tag{26.54}$$

The consistency of (26.53) can easily be checked using $\int_{\mathbb{R}} e^{\imath(k-k')z} dz = 2\pi\delta(k-k')$.

An acceleration g accumulating within a time interval Δt to a change in momentum of $\hbar\kappa = mg\Delta t$ along the z-axis was described in Sec. 23.7.1 by the kick operator $\mathcal{U}_{\rm kc}$, which acts on position and momentum states,

$$\boxed{\mathcal{U}_{\rm kc}(\kappa) \equiv e^{\imath \kappa \hat{z}} \quad , \quad \mathcal{U}_{\rm kc}(\kappa)|k\rangle = |k+\kappa\rangle \quad , \quad \mathcal{U}_{\rm kc}(\kappa)|z\rangle = e^{\imath \kappa z}|z\rangle} \ . \tag{26.55}$$

Obviously, the localized states $|z\rangle$ are the eigenstates of $\mathcal{U}_{\rm kc}(\kappa)$, and this holds even in the presence of a potential $V(z)$. However, the operator $\mathcal{U}_{\rm kc}(\kappa)$ does not commute with the Hamiltonian,

$$\mathcal{U}_{\rm kc}^\dagger(\kappa) \hat{H} \mathcal{U}_{\rm kc}(\kappa) = \mathcal{U}_{\rm kc}^\dagger(\kappa) \frac{\hbar^2 \hat{k}^2}{2m} \mathcal{U}_{\rm kc}(\kappa) = \frac{\hbar^2 (\hat{k}+\kappa)^2}{2m} \neq \hat{H} \ , \tag{26.56}$$

so that the eigenfunctions of the kick operator are NOT eigenfunctions of the Hamiltonian.

In the following, we will extend these thoughts to periodic potentials. In particular, we will see that Bloch and Wannier states represent a natural extension of momentum and position states $|k\rangle$ and $|z\rangle$, respectively. Also, we will use the kick operator extensively in Sec. 26.2.2 in the context of Bloch oscillations.

[3] Or $\langle \lambda^{-1}|z\rangle = e^{-2\pi\imath z/\lambda}$.

26.2.1.2 Periodic potentials

Let us now apply the translation operator (26.50) to particles subject to potentials,

$$\hat{H} = \frac{\hbar^2 \hat{k}^2}{2m} + V(\hat{z}) \ . \tag{26.57}$$

In this case,

$$\mathcal{U}_{\rm tr}^\dagger(a)\hat{H}U_{\rm tr}(a) = \frac{\hbar^2 \hat{k}^2}{2m} + V(\hat{z}+a) \neq \hat{H} \ . \tag{26.58}$$

We see that the translation operator only conserves energy if the potential is periodic, $V(\hat{z}) = V(\hat{z}+a_{\rm l})$ *and* if the distance of translation is $a = a_{\rm l}$. Indeed, in periodic systems,

$$\boxed{[\hat{H},\mathcal{U}_{\rm tr}(a_{\rm l})] = 0 \qquad \text{with} \qquad \mathcal{U}_{\rm tr}(a_{\rm l}) \equiv e^{-\imath \hat{k} a_{\rm l}}} \ . \tag{26.59}$$

If the translation operator commutes with the Hamiltonian, then any eigenstate of $\hat{H}$ is also an eigenstate of $\mathcal{U}_{\rm tr}(a_{\rm l})$, that is,

$$\hat{H}|\psi_k\rangle = E_k|\psi_k\rangle \quad \Longrightarrow \quad \mathcal{U}_{\rm tr}(a_{\rm l})|\psi_k\rangle = e^{-\imath k a_{\rm l}}|\psi_k\rangle \ , \tag{26.60}$$

and we can calculate,

$$\langle z - a_{\rm l}|\psi_k\rangle = \langle z|\mathcal{U}_{\rm tr}(a_{\rm l})|\psi_k\rangle = \langle z|e^{-\imath \hat{k} a_{\rm l}}|\psi_k\rangle = e^{-\imath k a_{\rm l}}\langle z|\psi_k\rangle \ , \tag{26.61}$$

or equivalently,

$$\boxed{\psi_k(z - a_{\rm l}) = e^{-\imath k a_{\rm l}}\psi_k(z)} \ . \tag{26.62}$$

26.2.1.3 Bloch waves

Let us study the kick operator (26.55) in a periodic potential. We define,

$$\hat{H}_{\rm u} \equiv \mathcal{U}_{\rm kc}^\dagger(k)\hat{H}\mathcal{U}_{\rm kc}(k) \qquad \text{and} \qquad |u_k\rangle \equiv \mathcal{U}_{\rm kc}^\dagger(k)|\psi_k\rangle \ , \tag{26.63}$$

so that, using the eigenvalue equation (26.60),

$$\hat{H}_{\rm u}|u_k\rangle = E_k|u_k\rangle \ . \tag{26.64}$$

I.e. the defined functions $|u_k\rangle$ are eigenfunctions of the Hamiltonian (26.63). Furthermore, using (26.62), we calculate,

$$\begin{aligned} u_k(z - a_{\rm l}) &= \mathcal{U}_{\rm kc}^\dagger(k)\psi_k(z - a_{\rm l}) = \mathcal{U}_{\rm kc}^\dagger(k)\mathcal{U}_{\rm tr}(a_{\rm l})\psi_k(z) \\ &= \mathcal{U}_{\rm kc}^\dagger(k)\mathcal{U}_{\rm tr}(a_{\rm l})\mathcal{U}_{\rm kc}(k)u_k(z) = e^{-\imath k(z-a_{\rm l})}e^{-\imath k a_{\rm l}}e^{\imath k z}u_k(z) = u_k(z) \ . \end{aligned} \tag{26.65}$$

This leads us to the Bloch theorem [34],

$$\boxed{\psi_k(z) = e^{\imath k z}u_k(z) \qquad \text{with} \qquad u_k(z) = u_k(z + a_{\rm l}) = u_k^*(z)} \ , \tag{26.66}$$

where we now label the wavefunction with the particle's momentum k. The amplitude $u_k(z)$, called *Bloch wave*, is periodic and can be chosen as real, since it doesn't depend on a phase factor any more. Do the Exc. 26.3.4.1.

In other words, the wavefunction of a particle moving in an infinite periodic potential is, apart from a phase factor $e^{\imath kz}$, periodic and has the amplitude,

$$u_k(z) \equiv |\psi_k(z)| \ . \tag{26.67}$$

Since the Bloch wave is periodic and real, it can be expanded into a Fourier series,

$$u_k(z) = \sum_{j\in\text{lattice}} c_j^k e^{2\imath j k_1 z} \ . \tag{26.68}$$

The expansion coefficients c_j^k are obtained by solving an eigenvalue problem derived from the Schrödinger equation ruling the particle's motion, i.e. they depend on the depth and the shape of the periodic potential. We will see this in the next section.

26.2.2 Band structure in the Bloch state basis

As already pointed out, a sinusoidal periodic potential, $V(z) = V(z + a_1)$, can be generated exploiting the dipolar force of two counterpropagating plane wave laser beams, $e^{\pm\imath k_1 z}$, with wavevectors k_1 and $-k_1$ and tuned to the red side of an atomic transition. In this situation the atoms are attracted to the maxima of the light intensity, the antinodes,

$$\boxed{V(z) = V_0 \cos^2 k_1 z = \tfrac{V_0}{4}|e^{\imath k_1 z} + e^{-\imath k_1 z}|^2 = \tfrac{V_0}{2}[1 + \cos(2k_1 z)]} \ , \tag{26.69}$$

with $V_0 < 0$. If the periodic potential is more complicated, it can be expanded into a Fourier series,

$$V(z) = \sum_{k_1} U_{k_1} e^{2\imath k_1 z} \ , \tag{26.70}$$

but the procedure detailed in the following for the sinusoidal potential can be applied analogously. For the sinusoidal potential the Fourier coefficients are simply $U_0 = \frac{V_0}{2}$ and $U_{\pm k_1} = \frac{V_0}{4}$, so that,

$$V(z) = V_0(\tfrac{1}{2} + \tfrac{1}{4}e^{2\imath k_1 z} + \tfrac{1}{4}e^{-2\imath k_1 z}) \ , \tag{26.71}$$

where we suppressed the band index on the field operators for simplicity of notation, when discussing single-band problems. The goal is obviously to solve the Schrödinger equation,

$$\hat{H}|\psi\rangle = \left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + V(z)\right)|\psi\rangle = E|\psi\rangle \ . \tag{26.72}$$

26.2.2.1 Solving the Schrödinger equation

To solve the Schrödinger equation, we expand the wavefunction into plane waves,

$$\psi(z) = \sum_k c_k e^{\imath kz} \ , \tag{26.73}$$

and insert this expansion into Schrödinger's stationary equation (26.72),

$$\left(\frac{-\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + V_0(\tfrac{1}{2} + \tfrac{1}{4}e^{2\imath k_1 z} + \tfrac{1}{4}e^{-2\imath k_1 z})\right)\sum_k c_k e^{\imath kz} = E\sum_k c_k e^{\imath kz} \ . \tag{26.74}$$

taking the potential from (26.71). We get,

$$\left(\frac{\hbar^2 k^2}{2m} + \frac{V_0}{2}\right) c_k + \frac{V_0}{4} c_{k-2k_1} + \frac{V_0}{4} c_{k+2k_1} = E c_k \ . \tag{26.75}$$

We now define two new parameters, the *quasi-momentum* q and the *Bloch band* n such that,

$$\boxed{k = q + 2jk_1 \qquad \text{with} \qquad q \in [-k_1, k_1] \qquad \text{and} \qquad j \in \mathbb{Z}} \ . \tag{26.76}$$

Also, we define an abbreviation called *recoil frequency* ω_{rec} and use it to scale the energies [4],

$$\omega_{\text{rec}} = \frac{\hbar {k_1}^2}{2m} \quad , \quad \tilde{V}_0 \equiv \frac{V_0}{\hbar\omega_{\text{rec}}} \quad , \quad \tilde{E} \equiv \frac{E}{\hbar\omega_{\text{rec}}} \quad , \quad \tilde{q} \equiv \frac{q}{k_1} \ . \tag{26.77}$$

With this, (26.75) reads,

$$[(2j+\tilde{q})^2 + \tfrac{1}{2}\tilde{V}_0] c_{2jk_1+q} + \tfrac{1}{4}\tilde{V}_0 c_{2jk_1+q-2k_1} + \tfrac{1}{4}\tilde{V}_0 c_{2jk_1+q+2k_1} = \tilde{E} c_{2jk_1+q} \ , \tag{26.78}$$

or in matrix notation,

$$\hat{H}\mathbf{c} = \hbar\omega_{\text{rec}}\tilde{E}\mathbf{c} \ . \tag{26.79}$$

where the matrix is around $j = .., -1, 0, +1, ..$:

$$\boxed{\hat{H} = \hbar\omega_{\text{rec}} \begin{pmatrix} \ddots & & & & \\ & (\tilde{q}-2)^2 + \frac{1}{2}\tilde{V}_0 & \frac{1}{4}\tilde{V}_0 & & \\ & \frac{1}{4}\tilde{V}_0 & \tilde{q}^2 + \frac{1}{2}\tilde{V}_0 & \frac{1}{4}V_0 & \\ & & \frac{1}{4}\tilde{V}_0 & (\tilde{q}+2)^2 + \frac{1}{2}\tilde{V}_0 & \\ & & & & \ddots \end{pmatrix} \quad , \quad \mathbf{c} = \begin{pmatrix} \vdots \\ c_{q-2k_1} \\ c_q \\ c_{q+2k_1} \\ \vdots \end{pmatrix}} \ . \tag{26.80}$$

The Hamiltonian in (26.80) is tridiagonal, i.e. it consists of only three diagonals, which is due to the sinusoidal shape of the optical potential. For non-sinusoidal potentials, whose Fourier expansion has more components, more side-diagonals will appear.

Solution of (26.80) yields a set of eigenenergies E and eigenvectors $\mathbf{c}$, whose number will be equal to the number of neighboring lattice sites j considered in the matrix of (26.80). Hence, for a given k, or equivalently (n, q),

$$\hat{H}|n, q\rangle = E_q^{(n)}|n, q\rangle \ , \tag{26.81}$$

[4] The reason for the terminology, which will become clear after a study of Sec. 43.2, is that the $\hbar\omega_{\text{rec}}$ is the kinetic energy of an atom having received two units of photonic momenta.

and we can compute the particle's wavefunction from (26.73) [5,6],

$$\boxed{\langle z|n,q\rangle = \psi_q^{(n)}(z) = \tfrac{1}{\sqrt{2\pi}} \sum_{j\in\text{lattice}} c_{q+2jk_1}^{(n)} e^{\imath(q+2jk_1)z}} \ , \tag{26.82}$$

where from now on we will call the particle state $|\psi\rangle$ given in the Bloch basis a *Bloch state* $|n,q\rangle$. The eigenenergies $E_q^{(n)}$ are shown in Fig. 26.3(a) as a function of q for the lowest-lying Bloch bands, and Fig. 26.3(b) shows the spatial Bloch functions for the lowest bands. Eq. (26.82) allows us to expand a Bloch state in a position basis,

$$|n,q\rangle = \int_{\mathbb{R}} |z\rangle\langle z|n,q\rangle dz = \tfrac{1}{\sqrt{2\pi}} \sum_{j\in\mathbb{Z}} c_{q+2jk_1}^{(n)} \int_{\mathbb{R}} |z\rangle e^{\imath(q+2jk_1)z} dz \ . \tag{26.83}$$

Fig. 26.3 shows the energy spectrum of optical lattices for different lattice depths. Also shown in Fig. 26.3(a,c) is the level structure of a harmonic oscillator approximating a lattice site. Also shown in Fig. 26.3(b,d) as black dashed and dotted lines is the free particle dispersion relation corresponding to $V_0 = 0$.

26.2.2.2 Band structure of the energy spectrum

The energy spectrum calculated in Fig. 26.3 displays a hybrid structure consisting of partially bound and partially free states. The spectrum breaks down into energy intervals called *bands*, where a quasi-momentum q can be found so that the energy E_q is within this interval, and *band gaps* where no such quasi-momentum exists. At low energies ($\tilde{E} \ll 0$), the energy width of the bands converges toward a δ-function. At very low energies near the bottom ($E \simeq V_0$) where the standing wave potential resembles a harmonic oscillator, the energy levels are equidistant. On the other hand, closer to the threshold ($\tilde{E} \lesssim 0$), the bands become larger, and this is due to the possibility of tunneling between adjacent potential sites: the particles are not totally localized, but not totally free neither. At high energies ($\tilde{E}\mathbf{G}g0$), the bands join to a continuum, while the band gaps disappear. The dispersion relation then resembles that of a free particle.

The energy spectrum thus consists of a discrete sequence (labeled by an integer number $n \in \mathbb{N}$) of bands within which any energy state $E_q^{(n)}$ can be reached via a proper choice of the quasi-momentum q. It is not surprising that, unlike for states of totally free particles $|k\rangle$ and states of totally bound particles $|n\rangle$, two quantum numbers are necessary to label all possible states $|n,q\rangle$ [7,8].

[5] The requirement that $\psi(z)$ satisfies the Schrödinger equation is equivalent to the condition that $\mathbf{c}$ satisfies an eigenvalue equation. Let $\mathcal{U}$ be the matrix of the eigenvectors of $\hat{H}$ and $\hat{E}$ the diagonal matrix of eigenvalues: $\hat{H} = \mathcal{U}^{-1}\hat{E}\mathcal{U}$ gives $\hat{E}\mathcal{U}\mathbf{c} = E\mathcal{U}\mathbf{c}$, such that $\mathcal{U}\mathbf{c}$ can be understood as eigenvectors.

[6] Alternatively, we define $d_{2jk_1+k} \equiv c_{2jk_1+k+2k_1}/c_{2jk_1+k}$, in which case Eq. (26.79) becomes,

$$d_{2jk_1+k-2k_1} = \frac{V_0}{\frac{\hbar^2}{m}(2jk_1+k)^2 - 2\varepsilon - V_0(2+d_{2jk_1+k})} \ .$$

[7] This is intuitively clear, considering the fact that tunneling introduces a coupling between different potential sites.

[8] The necessity of two quantum numbers indicates that two commuting observables are required to form a complete set for description of the system.

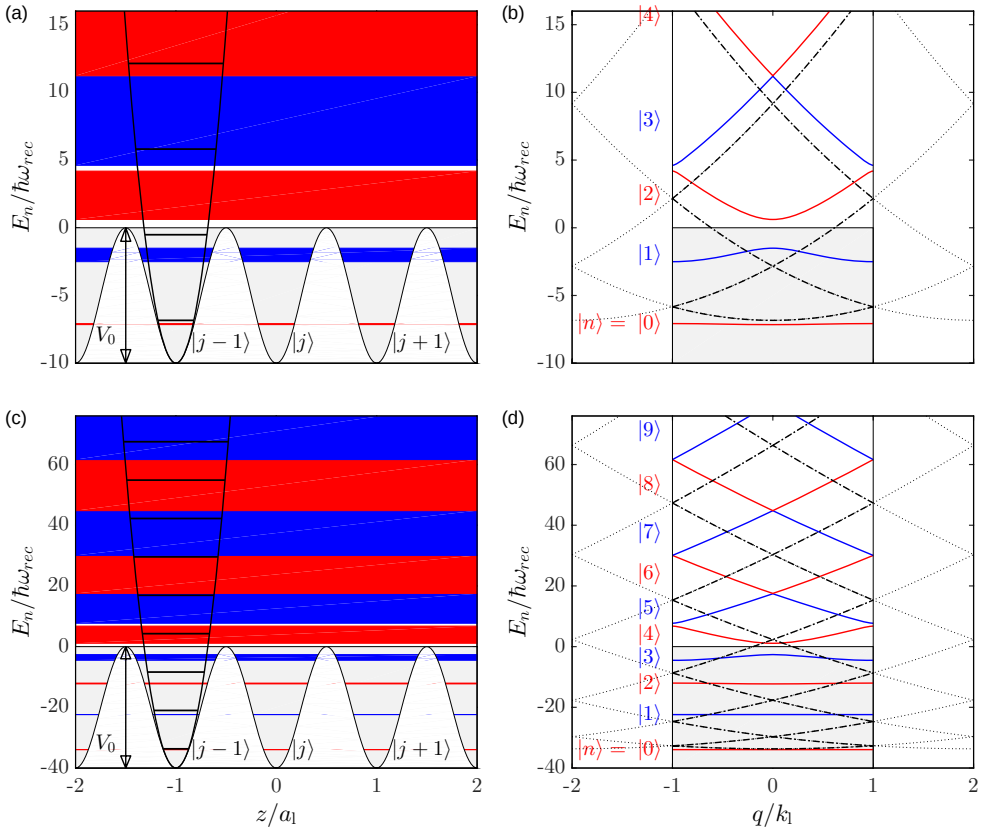

Figure 26.3: (code) (a,c) Lattice potential and band structure for $V_0/\hbar\omega_{\rm rec} = -10$ and -40, respectively. (b,d) Dispersion relation in momentum space and energy levels for the same potential depths as in (a,c). The colors of the solid lines correspond to the energy bands in (a,c).

To estimate the width of the forbidden band gap, we cut out a 2×2 matrix within the matrix $\hat{H}$ and neglect its coupling with the others submatrices,

$$\hat{H}_s = \hbar\omega_{\rm rec}\begin{pmatrix} (\tilde{q}-2)^2 + \frac{1}{2}\tilde{V}_0 & \frac{1}{4}\tilde{V}_0 \\ \frac{1}{4}\tilde{V}_0 & \tilde{q}^2 + \frac{1}{2}\tilde{V}_0 \end{pmatrix} . \tag{26.84}$$

At the edges of the Brillouin zone, $q = \pm k_l$, we get the eigenvalues,

$$E = \frac{2\hbar^2 {k_l}^2}{m} + V_0 \pm \tfrac{V_0}{2} = E_{\rm rec}\left(4 + \tilde{V}_0 + \tfrac{\tilde{V}_0}{2}\right) , \tag{26.85}$$

that is, the band gap is $\Delta E = V_0$.

Sufficiently large band gaps impede small forces to induce couplings to states with very different energies located in different bands. Exceptions are observed near band edges, where the bands approach each other and coupling may occur via Landau-Zener tunneling transitions.

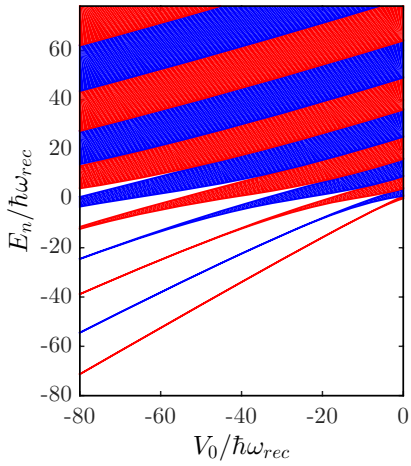

Figure 26.4: (code) Band structure as a function of potential depth. The colored areas are allowed energy bands.

Example 217 (*Very shallow and very deep potentials*): For very shallow potentials, $|V_0| \ll \hbar^2(2k_1)^2/2m$, we can neglect the coefficients V_0 in the Eq. (26.79) and we find,

$$E \simeq \frac{\hbar^2 q^2}{2m} = E_{\text{rec}} \frac{q^2}{{k_1}^2} \ , \tag{26.86}$$

which corresponds to the dispersion relation for free particles.
On the other hand, looking *at the bottom* of very deep potentials, $V_0 \mathbf{G} g \hbar^2 (2k_1)^2/2m$, we can harmonically approximate the cosine potential by $V(z) \approx 2V_0 + \frac{m}{2}\omega^2 z^2$ with $\omega = 2k_1\sqrt{V_0/m} = \hbar^{-1}\sqrt{2|V_0|E_{\text{rec}}}$. For this case we expect,

$$E \simeq 2V_0 + \hbar\omega\left(n + \tfrac{1}{2}\right) \ . \tag{26.87}$$

26.2.2.3 Momentum representation of Bloch states

Instead of projecting the Bloch state onto position space, as done in (26.82), we may also project it on momentum space,

$$\begin{aligned}\langle k|n,q\rangle &= \langle k| \int_{\mathbb{R}} |z\rangle\langle z|n,q\rangle dz \overset{(26.52)}{=} \tfrac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{-\imath kz} \langle z|n,q\rangle(z) dz \\ &\overset{(26.82)}{=} \tfrac{1}{2\pi} \int_{\mathbb{R}} e^{-\imath kz} \sum_{j\in\mathbb{Z}} c^{(n)}_{q+2jk_1} e^{\imath(q+2jk_1)z} dz = \sum_{j\in\mathbb{Z}} c^{(n)}_{q+2jk_1} \delta(q+2jk_1-k) \ .\end{aligned} \tag{26.88}$$

Hence, we find, that,

$$\boxed{\langle k|n,q\rangle = c^{(n)}_k} \ , \tag{26.89}$$

which allows us to expand a Bloch state in a momentum basis,

$$
\begin{aligned}
|n,q\rangle &= \int_{\mathbb{R}} |k\rangle\langle k|n,q\rangle dk = \int_{\mathbb{R}} |k\rangle c_k^{(n)} dk \\
&= \int_{\mathbb{R}} |k\rangle \sum_{j\in\text{lattice}} c_{q+2jk_l}^{(n)} \delta(q+2jk_l-k) dk = \sum_j |q+2jk_l\rangle c_{q+2jk_l}^{(n)} \ .
\end{aligned}
\tag{26.90}
$$

Apparently, each Bloch state with a given quasi-momentum consists of a comb of real momenta, $k = q, q \pm 2k_l, q \pm 4k_l, \ldots$.

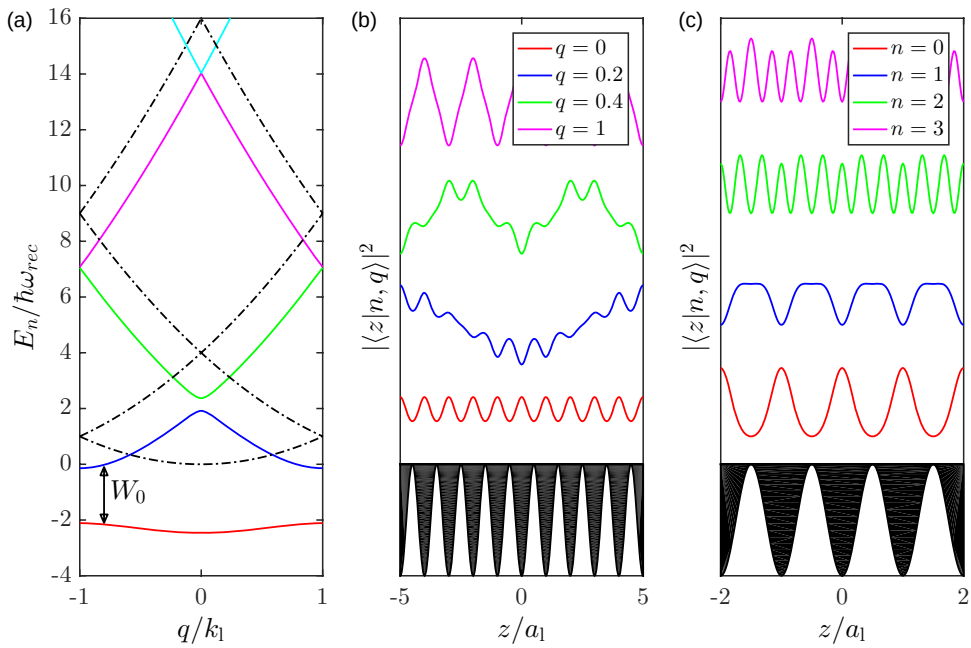

Figure 26.5: (code) (a) Bloch bands with a potential depth of $V_0 = -4\hbar\omega_{\text{rec}}$ and without potential, $V_0 = 0$ (black dash-dotted line). (b) Bloch waves for the same potential for the lowest Bloch band $n = 0$ at various quasi-momenta q. (c) Bloch waves for the four lowest Bloch bands at $q = 0.3k_l$.

Being eigenstates of a Hermitian operator, the Bloch states form an orthonormal basis,

$$
\boxed{\langle n',q'|n,q\rangle = \int_{\mathbb{R}} \langle n',q'|z\rangle\langle z|n,q\rangle dz = \int_{\mathbb{R}} \langle n',q'|k\rangle\langle k|n,q\rangle dk = \delta_{n,n'}\delta(q-q')} \ ,
\tag{26.91}
$$

and therefore behave much like momentum eigenstates.

26.2.3 Localization and tunneling in the Wannier state basis

In Sec. 26.2.2 we outlined the Bloch representation, which provides a basis *leaving the optical lattice Hamiltonian diagonal*,

$$\hat{H} = \sum_n \int_{-k_l}^{k_l} |n,q\rangle E_q^{(n)} \langle n,q| dq \ . \tag{26.92}$$

Thus, the Bloch basis is the basis of choice to calculate the energy spectra. For a given band, the Bloch states are (quasi-)momentum eigenstates q corresponding to plane waves in position space. Nevertheless, other auxiliary basis sets can be useful, e.g. for the description of transport phenomena. In the following, we will develop as an alternative the Wannier representation, which provides a basis of states localized in position space at lattice position sites j.

Table 26.1: Translation and kick acting on Bloch and Wannier states. Eigenvalue equations are emphasized in blue color.

	free space	lattice
Hamiltonian	$\hat{H} = \frac{\hbar^2 k^2}{2m}$	$\hat{H} = \frac{\hbar^2 k^2}{2m} + V_0 \cos^2 k_l z$

	$\mathcal{U}_{\rm kc}(\kappa)\lvert k\rangle = \lvert k+\kappa\rangle$	$\mathcal{U}_{\rm kc}(k_l)\lvert n,q\rangle = \lvert n+1,q\rangle$

Tab. 26.1 provides an overview comparing Bloch and Wannier states. We see that the Bloch states $|n,q\rangle$ are eigenstates of the translation operator $U_{\rm tr}(ja_l)$, and the eigenvalues are labeled by phase factors. Similarly, the Wannier states are eigenstates of the kick operator $U_{\rm kc}(k_l)$, and the eigenvalues are labeled by phase factors.

26.2.3.1 Localization

Let us for example consider a state perfectly localized at z_c in position space near a particular antinode of a standing wave, $|\psi_c\rangle \equiv |z_c\rangle$. According to (26.52), the wavefunctions of this in position and momentum space are,

$$\langle z|z_c\rangle = \delta(z - z_c) \qquad \text{and} \qquad \langle k|z_c\rangle = \tfrac{1}{\sqrt{2\pi}} e^{-\imath k z_c} \ , \tag{26.93}$$

which corresponds to a plane wave. Hence, we can expand the wavefunction in momentum space like,

$$|\psi_c\rangle = \tfrac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |k\rangle e^{-\imath k z_c} dk \equiv \tfrac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |k\rangle e^{\imath\varphi(k)} dk \ . \tag{26.94}$$

That is, to completely localize a particle, its momentum distribution must contain all components $k \in [-\infty, \infty]$ with equal amplitudes. For a particle in a single band of a 1D lattice, however, $q \in [-k_1, k_1]$ remembering $k_1 = 2\pi/\lambda_1 = \pi/a_1$, and the question is, which phase distribution $\varphi(q)$ can give optimal localization.

Example 218 (*Localization without potential*): The plane waves (26.93) are eigenstates of the particle's motion in the absence of a potential, $V_0 = 0$. Nevertheless, it is instructive to try localizing a particle within a single band,

$$|z_c\rangle = \int_{-k_1}^{k_1} |q\rangle e^{\imath\varphi(q)} dq \quad \Longrightarrow \quad \langle z|z_c\rangle = \frac{2\sin k_1(z - z_c)}{z - z_c} = 2k_1 \operatorname{sinc} \frac{z - z_c}{a_1} \ . \tag{26.95}$$

It is now remarkable, that states $|\psi_{z_c}\rangle$ localized at discrete values of the position coordinate, $z_c = ja_1$ with $j \in \mathbb{Z}$, are orthogonal. Indeed, we find,

$$\begin{aligned} \langle z_c'|z_c\rangle = \int_{-k_1}^{k_1}\int_{-k_1}^{k_1} \langle q'|q\rangle e^{\imath(q' z_c' - q z_c)} dq dq' &= \frac{2\sin k_1(z_c' - z_c)}{z_c' - z_c} \\ &\longrightarrow \frac{2\sin k_1(j' - j)a_1}{(j' - j)a_1} = 2k_1\delta_{j'j} \ . \end{aligned} \tag{26.96}$$

26.2.3.2 Wannier functions for 1D optical lattices

In a (red-detuned) standing light wave generating a dipolar potential, we call 'lattice sites' the locations on the z-axis where the potential is minimized. For the cosine potential (26.69) with $V_0 < 0$ these locations are given by $z_j = ja_1$. We define the Wannier state localized near a lattice site as [9],

$$\boxed{|n, j\rangle \equiv \sqrt{a_1}|n, z_j\rangle = \sqrt{\tfrac{a_1}{2\pi}} \int_{-k_1}^{k_1} e^{-\imath q z_j} |n, q\rangle dq} \ , \tag{26.97}$$

[9] Remember that, with this definition, the Bloch states $|n, q\rangle$ have units of cm$^{1/2}$, the Wannier states defined as $|n, z_j\rangle$ of cm$^{-1/2}$, and the Wannier states defined as $|n, j\rangle \equiv \sqrt{a_1}|n, z_j\rangle$ are dimensionless. The normalization factor 2π appearing in the Fourier transform is symmetrically divided with the inverse Fourier transform.

where $|n,q\rangle$ is the Bloch state. Applying the discrete translation operator (26.56) to Bloch states,

$$\mathcal{U}_{\rm tr}(a_1)|n,q\rangle = e^{-\imath q a_1}|n,q\rangle \ , \tag{26.98}$$

we find that,

$$\mathcal{U}_{\rm tr}(a_1)|n,z_j\rangle = \mathcal{U}_{\rm tr}(a_1)\int_{-k_1}^{k_1}|n,q\rangle\tfrac{e^{-\imath q z_j}}{\sqrt{2\pi}}dq = \int_{-k_1}^{k_1}e^{-\imath q a_1}\tfrac{e^{-\imath q j a_1}}{\sqrt{2\pi}}|n,q\rangle dq = |n,z_{j+1}\rangle \ . \tag{26.99}$$

Because of this, we can reference all Wannier functions $|n,z_j\rangle$ to the $j=0$ one, so that each band has a unique Wannier function $|n,z_0\rangle$. We have,

$$|n,z_j\rangle = \mathcal{U}_{\rm tr}(z_j)|n,z_0\rangle = e^{-\imath q z_j}\int_{-k_1}^{k_1}\tfrac{1}{\sqrt{2\pi}}|n,q\rangle dq \ . \tag{26.100}$$

The inverse relationship to the definition (26.97) is easily derived,

$$|n,q\rangle = \int_{-k_1}^{k_1}\delta(q-q')|n,q'\rangle dq' = \tfrac{a_1}{2\pi}\int_{-k_1}^{k_1}\sum_j e^{\imath j(q-q')a_1}|n,q'\rangle dq' = \sum_j \tfrac{a_1}{\sqrt{2\pi}}e^{\imath q z_j}|n,z_j\rangle \ . \tag{26.101}$$

Example 219 (*Equivalence of Bloch and Wannier state basis*): At first glance, the equivalence of the continuous basis of Bloch states labeled by their quasi-momentum q and the discrete basis of Wannier states labeled by their lattice sites may be surprising. The equivalence is, however, due to an approximation done by taking the continuum limit, $\sum_q \longrightarrow a_1\int dq/2\pi$. For finite lattices extending over M sites, the allowed quasi-momenta are $q=\pi j/Ma_1$ with $j=-M/2+1,...,M/2$.
The mechanism at the origin of the formation of energy bands in periodic potentials is readily understood in a toy model. Fig. 26.6 shows numerically calculated wavefunctions of bound states in a double-well potential. We observe that the bound states split into a symmetric wavefunction with a large amplitude inside the barrier and an anti-symmetric wavefunction with a small amplitude. The energy distance decreases at larger barriers.

The **spatial representation** of a Wannier state is obtained by projecting onto position space,

$$\boxed{\langle z|n,z_j\rangle = \langle z|\int_{-k_1}^{k_1}\tfrac{e^{-\imath q z_j}}{\sqrt{2\pi}}|n,q\rangle dq = \int_{-k_1}^{k_1}\tfrac{e^{-\imath q z_j}}{\sqrt{2\pi}}\langle z|n,q\rangle dq} \ . \tag{26.102}$$

Again, because of $\langle z|n,z_j\rangle = \langle z-z_j|n,z_j\rangle$, there is a unique Wannier function for each band copied to each lattice site. Inserting the solution (26.82) for the Bloch states, we find,

$$\langle z|n,z_j\rangle = \tfrac{1}{2\pi}\int_{-k_1}^{k_1}e^{-\imath q z_j}\sum_{j\in\mathbb{Z}}c^{(n)}_{q+2jk_1}e^{\imath(q+2jk_1)z}dq \ . \tag{26.103}$$

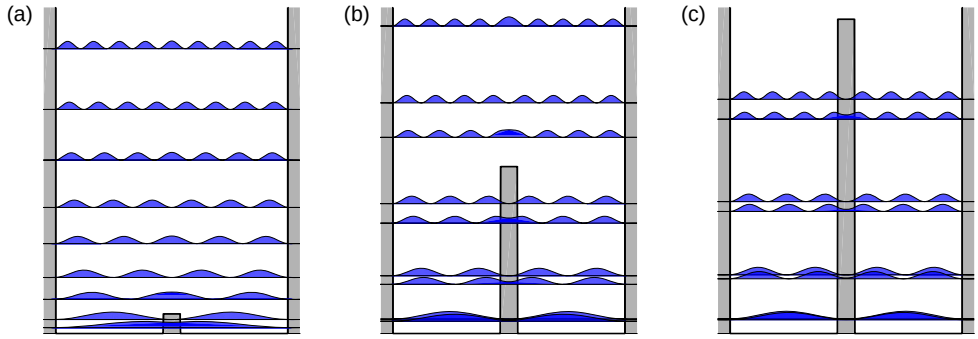

Figure 26.6: (code) Wavefunctions of bound states in a double-well potential calculated using the Fourier grid method (see Sec. 24.4.2).

Wannier function are real, definite parity, and decay exponentially fast at infinity,

$$\langle z|n,z_0\rangle = \langle z|n,z_0\rangle^* = \pm\langle -z|n,z_0\rangle \ . \tag{26.104}$$

Let us now calculate the **momentum representation** of Wannier states, which is obtained by projecting onto momentum space,

$$\boxed{\langle k|n,z_j\rangle = \langle k|\int_{-\infty}^{\infty}|z\rangle\langle z|n,z_j\rangle dz = \int_{-\infty}^{\infty}\frac{e^{-\imath kz}}{\sqrt{2\pi}}\langle z|n,z_j\rangle dz} \ . \tag{26.105}$$

The momentum representation of Wannier states is also related to the momentum representation of Bloch states,

$$\langle k|z_j\rangle = \langle k|\int_{-k_1}^{k_1}|n,q\rangle\langle n,q|n,z_j\rangle dq \overset{(26.89)}{=} \int_{-k_1}^{k_1}\frac{e^{-\imath qz_j}}{\sqrt{2\pi}}\langle k|n,q\rangle dk \ . \tag{26.106}$$

Hence we find that, in the same way as $|z\rangle$ and $|k\rangle$ in free space are Fourier transform pairs related by $\langle k|z\rangle = e^{-\imath kz}/\sqrt{2\pi}$, in a periodic potential $|n,q\rangle$ and $|n,z_j\rangle$ are Fourier transform pairs related by,

$$\langle n,q|n,z_j\rangle = \frac{e^{-\imath qz_j}}{\sqrt{2\pi}} = \frac{e^{-\imath\pi j\bar{q}}}{\sqrt{2\pi}} \ . \tag{26.107}$$

Inserting the solution (26.82) for the Bloch states, we find,

$$\begin{aligned}\langle k|n,z_j\rangle &= \int_{-k_1}^{k_1}\frac{e^{-\imath qz_j}}{\sqrt{2\pi}}c_k^{(n)}dq \qquad (26.108)\\ &= \frac{1}{\sqrt{2\pi}}\sum_{j\in\mathbb{Z}}\int_{-k_1}^{k_1}e^{-\imath qz_j}c_{q+2jk_1}^{(n)}\delta(q+2jk_1-k)dq = \sum_{j\in\mathbb{Z}}\frac{e^{\imath(2jk_1-k)z_j}}{\sqrt{2\pi}}c_k^{(n)} \ .\end{aligned}$$

In other words, $\langle k|n,z_0\rangle$ is the continuous function that includes all the 'comb teeth' of the Bloch functions. We can then rewrite any Bloch function in terms of $\langle k|n,z_0\rangle$ using

(18.105) [10],

$$\langle k|n,q\rangle = \sum_{j\in\mathbb{Z}} \langle k|n,z_j\rangle\langle n,z_j|n,q\rangle = \sum_{j\in\mathbb{Z}} \frac{e^{\imath q z_j}}{\sqrt{2\pi}} \langle k|n,z_j\rangle \ . \tag{26.109}$$

Wannier states form an orthonormal basis just like Bloch states,

$$\boxed{\langle n',z_{j'}|n,z_j\rangle = \int \langle n',z_{j'}|z\rangle\langle z|n,z_j\rangle dz = \int \langle n',z_{j'}|k\rangle\langle k|n,z_j\rangle dk = \delta_{n,n'}\delta_{j,j'}} \ , \tag{26.110}$$

as we will show in Exc. 26.3.4.2.

In Exc. 26.3.4.3 we approximate Wannier functions for sinusoidal potentials.

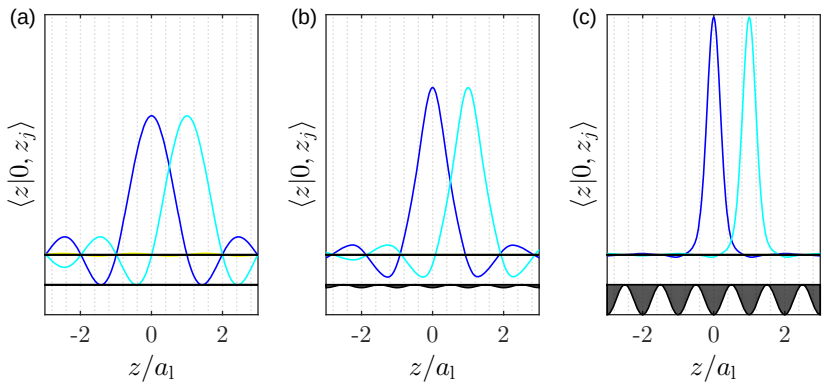

Figure 26.7: (code) Wannier functions for the lowest Bloch band $n = 0$ and different trap depths (a) $\tilde{E} = 0$, (b) $\tilde{E} = 1$, and (c) $\tilde{E} = 10$. The cyan curves are displaced with respect to the blue ones by one lattice site.

26.2.3.3 Tunneling between adjacent lattice sites

With *tunneling* we mean quantum transport between adjacent lattice sites. To develop the formalism for this phenomenon we use the second-quantized notation [914] in analogy to the procedure introduced for the harmonic oscillator in Sec. 24.5.1. The advantage of this formalism is that it not only allows to describe single atom dynamics, but can be extended to account for many interacting particles obeying certain exchange statistics, as we will see in Sec. 51.4.2.

From the single-atom eigenenergies of the Hamiltonian, that has already been

[10] Remembering Fourier transform and series,

$$\int_{\mathbb{R}} e^{\imath(k-k')x}dx = 2\pi\delta(k-k') \quad \Leftrightarrow \int_{\mathbb{R}} e^{\imath k(x-x')}dk = 2\pi\delta(x-x') \ , \quad \int_{\mathbb{R}} x e^{\imath k(x-x')}dx = 2\pi\delta(x-x')\imath\frac{d}{dk} \ ,$$
$$\sum_{j\in\mathbb{Z}} e^{\imath(k-k')ja} = \tfrac{2\pi}{a}\delta(k-k') \quad \Leftrightarrow \int_{-k_1}^{k_1} e^{\imath k(j-j')a}dk = \tfrac{2\pi}{a}\delta_{jj'} \ , \quad \sum_{j\in\mathbb{Z}} j e^{\imath(k-k')ja} = \tfrac{2\pi}{a}\delta(k-k')\tfrac{\imath}{a}\frac{d}{dk} \ .$$

Table 26.2: Summary of scalar products between states of the Bloch, Wannier, and Wannier-Stark basis in position and momentum representation. Red formulas are completeness relations. Green formulas establish links between the Bloch and Wannier pictures. Band indices are suppressed for clarity. The $\check{\cdot}$ on exponential functions simply indicates that the term should be divided by $\sqrt{2\pi}$.

	$\lvert z\rangle$	$\lvert k\rangle$	$\lvert n,q\rangle$	$\lvert n,z_j\rangle = \lvert n,j\rangle/\sqrt{a_1}$	$\lvert n,\ell\rangle$
$\langle z'\rvert$	$= \delta(z-z')$ $\mathbb{I} = \int_{\mathbb{R}} \lvert z\rangle\langle z\rvert dz$	$= \check{e}^{-ikz'}$	$= \sum_{j\in\mathbb{Z}} e^{iqz_j}\langle z'\rvert n,z_j\rangle$ $= \sum_{j\in\mathbb{Z}} c_{q+2jk_1} e^{i(q+2jk_1)z'}$ $= \int_{\mathbb{R}} \check{e}^{ikz'}\langle k\rvert n,q\rangle dk$	$= \int_{-k_1}^{k_1} \check{e}^{-iqz_j}\langle z'\rvert n,q\rangle dz'$ $= \int \sum_{j\in\mathbb{Z}} c_k \check{e}^{ikz'-iqz_j} dq$ $= \int_{\mathbb{R}} e^{iqz_j}\langle k\rvert z_j\rangle dk$	$= \sum_{j'\in\mathbb{Z}} J_{j'-\ell}(\nu)\langle z'\rvert n,j'\rangle$
$\langle k'\rvert$	$\check{e}^{ik'z}$	$= \delta(k-k')$ $\mathbb{I} = \int_{\mathbb{R}} \lvert k\rangle\langle k\rvert dk$	$= \int_{\mathbb{R}} \check{e}^{-iqz}\langle z\rvert n,q\rangle dz$ $\overset{(26.89)}{=} c_{k'}$ $= \sum_{j\in\mathbb{Z}} e^{iqz_j}\langle k\rvert w_j\rangle$	$= \int_{\mathbb{R}} \check{e}^{-ik'z}\langle z\rvert z_j\rangle dz$ $= \int_{-k_1}^{k_1} c_{k'} \check{e}^{-iqz_j} dq$ $= \int_{-k_1}^{k_1} \check{e}^{-iqz_j}\langle k\rvert n,q\rangle dq$	$= \sum_{j'\in\mathbb{Z}} J_{j'-\ell}(\nu)\langle k'\rvert n,j'\rangle$
$\langle n',q'\rvert$	$= \psi_{q'}^{(n')}(z)^*$		$= \delta(q-q')\delta_{n,n'}$ $\mathbb{I} = \sum_{n\in\mathbb{Z}} \int_{-k_1}^{k_1} \lvert n,q\rangle\langle n,q\rvert dq$	$= \check{e}^{-iq'z_j}$	$= \sqrt{a_1}\check{e}^{-i(q'z_\ell+\nu\sin a_1 q)}$
$\langle n',z_{j'}\rvert$			$= \check{e}^{iqz_{j'}}$	$= \frac{1}{a_1}\delta_{jj'}\delta_{n,n'}$ $\mathbb{I} = \sum_{n\in\mathbb{Z}}\sum_{j\in\mathbb{Z}} \lvert n,j\rangle\langle n,j\rvert$	$= J_{j'-\ell}(\nu)$
$\langle n',\ell'\rvert$					$= \delta_{\ell\ell'}\delta_{n,n'}$

diagonalized in (26.80), the total energy of the system is then obtained as the sum,

$$E = \sum_{n,q} E_q^{(n)} N_q^{(n)} \longrightarrow \sum_n \tfrac{a_1}{2\pi} \int_{-k_1}^{k_1} E_q^{(n)} N_q^{(n)} dq \ , \tag{26.111}$$

where $N_q^{(n)}$ is the number of atoms with quasi-momentum q in the n-th band and $E_q^{(n)}/2k_1$ is the spectral energy density. The transition to a continuous spectrum is valid in the limit of a large number of lattice sites. As usual, the 2nd quantization is done via the prescription,

$$N_q^{(n)} \quad \longrightarrow \quad \hat{N}_q^{(n)} \equiv \hat{\psi}_q^{(n)\dagger} \hat{\psi}_q^{(n)} \ , \tag{26.112}$$

where we defined a creation and an annihilation operator of a Bloch state, which satisfy a bosonic or fermionic commutation relation. In the tight binding limit, $\hat{H}$ breaks into bands, so that we can consider each band separately,

$$\hat{H} = \sum_n \hat{H}^{(n)} \qquad \text{with} \qquad \hat{H}^{(n)} = \tfrac{1}{2k_1} \int_{-k_1}^{k_1} E_q^{(n)} \hat{\psi}_q^\dagger \hat{\psi}_q dq \ , \tag{26.113}$$

where we suppressed the band index n at the field operators for simplicity of notation. This Hamiltonian coincides with the (26.92) provided we define the operator $\hat{\psi}_q^\dagger$ creating a Bloch state containing a single atom from vacuum as,

$$|n, q\rangle = \tfrac{1}{\sqrt{2k_1}} \hat{\psi}_q^\dagger |vac\rangle \ . \tag{26.114}$$

Correspondingly, the operator $\hat{w}_q^\dagger$ creates a Wannier state containing a single atom from vacuum,

$$|n, z_j\rangle \overset{(26.97)}{=} \int_{-k_1}^{k_1} \tfrac{e^{-\imath q z_j}}{\sqrt{2\pi}} |n, q\rangle dq = \tfrac{1}{\sqrt{2k_1}} \int_{-k_1}^{k_1} \tfrac{e^{-\imath q z_j}}{\sqrt{2\pi}} \hat{\psi}_q^\dagger |vac\rangle dq \equiv \tfrac{1}{\sqrt{a_1}} \hat{w}_j^\dagger |vac\rangle \ , \tag{26.115}$$

which satisfy the commutation relation $[\hat{w}_j, \hat{w}_j^\dagger] = 1$. From this follows,

$$\hat{w}_j^\dagger = \tfrac{1}{2k_1} \int_{-k_1}^{k_1} e^{-\imath q z_j} \hat{\psi}_q^\dagger dq \qquad \text{and} \qquad \hat{\psi}_q^\dagger = \sum_j e^{\imath q z_j} \hat{w}_j^\dagger \ . \tag{26.116}$$

Substituting the Bloch field operators, we can now rewrite the number operator and the Hamiltonian (26.113) in Wannier representation,

$$\begin{aligned} \hat{N}_j^{(n)} &= \hat{w}_j^\dagger \hat{w}_j \\ \hat{H}^{(n)} &= \tfrac{a_1}{2\pi} \sum_{j,j'} \int_{-a_1/\pi}^{a_1/\pi} E_q^{(n)} e^{\imath q (z_j - z_{j'})} \hat{w}_j^\dagger \hat{w}_{j'} dq \equiv - \sum_{j,j'} \mathfrak{J}(\Delta j) \hat{w}_j^\dagger \hat{w}_{j'} \ , \end{aligned} \tag{26.117}$$

where we defined as an the abbreviation the $\mathfrak{J}(\Delta j)$, called tunneling rate. *Notice, that the Hamiltonian is NOT diagonal in the Wannier basis, i.e. the Wannier states are NOT eigenstates of the optical lattice Hamiltonian, but of the kick operator, as stated in Sec. 26.2.3.* The expression $\hat{w}_j^\dagger \hat{w}_{j'}$ describes annihilation of an atom at lattice

site j' followed by its recreation at site j, that is, hopping from j' to j via quantum tunneling, if the lattice depth is deeper than the atom's energy. The tunneling rate is on one hand related to the matrix element, since,

$$\begin{aligned}\langle n, z_{j'}|\hat{H}^{(n)}|n, z_j\rangle &= -\langle n, z_{j'}|\sum_{i,i'}\mathfrak{J}(\Delta j)\hat{w}_{i'}^{\dagger}\hat{w}_i|n, z_j\rangle \\ &= -\langle vac|\sum_{i,i'}\mathfrak{J}(\Delta j)\delta_{i'j'}\delta_{ij}|vac\rangle = -\mathfrak{J}(\Delta j)\ .\end{aligned} \tag{26.118}$$

On the other hand,

$$\langle n, z_{j'}|\hat{H}^{(n)}|n, z_j\rangle = \int_{\mathbb{R}}\int_{\mathbb{R}}\langle n, z_{j'}|z'\rangle\langle z'|\left(\frac{\hat{p}_z^2}{2m} + V_0\cos^2 k_1\hat{z}\right)|z\rangle\langle z|n, z_j\rangle dz dz'\ . \tag{26.119}$$

With this we find,

$$\mathfrak{J}(\Delta j) = \mathfrak{J}(-\Delta j) = \mathfrak{J}^*(\Delta j)\ . \tag{26.120}$$

From the definition of $\mathfrak{J}(\Delta j)$ (26.117),

$$\boxed{-\mathfrak{J}(\Delta j) = \tfrac{a_1}{2\pi}\int_{-k_1}^{k_1} E_q^{(n)} e^{\imath q(z_{j'}-z_j)}dq = \int_{-1}^{1} E_q^{(n)}\cos(\pi\tilde{q}\Delta j)d\tilde{q}}\ , \tag{26.121}$$

where we exploited the fact $E_{-q}^{(n)} = E_q^{(n)}$. The expression (26.121) can be interpreted as Fourier coefficients of a Fourier expansion of the periodic function $E_q^{(n)}$,

$$E_q - \bar{E}_q = -2\sum_{\Delta j=1}^{\infty}\mathfrak{J}(\Delta j)\cos(a_1 q\Delta j)\ . \tag{26.122}$$

In other words, the dispersion relation $E_q^{(n)}$ allows evaluation of the tunneling rate between specific lattice sites j and j' via (26.121). The Hamiltonian in the Wannier state basis finally reads,

$$\boxed{\hat{H} = \sum_n\sum_{j,j'}\int_{-1}^{1} E_q^{(n)}\cos(\pi\tilde{q}\Delta j)d\tilde{q}\ \hat{w}_j^{\dagger}\hat{w}_{j'}\ .} \tag{26.123}$$

Example 220 (*Tight binding limit*): From Fig. 26.7 we see that for deep lattice, i.e. in the so-called *tight-binding regime* defined by $-V \gg \hbar\omega_{\text{rec}}$ [414, 70, 217], the Wannier function decreases rapidly with the distance from the site. Then only nearest neighbor interactions are relevant, and the Hamiltonian simplifies to,

$$\begin{aligned}\hat{H} &= -\mathfrak{J}a_1\sum_{j,j'}|n, z_j\rangle\langle n, z_{j'}| \\ &\longrightarrow -\mathfrak{J}\sum_j|n, j+1\rangle\langle n, j| - \mathfrak{J}\sum_j|n, j-1\rangle\langle n, j| = -\mathfrak{J}[U_{\text{tr}}(a_1) + U_{\text{tr}}^{\dagger}(a_1)]\ ,\end{aligned} \tag{26.124}$$

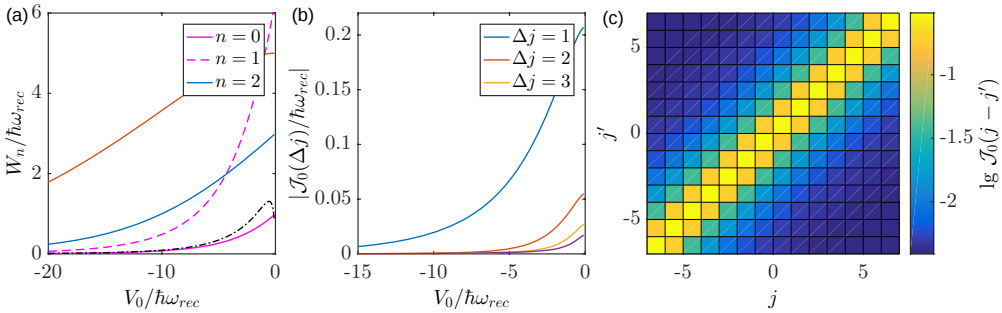

Figure 26.8: (code) (a) Width of allowed bands W_n as a function of potential depth V_0 for the lowest bands (see also Fig. 26.4). The dash-dotted line shows the tight-binding approximation (26.126). The magenta dashed line shows the width $W_0/\hbar\omega_{\rm blo}$ of the lowest band scaled to the Bloch oscillation frequency under the action of a force corresponding to $\omega_{\rm blo}/\omega_{\rm rec} = 0.158$, see Sec. 26.2.2. (b) Hopping rates between lattices sites distant by Δj as a function of V_0. (c) Two-dimensional representation of the hopping rates on a logarithmic false color scale $\lg W_0/\hbar\omega_{\rm rec}$.

and from (26.122),

$$E_q = -2\mathfrak{J}\cos(\pi\tilde{q}) \ . \tag{26.125}$$

As already illustrated in Fig. 26.4, with deepening potential $-V \longrightarrow \infty$ the allowed energy bands become thinner until they become discrete energy levels. This can be understood as an expression of a diminishing coupling between lattice sites, i.e. a diminishing tunneling rate. The band width can be shown to be approximated by [217],

$$\tilde{W}_1 \simeq \tfrac{16}{\sqrt{\pi}}\tilde{V}^{3/4}e^{-2\tilde{V}^{1/2}} \ , \tag{26.126}$$

in units of the recoil energy. The approximation is included in Fig. 26.8.

26.3 Bloch oscillations

Electrons moving in a crystal and exposed to electric fields undergo Bloch oscillations, as discussed in Sec. 26.1.4. An analogous phenomenon can be observed when neutral atoms in a vertical optical lattice are accelerated by gravity [213, 720]. To treat this case, we could simply replace the electric force $-e\vec{\mathcal{E}}$ in the expression (26.49) by the gravitational force mg and obtain the result,

$$\omega_{\rm blo} = \frac{mg\lambda_{\rm l}}{2\hbar} \ , \tag{26.127}$$

with the wavelength $\lambda_{\rm l} = 2a_{\rm l}$ of the counterpropagating lasers generating the standing wave. For didactic reasons, however, we will formulate the problem in the quantum optics language introduced in the previous section.

26.3.1 Bloch oscillations in shallow lattices in momentum space

26.3.1.1 Time-dependent Schrödinger equation

To reproduce the dynamics of a matter wave, we start from the time-dependent Schrödinger equation with the same periodic potential. We again expand the time-dependent wavefunction into plane waves via,

$$\psi(z,t) = \sum_{j=-\infty}^{\infty} c_j(t) e^{2\imath j k_1 z} \ , \tag{26.128}$$

and insert this ansatz into the Schrödinger equation,

$$\imath\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m}\frac{\partial^2 \psi}{\partial z^2} + \frac{V_0}{2}\cos(2k_1 z)\psi \ , \tag{26.129}$$

obtaining a set of equations of motion for the expansion coefficients c_n,

$$\boxed{\dot{c}_j = -4\imath\omega_{\rm rec} j^2 c_j + \frac{V_0}{2\imath\hbar}(c_{j+1} + c_{j-1})} \ . \tag{26.130}$$

The temporal evolution of the coefficients $c_j(t)$ can be simulated numerically.

Now we extend the Hamiltonian by the gravitational potential [11] (see also Exc. 23.7.6.2),

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + \frac{V_0}{2}\cos 2k_1\hat{z} + mg\hat{z} \ . \tag{26.131}$$

We define the transformation $\mathcal{U} \equiv e^{-\imath mg\hat{z}t/\hbar}$ and find with (23.267) and (23.315) the Hamiltonian in the accelerated frame,

$$\tilde{H} = \mathcal{U}^\dagger \hat{H}\mathcal{U} + \imath\hbar\dot{\mathcal{U}}^\dagger\mathcal{U} = \frac{\tilde{p}^2}{2m} + \frac{V_0}{4}\left(e^{2\imath k_1\hat{z}} + e^{-2\imath k_1\hat{z}}\right) \ . \tag{26.132}$$

with

$$\tilde{p} \equiv \hat{p} - mgt = \mathcal{U}^\dagger \hat{p}\mathcal{U} \ . \tag{26.133}$$

Now, we expand the operators using the rules (23.209) and (23.315) [12],

$$\tilde{p} = \int p|p\rangle\langle p|dp \longrightarrow \sum_j (p + 2j\hbar k_1)|p + 2j\hbar k_1\rangle\langle p + 2j\hbar k_1| \tag{26.134}$$

$$e^{2\imath k_1\hat{z}} = \int |p + 2\hbar k_1\rangle\langle p|dp \longrightarrow \sum_j |p + 2(j+1)\hbar k_1\rangle\langle p + 2j\hbar k_1| \ ,$$

based on the assumption that every atom can only exist in a superposition of discrete momentum states separated by $2\hbar k_1$, but can have an 'offset' momentum $p = mv$,

[11] For Bose-Einstein condensates, the procedure should be generalized taking into account the energy of the mean field due to interatomic collisions.

[12] See also (48.103) and (48.110).

e.g. due to thermal motion. Disregarding thermal motion, we may set in the accelerated frame $p = 0$. Then,

$$\tilde{p} = \sum_j 2j\hbar k_l |2j\hbar k_l\rangle\langle 2j\hbar k_l| \qquad \text{and} \qquad e^{2\imath k_l \hat{z}} = \sum_j |2j\hbar k_l + 2\hbar k_l\rangle\langle 2j\hbar k_l| \ , \tag{26.135}$$

such that,

$$\tilde{H} = \sum_j 4j^2\hbar\omega_{\rm rec}|2j\hbar k_l\rangle\langle 2j\hbar k_l| + \tfrac{V_0}{4}\sum_j \left(|2j\hbar k_l + 2\hbar k_l\rangle\langle 2j\hbar k_l| + |2j\hbar k_l\rangle\langle 2j\hbar k_l + 2\hbar k_l|\right) \ . \tag{26.136}$$

With the expansion of the wavefunction $|\tilde{\psi}\rangle = \sum_j c_j|2j\hbar k_l\rangle$ the Schrödinger equation becomes [807, 808],

$$\begin{aligned} \imath\hbar\frac{d}{dt}|\tilde{\psi}\rangle &= \imath\hbar\sum_j \dot{c}_j|2j\hbar k_l\rangle \\ &= \sum_j \left(4j^2\hbar\omega_{\rm rec}c_j + \tfrac{V_0}{4}(c_{j-1} + c_{j+1})\right)|2j\hbar k_l\rangle = \tilde{H}|\tilde{\psi}\rangle \ , \end{aligned} \tag{26.137}$$

that is,

$$\dot{c}_j = -4\imath j^2\omega_{\rm rec}c_j + \frac{V_0}{4\imath\hbar}(c_{j-1} + c_{j+1}) \ . \tag{26.138}$$

In the lab frame the wavefunction reads,

$$\begin{aligned} |\psi\rangle = \mathcal{U}|\tilde{\psi}\rangle &= e^{-\imath mg\hat{z}t/\hbar}\sum_j c_j|2j\hbar k_l\rangle \\ &= \sum_j c_j|2n\hbar k_l - mgt\rangle = \sum_j c_j|2\hbar k_l(j - \nu_{\rm blo}t)\rangle \ , \end{aligned} \tag{26.139}$$

where we introduced the *Bloch frequency*,

$$\boxed{\nu_{\rm blo} = \frac{mg}{2\hbar k_l}} \ . \tag{26.140}$$

Finally,

$$\boxed{\dot{c}_j = -4\imath(j - \nu_{\rm blo}t)^2\omega_{\rm rec}c_j + \frac{V_0}{4\imath\hbar}(c_{j-1} + c_{j+1})} \ . \tag{26.141}$$

The center-of-the mass momentum of the atomic matter wave is,

$$\frac{\langle p\rangle_{lab}}{\hbar k_l} = \sum_j j|c_j(t)|^2 + \nu_{\rm blo}t \ . \tag{26.142}$$

26.3.1.2 Interpretation of Bloch oscillations as Bragg reflections

The Bloch oscillations can be understood in various pictures. The first one, illustrated in 26.9(a), is based on *Bragg reflection*: A resting atom has infinite de Broglie wavelength. Being constantly accelerated by gravity, the matter wave reduces its de

Broglie wavelength from ∞ to a value, where it becomes commensurate with the periodicity of the standing light wave potential. At this moment Bragg scattering comes into play, reflecting the atomic motion back into upward direction, and the process starts over again. The atoms evolve like jumping on a trampoline with a frequency given by $\nu_{\rm blo}$.

To understand the second picture, we need to address a question we have left aside so far, as this requires a notion of optical forces. It is the question in which way the matter wave interacts with the standing light wave. For the present discussion, it is sufficient to know that the atom must have an internal transition capable of scattering photons from the light beams. As any absorption and emission process transfers a recoil momentum of $\hbar k_{\rm l}$ to the atom, we can understand the Bragg scattering process as a so-called *Raman scattering* process: a photon of the laser beam generating the optical lattice coming from the left is absorbed and re-emitted to the left. This is best illustrated in the momentum domain sketched in Fig. 26.9(b). This Raman scattering transfers twice the photonic recoil to the atom. The requirement for commensurability of the Broglie wavelength and wavelength of the standing light wave is equivalent to saying that the matter wave momentum is equal to the recoil of a single photon. In other words, the matter wave always Bragg-reflected at the edge of a Brillouin zone.

Finally, in the *Bloch state picture*, the dispersion relation of a free particle is distorted due to the periodicity of the potential generated by the standing light wave such as to open a forbidden band. As a consequence, instead of being accelerated without limits, the atom enters the second Brillouin zone, which is to say that it is reflected to the other side of the first Brillouin zone.

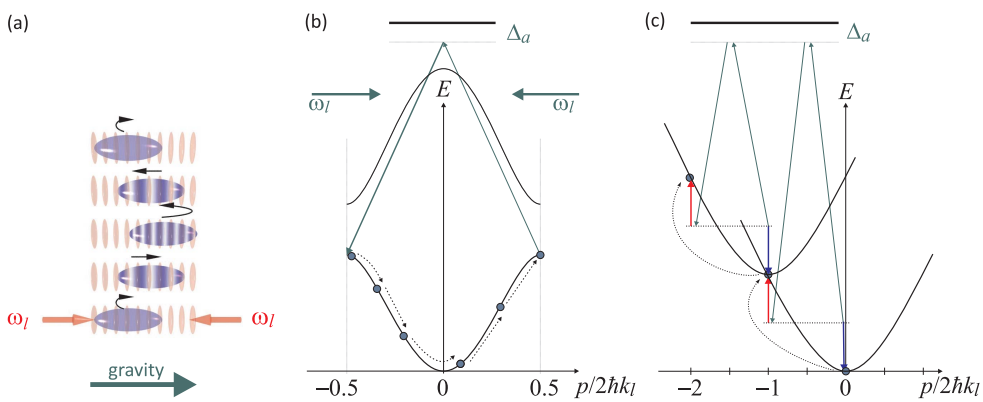

Figure 26.9: Illustration of Bloch oscillations (a) in real space, (b) in momentum space, and (c) in the moving frame. You may also run a movie of Bloch oscillations clicking on (watch movie)!

The additional term, which contains the frequency of the Bloch oscillation $\nu_{\rm blo}$, increases linearly over time. As time goes by, a resonance is crossed when $t = -j\tau_{\rm blo}$, and the crossing is periodically repeated at every $j = -1, -2, 0, \ldots$ Tracing the matter wave evolution in the laboratory system, we see that whenever the resonance is crossed, the momentum undergoes a change of sign corresponding to a reflection of its motion. We expand the population of the momentum states into plane (Bloch)

waves with $|c_j(t)|^2$.

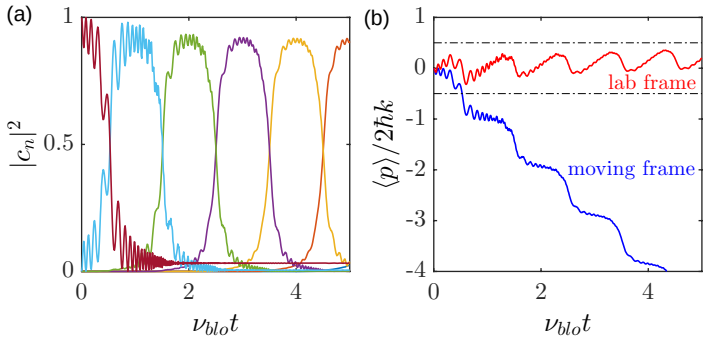

Figure 26.10: (code) Dynamics of Bloch's oscillations calculated from Eq. (26.130). (a) The colored curves show successively populated momentum states. (b) Center-of-mass motion of the wave packet in the lab frame (red) and in the moving frame (blue). The used parameters are $\omega_{\rm rec} = (2\pi)\ 4.8\,{\rm kHz}$, $2\pi\nu_{\rm blo} = 0.3\omega_{\rm rec}$, and $V_0 = -0.7\omega_{\rm rec}$.

Of course there are some conditions that need to be met to observe Bloch oscillations. The transfer of momentum is efficient only in the rapid adiabatic passage (ARP) regime characterized by the conditions $2(\nu_{\rm blo}/\omega_{\rm rec}) \ll (V_0/4\omega_{\rm rec})^2 \ll 16$. The first condition requires that the force that drives the atoms to perform the Bloch oscillations must be weak enough to avoid transitions between Bloch bands, which guarantees the adiabaticity of the process. The other condition requires that the optical lattice be weak enough so that the dynamics involves only two adjacent momentum states at the same time and the transfer between the two is successful. A talk on this subject can be watched at (watch talk). Do the Excs. 26.3.4.5 and 26.3.4.6.

We will come back to the topic of optical lattices holding matter waves in Sec. 51.4.2 in the context of Mott insulating states of Bose-Einstein condensates.

26.3.2 Bloch oscillations in the tight binding regime in position space

26.3.2.1 Wannier-Stark ladder

In the presence of an external force, the tight-binding Hamitonian (26.124) in the Wannier basis is generalized to,

$$\begin{aligned}\hat{H} &= -\mathfrak{J}\sum_{\pm}\sum_{j\in\mathbb{Z}}\hat{w}^\dagger_{j\pm1}\hat{w}_j + mga_{\rm l}\sum_{j\in\mathbb{Z}} j\hat{w}^\dagger_j\hat{w}_j \\ &= -\mathfrak{J}a_{\rm l}\sum_{\pm}\sum_{j\in\mathbb{Z}}|n,z_{j\pm1}\rangle\langle n,z_j| + mga_{\rm l}{}^2\sum_{j\in\mathbb{Z}} j|n,z_j\rangle\langle n,z_j|\ .\end{aligned} \tag{26.143}$$

Expanding the Wannier states in the Bloch basis via insertion of the completeness relation $\mathbb{I} = \int_{-k_{\rm l}}^{k_{\rm l}}|n,q\rangle\langle n,q|dq$, using $\langle n,z_j|n,q\rangle \overset{(26.107)}{=} \check{e}^{\imath jqa_{\rm l}}$, and $\hat{w}^\dagger_j|vac\rangle \overset{(26.115)}{=}$

$|n,j\rangle$, we obtain,

$$\begin{aligned}\hat{H} &= -\mathfrak{J}a_1\frac{1}{2\pi}\sum_{\pm}\int_{-k_1}^{k_1}\int_{-k_1}^{k_1}|n,q\rangle e^{\mp\imath a_1 q}\sum_{j\in\mathbb{Z}}e^{\imath(q'-q)ja_1}\langle n,q'|dqdq' \\ &\qquad + mga_1{}^2\frac{1}{2\pi}\int_{-k_1}^{k_1}\int_{-k_1}^{k_1}|n,q\rangle\sum_{j\in\mathbb{Z}}je^{\imath(q'-q)ja_1}\langle n,q'|dqdq' \\ &= -\mathfrak{J}a_1\frac{1}{2\pi}\sum_{\pm}\int_{-k_1}^{k_1}\int_{-k_1}^{k_1}|n,q\rangle e^{\mp\imath a_1 q}\frac{2\pi}{a_1}\delta(q'-q)\langle n,q'|dqdq' \\ &\qquad + mga_1{}^2\frac{1}{2\pi}\int_{-k_1}^{k_1}\int_{-k_1}^{k_1}|n,q\rangle\frac{2\pi}{a_1}\delta(q'-q)\frac{\imath}{a_1}\frac{d}{dq}\langle n,q'|dqdq' \\ &= -\int_{-k_1}^{k_1}|n,q\rangle\left(2\mathfrak{J}\cos a_1 q - mg\,\imath\frac{d}{dq}\right)\langle n,q|dq \equiv \int_{-k_1}^{k_1}|n,q\rangle\hat{H}(q)\langle n,q|dq\ ,\end{aligned} \tag{26.144}$$

using the definition of the Bloch frequency (26.140), $mga_1 = \hbar\omega_{\rm blo}$. Obviously, the Hamiltonian (26.144) is diagonal in the quasi-momentum basis. The first term is the force-free dispersion relation, while the second one introduces an energy shift known as *Wannier-Stark ladder*. The eigenstates of the Hamiltonian

$$\hat{H}\langle n,q|\ell\rangle = \left(-2\mathfrak{J}\cos a_1 q + mg\,\imath\frac{d}{dq}\right)\langle n,q|\ell\rangle = E\langle n,q|\ell\rangle \tag{26.145}$$

are the Wannier-Stark states, whose **Bloch** or **quasi-momentum representation** is given by,

$$\langle n,q|n,\ell\rangle = \sqrt{\tfrac{a_1}{2\pi}}e^{-\imath[\ell q a_1 + 2\mathfrak{J}\sin(a_1 q)/(\hbar\omega_{\rm blo})]} = \sqrt{\tfrac{a_1}{2\pi}}e^{-\imath(jqa_1+\nu\sin a_1 q)}\ . \tag{26.146}$$

where we introduced the abbreviation,

$$\nu \equiv \frac{2\mathfrak{J}}{mga_1}\ . \tag{26.147}$$

With this normalization factor, these states obviously form an orthonormal basis,

$$\langle n,\ell'|n,\ell\rangle = \int_{-k_1}^{k_1}\langle n,\ell'|n,q\rangle\langle n,q|n,\ell\rangle dq = \delta_{\ell'\ell}\ . \tag{26.148}$$

Inserting them into the differential equation (26.145), we find,

$$\boxed{E_\ell = \ell\hbar\omega_{\rm blo} = \ell a_1 mg\ .} \tag{26.149}$$

26.3.2.2 Various representations of Wannier-Stark states

Apart from the Bloch representation (26.146), which projects the Wannier-Stark states $|n,\ell\rangle$ onto the Bloch basis $\langle n,q|$, we already got to know three other representations: The Wannier representation projecting onto the Wannier basis $\langle n,z_j|$, the position representation projecting onto $\langle z|$, and the momentum representation

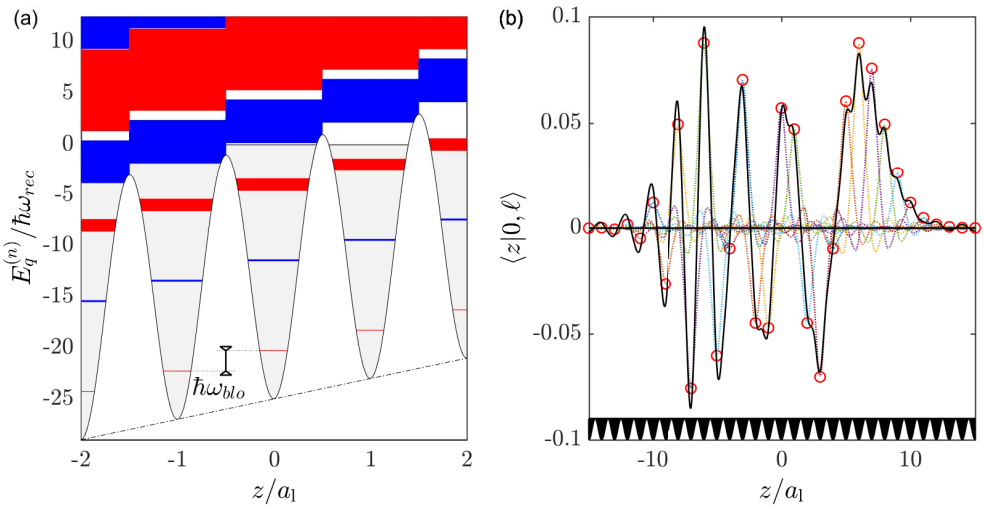

Figure 26.11: (code) (a) Wannier-Stark ladder for $V_0 = -25\hbar\omega_{\rm rec}$ and $\omega_{\rm blo} = 2\omega_{\rm rec}$. (b) Wannier representation (red circles) and position representation (black solid line) for $V_0 = -\hbar\omega_{\rm rec}$ and $\omega_{\rm blo} = 0.1\omega_{\rm rec}$ corresponding to $\nu = 7.7$ [414].

projecting onto $\langle k|$. Let us now derive the explicit wavefunctions of the various representations.

The **Wannier** or **lattice site representation** of the Wannier-Stark states is obtained from the Bloch representation (26.146) via Fourier transform, $\langle n, z_j|n, q\rangle = e^{\imath q z_j}/\sqrt{2\pi}$,

$$\begin{aligned}\langle n, z_j|n, \ell\rangle &= \int_{-k_l}^{k_l} \langle n, z_j|n, q\rangle\langle n, q|n, \ell\rangle dq \\ &= \int_{-k_l}^{k_l} \tfrac{e^{\imath q z_j}}{\sqrt{2\pi}}\sqrt{\tfrac{a_l}{2\pi}} e^{-\imath(\ell q a_l - \nu \sin a_l q)} dq \\ &= \tfrac{1}{2\pi\sqrt{a_l}} \int_{-\pi}^{\pi} e^{\imath(j-\ell)\tilde{q} - \imath\nu\sin\tilde{q}} d\tilde{q} = \tfrac{1}{\sqrt{a_l}} J_{j-\ell}(\nu)\ ,\end{aligned} \tag{26.150}$$

with the definition of the Bessel function [13]. Hence,

$$|n, \ell\rangle = a_l \sum_j |n, z_j\rangle\langle n, z_j|n, \ell\rangle = \sum_j J_{j-\ell}(\nu)|n, j\rangle\ . \tag{26.151}$$

The **position** and the **momentum representation** of the Wannier-Stark states are obtained from the position (respectively momentum) representations of the Wannier states,

$$\langle z|n, \ell\rangle = \sqrt{a_l}\sum_j J_{j-\ell}(\nu)\langle z|n, z_j\rangle \quad , \quad \langle k|n, \ell\rangle = \sqrt{a_l}\sum_j J_{j-\ell}(\nu)\langle k|n, z_j\rangle\ . \tag{26.152}$$

[13] $J_{m-n}(x) = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{\imath(m-n)u - \imath x\sin u} du$.

The position representation is visualized in Fig. 26.11(b). The momentum representation can alternatively be derived from (26.146),

$$\langle k|n,\ell\rangle = \langle k|\int_{-k_1}^{k_1}|n,q\rangle\langle n,q|dq|n,\ell\rangle = \int_{-k_1}^{k_1} c_k e^{-\imath(jqa_1-\nu\sin a_1 q)}dq\ . \tag{26.153}$$

From the properties of the Bessel functions we know that $J_{j-\ell}(\nu)$ is mainly localized in the interval $|j-\ell|<\nu$, i.e. the Wannier-Stark states extend over an interval ν. Outside this interval, the Bessel functions decay as $J_j(\nu)\propto\nu^j$. Furthermore, the Bessel functions strongly oscillate for negative values of the index because of the property $J_{-j}(\nu)=(-1)^jJ_j(\nu)$. We will see that the spatial extension of the Wannier-Stark state determines the boundaries of the Bloch oscillations [14]. The various representations of Wannier-Stark states are included in Tab. 26.2.

26.3.2.3 Bloch oscillations

Without external forcing the periodic potential is translation invariant, which entails complete delocalization of the spatial wavefunction in steady-state: If an atom can tunnel from site j to $j+1$, it also can tunnel from $j+1$ to $j+2$. The situation changes when an external force is applied because, according to Eq. (26.149), the energy bands are shifted between sites by an amount $h\nu_{\rm blo}$, see Fig. 26.11. This energy mismatch spoils the overlap between the Wannier functions at different sites and, as no energy is dissipated, energy conservation requires the states to remain localized: Tunneling violating energy conservation is only possible during a time period corresponding to the Heisenberg uncertainty relation, $\Delta t = h/\Delta E = \nu_{\rm blo}^{-1}$. That is, an atom trying to tunnel to other lattice site must return to its original position after a period $\nu_{\rm blo}^{-1}$. Let us now derive this quantitatively.

The evolution operator in the Bloch state basis [414] is obtained inserting the Wannier-Stark states (26.146) and the energy spectrum (26.149) into the propagator,

$$\begin{aligned}\mathcal{U}_{qq'}(t) &= \langle n,q'|e^{-\imath\hat{H}t}|n,q\rangle = \sum_j\langle n,q'|\ell\rangle e^{-\imath E_j t}\langle\ell|n,q\rangle \\ &= \tfrac{a_1}{2\pi}e^{-\imath\nu(\sin a_1 q-\sin a_1 q')}\sum_j e^{\imath j[(q-q')a_1-\hbar\omega_{\rm blo}t]} \\ &= e^{-\imath\nu(\sin a_1 q-\sin a_1 q')}\delta(q-q'-mgt)\ .\end{aligned} \tag{26.154}$$

The evolution operator in the Wannier state basis will be derived in Exc. 26.3.4.9,

$$\begin{aligned}\mathcal{U}_{jj'}(t) &= \langle n,j'|e^{-\imath\hat{H}t}|n,j\rangle = \sum_\ell\langle n,j'|\ell\rangle e^{-\imath E_\ell t}\langle\ell|n,j\rangle \\ &= e^{\imath(j-j')(\pi-\omega_{\rm blo}t)/2-\imath j'\omega_{\rm blo}t}J_{j-j'}(2\nu\sin\tfrac{\omega_{\rm blo}t}{2})\ .\end{aligned} \tag{26.155}$$

The propagators (26.154), respectively, (26.155) allow to calculate the time evolution of a wave packet. Fig. 26.12 visualizes the dynamics of a wave packet in a tilted

[14] The Wannier-Stark states are orthonormalized. However, this breaks down in the presence of a cavity. After delocalization, only the overlap between the Wannier-Stark states and the cavity mode function couples to the cavity.

periodic potential for different initial conditions, localized or spread over several lattice sites. We see that the Wannier states extend over a maximum number of populated sites,

$$|j| < \nu \left|\sin \tfrac{\nu_{\rm blo} t}{\pi}\right| \ , \tag{26.156}$$

The spreading of a wave packet is proportional to the width of an energy band, but depends inversely on $h\nu_{\rm blo}$, see Fig. 26.8(c). Hence, in order to maximize the spreading it is important to use a band n near the threshold $E^{(n)} \lesssim 0$.

Fig. 26.12 shows a simulation of,

$$\langle n, z_j | n, \ell(t)\rangle = \langle n, z_j | \mathcal{U}_{jj'}(t) | n, \ell(0)\rangle \tag{26.157}$$

with some initial distribution $\ell(0)\rangle = \sum_j c_j(0)|n, j\rangle$. The simulation reveals, that initial incoherent superpositions of many Wannier states localized in adjacent sites tend to wash out the oscillations.

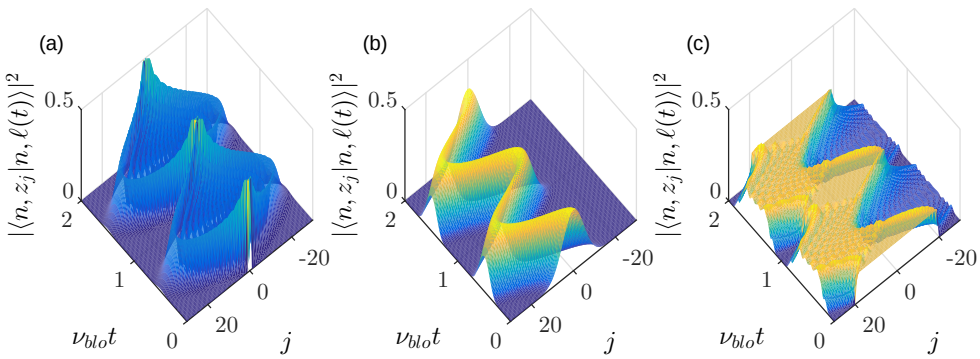

Figure 26.12: (code) Bloch oscillations in the tight-binding limit for $\nu = 25$. (a) The wave packet is assumed initially perfectly localized at a single lattice site, $|n, \ell(0)\rangle = \sum_j \delta_{0,j}|0, j\rangle$. (b) The wave packet is assumed initially spread over a $\sigma = 5$ lattice site large Gaussian distribution, $|n, \ell(0)\rangle = (\pi\sigma^2)^{-1/4} \sum_j e^{-j^2/2\sigma^2}|0, j\rangle$. (c) The wave packet is assumed initially spread equally over $j_{\max} = 25$ lattice sites, $|n, \ell(0)\rangle = (2j_{\max})^{-1/2} \sum_j \Theta(j_{\max} - |j|)|0, j\rangle$.

Example 221 (*Wavepacket propagation in the tight binding limit*): It is possible to impart a momentum to the wavepacket by multiplying the initial Wannier state distribution with a phase factor,

$$|n, \ell(0)\rangle = \sum_j e^{\imath j p} |n, j\rangle \ ,$$

as shown in Fig. 26.13(a).

Interestingly, the Bloch oscillations can be used to realize unidirectional quantum transport in a flipped *quantum ratchet* scheme. One just has to phase shift the standing wave potential after each Bloch oscillation period, as shown in Fig. 26.13(b) [414, 599, 790].

Example 222 (*Exciting and probing Bloch oscillations*): Bloch oscillations may excited by sudden quench or periodic modulation [1010]. They may be probed by Raman spectroscopy [70], see Fig. 26.11(b).

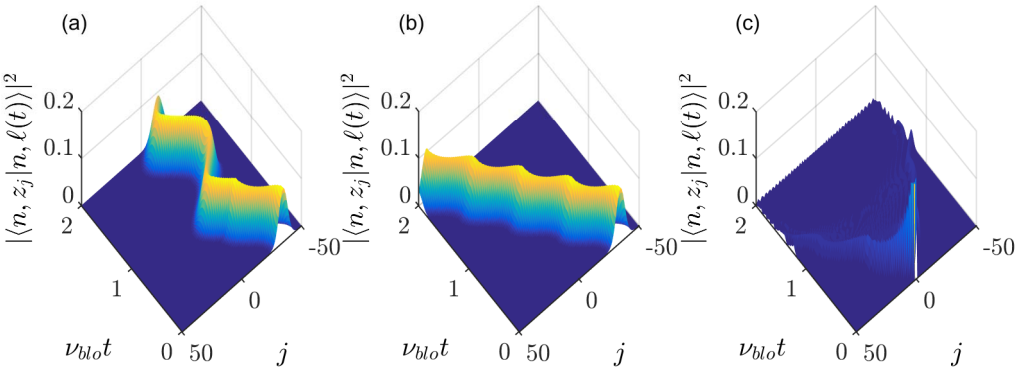

Figure 26.13: (code) (a) Propagation of a Gaussian wavepacket spread over a $\sigma = 5$ and initially localized around $z_j = -35a_l$. At time $t = \pi/2\omega_{\rm blo}$ a momentum kick $p = \pi$ is imparted to the wavepacket. (b) Propagation of the same Gaussian wavepacket when the phase of the periodic potential is shifted by π after each Bloch period. (c) Same as (b), but the particle is initially localized at a single lattice site $z_j = 0$.

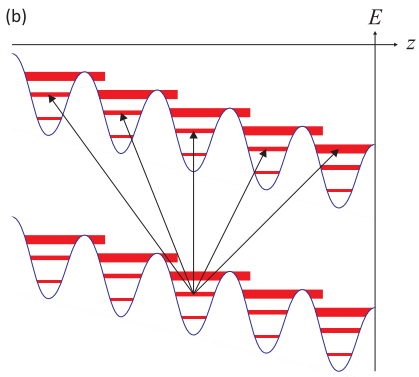

Figure 26.14: (b) Raman spectroscopy of the ladder states [70].

26.3.3 Extensions of the Bloch-Wannier model

26.3.3.1 Interacting atoms and three-dimensional lattices

As long as the particles in the lattice do not interact with each other the Bloch-Wannier model developed so far is sufficient to grasp all phenomena. Indeed, as long as the atoms evolve independently, the occupation probabilities of lattice sites are simply reinterpreted as populations. Nevertheless, an important advantage of Wannier basis is that it can be generalized to include interatomic interactions. The model, called the *Hubbard model*, will be investigated later in Sec. 51.4.2, where we will also extend it to three dimensions.

26.3.3.2 Interband transitions

The bands are separated by gaps. Hence, transitions can only occur due to time-dependent perturbations with Fourier frequencies sufficiently high to bridge the gap, see Sec. 27.4.3. The motion of an atom in the lattice potential represents such a perturbation, provided it is sufficiently fast. Such transitions are called *Landau-Zener transitions*. A rapid change of the lattice depth or energetic interatomic collisions represent other sources of interband transitions.

26.3.4 Exercises

26.3.4.1 Ex: Bloch theorem

Verify that,

$$\hat{H}|\psi_k\rangle = E_k|\psi_k\rangle \quad \Longrightarrow \quad \left(\frac{(\hat{k}+\kappa)^2}{2m} + V(z)\right)|u_k\rangle = E_k|u_k\rangle \ .$$

26.3.4.2 Ex: Spatial wavefunction of the Wannier state for the first band

Find the spatial wavefunction of the Wannier state for the first band, $w^{(1)}(z)$, in the case of $V = 0$. Plot the function, and give the location of its nodes.

26.3.4.3 Ex: Orthonormality of Wannier states

Show that, for the ground band, $|w_j\rangle$ and $|w_{j'}\rangle$ are orthogonal for $j \neq j'$.

26.3.4.4 Ex: Gaussian approximation for Wannier function

Consider a standing light wave producing a dipolar potential of the shape $V(x) = W_0 \sin^2 kx = \frac{W_0}{2} - \frac{W_0}{2}\cos 2kx$ with $W_0 \mathbf{G} g E_{\rm rec} = (\hbar k)^2/2m$.
a. Approximate the potential of a single lattice site around $x = 0$ by a harmonic potential. Calculate for which depth of the dipolar potential the approximated potential supports at least one bound state. What is the spacing of the levels and the characteristic size of the harmonic oscillator $a_{\rm ho}$. Write down the normalized ground state wavefunction of the harmonic oscillator.
b. Now, let us consider a 3D cubic lattice made of three identical orthogonal standing light waves. Approximate the ground state *Wannier function* of a lattice site by appropriately normalized ground state wavefunctions of a harmonic oscillator. Derive the formula $U^{\rm 3D} = \frac{8}{\pi} k a_d \left(\frac{W_0}{E_{\rm rec}}\right)^{3/4}$ starting from,

$$U^{\rm 3D} = g^{\rm 3D} \int \omega^4_{(0,0)}(x,y,z) d^3r$$

with $g^{\rm 3D} = \frac{4\pi\hbar a_d}{m}$.

26.3.4.5 Ex: Purification of Bloch oscillations

Simulations of Bloch oscillations of atoms in an optical lattice for $V_0 = 0.4\omega_{\text{rec}}$ and $0.8\omega_{\text{rec}}$ produce the dynamics exhibited in Fig. 26.15. Interpret the different behaviors.

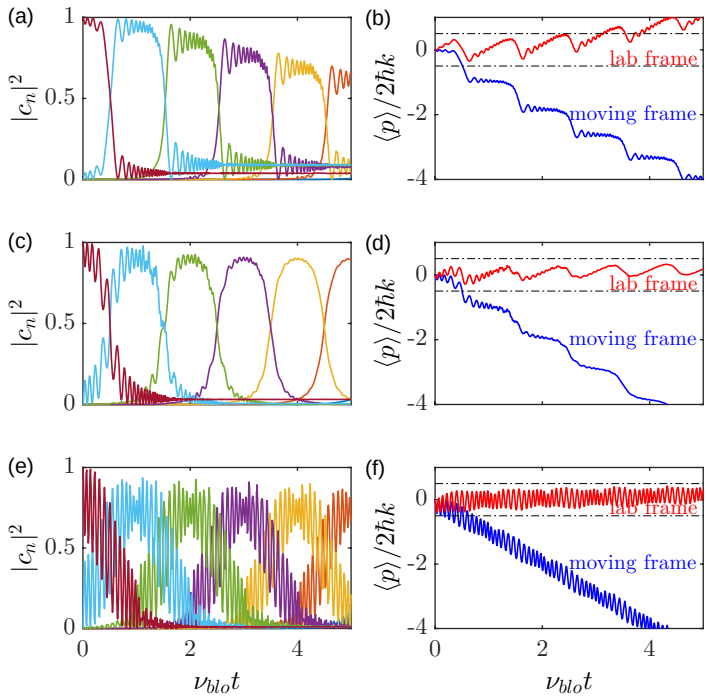

Figure 26.15: (code) Dynamics of Bloch oscillations (a-b) for $V_0 = 0.4\omega_{\text{rec}}$, (c-d) for $V_0 = 0.8\omega_{\text{rec}}$, and (e-f) for $V_0 = 1.6\omega_{\text{rec}}$. Furthermore, $\omega_{\text{rec}} = (2\pi)\ 4.8\,\text{kHz}$ and $\nu_{\text{blo}} = 0.05\omega_{\text{rec}}$.

26.3.4.6 Ex: Two-mode model for Bloch oscillations

Simplify the Bloch oscillation model assuming that at any time *at most* two momentum modes can be coupled via Bragg reflection.

26.3.4.7 Ex: Perturbative treatment of a weak lattice

A weak lattice potential with $V_0 < E_{\text{rec}}$ can be treated in perturbation theory to motivate the resulting opening of a gap in the refolded energy parabola. The unperturbed Hamiltonian $\hat{H}_0 = p^2/2m$ contains only the kinetic energy and the perturbation is $V(z) = V\sin^2(kz) = \frac{1}{2}V - \frac{1}{4}V(e^{2\imath kz} + e^{-2\imath kz})$.

a. Calculate $\hat{V}(z)\phi_p(z)$ and show that $\langle\phi_{p\pm\hbar k}|\hat{V}|\phi_p\rangle$ are the only non-zero matrix elements of the perturbation $V(z)$ between the eigenstates of $\hat{H}_0$ (which are the orthonormal plane waves $\phi_p = e^{\imath pz/\hbar}$). Neglect the constant term of the potential, which only yields a global energy shift.

b. This coupling is relevant around those momenta p, where ϕ_p has the same energy $\phi_{p+\hbar k}$ or $\phi_{p-\hbar k}$. Show that these momenta are $p = \mp\hbar k$.
c. Consider the perturbed system restricted to the basis $\{|p = -\hbar k\rangle, |p = +\hbar k\rangle\}$ and give the Hamiltonian as 2×2 matrix.
d. Diagonalize the matrix and consider the difference of the eigenenergies. Use them to estimate the size of the gap, that the lattice opens between the two lowest bands.
e. Calculate the eigenstates and interpret them by comparing the probability density to the lattice potential.

26.3.4.8 Ex: Wannier-Stark ladder for strontium

For the strontium intercombination line the Bloch and the recoil frequencies are $\omega_{\text{blo}} = 2\pi \frac{mg}{2\hbar k} = (2\pi)\,786\,\text{Hz}$ and $\omega_{\text{rec}} = \frac{\hbar k^2}{2m} = (2\pi)\,4530\,\text{kHz}$, respectively. Calculate the Wannier-Stark ladder.

26.3.4.9 Ex: Propagator for Bloch oscillations in the Wannier basis

Derive the formula (26.155) for the time evolution in the Wannier basis.

Chapter 27

Approximation methods

Virtually every problem going beyond the potential well, the harmonic oscillator, or the hydrogen atom without spin and external fields is impossible to solve analytically. In this chapter we will talk about techniques to solve approximately problems in more realistic situations. There are a number of methods of which we will discuss the only following: 1. The stationary or time-dependent perturbation method is useful for evaluating small perturbations of the system, for example, caused by external electric or magnetic fields; 2. the variational method, which serves to find and improve trial wavefunctions, the initial shapes of which are generally motivated by the symmetries of the system; 3. the semi-classical WKB method; 4. and finally the method of self-consistent fields, which is an iterative method of solving the Schrödinger equation.

27.1 Stationary perturbations

27.1.1 Time-independent perturbation theory

We first introduce *time-independent perturbation theory* (TIPT) for multilevel systems. We separate the Hamiltonian into an unperturbed part,

$$\hat{H}^{(0)}|\psi^{(0)}\rangle = E^{(0)}|\psi^{(0)}\rangle \ , \tag{27.1}$$

and perturbations, which are proportional to a small parameters λ,

$$\hat{H} = \hat{H}^{(0)} + \lambda\hat{H}^{(1)} + \lambda^2\hat{H}^{(2)} + .. \ . \tag{27.2}$$

The perturbed wavefunctions are,

$$|\psi\rangle = |\psi^{(0)}\rangle + \lambda|\psi^{(1)}\rangle + \lambda^2|\psi^{(2)}\rangle + .. \ , \tag{27.3}$$

and the energies

$$E = E^{(0)} + \lambda E^{(1)} + \lambda^2 E^{(2)} + .. \ . \tag{27.4}$$

The contributions $\propto \lambda^n$ are the *corrections* of order n. The equation we need to solve now is,

$$\hat{H}|\psi\rangle = E|\psi\rangle \ . \tag{27.5}$$

By inserting all the expansions above and segregating all orders of λ^k, we find the following system of equations,

$$\begin{aligned}
\hat{H}^{(0)}|\psi^{(0)}\rangle &= E^{(0)}|\psi^{(0)}\rangle \\
(\hat{H}^{(0)} - E^{(0)})|\psi^{(1)}\rangle &= (E^{(1)} - \hat{H}^{(1)})|\psi^{(0)}\rangle \\
(\hat{H}^{(0)} - E^{(0)})|\psi^{(2)}\rangle &= (E^{(2)} - \hat{H}^{(2)})|\psi^{(0)}\rangle + (E^{(1)} - \hat{H}^{(1)})|\psi^{(1)}\rangle \\
&\dots .
\end{aligned} \tag{27.6}$$

27.1.1.1 First order energy correction

We now consider eigenstates $|\psi_n^{(1)}\rangle$ of the perturbed system and expand the first-order correction of the wavefunction in a linear combination of unperturbed eigenvectors $|\psi_n^{(0)}\rangle \equiv |n\rangle$,

$$|\psi_n^{(1)}\rangle = \sum_m |m\rangle\langle m|\psi_n^{(1)}\rangle \ . \tag{27.7}$$

We insert this expansion into the second equation (27.6) and multiply with $\langle n|$,

$$\langle n|(\hat{H}^{(0)} - E_n^{(0)})\sum_m |m\rangle\langle m|\psi_n^{(1)}\rangle = 0 = \langle n|E_n^{(1)} - \hat{H}^{(1)}|n\rangle \ . \tag{27.8}$$

We obtain for the first order correction of the energy of unperturbed states,

$$\boxed{E_n^{(1)} = \langle n|\hat{H}^{(1)}|n\rangle} \ . \tag{27.9}$$

As a first example we will calculate in Exc. 27.1.3.1 the first order correction for the energy of a slightly deformed one-dimensional box potential.

27.1.1.2 First order correction for the wavefunction

Now let us have a look at the first-order correction for the wavefunction again considering the second equation (27.6),

$$\langle m|\hat{H}^{(0)} - E_n^{(0)}|\psi_n^{(1)}\rangle = \langle m|E_n^{(1)} - \hat{H}^{(1)}|n\rangle \ . \tag{27.10}$$

When $n = m$, the left side of this equation disappears. Therefore, $E_n^{(1)} - \langle n|\hat{H}^{(1)}|n\rangle = 0$, and we can restrict to the terms $n \neq m$ discarding the terms in $E_n^{(1)}$,

$$\langle m|\psi_n^{(1)}\rangle = \frac{E_n^{(1)}\delta_{mn} - \langle m|\hat{H}^{(1)}|n\rangle}{E_m^{(0)} - E_n^{(0)}} = \frac{\langle m|\hat{H}^{(1)}|n\rangle}{E_n^{(0)} - E_m^{(0)}} \ . \tag{27.11}$$

We obtain for the first-order correction for the energy of the states,

$$\boxed{|\psi_n^{(1)}\rangle = \sum_m |m\rangle\langle m|\psi_n^{(1)}\rangle = \sum_{m\neq n} |m\rangle \frac{\langle m|\hat{H}^{(1)}|n\rangle}{E_n^{(0)} - E_m^{(0)}}} \ . \tag{27.12}$$

This procedure simulates the distortion of the state by blending it with other states. The perturbation induces virtual transitions to other states. The perturbation is large when the blended levels are close.

See Exc. 27.1.3.2. In Exc. 27.1.3.3 we calculate the first order correction due to the finite extension of the hydrogen nucleus. In Exc. 27.1.3.4 we treat the coupling of the energy levels of a two-level system as a first order perturbation, and compare the result with the exact solution. The Stark effect for an electron confined in a box can be discussed (see Exc. 27.1.3.5) in first order TIPT.

27.1.1.3 Second order correction for the energy

To calculate the second order correction for the energy we expand the second order correction,

$$|\psi_n^{(2)}\rangle = \sum_m |m\rangle\langle m|\psi_n^{(2)}\rangle \ , \tag{27.13}$$

import it into the third equation (27.6) and multiply with $\langle n|$,

$$\langle n|(\hat{H}^{(0)}-E_n^{(0)})\sum_m |m\rangle\langle m|\psi_n^{(2)}\rangle = \langle n|(E_n^{(2)}-\hat{H}^{(2)})|n\rangle+\langle n|(E_n^{(1)}-\hat{H}^{(1)})\sum_m |m\rangle\langle m|\psi_n^{(1)}\rangle \ . \tag{27.14}$$

Now,

$$\sum_m \langle m|\psi_n^{(2)}\rangle(E_n^{(0)}-E_m^{(0)})\delta_{nm} = 0 = E_n^{(2)}-\langle n|\hat{H}^{(2)}|n\rangle+\sum_m \langle m|\psi_n^{(1)}\rangle\left(E_n^{(1)}\delta_{nm} - \langle n|\hat{H}^{(1)}|m\rangle\right) \ . \tag{27.15}$$

The left-hand side of this equation disappears. Also, on the right-hand side, for $n \neq m$, the term $E_n^{(1)}\delta_{nm}$ disappears, and for $n = m$ the whole parenthesis disappears. Therefore, we can discard the term $E_n^{(1)}$ and restrict the sum to terms with $n \neq m$. Inserting the coefficients $\langle m|\psi_n^{(1)}\rangle$ calculated in (27.11), we finally obtain,

$$\boxed{E_n^{(2)} = \langle n|\hat{H}^{(2)}|n\rangle + \sum_{m\neq n} \frac{\langle n|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|n\rangle}{E_n^{(0)} - E_m^{(0)}}} \ . \tag{27.16}$$

The first term is similar to the first order correction; the eigenvalue of the second order perturbation calculated in the base of the unperturbed states. The second term describes the shift of the energies through possible temporary transitions to other states.

In Exc. 27.1.3.6 we treat a system of three coupled levels up to the second perturbative order. The Stark effect discussed in Exc. 27.1.3.7 needs the TIPT calculation up to the second order.

27.1.2 TIPT with degenerate states

Exact calculations show that the effect of a perturbation is larger – but finite – for degenerate states. On the other hand, from the above expressions for the corrections of both energies and wavefunctions, we would infer that these corrections can become very large for small perturbations or even diverge.

Fortunately, the fact that every linear combination of degenerate wavefunctions is an eigenfunction of the Hamiltonian as well gives us the freedom to choose the combination, which is most similar to the final form of the perturbed wavefunctions.

For example, considering a perturbation by a magnetic field it may be advantageous to expand the spherical functions Y_{lm} on a basis of cylindrical coordinates [1]. We will see in the following that we can solve both problems, the selection of the initial combination and the prevention of divergent denominators at once, without explicitly specifying the expansion.

We consider eigenstates $|n,\nu\rangle$ with the energy $E_n^{(0)}$ being r times degenerate with respect to the quantum number ν, where $\nu = 1,..,r$. All states satisfy

$$\hat{H}^{(0)}|n,\nu\rangle = E_n^{(0)}|n,\nu\rangle \ . \tag{27.17}$$

We construct linear combinations that most resemble the perturbed states

$$|\psi_{n\mu}^{(0)}\rangle = \sum_{\nu=1}^{r} c_{\mu\nu}|n,\nu\rangle \ . \tag{27.18}$$

When the perturbation $\hat{H}^{(1)}$ is applied, we assume that the state $|\psi_{n\mu}^{(0)}\rangle$ is distorted towards the similar state $|\psi_{n\mu}\rangle$, and the energy changes from $E_n^{(0)}$ to $E_{n\mu}$. We now need the index μ to label the energy, since the degeneracy can be removed by the perturbation. As before, we write now,

$$\begin{aligned} \hat{H} &= \hat{H}^{(0)} + \lambda\hat{H}^{(1)} + .. \\ |\psi_{n\mu}\rangle &= |\psi_{n\mu}^{(0)}\rangle + \lambda|\psi_{n\mu}^{(1)}\rangle + .. \\ E_{n\mu} &= E_n^{(0)} + \lambda E_{n\mu}^{(1)} + .. \ . \end{aligned} \tag{27.19}$$

The replacement of these expansions in $\hat{H}|\psi_{n\mu}\rangle = E_{n\mu}|\psi_{n\mu}\rangle$, and a collection of the terms in λ up to first order gives,

$$\begin{aligned} \hat{H}^{(0)}|\psi_{n\mu}^{(0)}\rangle &= E_n^{(0)}|\psi_{n\mu}^{(0)}\rangle \\ (E_n^{(0)} - \hat{H}^{(0)})|\psi_{n\mu}^{(1)}\rangle &= (E_{n\mu}^{(1)} - \hat{H}^{(1)})|\psi_{n\mu}^{(0)}\rangle \ . \end{aligned} \tag{27.20}$$

As before, we try to express the first-order corrections for the wavefunctions through degenerate unperturbed wavefunctions $|\psi_{n\mu}^{(0)}\rangle$ and non-degenerate wavefunctions [2] $|\psi_m^{(0)}\rangle$:

$$|\psi_{n\mu}^{(1)}\rangle = \sum_{\nu} b_{\mu\nu}|\psi_{n\nu}^{(0)}\rangle + \sum_{m} a_{nm}|\psi_m^{(0)}\rangle \ . \tag{27.21}$$

Inserting this into the first-order equation (27.20), we obtain,

$$\sum_{\nu} b_{\mu\nu}(E_n^{(0)} - E_n^{(0)})|\psi_{n\nu}^{(0)}\rangle + \sum_{m} a_{nm}(E_m^{(0)} - E_n^{(0)})|\psi_m^{(0)}\rangle = (E_{n\mu}^{(1)} - \hat{H}^{(1)})|\psi_{n\mu}^{(0)}\rangle \ . \tag{27.22}$$

The first term disappears. Inserting the expansion (27.18),

$$\sum_{m} a_{nm}(E_m^{(0)} - E_n^{(0)})|\psi_m^{(0)}\rangle = (E_{n\mu}^{(1)} - \hat{H}^{(1)})\sum_{\nu} c_{\mu\nu}|n,\nu\rangle \ , \tag{27.23}$$

[1] Another example would be the preference for the coupled base $|(l,s)j,m_j\rangle$ in comparison to the decoupled base $|l,m_l,s,m_s\rangle$ knowing that the degeneracy in j is lifted, when there is an energy associated with interacting angular momenta and the degeneracy in m_j is lifted, when we apply a magnetic field.

[2] Note that we label all states *which are not degenerate with the state under investigation* $|\psi_{n\mu}^{(1)}\rangle$ with the index m, even if there are degeneracies between them.

and multiplying the two sides with $\langle n,\mu|$, we get zero on the left-hand side, since we can choose the non-degenerate states to be orthogonal $\langle n,\nu|m\rangle = \delta_{m,n}$. Hence,

$$\boxed{\sum_\nu c_{\mu\nu}\left[E^{(1)}_{n\mu}\langle n,\mu|n,\nu\rangle - \langle n,\mu|\hat{H}^{(1)}|n,\nu\rangle\right] = 0} \ . \tag{27.24}$$

This *secular equation* (one for each μ) represents, in fact, a set of r linear equations for the coefficients $c_{\mu\nu}$. The condition for having non-trivial solutions is,

$$\det\left(\langle n,\nu|\hat{H}^{(1)}|n,\mu\rangle - E^{(1)}_{n\mu}\delta_{\mu,\nu}\right)_{\mu,\nu} = 0 \ . \tag{27.25}$$

The solution of this *secular determinant* yields the solicited energies $E^{(1)}_\mu$. Now, the solution of the secular equation (27.24) *for each energy value* produces those coefficients, which represent the best linear combinations adapted to the perturbation. Unlike in previous calculations with degenerate states, here we consider linear combinations of vectors of the degenerate subspace prior to switching on the perturbation.

In practice, we apply perturbation theory only to the lowest relevant order. That is, we only calculate the second order correction if first order corrections vanish. One famous example is the *quadratic Stark effect* discussed in Sec. 33.3. In the case of eigenvalues, which are degenerate in the absence of perturbation, the first order will always produce a remarkable correction, as in the example of the *linear Stark effect*, also discussed in Sec. 33.3. For this reason, we need not discuss higher perturbation orders in the case of degenerate eigenvalues.

Example 223 (*Perturbation in a system with two degenerate states*): As an example, we consider the following Hamiltonian,

$$\hat{H} = \begin{pmatrix} \Delta & \Omega \\ \Omega & \Delta \end{pmatrix} \ .$$

The exact solution gives the eigenvalues and eigenvectors,

$$E_1 = \Delta + \Omega \quad , \quad E_2 = \Delta - \Omega \quad , \quad |\psi_1\rangle = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ 1 \end{pmatrix} \quad , \quad |\psi_2\rangle = \tfrac{1}{\sqrt{2}}\begin{pmatrix} -1 \\ 1 \end{pmatrix} \ .$$

Now we divide the Hamiltonian into an unperturbed part and a perturbation,

$$\hat{H} \equiv \hat{H}^{(0)} + \hat{H}^{(1)} = \begin{pmatrix} \Delta & 0 \\ 0 & \Delta \end{pmatrix} + \begin{pmatrix} 0 & \Omega \\ \Omega & 0 \end{pmatrix} \ .$$

We get in zero order,

$$E^{(0)}_1 = \Delta = E^{(0)}_2 \quad , \quad |1\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad , \quad |2\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \ ,$$

The application of non-degenerate perturbation theory in first order would give,

$$\langle 1|\hat{H}^{(1)}|1\rangle = 0 = \langle 2|\hat{H}^{(1)}|2\rangle \quad , \quad |\psi^{(1)}_1\rangle = |1\rangle\frac{\langle 1|\hat{H}^{(1)}|2\rangle}{E^{(0)}_1 - E^{(0)}_2} \to \infty \leftarrow -|\psi^{(1)}_2\rangle \ .$$

That is, the correction of the energy vanishes in first order, while the correction of the wavefunction diverges. Obviously, the $|\nu\rangle$ obtained by the diagonalization of the matrix $\hat{H}^{(0)}$ is not adapted to the calculation of the matrix elements $\hat{H}^{(1)}$. Now, applying degenerate perturbation theory, we obtain by the secular determinant,

$$0 = \det\left[\langle\nu|\hat{H}^{(1)}|\mu\rangle - E_\mu^{(1)}\delta_{\mu,\nu}\right] = \det\begin{pmatrix} -E_\mu^{(1)} & \Omega \\ \Omega & -E_\mu^{(1)} \end{pmatrix} = (E_\mu^{(1)})^2 - \Omega^2 \ ,$$

eigenvalues are $E_1^{(1)} = \Omega$ and $E_2^{(1)} = -\Omega$ allowing the establishment of the secular equation,

$$\begin{aligned} c_{11}\left[E_1^{(1)} - \langle 1|\hat{H}^{(1)}|1\rangle\right] - c_{12}\langle 1|\hat{H}^{(1)}|2\rangle &= c_{11}[\Omega - 0] - c_{12}\Omega = 0 \\ -c_{21}\langle 2|\hat{H}^{(1)}|1\rangle + c_{22}\left[E_2^{(1)} - \langle 2|\hat{H}^{(1)}|2\rangle\right] &= -c_{21}\Omega + c_{22}[-\Omega - 0] = 0 \ . \end{aligned}$$

We obtain $c_{11} = c_{12}$ and $c_{21} = -c_{22}$ and with this,

$$|\psi_1^{(0)}\rangle = \sum_\nu c_{1\nu}|\nu\rangle = c_{11}|1\rangle + c_{12}|2\rangle = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 \\ 1 \end{pmatrix} \quad , \quad |\psi_2^{(0)}\rangle = c_{21}|1\rangle + c_{22}|2\rangle = \tfrac{1}{\sqrt{2}}\begin{pmatrix} -1 \\ 1 \end{pmatrix} \ .$$

Thus, we can verify that the corrections for the eigenenergies,

$$E_1 = E_1^{(0)} + \langle\psi_1^{(0)}|\hat{H}^{(1)}|\psi_1^{(0)}\rangle = \Delta + \Omega \quad , \quad E_2 = E_2^{(0)} + \langle\psi_2^{(0)}|\hat{H}^{(1)}|\psi_2^{(0)}\rangle = \Delta - \Omega \ ,$$

coincides with the exact calculation made at the beginning. The eigenfunctions $|\psi_1^{(0)}\rangle$ should be already corrected in zeroth order, which we verify by calculating,

$$|\psi_1^{(1)}\rangle = |\psi_1^{(0)}\rangle \frac{\langle\psi_1^{(0)}|\hat{H}^{(1)}|\psi_2^{(0)}\rangle}{E_1 - E_2} = 0 = |\psi_2^{(1)}\rangle \ .$$

In Exc. 27.1.3.8 we study a partially degenerate three-level system and the breakdown of the degeneracy due to a perturbation. And in Exc. 27.1.3.9 we will treat a perturbation in a box potential with degenerate energy levels.

27.1.3 Exercises

27.1.3.1 Ex: One-dimensional well with a deformation in the centre

Consider a one-dimensional potential well between $-L/2$ and $L/2$ with infinitely high walls. In the center of the well is a small deformation,

$$H^{(1)} = \begin{cases} \epsilon \text{ for } \frac{-a}{2} \leq x \leq \frac{a}{2} \\ 0 \text{ outside that region} \ . \end{cases}$$

Calculate the correction for the eigenenergies in first order and discuss the limits $a \ll L$ and $a \to L$.

27.1.3.2 Ex: Perturbation

Show that the scalar product $\langle\psi_n^{(0)}|\psi_n^{(1)}\rangle$ (from the first-order correction to the state of the 'perturbed' system with the n-th state of the free Hamiltonian), cancels out when we impose that the 'perturbed' state $|\psi(\lambda)\rangle$ be normalized and the the product $\langle\psi_n^{(0)}|\psi(\lambda)\rangle$ be real [3].

27.1.3.3 Ex: Extended nucleus

The expression $V(r) = -e^2/4\pi\varepsilon_0 r$ for the potential energy of an electron in the hydrogen atom implies that the nucleus (the proton) is treated as a point particle. Now suppose that, on the contrary, the charge of the proton $+e$ is evenly distributed over a sphere of radius $R = 10^{-13}$ cm.
a. Derive the modified potential V_{m}, which corresponds to this distribution of the nuclear charge.
b. Assume that the wavefunction of the hydrogen atom does not change much due to the modified potential. Calculate in lowest order in R/a_{B} the average energetic displacement $\langle\Delta V\rangle$ for the state $(n = 1, \ell = 0, m = 0)$. How will the energy displacement be in comparison to the states $(n = 2, \ell = 0, m = 0)$ and $(n = 2, \ell = 1, m = 0)$?
c. Calculate in the same way $\langle\Delta V\rangle$ for muonic hydrogen in the ground state.

27.1.3.4 Ex: Perturbation of a two-level system

We consider a two-level system. Without perturbation the system would have the Hamiltonian $H^{(0)}$, the eigenenergies $E_{1,2}^{(0)}$ and the eigenfunctions $\psi_{1,2}^{(0)}$. Now we switch on a stationary perturbation of the form $H^{(1)} = \epsilon(|1\rangle\langle 2| + |2\rangle\langle 1|)$.
a. Calculate the eigenenergies directly solving the perturbed Schrödinger equation.
b. Calculate the perturbed energies using TIPT and compare to the exact calculation of the eigenenergies.
c. Calculate the eigenstates directly solving the perturbed Schrödinger equation.
d. Calculate the perturbed states using TPIT and compare to the exact calculation of the eigenfunctions.

27.1.3.5 Ex: Stark effect for an electron in a box

Consider an electron in a one-dimensional box, that is, in a well inside the interval $x \in [0, a]$ delimited by infinite walls. When a uniform electric field $\mathcal{E}$ is applied, also in x-direction, the electron experiences a force equal to $-e\mathcal{E}$, being $-e$ the electron charge, so that the potential energy inside the box becomes $e\mathcal{E}x$.
a. What is the energy of the ground state of the electron (in first order approximation)? We can assume that $e\mathcal{E}a$ is much smaller than the ground state energy the electron would have in the absence of electric fields.
b. Use first-order TIPT to get an approximation for the ground state wavefunction by calculating the first term of the correction.

[3] See [184], Cap XI, A-2.

27.1.3.6 Ex: Perturbed 3-level system until second order TIPT

Consider the following perturbed Hamiltonian:

$$H = H_0 + H_\lambda = \begin{pmatrix} E_1 & 0 & 0 \\ 0 & E_2 & 0 \\ 0 & 0 & E_3 \end{pmatrix} + \begin{pmatrix} 0 & \lambda & 0 \\ \lambda & 0 & \lambda \\ 0 & \lambda & 0 \end{pmatrix} .$$

a. Determine the perturbed eigenvalues and eigenfunctions in first order TIPT.
b. Determine the eigenvalues in second order TIPT.

27.1.3.7 Ex: Stark effect for a charge in a harmonic oscillator

Consider a charged harmonic oscillator, immersed in a uniform electric field $\mathcal{E}$, described by the Hamiltonian $\hat{H}^{(1)} = \hat{H} + e\mathcal{E}\hat{x}$, being $\hat{H} = \hat{p}^2/2m + m\omega^2\hat{x}^2/2$ the Hamiltonian of the free one-dimensional oscillator, and e the charge of the oscillator.
a. Obtain, through TIPT, the eigenenergies (first and second order corrections). Compare the results obtained by TIPT with the analytical ones [4].
b. Same thing for a perturbation of the form $\rho m\omega^2\hat{x}^2/2$.
c. Same thing for a perturbation $\sigma\hbar\omega\hat{x}^3$.

27.1.3.8 Ex: Three-level system with degeneracy

Consider the following Hamiltonian $\hat{H}^{(0)}$ and its perturbation $\hat{H}^{(1)}$

$$\hat{H}^{(0)} + \hat{H}^{(1)} = \begin{pmatrix} \Delta & 0 & 0 \\ 0 & \Delta & 0 \\ 0 & 0 & \Delta' \end{pmatrix} + \begin{pmatrix} 0 & \Omega & 0 \\ \Omega & 0 & \Omega \\ 0 & \Omega & 0 \end{pmatrix} .$$

Calculate the corrections for the eigenvalues and eigenfunctions up to first order.

27.1.3.9 Ex: Perturbation in a 3D well with degeneracy

Consider a particle confined to a three-dimensional, infinite cubic well described by the potential energy $V(x, y, z) = 0$ for $0 < x < a$, $0 < y < a$ and $0 < z < a$ and $V(x, y, z) = \infty$ outside this region. We know that the particle's stationary states are $\Psi^{(0)}_{n_x,n_y,n_z}(x, y, z) = \left(\frac{2}{a}\right)^{3/2} \sin\left(\frac{n_x\pi}{a}x\right) \sin\left(\frac{n_y\pi}{a}y\right) \sin\left(\frac{n_z\pi}{a}z\right)$, being n_x, n_y, n_z positive integers. The associated energies are $E^{(0)}_{n_x,n_y,n_z} = \frac{\pi^2\hbar^2}{2ma^2}(n_x^2 + n_y^2 + n_z^2)$. Note that the ground state is not degenerate while the first excited state is three times degenerate. Consider that the particle in this box is subject to a perturbation of the shape $H^{(1)} = V_0$ for $0 < x < a/2$ and $0 < y < a/2$ and $H^{(1)} = 0$ outside this region.
a. Obtain the first-order correction for the ground state energy.
b. Obtain the first-order correction for the (degenerate) energy of the first excited state, in addition to the *optimal base* (which follows from the linear combinations of degenerate states) which most closely approximates the perturbed states.

[4] See [184], Complement A_XI.

27.1.3.10 Ex: Vanishing perturbation orders

Show that it is impossible to design a perturbation Hamiltonian of the form,

$$\hat{H} = \hat{H}^{(0)} + \hat{H}^{(1)} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & E_2 & 0 \\ 0 & 0 & E_3 \end{pmatrix} + \begin{pmatrix} 0 & \Omega_{12} & \Omega_{13} \\ \Omega_{12}^* & 0 & \Omega_{23} \\ \Omega_{13}^* & \Omega_{23}^* & 0 \end{pmatrix}$$

such that the first and second order corrections vanish.

27.2 Variational method

27.2.1 The Rayleigh fraction

Let us assume that we want to calculate the ground state energy E_{g} of a system described by a Hamiltonian $\hat{H}$, but we do not know the wavefunction, and we do not know how to solve the Schrödinger equation. If at least we had a good idea of the generic form of the solution (Gaussian, sinusoidal, ...), we could choose a trial function with a free parameter and optimize this parameter minimizing the energy, which ought to be minimal for the ground state. This is precisely the idea of the *variational method*. Note that the variational method only works for the ground state. Numerically it can be implemented by the method of steepest descent presented in Sec. 24.4.3.

For any function ψ we know that the *Rayleigh fraction* $\mathcal{E}$ satisfies,

$$E_{\mathrm{g}} \leq \frac{\langle\psi|\hat{H}|\psi\rangle}{\langle\psi|\psi\rangle} \equiv \mathcal{E} \ , \tag{27.26}$$

not only when ψ is the wavefunction of an excited state, but even when it represents a (imperfect) trial to the ground state. Assuming normalized wavefunctions we can discard the denominator $\langle\psi|\psi\rangle = 1$. To verify the theorem, we expand the function ψ into orthonormal (unknown) eigenfunctions, $|\psi\rangle = \sum_n c_n|\psi_n\rangle$. Since ψ is normalized,

$$1 = \langle\psi|\psi\rangle = \sum_{m,n} \langle\psi_m|c_m^* c_n|\psi_n\rangle = \sum_n |c_n|^2 \ . \tag{27.27}$$

In the same way,

$$\langle\psi|\hat{H}|\psi\rangle = \sum_{m,n} \langle\psi_m|c_m^* \hat{H} c_n|\psi_n\rangle = \sum_n E_n|c_n|^2 \ . \tag{27.28}$$

As the ground state is that of the lowest energy, $E_{\mathrm{g}} \leq E_n$, we have demonstrated the relationship (27.26)

$$E_{\mathrm{g}} = E_{\mathrm{g}} \sum_n |c_n|^2 \leq \sum_n E_n|c_n|^2 = \langle\hat{H}\rangle \ . \tag{27.29}$$

In practice, we arrange for the trial wavefunction to depend on a free parameter α. This ansatz ψ_α for the ground state wavefunction then allows us to calculate an

energy that must be minimized via

$$\boxed{\frac{\partial\langle\psi_\alpha|\hat{H}|\psi_\alpha\rangle}{\partial\alpha}=0}\ . \tag{27.30}$$

In the Excs. 27.2.3.1 and 27.2.3.2 we will approach the fundamental state of a quartic potential and a harmonic oscillator, respectively, by trying several trial wavefunctions and optimizing their free parameters.

27.2.2 Rayleigh-Ritz method

A modification of the variational method is the *Rayleigh-Ritz method*. Here, instead of using a trial function, we use a linear combination of eigenfunctions with variable coefficients: $|\psi\rangle = \sum_k c_k|k\rangle$. These variables are then optimized to minimize the Rayleigh fraction,

$$E_{\rm g} \leq \frac{\sum_{k,m} c_k^* c_m \langle k|\hat{H}|m\rangle}{\sum_{k,m} c_k^* c_m \langle k|m\rangle} = \mathcal{E}\ , \tag{27.31}$$

where we assume real coefficients and eigenfunctions. For this, the derivatives with respect to all coefficients must vanish:

$$\begin{aligned} 0 \equiv \frac{\partial\mathcal{E}}{\partial c_q} &= \frac{\sum_{k,m}\frac{\partial}{\partial c_q} c_k^* c_m \langle k|\hat{H}|m\rangle}{\sum_{k,m} c_k^* c_m \langle k|m\rangle} - \frac{\sum_{k,m} c_k^* c_m \langle k|\hat{H}|m\rangle \sum_{k,m}\frac{\partial}{\partial c_q} c_k^* c_m \langle k|m\rangle}{\left(\sum_{k,m} c_k^* c_m \langle k|m\rangle\right)^2} \\ &= \frac{\sum_{k,m} c_k^* \delta_{qm} \langle k|\hat{H}|m\rangle}{\sum_{k,m} c_k^* c_m \delta_{km}} - \mathcal{E}\frac{\sum_{k,m} c_k^* \delta_{qm}\delta_{km}}{\sum_{k,m} c_k^* c_m \delta_{km}} = \sum_k c_k^* \langle k|\hat{H}|q\rangle - \mathcal{E} c_q^*\ , \end{aligned} \tag{27.32}$$

using the definition of $\mathcal{E}$ (27.31). For the expression $\partial\mathcal{E}/\partial c_q^*$ we get analogous results. Hence,

$$\boxed{0 = \sum_m c_m(\langle q|\hat{H}|m\rangle - \mathcal{E}\langle q|m\rangle)}\ . \tag{27.33}$$

The condition for the existence of solutions is that the secular determinant disappears,

$$0 = \det(\langle q|\hat{H}|m\rangle - \mathcal{E}\langle q|m\rangle)\ . \tag{27.34}$$

The solution of this equation leads to a set of values $\mathcal{E}$, and the lowest value, $\mathcal{E}_{\rm min}$, is the best approximation for the ground state energy. The coefficients of the wavefunction are obtained by solving the eigenvalue equation (27.33) with $\mathcal{E}_{\rm min}$.

In Exc. 27.2.3.3 we derive the regression formulas for a linear *least squares fit* from a Rayleigh-Ritz variational. In Exc. 27.2.3.4 we will use the Rayleigh-Ritz method to estimate the effect of a finite nuclear mass of the hydrogen atom on the energy levels. In Exc. 27.2.3.5 we will use the Rayleigh-Ritz method to find the maximum number of atoms allowing for a stable Bose-Einstein condensate made of atoms subject to an attractive interatomic force.

27.2.3 Exercises

27.2.3.1 Ex: Variational method applied to a quartic potential

Determine the ground state energy of the quartic potential $V(x) = bx^4$ making the variational ansatz $\psi_\alpha(x) = (\alpha/\pi)^{1/4} e^{-\alpha x^2/2}$. **Formulae**:

$$\int_{-\infty}^{\infty} e^{-x^2} dx = \sqrt{\pi} \quad , \quad \int_{-\infty}^{\infty} x^2 e^{-x^2} dx = \tfrac{1}{2}\sqrt{\pi} \quad , \quad \int_{-\infty}^{\infty} x^4 e^{-x^2} dx = \tfrac{3}{4}\sqrt{\pi}$$

27.2.3.2 Ex: Variational method applied to the harmonic oscillator

Obtain, through the variational method, the ground state energy of the one-dimensional harmonic oscillator described by the Hamiltonian $\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + \frac{1}{2}m\omega^2 x^2$, and the corresponding wavefunction from the test functions
a. $\psi(x) = Ae^{-\alpha x^2}$ being α a constant;
b. $\psi(x) = A/(x^2 + \beta^2)$ being β a constant;
c. $\psi(x) = A\cos(\pi x/a)$ between the limits $\pm a/2$ being a a constant.

27.2.3.3 Ex: Linear least squares

Use the Raleigh-Ritz method to derive the regression coefficients for a linear fit $f(x_k) = ax_k + b$ to a set of data points (x_k, y_k).

27.2.3.4 Ex: Effect of finite nuclear mass on hydrogen via Rayleigh-Ritz

Use the Rayleigh-Ritz method to estimate the impact of the finite mass of the nucleus of the hydrogen atom. To do this, calculate the ground state energy using the exact Hamiltonian, but a basis of wavefunctions assuming an infinitely heavy nucleus. Only take into account the states ψ_{100} and ψ_{200}. **Help:** Express the exact Hamiltonian in terms of the infinite-mass Hamiltonian approximating for small corrections of the reduced mass: $m \equiv m_e/(1+\gamma) \simeq (1-\gamma)m_e$, where $\gamma \equiv m_e/m_p$.

27.2.3.5 Ex: Collapse of a condensate with attractive interactions

A Bose-Einstein condensate of ^{7}Li may become unstable due to attractive interatomic force, the scattering length being $a_s = -27.3a_\mathrm{B}$. Consider the radial Gross-Pitaevskii Hamiltonian derived in Exc. 25.1.5.2 with an external harmonic potential with the oscillation frequency $\omega_{trp}/(2\pi) = 50$ Hz. Using the variational method to determine the maximum number of atoms allowing for a stable condensate. (Note that the derived minimization condition must be evaluated numerically.)

27.3 WKB approximation

The *WKB approximation* (from Wentzel-Kramers-Brillouin) [130, 540, 967] is a method to find approximate solutions for linear differential equations with spatially variable coefficients. It is typically used for calculations in quantum mechanics where the wavefunction is reformulated as an exponential semi-classically expanded function,

and then the amplitude or phase is slowly changed. In the following, we present the WKB approximation applied to the Schrödinger equation and exemplify it in some canonical systems.

27.3.1 WKB approximation applied to the Schrödinger equation

Starting from the time-independent Schrödinger equation,

$$-\frac{\hbar^2}{2m}\frac{d^2}{dx^2}\psi(x) + V(x)\psi(x) = E\psi(x) \ , \tag{27.35}$$

and rewrite it as follows,

$$\frac{d^2\psi}{dx^2} = k(x)\psi(x) \ . \tag{27.36}$$

with $k(x) = \sqrt{2m[E - V(x)]/\hbar^2}$. For now, we will restrict ourselves to energies $E > V(x)$. In this scheme, the wavefunctions are usually complex functions, so that we can write them in polar coordinates, containing an amplitude $A(x)$ and a phase $\phi(x)$, which are both real numbers:

$$\psi(x) = A(x)e^{\imath\phi(x)} \ . \tag{27.37}$$

Substituting this function into the Schrödinger equation we obtain a system of coupled equations in terms of $A(x)$ and $\phi(x)$,

$$A'' = A\Big[(\phi')^2 - k^2\Big] \qquad \text{and} \qquad (A^2\phi')' = 0 \ . \tag{27.38}$$

The equations (27.39) and (27.37) are completely equivalent to the Schrödinger equation. The second Eq. (27.38) is easy to solve,

$$A = \frac{C}{\sqrt{\phi'}} \ , \tag{27.39}$$

being C a real constant. We can not say the same thing about the solution of the first Eq. (27.38). In order to solve it we are going to use the WKB approach, assuming that A varies slowly, so the term $A'' \to 0$. By doing this approximation we can rewrite Eq. (27.39) in this way:

$$(\phi')^2 = k^2 \ . \tag{27.40}$$

Solving this last expression we obtain two linearly independent solutions, $\phi' = \pm k$. So we get the expression for the phase:

$$\phi(x) = \pm\int k(x)dx \ . \tag{27.41}$$

We write this indefinite integral, because the constant term can be absorbed by the constant C. Finally, we obtain the expression for the wavefunction in the WKB approximation:

$$\boxed{\psi(x) = \frac{C}{\sqrt{|k(x)|}}e^{\pm\int|k(x)|dx}} \ . \tag{27.42}$$

Here, taking the absolute value of the wavevector, we have already generalized for the case that the energy E of the particle is lower than the potential $V(x)$ (classically forbidden region).

Example 224 (*WKB approximation*): The WKB approach is a semiclassical method for the solution of the Schrödinger equation that does not require the potential to be a perturbation of a soluble problem. Instead, it only assumes that certain classical quantities having the dimension of an action (energy per time) are much larger than Planck's constant. Inserting the ansatz

$$\psi(x) = Ae^{\imath S(x)/\hbar} \ ,$$

into the one-dimensional time-independent Schrödinger equation, we find,

$$-\tfrac{i\hbar}{2m} S''(x) + \tfrac{1}{2m} S'(x)^2 + V(x) - E = 0 \ .$$

Now we expand the exponent in orders of $\hbar$,

$$S(x) = S_0(x) + \hbar S_1(x) + \tfrac{\hbar^2}{2} S_2(x) + \dots \ ,$$

and insert it in the above equation. Collecting the orders in $\hbar$, we find in the first orders,

$$\begin{aligned} \left[\tfrac{1}{2m} S_0'(x)^2 + V(x) - E\right] \hbar^0 &= 0 \\ \left[-\tfrac{\imath\hbar}{2m} S_0''(x) + \tfrac{1}{m} S_0'(x) S_1'(x)\right] \hbar^1 &= 0 \\ \left[\tfrac{1}{2m} S_1'(x)^2 - \tfrac{\imath}{2m} S_1''(x)\right] \hbar^2 &= 0 \ . \end{aligned}$$

The solution of the zeroth order equation, $S_0(x) = \pm \int^x \sqrt{2m[E - V(x')}dx'$, gives

$$\psi(x) = Ae^{\pm \frac{\imath}{\hbar} \int^x \sqrt{2m[E - V(x')}dx'} \ .$$

The WKB approximation can be used to describe continuous potentials (or barriers) by stepwise constant potentials. The transmission $|T|^2$ through these parts can be obtained by multiplying the individual tunneling probabilities,

$$\ln |T|^2 \simeq -2 \int_{barrier} \kappa(x) dx \ ,$$

with $\kappa(x) = \frac{1}{\hbar}\sqrt{2m[V(x) - E]}$.

27.3.2 Connection formulas

Now let us derive the connection formulas that interconnect solutions with E above and below $V(x)$ at the turning points, precisely those regions where WKB fails. We will apply the derivation to a generic confining potential shown in Fig. 27.1.

Let us start with the right turning point Fig. 27.1(a)]. First, we shift the coordinate system so that the turning point coincides with zero, as shown in Fig. 27.1(b). As seen above, the WKB solutions will be given by the following equations:

$$\psi(x) \approx \begin{cases} \frac{1}{\sqrt{k(x)}} \left[Be^{\imath \int_x^0 k(x')dx'} + Ce^{-\imath \int_x^0 k(x')dx'} \right] & \text{if} \quad x \le 0 \\ \frac{1}{\sqrt{k(x)}} De^{-\int_0^x |k(x')|dx'} & \text{if} \quad x \ge 0 \end{cases} \ . \tag{27.43}$$

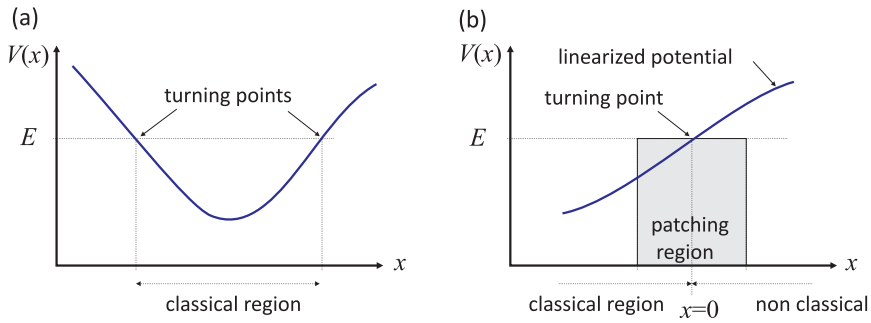

Figure 27.1: (a) Potential for which we want to obtain the connection formula. (b) Turning point.

In the vicinity of the turning point we approximate the potential by a straight line (Taylor series expansion up to first order) with the following functional dependence,

$$V(x) \approx E + V'(0)x \ . \tag{27.44}$$

The Schrödinger equation for this potential acquires the following format,

$$\frac{d^2\psi_{\rm t}}{dx^2} = \alpha^3 x \psi_{\rm t} \ , \tag{27.45}$$

with $\alpha = [\frac{2m}{\hbar^2}V'(0)]^{1/3}$. Through a change of variables, $z = \alpha x$, we fall back on Airy's equation,

$$\frac{d^2\psi_{\rm t}}{dz^2} = z\psi_{\rm t} \ , \tag{27.46}$$

having as solution a linear combination of the two solutions of the Airy equation,

$$\psi_{\rm t}(x) = a{\rm Ai}(\alpha x) + b{\rm Bi}(\alpha x) \ . \tag{27.47}$$

Now let's have a look at the WKB solutions in the two regions in the vicinity of the turning point. In the classically forbidden region we have $k(x) = \alpha^{3/2}\sqrt{-x}$, thus being $\int_0^x |k(x')|dx' = \frac{2}{3}(\alpha x)^{3/2}$. Thus, the WKB solution in the classically forbidden region near the turning point will be given by:

$$\psi(x) \approx \frac{D}{\sqrt{\hbar}\alpha^{3/4}x^{1/4}} e^{-\frac{2}{3}(\alpha x)^{3/2}} \ . \tag{27.48}$$

Using the asymptotic forms of Airy functions in the solution (27.47) we obtain the following expression for $\psi_t(x)$,

$$\psi_p(x) \approx \frac{a}{2\sqrt{\pi}(\alpha x)^{1/4}} e^{-\frac{2}{3}(\alpha x)^{3/2}} + \frac{b}{\sqrt{\pi}(\alpha x)^{1/4}} e^{\frac{2}{3}(\alpha x)^{3/2}} \ , \tag{27.49}$$

which when compared to equation (27.48) shows us that $a = \sqrt{\frac{4\pi}{\alpha\hbar}}D$ and $b = 0$. Repeating the previous steps in the negative region we see that the WKB solution in

the asymptotic forms of the Airy solutions for approximately linear potentials takes the following format (with $b = 0$):

$$\psi(x) \approx \frac{1}{\sqrt{\hbar}\alpha^{3/4}(-x)^{1/4}}\left[Be^{\imath\frac{2}{3}(-\alpha x)^{3/2}} + Ce^{-\imath\frac{2}{3}(-\alpha x)^{3/2}}\right], \tag{27.50}$$

and

$$\psi_p(x) \approx \frac{a}{\sqrt{\pi}(-\alpha x)^{1/4}}\frac{1}{2\imath}\left[e^{\imath\pi/4}e^{\imath\frac{2}{3}(-\alpha x)^{3/2}} - e^{-\imath\pi/4}e^{-\imath\frac{2}{3}(-\alpha x)^{3/2}}\right]. \tag{27.51}$$

When compared, $\frac{a}{2\imath\sqrt{\pi}}e^{\imath\pi/4} = \frac{B}{\sqrt{\hbar\alpha}}$ and $-\frac{a}{2\imath\sqrt{\pi}}e^{-\imath\pi/4} = \frac{C}{\sqrt{\hbar\alpha}}$. Having all this information we can rewrite the WKB solutions for all positions in the potential, including the turning points [5]:

$$\psi(x) \approx \begin{cases} \frac{2D}{\sqrt{k(x)}}\sin\left[\int_x^{x_2} k(x')dx' + \frac{\pi}{4}\right], & \text{if } x \le x_2 \\ \frac{D}{\sqrt{k(x)}}e^{-\int_{x_2}^{x}|k(x')|dx'}, & \text{if } x \ge x_2 \end{cases}. \tag{27.52}$$

Repeating the process for a decreasing turning point [left turning point of the potential of Fig. 27.1(a)], we obtain the following expression:

$$\psi(x) \approx \begin{cases} \frac{D'}{\sqrt{k(x)}}e^{-\int_x^{x_1}|k(x')|dx'}, & \text{if } x \le x_1 \\ \frac{2D'}{\sqrt{k(x)}}\sin\left[\int_{x_1}^{x} k(x')dx' + \frac{\pi}{4}\right], & \text{if } x \ge x_1 \end{cases}. \tag{27.53}$$

Example 225 (*Harmonic oscillator*): Now we apply the WKB method to a well-known system: the harmonic oscillator. We will calculate its energy levels and the respective eigenfunctions.
Eigenenergies: First, note that for a confining potential, and more specifically in the region where $E \ge V(x)$, we have the solutions obtained for the left and right turning point, these two solutions must match each other, that is,

$$\frac{2D}{\sqrt{k(x)}}\sin\left[\int_x^{x_2} k(x')dx' + \frac{\pi}{4}\right] \simeq \frac{2D'}{\sqrt{k(x)}}\sin\left[\int_{x_1}^{x} k(x')dx' + \frac{\pi}{4}\right],$$

and hence the zeros of these functions, so the arguments of those sines must be equal (except for a multiple of π),

$$\begin{aligned} \int_x^{x_2} kdx' + \frac{\pi}{4} &= -\int_{x_1}^{x_1} kdx' - \frac{\pi}{4} + n\pi \\ \left(\int_{x_1}^{x} + \int_x^{x_2}\right)kdx' &= \left(n - \frac{1}{2}\right)\pi \\ \int_{x_1}^{x_2} kdx' &= \left(n - \frac{1}{2}\right)\pi, \end{aligned} \tag{27.54}$$

with $n = 1, 2...$ [6]. With this information we take a harmonic potential of the type $V(x) = \frac{1}{2}\kappa x^2$. In this case, the turning points for a given energy E will be at

[5] Note that we shifted the turning point to an arbitrary position x_2.
[6] Note that $n \neq 0$, because the integral (27.54) has to be greater than zero.

$-\sqrt{\frac{2E}{\kappa}}$ and $\sqrt{\frac{2E}{\kappa}}$. For this potential we will have that $k(x) = \sqrt{\frac{2m}{\hbar^2}(E - \frac{1}{2}\kappa x^2)}$. Calculating the integral of $k(x)$ between these two turning points we get,

$$\int_{x_1}^{x_2} k(x)dx = \frac{2m}{\hbar}\int_{-\sqrt{2E/k}}^{\sqrt{2E/k}} \sqrt{E - \frac{1}{2}\kappa x^2}dx = \pi E\frac{m}{\kappa} = \left(n - \frac{1}{2}\right)\pi\hbar \ ,$$

isolating E and taking $\omega = \sqrt{\kappa/m}$ we have,

$$E = (n - \tfrac{1}{2})\hbar\omega \ ,$$

with $n = 1, 2...$, the exact spectrum of the harmonic oscillator, but this is just a coincidence.

Eigenstates: Now we will calculate the eigenstates of the harmonic oscillator. The eigenfunctions were calculated on a computer. The first graph (Fig. 27.2) compares the first exact excited state with that obtained using the WKB method.

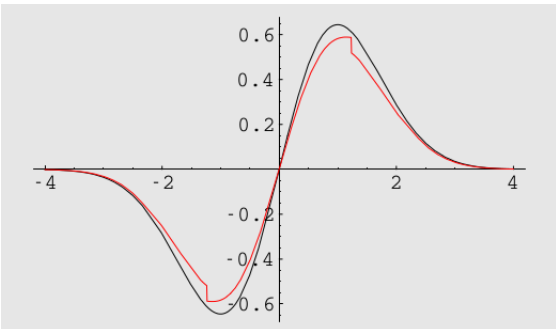

Figure 27.2: First excited state calculated accurately and through the WKB approximation.

Note that the WKB approach is very good when $x \to 0$ and $x \to \infty$, regions where the difference between the oscillator energy and the potential are large ($E \gg V(x \to 0)$ and $E \ll V(x \to \infty)$), because in these regions the wavelength $\lambda(x)$ acquires the lowest values, since it is proportional to $|1/\sqrt{E - V(x)}|$. Hence, the spatial region in which the potential needs to be practically constant is smaller, which explains why the approximation is closer to the exact solution. In the intermediate regions the difference between E and $V(x)$ begins to decrease, and the WKB approximation delivers its worst results.

As we increase the energy of the harmonic oscillator, the approximation becomes better (for the same reason as discussed in the previous paragraph). The following graph illustrates this effect for $n = 10$.

Example 226 (*Hydrogen atom*): Eigenenergies: For the hydrogen atom the effective potential is given by,

$$V(x) = -\frac{e^2}{4\pi\varepsilon_0}\frac{1}{r} + \frac{\hbar^2}{2m}\frac{l(l+1)}{r^2} \ .$$

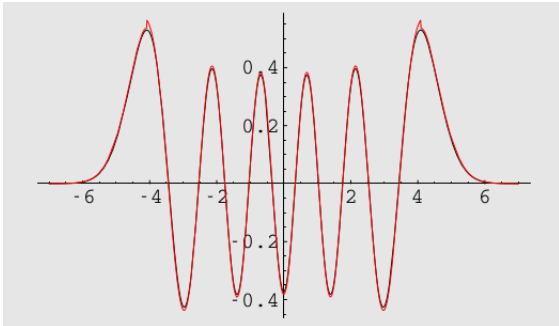

Figure 27.3: Wavefunction of the vibrational state $n = 10$ calculated exactly and using the WKB approximation.

Note that the WKB method for this case obeys the relation (27.54), hence we get,

$$\begin{aligned}\int_{r_1}^{r_2} p(r)dr &= \sqrt{2m}\int_{r_1}^{r_2}\sqrt{E + \frac{e^2}{4\pi\varepsilon_0}\frac{1}{r} - \frac{\hbar^2}{2m}\frac{l(l+1)}{r^2}}dr \\ &= \sqrt{-2mE}\int_{r_1}^{r_2}\frac{1}{r}\sqrt{-r^2 - \frac{e^2}{4\pi\varepsilon_0 E}r + \frac{\hbar^2}{2mE}l(l+1)}dr\ .\end{aligned}$$

Notice that $E < 0$. Let us make the following substitution to facilitate algebraic manipulations,

$$B = -\frac{e^2}{4\pi\varepsilon_0 E} \qquad \text{and} \qquad C = -\frac{\hbar^2}{2mE}l(l+1)\ .$$

The turning points r_1 and r_2 are given by the following expressions,

$$r_1 = \frac{B - \sqrt{B^2 - 4C}}{2} \qquad \text{and} \qquad r_2 = \frac{B + \sqrt{B^2 - 4C}}{2}\ .$$

Thus, returning to the integral we will have the following:

$$\begin{aligned}\int_{r_1}^{r_2} p(r)dr &= \sqrt{-2mE}\int_{r_1}^{r_2}\frac{1}{r}\sqrt{(r-r_1)(r_2-r)}dr = \sqrt{-2mE}\frac{\pi}{2}(\sqrt{r_2}-\sqrt{r_1})^2 \\ &= \sqrt{-2mE}\frac{\pi}{2}(r_1 + r_2 - 2r_1r_2) = \sqrt{-2mE}\frac{\pi}{2}(B - 2\sqrt{C}) \\ &= \frac{\pi}{2}\Big(-\frac{e^2\sqrt{2m}}{4\pi\varepsilon_0\sqrt{-E}} - 2\hbar\sqrt{l(l+1)}\Big) = \Big(n - \frac{1}{2}\Big)\pi\hbar\ .\end{aligned}$$

Isolating E we obtain the energy spectrum of the hydrogen atom in the WKB approximation:

$$E = -\frac{m}{2\hbar}\Big(\frac{e^2}{4\pi\varepsilon_0}\Big)^2\frac{1}{\Big[n - 1/2 + l(l+1)\Big]^2} = -\frac{13.6}{\Big[n - 1/2 + l(l+1)\Big]^2}eV\ .$$

For high energies ($n \gg l$), we recover Bohr's expression.

27.3.3 Exercises

27.3.3.1 Ex: Energy levels of hydrogen via WKB

Use the WKB approach to calculate the energy levels of the hydrogen atom.

27.4 Time-dependent perturbations

Temporal perturbations typically occur when we suddenly switch on an external field that influences the motion or spin of the particles, or when the field varies over time, for example, an electromagnetic field. Let us first study a two-level system subject to a temporal perturbation.

27.4.1 Two-level systems

We write the perturbation as

$$\hat{H} = \hat{H}^{(0)} + \hat{H}^{(1)}(t) \ . \tag{27.55}$$

As in the case of a stationary perturbation, we write the eigenenergies and -functions of the unperturbed system as

$$\hat{H}^{(0)}|n\rangle = E_n|n\rangle \ . \tag{27.56}$$

Recalling that this stationary Schrödinger equation was obtained from the time-dependent Schrödinger equation via a separation ansatz (23.167), the temporal evolution of these eigenfunctions is given by,

$$|\psi_n^{(0)}(t)\rangle = |n\rangle e^{-\imath E_n t/\hbar} \ . \tag{27.57}$$

For small perturbations we can expect that the ansatz,

$$|\psi^{(1)}(t)\rangle = a_1(t)|\psi_1^{(0)}(t)\rangle + a_2(t)|\psi_2^{(0)}(t)\rangle \ , \tag{27.58}$$

be good. Note that not only do eigenfunctions oscillate, but the coefficients also depend on time, because the composition of the states can change. The instantaneous probability of finding the system in state n is $|a_n(t)|^2$. Importing the above linear combination into the Schrödinger equation,

$$\left[\hat{H}^{(0)} + \hat{H}^{(1)}(t)\right]|\psi^{(1)}(t)\rangle = \imath\hbar\frac{\partial}{\partial t}|\psi^{(1)}(t)\rangle \ , \tag{27.59}$$

we find,

$$\begin{aligned} a_1\hat{H}^{(0)}|\psi_1^{(0)}\rangle + a_2\hat{H}^{(0)}|\psi_2^{(0)}\rangle + a_1\hat{H}^{(1)}|\psi_1^{(0)}\rangle + a_2\hat{H}^{(1)}|\psi_2^{(0)}\rangle \\ = \imath\hbar\left[\frac{\partial a_1}{\partial t}|\psi_1^{(0)}\rangle + \frac{\partial a_2}{\partial t}|\psi_2^{(0)}\rangle + a_1\frac{\partial|\psi_1^{(0)}\rangle}{\partial t} + a_2\frac{\partial|\psi_2^{(0)}\rangle}{\partial t}\right] \\ \implies a_1\hat{H}^{(1)}|\psi_1^{(0)}\rangle + a_2\hat{H}^{(1)}|\psi_2^{(0)}\rangle = \imath\hbar\dot{a}_1|\psi_1^{(0)}\rangle + \imath\hbar\dot{a}_2|\psi_2^{(0)}\rangle \ , \end{aligned} \tag{27.60}$$

because the other terms satisfy the Schrödinger equation of zero order. Replacing the stationary eigenfunctions,

$$a_1 e^{-\imath E_1 t/\hbar}\hat{H}^{(1)}|1\rangle + a_2 e^{-\imath E_2 t/\hbar}\hat{H}^{(1)}|2\rangle = \imath\hbar\dot{a}_1 e^{-\imath E_1 t/\hbar}|1\rangle + \imath\hbar\dot{a}_2 e^{-\imath E_2 t/\hbar}|2\rangle \ , \quad (27.61)$$

and multiplying this equation with $\langle 1|\times$ and $\langle 2|\times$, we find with the abbreviation $\hbar\omega_0 \equiv E_2 - E_1$,

$$\begin{aligned} \imath\hbar\dot{a}_1 &= a_1\langle 1|\hat{H}^{(1)}|1\rangle + a_2 e^{-\imath\omega_0 t}\langle 1|\hat{H}^{(1)}|2\rangle \\ \text{and} \qquad \imath\hbar\dot{a}_2 &= a_1 e^{\imath\omega_0 t}\langle 2|\hat{H}^{(1)}|1\rangle + a_2\langle 2|\hat{H}^{(1)}|2\rangle \ . \end{aligned} \quad (27.62)$$

Frequently, the perturbation induces only a coupling, but does not directly influence the energies very much, $\langle n|\hat{H}^{(1)}|n\rangle \simeq 0$,

$$\boxed{\dot{a}_1 = a_2\frac{e^{-\imath\omega_0 t}}{\imath\hbar}\langle 1|\hat{H}^{(1)}|2\rangle \qquad \text{and} \qquad \dot{a}_2 = a_1\frac{e^{\imath\omega_0 t}}{\imath\hbar}\langle 2|\hat{H}^{(1)}|1\rangle} \ . \quad (27.63)$$

Without perturbation, $\langle m|\hat{H}^{(1)}|n\rangle = 0$, no dynamics develops; the eigenfunctions evolve independently.

27.4.2 The time-dependent perturbation method

Now, let us turn our attention to systems with many levels.

In *time-dependent perturbation theory* (TDPT) we separate the Hamiltonian into a stationary part and a time-dependent part [7,8],

$$\hat{H}(t) = \hat{H}^{(0)} + \lambda\hat{H}^{(1)}(t) \ . \quad (27.64)$$

As usual, this Hamiltonian satisfies the Schrödinger equation,

$$\imath\hbar\frac{\partial}{\partial t}|\psi(t)\rangle = \hat{H}(t)|\psi(t)\rangle \ . \quad (27.65)$$

Now, we do a unitary transformation into the *interaction picture* with $S(t) = e^{-\imath\hat{H}^{(0)}t/\hbar}$ substituting $|\psi(t)\rangle \equiv S(t)|\psi_I(t)\rangle$ and $\hat{H}^{(1)}(t) \equiv S(t)\hat{W}(t)S^{-1}(t)$ in the Schrödinger equation. This procedure removes the stationary part, as shown in Sec. 23.6.4,

$$\imath\hbar\frac{\partial}{\partial t}|\psi_I(t)\rangle = \lambda\hat{W}(t)|\psi_I(t)\rangle \ . \quad (27.66)$$

If $\hat{W}(t)$ is also independent of time, the solution simply is $|\psi_I(t)\rangle = e^{-\imath\hat{W}t/\hbar}|\psi_I(0)\rangle$. Otherwise, we integrate the equation,

$$|\psi_I(t)\rangle = |\psi_I(0)\rangle + \frac{\lambda}{\imath\hbar}\int_0^t \hat{W}(\tau)|\psi_I(\tau)\rangle d\tau \ . \quad (27.67)$$

[7] See Becker-Sauter II, p.118ff and [910], p.104ff. An alternative treatment is found in [590], p.191ff or in Blochinzew, p.332ff.

[8] Note that by substituting $\hat{W}$ by $\hat{H}^{(1)}$, the equation (27.66), $\imath\hbar\partial_t|\psi_I(t)\rangle = \hat{H}^{(1)}(t)|\psi_I(t)\rangle$, corresponds to a first-order perturbative approximation, i.e., the perturbation eigenvalues $\hat{H}(1)$ are calculated with the eigenvectors of the unperturbed system. Thus, in first order TDPT we can substitute $\hat{W}$ for $\hat{H}^{(1)}$.

Substituting $|\psi_I(\tau)\rangle$ by $|\psi_I(t)\rangle$ we iterate this equation,

$$\begin{aligned}|\psi_I(t)\rangle &= |\psi_I(0)\rangle + \frac{\lambda}{\imath\hbar}\int_0^t \hat{W}(\tau_1)\left(|\psi_I(0)\rangle + \frac{\lambda}{\imath\hbar}\int_0^{\tau_1}\hat{W}(\tau_2)|\psi_I(\tau_2)\rangle d\tau_2\right)d\tau_1 \\ &= |\psi_I(0)\rangle + \frac{\lambda}{\imath\hbar}\int_0^t \hat{W}(\tau_1)d\tau_1|\psi_I(0)\rangle + \left(\frac{\lambda}{\imath\hbar}\right)^2\int_0^t \hat{W}(\tau_1)\int_0^{\tau_1}\hat{W}(\tau_2)|\psi_I(\tau_2)\rangle d\tau_2 d\tau_1\rangle \\ &= \left[\sum\nolimits_{n=1}^N\left(\frac{\lambda}{\imath\hbar}\right)^n\int_0^t \hat{W}(\tau_1)\int_0^{\tau_1}\hat{W}(\tau_2)...\int_0^{\tau_{n-1}}\hat{W}(\tau_n)d\tau_1 d\tau_2...d\tau_n\right]|\psi_I(0)\rangle + o(\lambda^{N+1})\ .\end{aligned} \tag{27.68}$$

This is called the *Dyson series*. For $N = 1$, we get the first order of the perturbation series [9],

$$|\psi_I(t)\rangle = \left(1 + \frac{\lambda}{\imath\hbar}\int_0^t \hat{W}(\tau)d\tau\right)|\psi_I(0)\rangle\ . \tag{27.69}$$

The stationary states of the unperturbed Hamiltonian are given by $\hat{H}^{(0)}|f\rangle = E_f|f\rangle$. Now, the perturbed states are expanded on this basis, $|\psi_I(t)\rangle = \sum_f |f\rangle a_f(t)$. The expansion coefficients are [10],

$$a_f(t) = \langle f|\psi_I(t)\rangle = \langle f|\psi_I(0)\rangle + \frac{\lambda}{\imath\hbar}\langle f|\int_0^t S^{-1}(\tau)\hat{H}^{(1)}(\tau)S(\tau)|\psi_I(0)\rangle d\tau\ . \tag{27.70}$$

Now, we assume that the system be initially in the eigenstate $|\psi_I(0)\rangle = |i\rangle$. The amplitudes then are,

$$\begin{aligned}a_{i\to f}(t) &= \langle f|i\rangle + \frac{\lambda}{\imath\hbar}\int_0^t e^{\imath E_f\tau/\hbar}\langle f|\hat{H}^{(1)}(\tau)|i\rangle e^{-\imath E_i\tau/\hbar}d\tau \\ &= \delta_{if} + \frac{\lambda}{\imath\hbar}\int_0^t \langle f|\hat{H}^{(1)}(\tau)|i\rangle e^{\imath\omega_{if}\tau}d\tau\ .\end{aligned} \tag{27.71}$$

The time-varying potential generates a perturbation causing a variation of the system's state. As the energy is not conserved, $[\partial_t, \hat{H}(t)] \neq 0$, the time-dependence is not separable and the system exchanges energy with the potential. In first-order perturbation theory we only consider weak perturbations, i.e. the initial state is emptied only slowly, $a_{i\to i}(dt) \simeq a_{i\to i}(0) = 1$. On the other hand, for an initially empty state f the gain is obviously considerable. For $i \neq f$ we have,

$$\boxed{da_{i\to f}(t) = a_{i\to f}(t+dt) - a_{i\to f}(t) = \frac{\lambda}{\imath\hbar}\langle f|\hat{H}^{(1)}(t)|i\rangle e^{\imath\omega_{if}t}dt}\ . \tag{27.72}$$

This formula is nothing more than a generalization of the formula (27.63) obtained for a two-level system assuming that the initial state does not deplete considerably. In Exc. 27.4.5.1 we calculate the dynamics of a harmonic oscillator perturbed by a decaying force.

[9] For higher orders,

$$|\psi_I(t)\rangle \approx \left[\sum\nolimits_{n=1}^N\left(\frac{\lambda}{\imath\hbar}\right)^n\left(\int_0^t \hat{W}(\tau)d\tau\right)^n\right]|\psi_I(0)\rangle = T\left[\exp\left(\frac{\lambda}{\imath\hbar}\int_0^t \hat{W}(\tau)d\tau\right)\right]|\psi_I(0)\rangle\ .$$

[10] We could define the coefficients in Schrödinger's picture, $a_f \equiv \langle f|\psi\rangle$, but this would only introduce a phase factor, $a_{i\to f} \to a_{i\to f}e^{\imath(E_f-E_i)t/\hbar}$, which is unimportant for absolute values $|a_{i\to f}|^2$. This corresponds to a transformation to a rotating system, which will be discussed in Sec. 39.3.2.

27.4.3 Specific perturbations

27.4.3.1 Sudden switch-on of a constant perturbation

To begin with, we consider a constant perturbation $\hat{H}^{(1)}$ suddenly switched on at $t = 0$. In Schrödinger's picture we can rewrite Eq. (27.71),

$$a_{i\to f}(t) = \delta_{if} + \frac{\lambda}{\imath\hbar}\langle f|\hat{H}^{(1)}|i\rangle \int_0^t e^{\imath\omega_{if}\tau} d\tau = \delta_{if} + \frac{\lambda}{\imath\hbar}\langle f|\hat{H}^{(1)}|i\rangle \frac{-1 + e^{\imath\omega_{if}t}}{\imath\omega_{if}} \ . \quad (27.73)$$

We obtain for $i \neq f$,

$$\boxed{|a_{i\to f}(t)|^2 = \frac{\lambda^2}{\hbar^2}|\langle f|\hat{H}^{(1)}|i\rangle|^2 \frac{\sin^2(\omega_{if}t/2)}{(\omega_{fi}/2)^2}} \ . \quad (27.74)$$

For long times we calculate the rate [11],

$$\frac{d}{dt}\,|a_{i\to f}(t)|^2 = \frac{\lambda^2}{\hbar^2}|\langle f|\hat{H}^{(1)}|i\rangle|^2 \frac{\sin\omega_{fi}t}{\omega_{fi}/2} \quad \overset{t\to\infty}{\longrightarrow} \quad \frac{2\pi\lambda^2}{\hbar^2}|\langle f|\hat{H}^{(1)}|i\rangle|^2 \delta(\omega_f - \omega_i) \ , \quad (27.75)$$

where we use the representation of the Dirac function,

$$\delta(x) = \lim_{t\to\infty} \tfrac{1}{2\pi} \int_{-t}^{t} e^{\imath kx} dk = \lim_{t\to\infty} \tfrac{t}{\pi} \mathrm{sinc}\ xt \ . \quad (27.76)$$

The δ-function in (27.75) ensures that, for infinitely sharp steps, transitions are impossible, unless the energy of the final state is the same as the one of the initial state. This points to the fact that infinitely sharp steps are not a realistic physical concept.

In practice, the changes applied to a system are often slow and the observation times are long, because the frequencies of the transitions are high $\omega_{fi}/2\pi \simeq$ THz. Let us assume that the perturbation be switched on within a time constant γ^{-1}. In Exc. 27.4.5.2 we will study how the rapidity of a perturbation influences the transition rate. We will see via a temporal analysis of $|a_{i\to f}(t)|^2$, that for slow variations, $\gamma \ll \omega_{fi}$, the system adiabatically approaches the final situation. For $\gamma \simeq \omega_{fi}$, the system receives a shock and exhibits oscillating transients. For $\gamma > \omega_{fi}$, we observe violent oscillations with largest amplitudes.

27.4.3.2 Periodic perturbations

We now consider the case of an oscillatory perturbation, for example an electromagnetic field. In principle, knowledge of the system's response to periodic perturbations allows us to treat arbitrary perturbations, since we can expand them in Fourier series. We first treat transitions between discrete levels, before considering states embedded in continua,

$$\hat{H}^{(1)}(t) = \begin{cases} 0 \ \text{ for } \ t < 0 \\ 2\hbar\hat{\Omega}_0 \cos\omega t \ \text{ for } \ t \geq 0 \end{cases} \ . \quad (27.77)$$

[11] We use the trigonometric rule $\sin x = 2\sin\frac{x}{2}\cos\frac{x}{2}$.

With the abbreviation $\Omega_{fi} \equiv \langle f|\hat{\Omega}_0|i\rangle$ the transition rate is,

$$\begin{aligned} a_{i\to f}(t) &= -\imath\Omega_{fi}\int_0^t 2e^{\imath\omega_{fi}\tau}\cos\omega\tau d\tau \\ &= -\imath\Omega_{fi}\left[\cancelto{0}{\frac{e^{\imath(\omega_{fi}+\omega)t}-1}{\imath(\omega_{fi}+\omega)}} + \frac{e^{\imath(\omega_{fi}-\omega)t}-1}{\imath(\omega_{fi}-\omega)}\right] . \end{aligned} \tag{27.78}$$

The first term being small, we neglect it doing a so-called *rotating wave approximation* (RWA). We obtain,

$$|a_{i\to f}(t)|^2 = |\Omega_{fi}|^2\frac{\sin^2\frac{1}{2}(\omega_{fi}-\omega)t}{\frac{1}{4}(\omega_{fi}-\omega)^2} . \tag{27.79}$$

This result coincides with the formula (27.74), except that the energy difference between the states ω_{fi} is shifted by the frequency of the perturbation ω. The quantity $\Delta_{fi} \equiv \omega - \omega_{fi}$ is called a detuning. The transition probability is maximal, when we are at resonance, that is $\Delta_{fi} = 0$. In this case,

$$|a_{i\to f}(t)|^2 \longrightarrow |\Omega_{fi}|^2 t^2 . \tag{27.80}$$

This can be seen by expanding the numerator in a Taylor series for small $(\omega_{fi}-\omega)t$.

Note, that the probability exceeds 1 for long times, which can not be. In fact, the restriction to the first order in the Taylor expansion used in the derivation of the last equation is no longer valid for long times, when $(\omega_{fi}-\omega)t > 1$, and we need to take into account higher orders.

Example 227 (*The Rabi formula*): Let us now come back to the two-level system studied in Sec. 27.4.1 and consider a periodic perturbation oscillating at frequency $\omega = \omega_0 + \Delta$, where Δ is called the *detuning* from the resonance whose frequency is ω_0,

$$H^{(1)} = -e\vec{\mathcal{E}}(\mathbf{r},t)\cdot\mathbf{r} = -e\mathcal{E}_0\hat{\varepsilon}\cos(kz-\omega t)\cdot\mathbf{r} . \tag{27.81}$$

Then,

$$\langle 2|H^{(1)}|1\rangle = -e\mathcal{E}_0\cos(kz-\omega t)\langle 2|r|1\rangle = \hbar\Omega\cos(kz-\omega t) , \tag{27.82}$$

where we call

$$\Omega \equiv \frac{-e\mathcal{E}_0\langle 2|r|1\rangle}{\hbar} \tag{27.83}$$

the *Rabi frequency*. With this abbreviation the Eqs. (27.63) become,

$$\dot{a}_1 = -\imath\Omega a_2 e^{-\imath\omega_0 t}\cos(kz-\omega t) \quad \text{and} \quad \dot{a}_2 = -\imath\Omega^* a_1 e^{\imath\omega_0 t}\cos(kz-\omega t) . \tag{27.84}$$

Neglecting fast-rotating terms doing the so-called *rotating wave approximation* (RWA) and choosing the position of the atom to be $z = 0$ we derive,

$$\dot{a}_1 \simeq -\frac{\imath\Omega}{2}a_2 e^{\imath\Delta t} \quad \text{and} \quad \dot{a}_2 \simeq -\frac{\imath\Omega^*}{2}a_1 e^{-\imath\Delta t} , \tag{27.85}$$

which coincides with the formulas derived in Sec. 27.4.1. With the equations of motion we can, starting from initial values for $a_1(0)$ and $a_2(0)$, calculate the temporal evolution.

We solve this system of differential equations by differentiating one and substituting the other,

$$\ddot{a}_2 = -\imath\dot{a}_1\frac{\Omega^*}{2}e^{-\imath\Delta t} - a_1\Delta\frac{\Omega^*}{2}e^{-\imath\Delta t} = -\frac{|\Omega|^2}{4}a_2 - \imath\Delta\dot{a}_2 \ . \tag{27.86}$$

We find solutions via the ansatz $a_2 = e^{-\imath\Delta t/2}(Ae^{\imath Gt/2}+Be^{-\imath Gt/2})$. The equation for a_2 yields,

$$\begin{aligned}&(\tfrac{\imath}{2}G - \tfrac{\imath}{2}\Delta)^2 Ae^{\imath(G-\Delta)t/2} + (-\tfrac{\imath}{2}G - \tfrac{\imath}{2}\Delta)^2 Be^{\imath(-G-\Delta)t/2} \\ &= -\tfrac{|\Omega|^2}{4}(Ae^{\imath(G-\Delta)t/2} + Be^{\imath(-G-\Delta)t/2} \\ &- \imath\Delta\left[(\tfrac{\imath}{2}G - \tfrac{\imath}{2}\Delta)Ae^{\imath(G-\Delta)t/2} + (-\tfrac{\imath}{2}G - \tfrac{\imath}{2}\Delta)Be^{\imath(-G-\Delta)t/2}\right] \ .\end{aligned} \tag{27.87}$$

Separating the parts in A and in B we obtain two equations with the same result,

$$G^2 = |\Omega|^2 + \Delta^2 \ . \tag{27.88}$$

G is called the *generalized Rabi frequency*. Using the initial conditions, $a_1(0) = 1$ and $a_2(0) = 0$, we can fix one of the coefficients A and B, since $a_2(0) = A+B = 0$,

$$a_2 = 2\imath Ae^{-\imath\Delta t/2}\sin\tfrac{G}{2}t \ . \tag{27.89}$$

We now import this solution into the differential equation for a_1,

$$\dot{a}_1 = -\imath\frac{\Omega}{2}a_2e^{\imath\Delta t} = \Omega Ae^{\imath\Delta t/2}\sin\tfrac{G}{2}t \ . \tag{27.90}$$

The integral is,

$$a_1(t) = \int_0^t \Omega Ae^{\imath\Delta t'/2}\sin\tfrac{G}{2}t'dt' = -\frac{2A}{\Omega^*}e^{\imath\Delta t/2}\left(G\cos\tfrac{G}{2}t - \imath\Delta\sin\tfrac{G}{2}t\right) \ . \tag{27.91}$$

Using the normalization condition,

$$\begin{aligned}1 = |a_1|^2 + |a_2|^2 &= \left|-\frac{2A}{\Omega^*}e^{\imath\Delta t/2}\left(G\cos Gt - \imath\Delta\sin\tfrac{G}{2}t\right)\right|^2 + \left|2\imath Ae^{-\imath\Delta t/2}\sin Gt\right|^2 \\ &= \frac{4A^2}{|\Omega|^2}\left(G^2\cos^2\tfrac{G}{2}t + \Delta^2\sin^2\tfrac{G}{2}t\right) + 4A^2\sin^2\tfrac{G}{2}t = 4A^2\frac{G^2}{|\Omega|^2} \ .\end{aligned} \tag{27.92}$$

Hence, $A = |\Omega|/2G$. In general, we can choose Ω real, and the final solution is,

$$\boxed{a_1(t) = -e^{\imath\Delta t/2}\left(\cos\tfrac{G}{2}t + \tfrac{-\imath\Delta}{G}\sin\tfrac{G}{2}t\right) \qquad \text{and} \qquad a_2(t) = \tfrac{\imath\Omega}{G}e^{-\imath\Delta t/2}\sin\tfrac{G}{2}t} \ . \tag{27.93}$$

This results has already been obtained in Exc. 23.6.7.1 using an exact (i.e. not perturbative) calculus. When the energies E_n are degenerate, under the influence of the perturbation, the populations of the system oscillate with the Rabi frequency Ω. When the energies are different, the oscillation frequency G is higher, but the amplitude decreases as well. The initially empty state never reaches unitary population. In Exc. 27.4.5.3 we calculate the time required to allow the perturbation to invert the population of a two-level system, in Exc. 27.4.5.4 we study the maximum achievable inversion as a function of detuning, and in Exc. 27.4.5.5 we analyze the dynamics of a system subject to sequences of pulses.

In Exc. 27.4.5.6 we show a derivation using the Laplace transformation method.

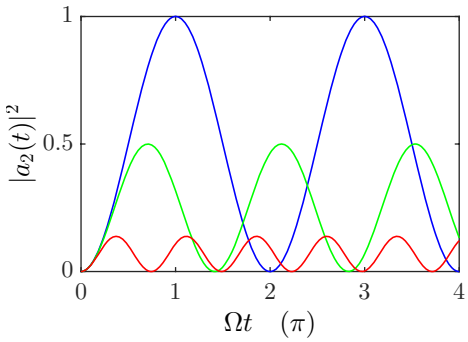

Figure 27.4: (code) Probability $|a_2(t)|^2$ for the atom to be in the excited state for $\Omega = \Gamma$ and $\Delta = 0$ (blue), $\Delta = \Gamma$ (green), and $\Delta = 2.5\Gamma$ (red). Time is in units of $1/\Gamma$.

27.4.3.3 Transitions to continuous levels

When there are several final states, $f \in F$, the formula (27.79) must be generalized. The total transition probability,

$$P_{i\to F}(t) = \sum_{f\in F} |a_{i\to f}(t)|^2 \ , \tag{27.94}$$

corresponds to the probability of the initial state $|i\rangle$ to be depleted. When the final state lies within a continuum, the sum in (27.94) must be replaced by an integral. With the *density of states* written in the form $\rho(E)$, where $\rho(E)dE$ is the number of states found in the energy range between E and $E + dE$, the transition probability is [12],

$$P_{i\to F}(t) = \int_{E_{\min}}^{E_{\max}} |a_{i\to f}(t)|^2 \rho(E_f) dE_f \ , \tag{27.95}$$

where $E \in [E_{\min}, E_{\max}]$ is the regime of energies within reach of the periodic perturbation. Now, plugging in the expression (27.79),

$$P_{i\to F}(t) = \int_{E_{\min}}^{E_{\max}} |\Omega_{fi}|^2 \frac{\sin^2 \frac{1}{2\hbar}(E_{fi} - E)t}{\frac{1}{4\hbar^2}(E_{fi} - E)^2} \rho(E_f) dE_f \ . \tag{27.96}$$

Again using the representation (27.76) of the Dirac function with the substitution $x \equiv (E_{fi} - E)/2\hbar$, we obtain after sufficiently long times [13],

$$P_{i\to F}(t) = \int_{E_{\min}}^{E_{\max}} |\Omega_{fi}|^2 t^2 \frac{\pi}{t} \delta(\tfrac{E_{fi}-E}{2\hbar}) \rho(E_f) dE_f = 2\pi\hbar t |\Omega_{fi}|^2 \rho(E_i + E) \ . \tag{27.97}$$

The transition rate is,

$$\frac{dP_{i\to F}(t)}{dt} = 2\pi\hbar |\Omega_{fi}|^2 \rho(E_i + E) \ . \tag{27.98}$$

[12] With $\rho(E) \equiv \sum_{f\in F} \delta(E_f - E)$ the integral is converted back into a sum.
[13] Remember $\delta(ax) = \frac{1}{a}\delta(x)$.

For a narrow distribution of final energies E centered around E_f we may substitute the density of states by a δ-distribution, $\rho(E) = \delta(E - E_f)$, so that,

$$\boxed{\frac{dP_{i\to F}}{dt} = \frac{2\pi}{\hbar}|\langle f|\hat{H}^{(1)}|i\rangle|^2\delta(E_{fi} - E)} \ , \tag{27.99}$$

where we went back to the definition of the perturbation Hamiltonian (27.77). This expression is called *Fermi's Golden rule*. In Exc. 27.4.5.7 we will calculate the *photoelectric effect*.

27.4.3.4 Continuous frequency distribution

To derive Eq. (27.79), we considered perturbations with fixed oscillation frequencies. To handle frequency distributions $\varrho(\omega)$, we must generalize this equation by calculating the integral,

$$\begin{aligned} |a_{i\to f}(t)|^2 &= |\Omega_{fi}|^2 \int \varrho(\omega)\frac{\sin^2\frac{1}{2}(\omega_{fi} - \omega)t}{\frac{1}{4}(\omega_{fi} - \omega)^2}d\omega \\ &\simeq |\Omega_{fi}|^2 t\varrho(\omega_{fi}) \int_{-\infty}^{\infty} \mathrm{sinc}^2 x dx = 2\pi t|\Omega_{fi}|^2\varrho(\omega_{fi} - \omega) \ , \end{aligned} \tag{27.100}$$

again using the representation (27.76) of the Dirac function. The approximation $\varrho(\omega) = \varrho(\omega_{fi})$ can be used if the width of the sinc function is much narrower than the frequency distribution, which is the case for sufficiently long times, $t \gg \pi/2\Delta_{fi}$.

27.4.4 Transition rates for higher-order perturbations

The evolution from an initial state $|i\rangle$ that the system occupies at time t_0 to some final state $|\psi\rangle$, which may be a superposition, occupied at time t, is ruled by the solution of the Schrödinger equation,

$$|\psi\rangle = e^{-\imath\hat{H}(t-t_0)/\hbar}|i\rangle \ . \tag{27.101}$$

The probability to encounter $|\psi\rangle$ in a given state $|f\rangle$ is $|\langle f|\psi\rangle|^2$, and the *transition rate* is simply the derivative of this. The transition rate *out of the initial state* into any other final state is, consequently

$$\boxed{\frac{1}{\tau} = \sum_f \frac{d}{dt}|\langle f|e^{-\imath\hat{H}(t-t_0)/\hbar}|i\rangle|^2} \ . \tag{27.102}$$

From this formula we can already see, that at short times, when we can expand the exponential to first order, we will recover the results of (27.72).

Let us now consider a time-independent perturbation in the Schrödinger picture,

$$\hat{H}(t) = \hat{H}^{(0)} + \hat{H}^{(1)} \ , \tag{27.103}$$

where the time dependence is entirely left to the wavefunction. Now, we expand the propagator $e^{-\imath\hat{H}(t-t_0)}$ in a perturbative series [14]. Unfortunately, generally $[\hat{H}^{(0)}, \hat{H}^{(1)}] \neq$

[14] We drop the $\hbar = 1$ for the following calculation to simplify the notation.

0, so that we cannot simply assume $e^{-\imath\hat{H}t} \neq e^{-\imath\hat{H}^{(0)}t}e^{-\imath\hat{H}^{(1)}t}$. But we can calculate,

$$\imath\frac{d}{dt}e^{\imath\hat{H}^{(0)}t}e^{-\imath\hat{H}t} = -\hat{H}^{(0)}e^{\imath\hat{H}^{(0)}t}e^{-\imath\hat{H}t} + e^{\imath\hat{H}^{(0)}t}\hat{H}e^{-\imath\hat{H}t} = e^{\imath\hat{H}^{(0)}t}\hat{H}^{(1)}e^{-\imath\hat{H}t} \ . \quad (27.104)$$

Integrating both sides and resolving for $e^{-\imath\hat{H}t}$,

$$e^{-\imath\hat{H}t} = e^{-\imath\hat{H}^{(0)}t}\left\{e^{\imath\hat{H}^{(0)}t_0}e^{-\imath\hat{H}t_0} - \imath\int_{t_0}^{t} e^{\imath\hat{H}^{(0)}t_1}\hat{H}^{(1)}e^{-\imath\hat{H}t_1}dt_1\right\} \ . \quad (27.105)$$

We want to analyze a steady-state situation, that is, we assume that the interaction as gradually built up in an infinitely remote past. Hence, we can set $\hat{H} = \hat{H}^{(0)}$ for $t_0 \to -\infty$,

$$e^{-\imath\hat{H}t} = e^{-\imath\hat{H}^{(0)}t}\left\{1 - \imath\int_{-\infty}^{t} e^{\imath\hat{H}^{(0)}t_1}\hat{H}^{(1)}e^{\varepsilon t_1}e^{-\imath\hat{H}t_1}dt_1\right\} \ , \quad (27.106)$$

where the term $e^{\varepsilon t_1}$, with $\varepsilon \to 0$, is inserted to guarantee a smooth switch-on. We iterate,

$$\boxed{\begin{aligned} e^{-\imath\hat{H}t} &= e^{-\imath\hat{H}^{(0)}t}\left\{1 - \imath\int_{-\infty}^{t} e^{\imath\hat{H}^{(0)}t_1}\hat{H}^{(1)}e^{\varepsilon t_1}\times\right. \\ &\times \left. e^{-\imath\hat{H}^{(0)}t}\left[1 - \imath\int_{-\infty}^{t_1} e^{\imath\hat{H}^{(0)}t_2}\hat{H}^{(1)}e^{\varepsilon t_2}e^{-\imath\hat{H}t_2}dt_2\right]dt_1\right\} \end{aligned}} \ . \quad (27.107)$$

We calculate the matrix elements up to second order substituting $\hat{H}$ with $\hat{H}^{(0)}$ in the last integral,

$$\begin{aligned} &\langle f|e^{-\imath\hat{H}t}|i\rangle \qquad (27.108) \\ &\simeq \langle f|e^{-\imath\hat{H}^{(0)}t}\left\{1 - \imath\int_{-\infty}^{t} e^{\imath\hat{H}^{(0)}t_1}\hat{H}^{(1)}e^{\varepsilon t_1}e^{-\imath\hat{H}^{(0)}t_1}\left[1 - \imath\int_{-\infty}^{t_1} e^{\imath\hat{H}^{(0)}t_2}\hat{H}^{(1)}e^{\varepsilon t_2}e^{-\imath\hat{H}^{(0)}t_2}dt_2\right]dt_1\right\}|i\rangle \\ &= e^{-\imath\omega_f t}\langle f|i\rangle - \imath e^{-\imath\omega_f t}\int_{-\infty}^{t} e^{\imath\omega_f t_1}\langle f|\hat{H}^{(1)}|i\rangle e^{\varepsilon t_1}e^{-\imath\omega_i t_1}dt_1 \\ &\quad - e^{-\imath\omega_f t_1}\int_{-\infty}^{t} e^{\imath\omega_f t_1}\langle f|\hat{H}^{(1)}e^{\varepsilon t_1}e^{-\imath\omega_i t_1}\sum_m |m\rangle\langle m|\int_{-\infty}^{t_1} e^{\imath\hat{H}^{(0)}t_2}\hat{H}^{(1)}|i\rangle e^{\varepsilon t_2}e^{-\imath\omega_i t_2}dt_2dt_1 \ . \end{aligned}$$

where we separated the perturbation orders and inserted $\sum_m |m\rangle\langle m| = \mathbb{I}$ using the

closure relation. Using the time-independence of $\hat{H}^{(1)}$,

$$\begin{aligned}
\langle f|e^{-\imath\hat{H}t}|i\rangle &\simeq e^{-\imath\omega_{fi}t}\delta_{fi} - \imath e^{-\imath\omega_f t}\langle f|\hat{H}^{(1)}|i\rangle \int_{-\infty}^{t} e^{(\imath\omega_f - \imath\omega_i + \varepsilon)t_1} dt_1 \\
&\quad - e^{-\imath\omega_f t}\sum_m \langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle \int_{-\infty}^{t} e^{(\imath\omega_f - \imath\omega_i + \varepsilon)t_1} \int_{-\infty}^{t_1} e^{(\imath\omega_m - \imath\omega_i + \varepsilon)t_2} dt_2 dt_1 \\
&= e^{-\imath\omega_{fi}t}\delta_{fi} - \imath e^{-\imath\omega_f t}\langle f|\hat{H}^{(1)}|i\rangle \frac{e^{(\imath\omega_f - \imath\omega_i + \varepsilon)t}}{\imath(\omega_f - \omega_i) + \varepsilon} \\
&\quad - e^{-\imath\omega_f t}\sum_m \langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle \int_{-\infty}^{t} e^{(\imath\omega_f - \imath\omega_m + \varepsilon)t_1} \frac{e^{(\imath\omega_m - \imath\omega_i + \varepsilon)t_1}}{\imath(\omega_m - \omega_i) + \varepsilon} dt_1 \\
&= e^{-\imath\omega_{fi}t}\delta_{fi} - \imath\langle f|\hat{H}^{(1)}|i\rangle \frac{e^{(-\imath\omega_i + \varepsilon)t}}{\imath(\omega_f - \omega_i) + \varepsilon} \\
&\quad - e^{-\imath\omega_f t}\sum_m \frac{\langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle}{\imath(\omega_m - \omega_i) + \varepsilon} \int_{-\infty}^{t} e^{(\imath\omega_f - \imath\omega_i + 2\varepsilon)t_1} dt_1 \\
&= e^{-\imath\omega_{fi}t}\delta_{fi} - \imath\langle f|\hat{H}^{(1)}|i\rangle \frac{e^{(-\imath\omega_i + \varepsilon)t}}{\imath(\omega_f - \omega_i) + \varepsilon} - \sum_m \frac{\langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle}{\imath(\omega_m - \omega_i) + \varepsilon} \frac{e^{(-\imath\omega_i + 2\varepsilon)t}}{\imath(\omega_f - \omega_i) + 2\varepsilon} \ .
\end{aligned} \tag{27.109}$$

These three terms represent the zeroth, first, and second perturbation orders of the propagation operator (27.101). They are also called *Feynman propagators*. Now, we can calculate the transition rate up to second order,

$$\begin{aligned}
\frac{1}{\tau} &= \frac{d}{dt}\sum_f \left|\langle f|e^{-\imath\hat{H}t}|i\rangle\right|^2 \\
&= \lim_{\varepsilon\to 0}\sum_f \left|\langle f|\hat{H}^{(1)}|i\rangle - \sum_m \frac{\langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle}{-\imath\hbar(\omega_m - \omega_i) - \imath\varepsilon}\right|^2 \frac{d}{dt}\left|\frac{e^{(-\imath\omega_i + \varepsilon)t}}{\imath(\omega_f - \omega_i) + \varepsilon}\right|^2 \\
&= \sum_f \left|\langle f|\hat{H}^{(1)}|i\rangle - \sum_m \frac{\langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle}{(\omega_m - \omega_i)}\right|^2 \lim_{\varepsilon\to 0}\frac{2\varepsilon e^{2\varepsilon t}}{(\omega_f - \omega_i)^2 + \varepsilon^2} \ .
\end{aligned} \tag{27.110}$$

The last fraction is a representation of the δ-function. Reintroducing $\hbar$, we finally obtain,

$$\boxed{\frac{1}{\tau} = \frac{2\pi}{\hbar^2}\sum_f \left|\langle f|\hat{H}^{(1)}|i\rangle + \frac{1}{\hbar}\sum_m \frac{\langle f|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i\rangle}{\omega_i - \omega_m}\right|^2 \delta(\omega_f - \omega_i)} \ . \tag{27.111}$$

The first term is *Fermi's Golden rule*, the second order corresponds to the *Kramers-Heisenberg formula*, which serves to describe Thomson, Rayleigh and Raman scattering. The generalization of this transition rate to all perturbation orders can be written,

$$\begin{aligned}
\frac{1}{\tau} &= \frac{2\pi}{\hbar^2}\sum_f \left|\langle f|\left(\hat{H}^{(1)} + \frac{1}{\hbar}\sum_m \frac{\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}}{\omega_i - \omega_m} + \ ...\right.\right. \\
&\quad \left.\left. + \frac{1}{\hbar^{n-1}}\sum_{m_1,\ldots,m_{n-1}} \frac{\hat{H}^{(1)}|m_1\rangle\langle m_1|...|m_{n-1}\rangle\langle m_{n-1}|\hat{H}^{(1)}}{(\omega_i - \omega_{m_1})...(\omega_i - \omega_{m_{n-1}})}\right)|i\rangle\right|^2 \delta(\omega_{fi}) \ .
\end{aligned} \tag{27.112}$$

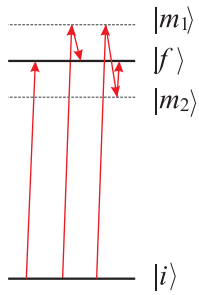

Figure 27.5: Graphical illustration of the various transitions orders. From left to right: absorption, Raman transition via an intermediate virtual state $|m_1\rangle$, three-photon process via two intermediate virtual states $|m_1\rangle$ and $|m_2\rangle$.

27.4.5 Exercises

27.4.5.1 Ex: Perturbed harmonic oscillator

Consider a one-dimensional harmonic oscillator (HO) initially prepared ($t = -\infty$) in the ground state $|0\rangle$ of the unperturbed Hamiltonian $H^{(0)} = \hbar\omega\hat{a}^\dagger\hat{a}$, such that $H^{(0)}|n\rangle = E_n|n\rangle$ with $E_n = n\hbar\omega$.
a. Through the expression, $a_f(t) \approx \frac{1}{\imath\hbar}\int_{t_i}^{t_f} W_{fi}e^{i\omega_{fi}t}dt$, and the perturbative Hamiltonian $W(t) = -e\mathcal{E}xe^{-t^2/\tau^2}$ (x is the position operator of the HO), applied between $t = -\infty$ and $t = +\infty$, calculate the probability of the system to be in the excited state $|n\rangle$, specifying n, at $t = +\infty$. Analyze the result.
b. Do the same for a shape-changing perturbation, $W(t) = \Lambda x^2 e^{-t^2/\tau^2}$.

27.4.5.2 Ex: Impact of the rapidity of a perturbation

Here we consider a slow variation,

$$\hat{W}(t) = \begin{cases} 0 & \text{for} \quad t < 0 \\ W_0(1 - e^{-\gamma t}) & \text{for} \quad t \geq 0 \end{cases},$$

with $\gamma \ll \omega_{fi}$.
a. Calculate the transition rate for long times, $t \gg \gamma^{-1}$.
b. Analyze the transition rate at a given time as a function of γ.

27.4.5.3 Ex: Rabi oscillation

The population of a degenerate two-level system be initially in state $|1\rangle$. What should be the duration of a perturbation to transfer the population to state $|2\rangle$?

27.4.5.4 Ex: Rabi method

Free atoms be illuminated by light pulses characterized by the Rabi frequency Ω, whose pulse area is (i) $\int_0^t \Omega\, dt = \pi$ and (ii) $= 2\pi$. For which frequency tuning $\Delta = \omega - \omega_0$ the excited state population is maximum? Draw the spectral profile of the population in the range $-5 < \Delta/\Omega < 5$.

27.4.5.5 Ex: Ramsey fringes

a. Consider a two-level atom illuminated by a $\frac{\pi}{2}$-pulse of nearly resonant light, $G \simeq \Omega$, and calculate the ground and excited state amplitudes.
b. How do the amplitudes evolve after the pulse if the detuning Δ is small but non-zero?
c. Derive the solution for $|a_2(t)|^2$ of the equations (27.63) for the resonant case ($\Delta = 0$) assuming the following initial conditions, $a_2(0) = \frac{e^{\imath\phi}}{\sqrt{2}}$ and $a_2(t = \frac{\pi}{2\Omega}) = 0$ if $\phi = 0$.
d. Discuss the case of two consecutive $\frac{\pi}{2}$-pulses separated by a time interval T.

27.4.5.6 Ex: Two-level atom via Laplace transformation

Solve the problem of a two-level atom interacting with a laser using the Laplace transformation method.

27.4.5.7 Ex: Photoelectric effect

A hydrogen atom ground state in the ground state $1s$ is placed in an electric field $\mathbf{E}(t) = \vec{\mathcal{E}}_0 \cos\omega t$, such that $W(t) = -e\mathbf{r}\cdot\vec{\mathcal{E}}(t) = W_0 e^{-\imath\omega t} + W_0^\dagger e^{\imath\omega t}$ with $W_0 = e\mathbf{r}\cdot\vec{\mathcal{E}}_0/2$. Find, via Fermi's Golden rule,

$$R = \frac{2\pi}{\hbar}|\langle f|W(t)|i\rangle|^2 \rho(E_f - E_i \mp \hbar\omega) \ ,$$

using the density of states $\rho(E_k)dE_k = V/(2\pi)^3 k^2 dk d\Omega$, the probability per unit of time for the atom to be ionized, by exciting from the ground state $\psi_{100}(\mathbf{r}) = e^{-r/a_\mathrm{B}}/(\pi a_\mathrm{B}^3)^{1/2}$ to the state described by the plane wave $\psi_\mathbf{k}(\mathbf{r}) = e^{-\imath\mathbf{k}\cdot\mathbf{r}}/V^{1/2}$. Simplify the calculation by assuming $\vec{\mathcal{E}}_0 = \mathcal{E}_0\hat{\mathbf{e}}_z$ and $\mathbf{k} = k\hat{\mathbf{e}}_z$.

27.4.5.8 Ex: Kicked harmonic oscillator in second order perturbation

Consider a one-dimensional harmonic oscillator initially in its ground state kicked via the $\hat{H}^{(1)}(t) = e^{\imath k\hat{x}}\Theta(t)$, as discussed in Sec. 24.6.2. Calculate the transition rate (27.102) to the final state $|f\rangle = |0\rangle$ in first and second order perturbation theory.

27.4.5.9 Ex: Dynamic Stark shift induced by blackbody radiation

Calculate the dynamic Stark shift induced by blackbody radiation at $T = 300\,\mathrm{K}$ on the 1 mHz large strontium intercombination line at 698 nm.

Chapter 28

Appendices to 'Quantum Mechanics'

This chapter compiles some fundamental functions and polynomials, which are relevant in quantum theory.

28.1 Quantities and formulas in quantum mechanics

28.1.1 Notations and conventions

quantity	notation	examples
scalars	italic letters	T
vectors	bold letters	$\mathbf{F}$
electromagnetic fields	calligraphic letters	$\vec{\mathcal{E}}$
Green function	calligraphic	$\mathcal{G}$
quantum observables	hat	$\hat{\mathbf{p}}$
(many-body) Hamiltonian		$\hat{H}$
single-particle Hamiltonian	gothic	$\mathfrak{H}$
Liouvillean	gothic	$\mathfrak{L}$
unitary transform	calligraphic	$\mathcal{U}$
displacement	calligraphic	$\mathcal{D}$
Laplace & Fourier transform	calligraphic	$\mathcal{L}$ & $\mathcal{F}$
number spaces		$\mathbb{N}, \mathbb{Z}, \mathbb{R}$
Hilbert space		$\mathbb{H}$

28.1.2 Atomic units

A commonly used system of units in atomic physics is the one of *atomic units*. This system is based on the system of Gaussian units (CGS) [1] defined by setting,

$$e_{\text{cgs}} \equiv \frac{e}{\sqrt{4\pi\varepsilon_0}} \qquad \text{and} \qquad \hbar \equiv 1 \ , \tag{28.1}$$

using $\alpha = e^2/4\pi\varepsilon_0\hbar c$ and $a_{\text{B}} = 4\pi\varepsilon_0\hbar^2/m_e e^2$ and giving the energy in terms of $e_{\text{cgs}}^2/a_{\text{B}} = 1/\alpha^2 m_e c^2 \approx 4.36 \cdot 10^{-18}$ J, the wavevector in terms of $1/a_{\text{B}}$, the distance in terms of a_{B} and the mass in terms of m_e we find,

$$\boxed{\begin{aligned} \tilde{E} &= E/(e_{\text{cgs}}^2/a_{\text{B}}) \\ \tilde{k} &= k a_{\text{B}} \\ \tilde{R} &= R/a_{\text{B}} \\ \tilde{\mu} &= \mu/m_e \end{aligned}} \ . \tag{28.2}$$

This notation simplifies formulas in atomic physics. For example,

$$k = \sqrt{\tfrac{2\mu}{\hbar^2}(E-V)} \qquad \text{becomes} \qquad \tilde{k} = \sqrt{2\tilde{\mu}(\tilde{E}-\tilde{V})} \tag{28.3}$$

and the van der Waals potential

$$V = \frac{C_n}{R^n} \qquad \text{becomes} \qquad \tilde{V} = \frac{\tilde{C}_n}{\tilde{R}^n} \qquad \text{with} \qquad \tilde{C}_n \equiv \frac{C_n}{e_{\text{cgs}}^2 a_{\text{B}}^{n-1}} \ . \tag{28.4}$$

Note that energies are sometimes given in wavenumbers,

$$V_{\text{wn}} \equiv V/(100hc) \ . \tag{28.5}$$

28.2 Clebsch-Gordan and Wigner symbols

28.2.1 Clebsch-Gordan symbols

Clebsch-Gordan coefficients are used to describe spin coupling [2],

$$\langle j_1, m_1; j_2, m_2 | (j_1 j_2) j, m\rangle = \left(\begin{array}{cc|c} j_1 & j_2 & j \\ m_1 & m_2 & m \end{array}\right) = (-1)^{j_1-j_2+m}\sqrt{\Delta(j_1 j_2 j)}\times \tag{28.6}$$
$$\times \sqrt{(j_1+m_1)!(j_1-m_1)!(j_2+m_2)!(j_2-m_2)!(j+m)!(j-m)!}$$
$$\sum_t \frac{(-1)^t}{t!(-j_2+m_1+j+t)!(-j_1-m_2+j+t)!(j_1+j_2-j-t)!(j_1-m_1-t)!(j_2+m_2-t)!} \ .$$

[1] See script on *Electrodynamics* (2023).
[2] See [39], p.111 or [910], p.119.

28.2.2 $\{3j\}$-symbols

The Clebsch-Gordans are related to Wigner's *$\{3j\}$-symbols*,

$$\left(\begin{array}{cc|c} j_1 & j_2 & j \\ m_1 & m_2 & m \end{array}\right) = (-1)^{-j_1+j_2-m}\sqrt{2j+1}\begin{pmatrix} j_1 & j_2 & j \\ m_1 & m_2 & -m \end{pmatrix} , \tag{28.7}$$

with the abbreviation,

$$\Delta(j_1 j_2 j_3) \equiv \frac{(j_1+j_2-j_3)!(j_1-j_2+j_3)!(-j_1+j_2+j_3)!}{(j_1+j_2+j_3+1)!} . \tag{28.8}$$

Particular $\{3j\}$-symbols are,

$$\begin{pmatrix} j_1 & j_2 & j \\ 0 & 0 & 0 \end{pmatrix} = \frac{(-1)^{(j_1+j_2+j)/2}}{j_1/2+j_2/2+j/2+1}\frac{\sqrt{\Delta(j_1 j_2 j)}}{\Delta(\frac{j_1}{2}\frac{j_2}{2}\frac{j}{2})} , \tag{28.9}$$

and

$$\begin{pmatrix} 0 & j & j \\ 0 & 0 & 0 \end{pmatrix} = \frac{(-1)^j}{\sqrt{2j+1}} . \tag{28.10}$$

28.2.3 $\{6j\}$-symbols

$\{6j\}$-symbols describe the recoupling of two spins. They can be evaluated by,

$$\begin{Bmatrix} j_1 & j_2 & j_3 \\ J_1 & J_2 & J_3 \end{Bmatrix} = \sqrt{\Delta(j_1 j_2 j_3)\Delta(j_1 J_2 J_3)\Delta(J_1 j_2 J_3)\Delta(J_1 J_2 j_3)}\sum_t \frac{(-)^t(t+1)!}{f(t)} , \tag{28.11}$$

where,

$$\begin{aligned} f(t) = {} & (t-j_1-j_2-j_3)!(t-j_1-J_2-J_3)!(t-J_1-j_2-J_3)!(t-J_1-J_2-j_3)! \\ & (j_1+j_2+J_1+J_2-t)!(j_2+j_3+J_2+J_3-t)!(j_3+j_1+J_3+J_1-t)! . \end{aligned} \tag{28.12}$$

28.2.4 $\{9j\}$-symbols

$\{3j\}$-symbols describe the recoupling of three spins. They can be evaluated by,

$$\begin{Bmatrix} j_1 & j_2 & J_{12} \\ j_3 & j_4 & J_{34} \\ J_{13} & J_{24} & J \end{Bmatrix} = \sum_g (-)^{2g}(2g+1)\begin{Bmatrix} j_1 & j_2 & J_{12} \\ J_{34} & J & g \end{Bmatrix}\begin{Bmatrix} j_3 & j_4 & J_{34} \\ j_2 & g & J_{24} \end{Bmatrix}\begin{Bmatrix} J_{13} & J_{24} & J \\ g & j_1 & j_3 \end{Bmatrix} . \tag{28.13}$$

$\{9j\}$-symbols satisfy the following orthogonality relation,

$$\sum_{J_{12},J_{34}} \hat{J}_{12}\hat{J}_{34}\hat{H}_{13}\hat{H}_{24}\begin{Bmatrix} j_1 & j_2 & J_{12} \\ j_3 & j_4 & J_{34} \\ H_{13} & H_{24} & J \end{Bmatrix}\begin{Bmatrix} j_1 & j_2 & J_{12} \\ j_3 & j_4 & J_{34} \\ J_{13} & J_{24} & J \end{Bmatrix} = \delta_{J_{13}H_{13}}\delta_{J_{24}H_{24}} . \tag{28.14}$$

28.3 Functions and polynomials

28.3.1 The Gauss function

Indefinite integrals:

$$\int_{-\infty}^{\infty} e^{-ax^2} dx = \sqrt{\pi/a} \quad \text{and} \quad \int_0^{\infty} x^n e^{-ax^2} dx = \frac{\Gamma(\frac{n+1}{2})}{2a^{\frac{n+1}{2}}} \ . \tag{28.15}$$

Higher momenta:

$$\int_{x_0}^{x_1} e^{-ax^2} dx = xe^{-ax^2}\Big|_{x_0}^{x_1} + 2a \int_{x_0}^{x_1} x^2 e^{-ax^2} dx \ . \tag{28.16}$$

28.3.2 Bessel functions

The integral definition of the *Bessel function*, the *von Neumann function*, and the *Hankel function* of the first and second kind are:

$$\begin{aligned} J_k(x) &= \frac{1}{\pi}\int_0^{\pi} \cos(k\tau - x\sin\tau) d\tau = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{\imath(x\sin\tau - k\tau)} d\tau \\ N_k(x) &= ... \\ H_k^{(1,2)} &= J_k \pm \imath N_k \ . \end{aligned} \tag{28.17}$$

The derivative,

$$2\frac{dJ_k(x)}{dx} = J_{k-1}(x) - J_{k+1}(x) \ . \tag{28.18}$$

Sum rules (empirically found),

$$\sum_{k=-\infty}^{\infty} J_k(x) = \sum_{k=-\infty}^{\infty} J_k(x)^2 = 1 \neq \sum_{k=-\infty}^{\infty} |J_k(x)|^2 \ . \tag{28.19}$$

The *spherical Bessel function*, the *spherical von Neumann function*, and the *spherical Hankel function* of the first and second kind are defined by:

$$\begin{aligned} j_k(x) &= \sqrt{\frac{\pi}{2x}} J_{k+1/2}(x) \\ n_k(x) &= \sqrt{\frac{\pi}{2x}} N_{k+1/2}(x) = (-1)^{k+1}\sqrt{\frac{\pi}{2x}} J_{-k-1/2}(x) \\ h_k^{(1,2)} &= j_k \pm \imath n_k \ . \end{aligned} \tag{28.20}$$

The series,

$$j_k(x) = (-x)^k \left(\frac{1}{x}\frac{d}{dx}\right)^k \frac{\sin x}{x} \quad , \quad n_k(x) = -(-x)^k \left(\frac{1}{x}\frac{d}{dx}\right)^k \frac{\cos x}{x} \ . \tag{28.21}$$

The derivative,

$$j_k'(x) = \frac{k}{x} j_k(x) - j_{k+1}(x) \ . \tag{28.22}$$

28.3.3 Hermite polynomials

The definition of the *Hermite polynomials*:

$$H_n(x) = \left(2x - \frac{d}{dx}\right)^n \cdot 1 = (-1)^n e^{x^2} \frac{d^n}{dx^n} e^{-x^2} = \frac{2^n}{\sqrt{\pi}} \int_{-\infty}^{\infty} (x + \imath t)^n e^{-t^2} dt \quad (28.23)$$

$$He_n(x) \equiv 2^{-n/2} H_n(x) \ .$$

Orthogonality and normalization:

$$\int_{-\infty}^{\infty} e^{-x^2} H_m(x) H_n(x) dx = \sqrt{\pi} 2^n n! \delta_{mn} \ . \quad (28.24)$$

Recursion:

$$\frac{d}{dx} H_n(x) = 2H_{n-1}(x) \quad (28.25)$$

$$\frac{d}{dx} e^{-x^2} H_n(x) = e^{-x^2} H_{n+1}(x)$$

$$H_{n+1}(x) = 2xH_n(x) - 2nH_{n-1}(x) \ .$$

Particular values:

$$H_{2n+1}(0) = 0 \quad (28.26)$$

$$H_{2n+1}(0) = (-1)^n 2^n (2n-1)!!$$

Series:

$$H_{2n}(x) = \sum_{k=0}^{\infty} \frac{(2n)!}{(2k)!} \frac{(-1)^{n-k}}{(n-k)!} (2x)^{2k} \quad (28.27)$$

$$H_{2n-1}(x) = \sum_{k=0}^{\infty} \frac{(2n+1)!}{(2k+1)!} \frac{(-1)^{n-k}}{(n-k)!} (2x)^{2k+1}$$

$$H_n(x) = n! \sum_{k=0}^{\mathrm{int}(n/2)} \frac{1}{k!} \frac{(-1)^k}{(n-2k)!} (2x)^{n-2k} \ .$$

28.3.4 Laguerre polynomials

The definition of the *Laguerre polynomials* is:

$$L_n^{(m)}(x) \equiv \frac{e^x x^{-m}}{m!} \frac{d^n}{dx^n} (e^{-x} x^{n+m}) \quad (28.28)$$

$$L_n \equiv L_n^{(0)}(x) \ .$$

Series:

$$L_n^{(m)}(x) = \sum_{k=0}^{n} \binom{n+m}{n-k} \frac{(-x)^k}{k!} \ . \quad (28.29)$$

Recursion:

$$\frac{d}{dx} L_n^{(m)}(x) = -L_{n-1}^{(m+1)}(x) \ . \quad (28.30)$$

Related functions:

$$u_{mn}(\varepsilon) \equiv e^{-\varepsilon^2} \cdot (\imath\varepsilon)^{n-m} \cdot \sqrt{\tfrac{m!}{n!}} \cdot L_m^{n-m}(\varepsilon^2) \tag{28.31}$$
$$u_{mn}(0) \approx (\imath\varepsilon)^{n-m} \cdot \sqrt{\tfrac{n!}{m!(n-m)!^2}}$$
$$u_{n+1,n}(0) \approx \imath\varepsilon \cdot \sqrt{n+1}\ .$$

Fourier transforms:

$$\int_{-\infty}^{\infty} e^{-ax^2} x^{2k} \cos xp \cdot dx = \tfrac{(-1)^k\sqrt{\pi}}{2^k\sqrt{a^{2k+1}}} \cdot e^{p^2/4a} \cdot He_{2k}(p/\sqrt{2a}) \tag{28.32}$$
$$\int_{-\infty}^{\infty} e^{-x^2/2} x^{2m} L_n^{2m}(x^2) \cos xp \cdot dx = \tfrac{(-1)^m\sqrt{\pi}}{\sqrt{2}n!} \cdot e^{-p^2/2} \cdot He_n(p) He_{n+2m}(p)$$
$$\int_{-\infty}^{\infty} e^{-x^2/2} x^{2m+1} L_n^{2m+1}(x^2) \sin xp \cdot dx = \tfrac{(-1)^m\sqrt{\pi}}{\sqrt{2}n!} \cdot e^{-p^2/2} \cdot He_n(p) He_{n+2m+1}(p)$$
$$\int_{-\infty}^{\infty} e^{-ax-bp} f(|x-p|) \cdot dxdp = \tfrac{1}{a+b}\left[\int_{-\infty}^{\infty} e^{-ax} f(x)dx + \int_{-\infty}^{\infty} e^{-bp} f(p)dp\right]\ .$$

28.3.5 Legendre polynomials

The definition of *Legendre polynomials* is:

$$P_n(x) \equiv \frac{1}{2^n n!}\frac{d^n}{dx^n}(x^2-1)^n \tag{28.33}$$
$$P_n^{(-m)}(x) \equiv (1-x^2)^{m/2}\frac{d^m}{dx^m}P_l(x)\ .$$

Series:

$$P_n^{(m)}(x) = \frac{(-1)^m(n+m)!}{2^m m!(n-m)!}(1-x^2)^{m/2}\left[\begin{array}{c} 1 - \frac{(n-m)!(m+n+1)!}{1!(m+1)!}\frac{1-x}{2} + \\ + \frac{(n-m)!(n-m+1)!(m+n+1)!(m+n+2)!}{2!(m+1)!(m+2)!}\left(\frac{1-x}{2}\right)^2 - \ldots \end{array}\right]\ . \tag{28.34}$$

28.3.6 Spherical harmonics

The definition of *spherical harmonics* is [966]:

$$Y_{\ell m}(\vartheta,\varphi) \equiv \sqrt{\frac{2\ell+1}{4\pi}}\sqrt{\frac{(\ell-|m|)!}{(\ell+|m|)!}}P_\ell^{|m|}(\cos(\vartheta)e^{im\varphi}\ . \tag{28.35}$$

The lowest *spherical harmonics* are:

$$\begin{array}{lcl@{\qquad}lcl} Y_0^{(0)} & = & \frac{1}{2}\sqrt{\frac{1}{\pi}} & Y_0^{(1)} & = & \frac{1}{2}\sqrt{\frac{3}{\pi}}\cos\theta \\ Y_{\pm1}^{(1)} & = & \mp\frac{1}{2}\sqrt{\frac{3}{2\pi}}\sin\theta e^{\pm i\phi} & Y_0^{(2)} & = & \frac{1}{4}\sqrt{\frac{5}{\pi}}(3\cos^2\theta-1) \\ Y_{\pm1}^{(2)} & = & \mp\frac{1}{2}\sqrt{\frac{15}{2\pi}}\sin\theta\cos\theta e^{\pm i\phi} & Y_{\pm2}^{(2)} & = & \frac{1}{4}\sqrt{\frac{15}{2\pi}}\sin^2\theta e^{\pm 2i\phi} \end{array} \tag{28.36}$$

28.3.7 Vector spherical harmonics

The definition of *vector spherical harmonics* is [966]:

$$\mathbf{Y}_{j\ell m}(\mathbf{r}) \equiv (-1)^{1-\ell-m}\sqrt{2j+1}\sum_q \begin{pmatrix} \ell & 1 & j \\ m-q & q & -m \end{pmatrix} Y_{\ell\ m-q}(\vartheta,\varphi)\hat{\mathbf{e}}_q \ . \tag{28.37}$$

28.3.7.1 The Gamma function

The definition of the *Gamma function* is:

$$\Gamma(x+1) = x\Gamma(x) \qquad , \qquad \Gamma(1/2) = \sqrt{\pi} \ . \tag{28.38}$$

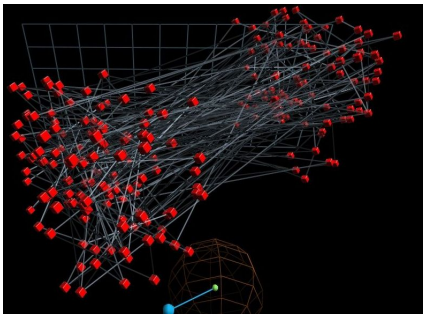
Part V

Statistical Physics and Atomic Quantum Fields

Preface to the part *Statistical Physics*



All thermodynamic quantities studied in Chp. 19 (extensive or intensive) are quasi-continuous, i.e. macroscopic. The laws of thermodynamics found to rule the behavior of large systems were discovered empirically via experimental observations. The nature of the laws is thus phenomenological, i.e. not derived from first principles. Until now we totally neglected the fact that matter (gases, fluid, or solids) is composed of microscopic elementary particles (atoms or molecules). Instead, the properties of matter have been resumed in material parameters, such as heat capacity and compressibility. Nevertheless, it already became clear that the behavior of a system is somehow related to the properties of the particles that compose it. E.g. the degrees of freedom of a molecule that can be excited have an influence on the heat capacity of a gas composed of these molecules; the Joule-Thomson effect is due to intermolecular forces; and what we experience as heat, is actually an outward manifestation of molecular and atomic motion, as we already pointed out in Sec. 19.1.2. Tracing back macroscopic properties and phenomena to microscopic models bears a formidable potential of deepening our level of understanding thermodynamic systems. It may even provide insight into the physical meaning of mysterious or elusive phenomenological concepts such as entropy production. Last not least, it may allow for a derivation of material parameters from first principles.

An atomistic description acknowledges the fact that matter is quantized into small portions called molecules [3]. Each molecule is understood as a (not necessarily rigid) body characterized by its center-of-mass coordinates, but also its rotations or internal vibrations. With typically 10^{23} atoms in just one liter of air the task of describing the *microstate* by all its coordinates is hopeless. The mathematical discipline that provides the tools capable of handling such big numbers is *statistics*, and the primary tool supplied for the purpose is the concept of the *distribution function*. The idea is to lump atoms having similar properties together to classes, e.g. energy levels. The distribution function then simply reports the number of particles in each class, which dramatically reduces the amount of information. The task of *statistical thermodynamics* is now the description of a thermodynamic state in terms of a distribution function

[3] The 'quantization' of matter is not to be understood in the quantum mechanical sense. Nevertheless, the particles themselves are generally microscopic and, under certain circumstances, may behave following rules dictated by quantum mechanics. This can lead to macroscopically observable phenomena studied in the area of quantum statistics, as we will learn in Chp. 29.2.

called *macrostate*. The formulation of statistical thermodynamics by *Boltzmann* and *Gibbs* provided a solid microscopic foundation of phenomenological thermodynamics.

In chapter 29 we develop the foundations of statistical mechanics and establish the link to phenomenological thermodynamics with special attention to the role the quantum statistical nature of the particles under study.

Chapter 29

Statistical thermodynamics

We will begin this chapter with a calculation of the *Boltzmann distribution* of microstates over the macrostates in Sec. 29.1 and introduce the concept of *partition function*, from which all macroscopic state functions may be computed. As applications of this algorithm we will revisit the ideal gas and the Einstein model of a crystalline solid.

29.1 Microstates, macrostates, and entropy

29.1.1 Probabilities of microstates and the partition function

We consider a unary thermodynamic system composed of a very large number N of identical (albeit distinguishable) particles, each one sufficiently specified by a set of numbers (coordinates and internal quantum numbers). The list combining the sets of all particles completely describes the microstate of the system. It changes if a single number of just one particle is changed. The microstate also changes when we just exchange two particles, although the physics of the system cannot change if the particles are identical. Clearly, the macrostate of a system is invariant upon particle exchange.

On the other hand, the number of macrostates we attribute to a system depends on the information we want to gather. For example, we could split the volume occupied by a gas into two parts, V_1 and V_2, and call macrostate the situation when a specific number N_1 of particles is in volume V_1, no matter which particles. Or we could classify the particles by their velocities and prepare a histogram. Any distribution of the particles over the possible velocity classes leading to the exact same histogram would then belong to the same macrostate.

In general, the microstates outnumber the macrostates by many orders of magnitude such that, when a system evolves through a thermodynamic process, it moves through a large number of microstates. And since, a priori, all microstates have the same probability, the likeliness of a macrostate is just the number of microstates it encompasses. Let $1, 2, .., j, .., r$ denote the possible single-particle states that the system has to offer, n_j the number of particles being in the single-particle state j, and $\{n_1, n_2, .., n_j, .., n_r\}$ the actual macrostate. The number of microstates contributing

to the same macrostate is easily found by combinatorial analysis,

$$\boxed{W_{\{n_j\}} = \frac{N!}{n_1!n_2!...n_r!} = N!\prod_{j=1}^{r}\frac{1}{n_j!}} \,, \tag{29.1}$$

with the total number of particles $N = n_1 + n_2 + ... + n_r$. The total number of possible microstates is obviously r^N. Hence, the probability to encounter the system in a particular macrostate is,

$$\mathfrak{P}_{\{n_j\}} = \frac{W_{\{n_j\}}}{r^N} = N!\prod_{j=1}^{r}\frac{1}{n_j!r^{n_j}} \,. \tag{29.2}$$

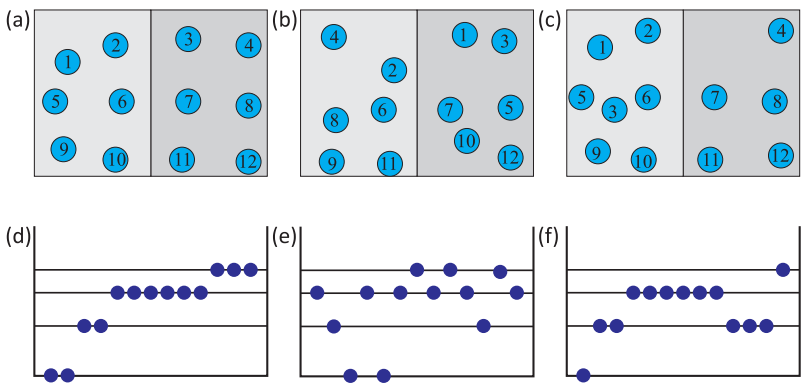


Figure 29.1: Illustration of micro- and macrostates with identical indistinguishable: (a-c) Distribution of 12 particles over 2 boxes. (d-f) Distribution of 13 particles over 4 energy levels. All schemes show different microstates, but only the schemes (a) and (b), respectively, (d) and (e) correspond to same macrostates.

Of all possible macrostates, there will be one containing the largest number of microstates, and the probability to encounter the system in this macrostate is highest. Examination of $\mathfrak{P}_{\{n_j\}}$ for a variety of macrostates $\{n_j\}$ reveals that the probability distribution is sharply peaked, and that macrostates deviating only slightly are already very unlikely. The most probable state is now interpreted as the *state of equilibrium*, and this hypothesis forms the basis for connecting phenomenological thermodynamics to an atomistic statistical description.

The equilibrium condition for highest probability in the statistical description is similar to the request for highest entropy in phenomenological thermodynamics, which suggests that both concepts are connected. But while the entropy is additive (the entropies of subsystems sum up to a global entropy), the number of macrostates is multiplicative. This led Boltzmann to his famous hypothesis,

$$\boxed{S = k_\mathrm{B} \ln W} \,. \tag{29.3}$$

Do the Excs. 29.1.7.1 to 29.1.7.7.

29.1.2 Equilibrium in statistical thermodynamics

Evaluating Eq. (29.3) involves computation of large factorials, which is a challenging numerical task. Fortunately, large factorials can be very well approximated by *Stirling's formula*,

$$\ln n! \simeq n \ln n - n \ . \tag{29.4}$$

With this formula we can simplify Eq. (29.3),

$$\begin{aligned} S &= k_{\rm B} \ln \frac{N!}{\prod_{j=1}^{r} n_j!} \simeq k_{\rm B}(N \ln N - N) - k_{\rm B} \sum_{j=1}^{r} (n_j \ln n_j - n_j) \\ &= k_{\rm B} N \ln N - k_{\rm B} \sum_{j=1}^{r} n_j \ln n_j = -k_{\rm B} \sum_{j=1}^{r} n_j \ln \frac{n_j}{N} \ . \end{aligned} \tag{29.5}$$

This expression allows to compute the entropy of any macrostate of the system.

To find the equilibrium macrostate $\{n_1, n_2, .., n_j, .., n_r\}_{\rm eq}$ in the atomistic description, we have to maximize the entropy (29.5). That is, we have to evaluate the total differential of entropy in the direction of changes $\{dn_1, dn_2, .., dn_j, .., dn_r\}$ of the macrostate under the constraint $N = \sum_{j=1}^{r} n_j$,

$$dS = \sum_{j=1}^{r} \left(\frac{\partial S}{\partial n_j}\right) dn_j + \left(\frac{\partial S}{\partial N}\right) dN = -k_{\rm B} \sum_{j=1}^{r} \left(1 + \ln \frac{n_j}{N}\right) dn_j + k_{\rm B} \sum_{j=1}^{r} \frac{n_j}{N} dN \ , \tag{29.6}$$

yielding,

$$\boxed{dS = -k_{\rm B} \sum_{j=1}^{r} \ln \frac{n_j}{N} \ dn_j} \ . \tag{29.7}$$

Application of the equilibrium criterion requires isolation from the environment, which sets constraints to the entropy evaluation in terms of particle and energy exchange,

$$N = \sum_{j=1}^{r} n_j \qquad \text{and} \qquad E = \sum_{j=1}^{r} \varepsilon_j n_j \ , \tag{29.8}$$

or equivalently [1],

$$dN = \sum_{j=1}^{r} dn_j = 0 \qquad \text{and} \qquad dE = \sum_{j=1}^{r} \varepsilon_j dn_j = 0 \ . \tag{29.9}$$

The maximum of the entropy function (29.5) under the constraints (29.9) can be found using the technique of Lagrange multipliers, which consists in solving the equation

$$0 = dS - \alpha k_{\rm B} \, dN - \beta k_{\rm B} \, dE = k_{\rm B} \sum_{j=1}^{r} \left(-\ln \frac{n_j}{N} - \alpha - \beta \varepsilon_j\right) dn_j \tag{29.10}$$

[1] Note that $d\varepsilon_j = 0$, if the energy levels do not vary along a thermodynamic process, only their population with particles.

for arbitrary factors α and β. This implies,

$$\frac{n_j}{N} = e^{-\alpha} e^{-\beta\varepsilon_j} \ , \tag{29.11}$$

for $j = 1, 2, ..., r$. The Lagrange multiplier α can readily be eliminated using the normalization constraint (29.8)(i),

$$1 = \sum_{j=1}^{r} \frac{n_j}{N} = e^{-\alpha} \sum_{j=1}^{r} e^{-\beta\varepsilon_j} \ , \tag{29.12}$$

leaving us with,

$$\frac{n_j}{N} = \frac{e^{-\beta\varepsilon_j}}{\sum_{j=1}^{r} e^{-\beta\varepsilon_j}} \ , \tag{29.13}$$

where we used the so-called canonical *partition function*,

$$\Xi_{\rm cn} \equiv \sum_{j=1}^{r} e^{-\beta\varepsilon_j} = e^{\alpha} \ . \tag{29.14}$$

To determine the Lagrange multiplier β, we compare the expressions obtained for the entropy variations in statistical and phenomenological thermodynamics. Solving (29.10) by dS and substituting α taken from (29.14) we get,

$$dS = -k_{\rm B} \sum_{j=1}^{r} \ln \frac{e^{-\beta\varepsilon_j}}{\Xi_{\rm cn}} \ dn_j = k_{\rm B} \sum_{j=1}^{r} (\beta\varepsilon_j + \ln \Xi_{\rm cn}) \, dn_j = k_{\rm B}\beta \ dE + k_{\rm B} \ln \Xi_{\rm cn} \ dN \ . \tag{29.15}$$

And from (19.157) we get,

$$dS = \frac{1}{T} dE + \frac{P}{T} dV - \frac{\mu}{T} dN \ , \tag{29.16}$$

where μ is the chemical potential per atom and $dV = 0$, since we assumed in this derivation, that every atom has access to the whole volume of the system. A comparison of the expressions (29.15) and (29.16) then yields,

$$\beta = \frac{1}{k_{\rm B} T} \qquad \text{and} \qquad \alpha = -\beta\mu = \ln \Xi_{\rm cn} \ . \tag{29.17}$$

Substitution into (29.13) and (29.14) finally yields,

$$\boxed{\frac{n_j}{N} = \frac{1}{\Xi_{\rm cn}} e^{-\varepsilon_j / k_{\rm B} T} \qquad \text{with} \qquad \Xi_{\rm cn} = \sum_{j=1}^{r} e^{-\varepsilon_j / k_{\rm B} T}} \ . \tag{29.18}$$

This expression is known as *Boltzmann distribution* [2,3,4].

29.1.3 Thermodynamic potentials in canonical ensembles

We wish now to express all state functions of the system in terms of the partition function (29.14). To this end we begin calculating the Helmholtz free energy using the expressions for the total energy (29.8)(ii) and the entropy (29.5),

$$F = E - TS = \sum_{j=1}^{r} n_j \varepsilon_j + k_{\mathrm{B}} T \sum_{j=1}^{r} n_j \ln \frac{e^{-\beta \varepsilon_j}}{\Xi_{\mathrm{cn}}} = -k_{\mathrm{B}} T \ln \Xi_{\mathrm{cn}} \ . \tag{29.19}$$

Hence, $\Xi_{\mathrm{cn}} = e^{-\beta F}$ and,

$$\frac{n_j}{N} = e^{\beta(F - \varepsilon_j)} \tag{29.20}$$

confirming the role of the free energy (19.66) for normalization of the canonical probability distribution.

The entropy function can now be expressed by the coefficient relation,

$$S = -\left(\frac{\partial F}{\partial T}\right)_V = k_{\mathrm{B}} \ln \Xi_{\mathrm{cn}} + k_{\mathrm{B}} T \left(\frac{\partial \ln \Xi_{\mathrm{cn}}}{\partial T}\right)_V \ , \tag{29.21}$$

the internal energy becomes,

$$E = F + TS = k_{\mathrm{B}} T^2 \left(\frac{\partial \ln \Xi_{\mathrm{cn}}}{\partial T}\right)_V \ , \tag{29.22}$$

and the heat capacity (19.75)(ii),

$$C_V = \left(\frac{\partial E}{\partial T}\right)_V = 2 k_{\mathrm{B}} T \left(\frac{\partial \ln \Xi_{\mathrm{cn}}}{\partial T}\right)_V + k_{\mathrm{B}} T^2 \left(\frac{\partial^2 \ln \Xi_{\mathrm{cn}}}{\partial T^2}\right)_V \ . \tag{29.23}$$

Note that for now we always consider fixed volumes, $dV = 0$. To compute the remaining thermodynamic potentials, V, H, G, and C_P, we need to generalize the partition function to include pressure dependence. This will be done later in Sec. ??.

[2] We obtained the Boltzmann distribution from a microcanonical derivation, but since the Boltzmann distribution holds for any ensemble of classical particles, we can use it to derive the distribution function for canonical ensembles.

[3] A system of non-interacting particles can be separated into independent parts. If such a system is described by a canonical ensemble, then each part can be seen as a system unto itself and described by a canonical ensemble having the same temperature as the whole. In this way, the canonical ensemble provides exactly the Maxwell-Boltzmann statistics for systems of any number of particles. In comparison, the justification of the Boltzmann distribution from the microcanonical ensemble only applies for systems with a large number of particles, that is, in the thermodynamic limit. The Boltzmann distribution itself is one of the most important tools in applying statistical mechanics to real systems, as it dramatically simplifies the study of systems that can be separated into independent parts (e.g. particles in a gas, electromagnetic modes in a cavity, etc.).

[4] In a system of strongly interacting particles, it is usually not possible to find a way to separate the system into independent subsystems as done in the Boltzmann distribution. In these systems it is necessary to resort to using the full expression of the canonical ensemble in order to describe the thermodynamics of the system when it is thermostatted to a heat bath. The *Ising model*, which is a widely discussed toy model for the phenomena of ferromagnetism, is one of the simplest models showing a phase transition.

In summary, the state of thermodynamic equilibrium is characterized by the fact the particles are distributed over the available energy levels according to the exponential function (29.11). Once the energy levels are known for a system, the partition function and all the thermodynamic potentials can be calculated. We will now study the algorithm at several examples.

29.1.4 Two-level systems

Let us consider a system consisting of only two allowed energy levels $\varepsilon_j = 0, \varepsilon$, that is, we set the energy of the ground state to zero. This system is relevant for atomic system in equilibrium with radiation fields driving electronic transitions between excitation levels. The Boltzmann partition function and the population (29.18) then become,

$$\Xi_{\text{cn}} = \sum_{j=1}^{r} e^{-\beta\varepsilon_j} = 1 + e^{-\beta\varepsilon} \quad , \tag{29.24}$$

$$\frac{n_1}{N} = \frac{1}{\Xi_{\text{cn}}} = \frac{1}{1+e^{-\beta\varepsilon}} \quad , \quad \frac{n_2}{N} = \frac{e^{-\beta\varepsilon}}{\Xi_{\text{cn}}} = \frac{e^{-\beta\varepsilon}}{1+e^{-\beta\varepsilon}} \ . \tag{29.25}$$

In particular, the ratio between populations of consecutive levels is, $n_2/n_1 = e^{-\beta\varepsilon}$. At low temperature, $k_{\text{B}}T \ll \varepsilon$, the excited state population is negligibly small, while at high temperature, $k_{\text{B}}T \gg \varepsilon$, both energy levels have almost the same population. Do the Exc. 29.1.7.8.

With the partition function it is easy to evaluate the potentials,

$$F = -Nk_{\text{B}}T \ln \Xi_{\text{cn}} = -Nk_{\text{B}}T \ln(1+e^{-\beta\varepsilon}) \tag{29.26}$$

$$S = Nk_{\text{B}} \ln \Xi_{\text{cn}} + Nk_{\text{B}}T \left(\frac{\partial \ln \Xi_{\text{cn}}}{\partial T}\right)_V = Nk_{\text{B}} \ln(1+e^{-\beta\varepsilon}) + \frac{N\varepsilon}{T}\frac{e^{-\beta\varepsilon}}{1+e^{-\beta\varepsilon}}$$

$$E = Nk_{\text{B}}T^2 \left(\frac{\partial \ln \Xi_{\text{cn}}}{\partial T}\right)_V = N\varepsilon \frac{e^{-\beta\varepsilon}}{1+e^{-\beta\varepsilon}}$$

$$C_V = 2Nk_{\text{B}}T \left(\frac{\partial \ln \Xi_{\text{cn}}}{\partial T}\right)_V + Nk_{\text{B}}T^2 \left(\frac{\partial^2 \ln \Xi_{\text{cn}}}{\partial T^2}\right)_V = \frac{N\varepsilon^2}{k_{\text{B}}T^2}\frac{e^{-\beta\varepsilon}}{(1+e^{-\beta\varepsilon})^2} \ .$$

29.1.5 Einstein-Debye model of solids

According to the equipartition theorem, every atom has three degrees of freedom due to its translational motion. Describing a solid simply as a conjunction of N atoms bound by a common potential, we expect the total energy and the specific heat following the *Dulong-Petit law*,

$$E = 3Nk_{\text{B}}T \qquad \text{resp.} \qquad C_V = \left(\frac{\partial E}{\partial T}\right)_V = 3Nk_{\text{B}} \ , \tag{29.27}$$

for all solids regardless of temperature.

It was observed, however, that the specific heat of solids decreases like $C_V \propto T^3$ as T approaches zero. Einstein proposed an alternative model treating the N atoms as three-dimensional harmonic oscillators vibrating in a lattice. Indeed, many solids are crystalline, which means that they arrange in a periodic structure, in the simplest

case a cubic lattice, where each atom has six neighbors arranged along Cartesian coordinates, as illustrated in Fig. 29.2. The interatomic bonds are described by springs storing energies like a quantized 3D harmonic oscillator,

$$\varepsilon_j = (j + \tfrac{3}{2})\hbar\omega \ . \tag{29.28}$$

The normal-mode frequency ω is related to the spring constant of the atomic bond and the atomic mass. The spectrum (29.27) completely defines the model.

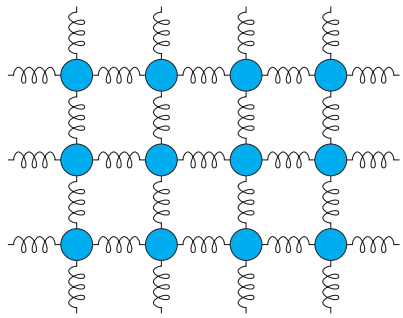

Figure 29.2: Einstein's model of a solid.

The partition function is,

$$\Xi_{\rm cn} = \sum_{j=1}^{r} e^{-\beta\varepsilon_j} = e^{-3\beta\hbar\omega/2}\sum_{j=1}^{r} e^{-\beta\hbar\omega j} \simeq e^{-3\beta\hbar\omega/2}\sum_{j=0}^{\infty} e^{-\beta\hbar\omega j} = \frac{e^{-3\beta\hbar\omega/2}}{1-e^{-\beta\hbar\omega}} \ . \tag{29.29}$$

The discrete energies $n\hbar\omega$ are identified with quasi-particles called *phonons*. The quantum nature of atoms does not matter, they just provide the medium supporting the phonons.

With the partition function it is easy to evaluate the potentials,

$$F = -Nk_{\rm B}T\ln\Xi_{\rm cn} = \frac{3N\hbar\omega}{2} + 3Nk_{\rm B}T\ln\left(1-e^{-\beta\hbar\omega}\right) \tag{29.30}$$

$$S = Nk_{\rm B}\ln\Xi_{\rm cn} + Nk_{\rm B}T\left(\frac{\partial\ln\Xi_{\rm cn}}{\partial T}\right)_V = -3Nk_{\rm B}\ln\left(1-e^{-\beta\hbar\omega}\right) + \frac{3N\hbar\omega}{T}\frac{1}{e^{\beta\hbar\omega}-1}$$

$$E = Nk_{\rm B}T^2\left(\frac{\partial\ln\Xi_{\rm cn}}{\partial T}\right)_V = \frac{3N\hbar\omega}{2}\frac{e^{\beta\hbar\omega}+1}{e^{\beta\hbar\omega}-1}$$

$$C_V = 2Nk_{\rm B}T\left(\frac{\partial\ln\Xi_{\rm cn}}{\partial T}\right)_V + Nk_{\rm B}T^2\left(\frac{\partial^2\ln\Xi_{\rm cn}}{\partial T^2}\right)_V = -3Nk_{\rm B}\left(\frac{\hbar\omega}{k_{\rm B}T}\right)^2\frac{e^{\beta\hbar\omega}}{(e^{\beta\hbar\omega}-1)^2} \ .$$

29.1.5.1 Debye model

In his model Einstein applied Planck's law on the distribution of energy in electromagnetic radiation, which treats radiation as a gas of *photons*, to the energy distribution of atomic vibrations in a solid, treating them as a gas of *phonons* in a box (the box being the solid). Most of the steps of the calculation are identical, as both are examples of a massless bosonic gas with linear dispersion relation.

Following the Bose-Einstein statistics, we must replace in (29.27),

$$k_{\rm B}T \longrightarrow \frac{\hbar\omega}{e^{\hbar\omega/k_{\rm B}T}-1} \ , \tag{29.31}$$

yielding,

$$E = \frac{3N\hbar\omega}{e^{\beta\hbar\omega}-1} \qquad \text{resp.} \qquad C_V = 3Nk_{\rm B}\left(\frac{\hbar\omega}{k_{\rm B}T}\right)^2 \frac{e^{\hbar\omega/k_{\rm B}T}}{(e^{\hbar\omega/k_{\rm B}T}-1)^2} \ , \tag{29.32}$$

in accordance with (29.30).

Still, the disappearance of the specific heat at low temperatures,

$$C_V \simeq \frac{3N(\hbar\omega)^2}{k_{\rm B}T^2} e^{-\hbar\omega/(k_{\rm B}T)} \ , \tag{29.33}$$

which is related to the finite localization energy of harmonic oscillators, does not describe experimental observations very well, and the model had to be refined by Debye, later on.

While Einstein assumed monochromatic lattice vibrations, *Debye's* approach was to allow a *spectrum* of vibrational frequencies. With the density-of-states,

$$\rho(\nu)d\nu = (4\pi V v^3)\nu^2 d\nu \ , \tag{29.34}$$

where v is the velocity of sound propagation, the formula is totally equivalent to the density-of-states for photons in a cavity. Assuming that there is an upper bound ν_m for the vibrational frequencies, we normalize as $3N_0 = \int_0^{\nu_m} \rho(\nu)d\nu$. The energy now is [5],

$$E = \int_0^{\nu_m} \frac{\hbar\omega}{e^{\hbar\omega/k_{\rm B}T}-1} \frac{4\pi V}{v^3} \nu d\nu = 9Nk_{\rm B}\frac{T^4}{\theta^3}\int_0^{\theta/T} \frac{x^3 dx}{e^x-1} \ . \tag{29.35}$$

The *Debye temperature* $\theta = h\nu_m/k_{\rm B}$ is characteristic for the metal. The derivative is then,

$$C_V = 9Nk_{\rm B}\left[4\left(\frac{T}{\theta}\right)^3 \int_0^{\theta/T} \frac{x^3 dx}{e^x-1} - \frac{\theta}{T}\frac{1}{e^{\theta/T}-1}\right] \ . \tag{29.36}$$

At low temperatures this formula reproduces the *Debye law*,

$$C_V \simeq 9Nk_{\rm B}\left[4\left(\frac{T}{\theta}\right)^3 \int_0^{\infty} \frac{x^3 dx}{e^x-1} - \frac{\theta}{Te^{\theta/T}}\right] = \frac{12\pi^4}{5} Nk_{\rm B}\left(T/\theta\right)^3 \ . \tag{29.37}$$

29.1.6 Maxwell-Boltzmann distribution of ideal gases

Here we consider a gas composed of identical monoatomic particles enclosed in a box of volume $V = \int_V d^3r$. The energy of every atom is just its kinetic energy associated with its flight through space,

$$\varepsilon = \frac{m}{2}v^2 = \frac{m}{2}v_x^2 + \frac{m}{2}v_y^2 + \frac{m}{2}v_z^2 \ . \tag{29.38}$$

[5] The fact that the electron gas also has a heat capacity is neglected.

Since the phase space of atomic motion is continuous, the partition function is now calculated as an integral,

$$\begin{aligned}\Xi_{\rm cn} &= \int_{\mathbb{R}^3}\int_{\mathbb{R}^3} e^{-\beta\varepsilon} d^3r d^3v \\ &= V\int_0^\infty 4\pi v^2 e^{-\beta m v^2/2} dv = V\left(\frac{2\pi k_{\rm B}T}{m}\right)^{3/2} .\end{aligned} \tag{29.39}$$

We will see later how to generalize the procedure in the presence of an inhomogeneous trapping potential $U(\mathbf{r})$. Insertion of the kinetic energy (29.38) generates the well-known *Maxwell-Boltzmann distribution*,

$$\boxed{\frac{n(\varepsilon)}{N} = \frac{1}{\Xi_{\rm cn}} e^{-\beta m v^2/2}} , \tag{29.40}$$

which will be studied in Excs. 29.1.7.9 to 29.1.7.16.

The potentials are easily calculated,

$$\begin{aligned} F &= -Nk_{\rm B}T\ln\Xi_{\rm cn} = -Nk_{\rm B}T\left(\ln V + \frac{3}{2}\ln\frac{2\pi k_{\rm B}T}{m}\right) \\ S &= Nk_{\rm B}\ln\Xi_{\rm cn} + Nk_{\rm B}T\left(\frac{\partial\ln\Xi_{\rm cn}}{\partial T}\right)_V = Nk_{\rm B}\left(\ln V + \frac{3}{2} + \frac{3}{2}\ln\frac{2\pi k_{\rm B}T}{m}\right) \\ E &= Nk_{\rm B}T^2\left(\frac{\partial\ln\Xi_{\rm cn}}{\partial T}\right)_V = \frac{3}{2}Nk_{\rm B}T \\ C_V &= 2Nk_{\rm B}T\left(\frac{\partial\ln\Xi_{\rm cn}}{\partial T}\right)_V + Nk_{\rm B}T^2\left(\frac{\partial^2\ln\Xi_{\rm cn}}{\partial T^2}\right)_V = \frac{3}{2}Nk_{\rm B} . \end{aligned} \tag{29.41}$$

Furthermore,

$$P = -\left(\frac{\partial F}{\partial V}\right)_T = \frac{Nk_{\rm B}T}{V} . \tag{29.42}$$

29.1.6.1 Inclusion of vibrational and rotational degrees of freedom

See [239], p.155.

29.1.7 Exercises

29.1.7.1 Ex: Probabilities

In a game, 5 ideal dice are rolled.
a. What is the probability that exactly two of these dice show the number one?
b. What is the probability that at least one die shows the number one?

29.1.7.2 Ex: Probabilities

With what probability have out of
a. 1000 random numbers between 1 and 100 exactly five the value 50;
b. 100 two people on birthday January 1st.

29.1.7.3 Ex: Probabilities

What is the probability that you inhale at least one molecule that Julius Caesar exhaled during his last breath (Tu quoque, Brute, fili mi!)? Assume a breathing volume of 1 liter and an atmosphere height of approximately $h = 10\,\mathrm{km}$. Assume the density of the atmosphere is approximately homogeneous.

29.1.7.4 Ex: Idiots roulette

A Bavarian, a Swabian and an East Frisian play Russian roulette together, each according to their own rules. The Bavarian inserts two cartridges into the drum of a six-shot revolver, sets the drum in a rapid rotation, aims at his own head and pulls the trigger once. The Swabian puts a cartridge in the revolver and pulls the trigger twice, the East Frisian puts a cartridge in the revolver, pulls the trigger once, turns the drum a second time and pulls the trigger again. What is the chance of survival of the three crazy people?

29.1.7.5 Ex: Students roulette

A student writes a multiple choice test in physics. It consists of 18 tasks. For each task, only one of the four proposed solutions is correct. Since he does not understand much about the topic, he trusts his luck and checks the possible solutions by chance. What is the probability that the student meets the minimum requirement of 8 correct answers?

29.1.7.6 Ex: Slot machine

A slot machine consists of three concentric rings. Each ring is evenly divided into 10 sections and the sections in each ring are labeled with letters from 'a' to 'j'. By pressing the start button, the three rings start to rotate independently. If the lock button is pressed, the rings brake independently of one another and three letters appear side by side in the viewing window. With three 'a' you win, with two 'a' there is a free spin.
a. Calculate the probability for one free spin per game.
b. What is the probability of getting exactly 3 free spins in 10 games?
c. What is the probability of winning at least once in 10 games?

29.1.7.7 Ex: Binomial distribution

Two drunks stagger on the x-axis. Starting from the origin, they take a step to the right or to the left with the same probability. The steps take place synchronously, and the steps of both people are the same and constant. Determine the probability that they will meet again after N steps.

29.1.7.8 Ex: Simple model for a solid

Consider a system of N atomic particles at a temperature T. The individual atoms can only be in one of two states. Either in state $|0\rangle$ at the energy $\varepsilon_0 = 0$ or in state $|1\rangle$ at energy $\varepsilon_1 = \varepsilon$. Apart from this energy ε_i the atoms have no kinetic or other

energies.
a. Choosing the Boltzmann distribution, determine the population n_i, that is, the probability that a certain atom is in state $|i\rangle$. How should the normalization be chosen?
b. Determine the statistical mean $\bar{\varepsilon}$ for the energy of one atom. Which value results for $k_\mathrm{B}T = \varepsilon$? What is the expression for the total energy E of N atoms?
c. Calculate the population $n_1(T_j)$ to find a certain atom at the energy ε for four different temperatures: $k_\mathrm{B}T_j = 0.1 \times j\varepsilon$ for $j = 1, 2, 3, 4$. Also calculate the energy per atom $E(T_j)/N$ of the entire system at these temperatures.
d. Find an expression for the heat capacity C of this N-atom system. Note: For this system, the total energy is identical to the thermal energy.
e. Calculate the heat capacities C_j especially for the temperatures T_j from subtask (c). What does the result have to do with 'freezing degrees of freedom'?

29.1.7.9 Ex: Velocity distribution

The Maxwellian velocity distribution or Boltzmann distribution of a one-dimensional ideal gas of identical particles of mass m at temperature T is,

$$f(v)dv = \sqrt{\frac{m}{2\pi k_\mathrm{B}T}} e^{-mv^2/2k_\mathrm{B}T} dv \ .$$

This gives the average kinetic energy for each molecule of $\langle E_\mathrm{kin}\rangle = \frac{1}{2}k_\mathrm{B}T$. According to the equipartition theorem, Maxwell's velocity distribution of a three-dimensional gas is given by $f(v_x)dv_x\ f(v_y)dv_y\ f(v_z)dv_z$.
a. Write down the velocity distribution explicitly and determine the average kinetic energy of a molecule in the three-dimensional gas at temperature T.
Determine the average absolute velocity $\langle v\rangle = \langle|\mathbf{v}|\rangle$ and compare $\langle v\rangle^2$ with $\langle v^2\rangle$ for the three-dimensional case.
c. What is the number of particles $F(v)dv$ with an absolute velocity $v = |\mathbf{v}|$ in the range v and $v + dv$.
d. Consider a gas made of rubidium atoms ($m = 87u$) and sketch $F(v)$ for temperatures between 100 K and 300 K.
e. Consider the rubidium gas at room temperature ($T = 300\,\mathrm{K}$). What is the proportion of molecules whose average velocity $\langle v\rangle$ is greater than 1000 m/s?

29.1.7.10 Ex: Maxwell-Boltzmann distribution

Calculate the number of particles in an ideal homogeneous gas having velocities slower than $2v_\mathrm{rms}$.

29.1.7.11 Ex: Maxwell-Boltzmann distribution

Using the Maxwell-Boltzmann distribution $f(v)$ and the following formulas, calculate the velocities $\bar{v} \equiv \int_0^\infty vf(v)v^2dv$ and $v_\mathrm{rms} \equiv \sqrt{\overline{v^2}}$:

$$\int_0^\infty x^n e^{-x^2} dx = \tfrac{1}{2}\Gamma(\tfrac{n+1}{2}) = \begin{cases} \frac{(2k-1)!!\sqrt{\pi}}{2^{k+1}} & \text{for} \quad n = 2k \\ \frac{k!}{2} & \text{for} \quad n = 2k+1 \end{cases} \ .$$

29.1.7.12 Ex: Mean velocity in a gas

The average velocity of the molecule in an ideal gas is 500 m/s. If the gas maintains the same temperature and the molecular masses are doubled, what will be the new average velocity?

29.1.7.13 Ex: Evaporation

a. A three-dimensional homogeneous gas consisting of $N = 10^8$ rubidium atoms (mass $m = 87u$) has the temperature $T = 100\,\mu\text{K}$. How many atoms are faster on average than $v_1 = 10\,\text{cm/s}$?
b. Now suppose that all atoms with a velocity $v > v_1$ were suddenly removed. After some time, a new thermal equilibrium is established due to collisions. What is the temperature of the gas now?

29.1.7.14 Ex: Trapped gases

The density distribution of a rubidium gas in a three-dimensional harmonic potential can be expressed by,

$$n(\mathbf{r})d^3r = n_0 e^{-U(\mathbf{r})/k_\text{B}T} d^3r \ ,$$

where $U(\mathbf{r}) = \frac{m}{2}\omega^2 r^2$. Numerical values: $m = 87u$ and $\omega = 2\pi \cdot 50\,\text{Hz}$.
a. Determine the expansion of the gas ($1/\sqrt{e}$ full width of the distribution) at a given temperature $T = 100\,\mu\text{K}$.
b. Determine the maximum density n_0 of the gas when $N = \int n(\mathbf{r})d^3r = 10^8$ is the total number of atoms.
c. The effective volume is defined by $V_\text{eff} = N/n_0$. How many atoms are in the effective volume?

29.1.7.15 Ex: Trapped gases

Calculate the internal energy and heat capacity of an ideal gas stored in a harmonic trap and compare the result with a free gas.

29.1.7.16 Ex: Trapped gases

An ultracold gas made of 10^8 rubidium atoms (mass number 87) is trapped in a three-dimensional potential of the form $U(r) = \frac{m}{2}\omega^2 r^2$ with the oscillation frequencies $\omega/2\pi = 100\,\text{Hz}$.
a. Assume the spatial distribution function for the atoms to be $n(\mathbf{r}) = n_0 e^{-U(r)/k_\text{B}T}$. What is its width at $1/\sqrt{e}$ of the maximum height? How does the width of the distribution function change when the number of atoms is doubled?
b. The trap potential is suddenly switched off. The atoms are robbed of their potential energy, while their kinetic energy leads to the ballistic expansion of the cloud. 20 ms after switching off the trapping potential, a $1/\sqrt{e}$ width of $\bar{r}_a = 0.2\,\text{mm}$ is experimentally measured for the distribution of the expanded atomic cloud. What was the temperature of the atomic cloud in the trap?
Help: Assume that the final size of the atomic cloud is much larger than the size of the trap. Neglect collisions between the atoms.

29.2 Quantum statistics

Considering a closed isolated system in a fixed volume (NVE-ensemble where $E, N, V = const$) we have derived in Sec. 29.1.1 the partition function for *microcanonical ensembles*, from which we obtained in Sec. 29.1.2 the *Boltzmann distribution* function.

The combinatorial derivation of the number of microstates contributing to the same macrostate (29.1) was based on the observation, that all particles constituting the system were identical, but distinguishable. The expression (29.1) is just the multinomial coefficient, i.e. the number of ways of arranging N items into r boxes, the j-th box holding n_j items, ignoring the permutation of items in each box. The problem, however, is that quantum mechanics postulates that identical particles are indistinguishable, and this has an impact on the numbers of states available upon permutation. Consequently, the partition function (29.1) needs to be corrected.

The problems ultimately results from the fact that *phase space* is quantized. If this weren't the case, the cells' size could be chosen so small that they admit at most one particle. Then quantum statistics would not apply, the system would be classical.

29.2.1 Wavefunction symmetrization and detailed balance

We learn in quantum mechanics, that (anti-)symmetrization of the total wavefunction of a multiparticle system leads to Bose-enhancement (Pauli blocking). Consider a product state of two particles 1 and 2, $\Psi_o = \psi_\alpha(1)\psi_\beta(2)$, and symmetrize it to

$$\Psi_{s,a} = \tfrac{1}{\sqrt{2}}[\psi_\alpha(1)\psi_\beta(2) \pm \psi_\alpha(2)\psi_\beta(1)] \ . \tag{29.43}$$

Now assume that the single particle wavefunctions do completely overlap,

$$\alpha = \beta \qquad \Longrightarrow \qquad |\Psi_{o,s,a}|^2 = (s+1)\ |\psi_\alpha(1)|^2|\psi_\beta(2)|^2 \ , \tag{29.44}$$

where $s = 0$ for Boltzmann particles (called *boltzons* here for simplicity), $s = 1$ for bosons, and $s = -1$ for fermions. Generalized to arbitrary numbers of particles we state: *If n bosons (fermions) are in state Ψ, the probability for another bosons (fermions) to joint this state is $1 + sn$ times the probability without (anti-)symmetrization.*

An intuitive derivation of the *quantum statistics* distribution function is based on the postulate of *detailed balance*. Let us consider the most fundamental process in physics, which is the collision between two particles initially in states 1 and 4 ending up in two other states 2 and 3 [see Fig. 29.3(a)]. All four states j are initially occupied with populations n_j. The detailed balance postulate claims that *equality of the rates $R_{14\to 23}$ for two particles to change their states and the rate for the inverse process $R_{23\to 14}$ is a sufficient condition for thermal equilibrium.* Using the bosonic enhancement (fermionic suppression) factor derived above, the postulate can be formulated,

$$\begin{aligned} R_{14\to 23} &= |M_{14,23}|^2 n_1 n_4 (1+sn_2)(1+sn_3) = \\ R_{23\to 14} &= |M_{14,23}|^2 n_2 n_3 (1+sn_1)(1+sn_4) \ , \end{aligned} \tag{29.45}$$

where $M_{14,23}$ is the matrix element of the collision process. Hence,

$$\frac{n_1}{1+sn_1}\frac{n_4}{1+sn_4} = \frac{n_2}{1+sn_2}\frac{n_3}{1+sn_3} \ . \tag{29.46}$$

Energy conservation requires,

$$\varepsilon_1 + \varepsilon_4 = \varepsilon_2 + \varepsilon_3 \ . \tag{29.47}$$

In a canonical ensemble in thermal equilibrium the population distribution among the levels must be a unique function of their energies,

$$n_j = f(\varepsilon_j) \ . \tag{29.48}$$

To satisfy Eqs. (29.46) and (29.47) f must have the functional form,

$$\boxed{f(\varepsilon_j) = \frac{1}{Ce^{\beta\varepsilon_j} - s}} \ , \tag{29.49}$$

where C is an arbitrary constant introduced to satisfy some normalization constraints. This can be verified easily by plugging the formula (29.49) into the Eq. (29.46).

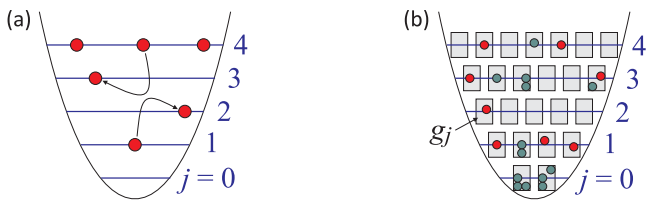

Figure 29.3: (a) Detailed balance entails thermal equilibrium. (b) Subdivision of energy levels j in subboxes g_j. Red circles are fermions and green particles bosons.

29.2.2 Microcanonical ensembles of indistinguishable particles

29.2.2.1 Boltzons

In order to hold for indistinguishable particles, the partition function (29.1) must be generalized allowing for the possibility that there is more than one way to put n_j particles into the box j. If the j-th box has a 'degeneracy', that is, it has g_j 'sub-boxes' with the same energy ε_j, such that any way of filling the j-th box where the number in the sub-boxes is changed is a distinct way of filling the box, then in order to get the right number of macrostates, the number of ways of filling the j-th box must be increased by the number of ways of distributing the n_j objects in the g_j sub-boxes. The number of ways of placing n_j distinguishable objects in g_j sub-boxes is $g_j^{n_j}$, since any particle can go into any of the g_j boxes. Thus the number of ways $W_{\{n_j\}}$ that a total of N particles can be classified into energy levels according to their energies, while each level j having g_j distinct states such that the j-th level accommodates n_j particles is,

$$\boxed{W_{\{n_j\}} = N! \prod_{j=1}^{r} \frac{g_j^{n_j}}{n_j!}} \ . \tag{29.50}$$

In analogy to the procedure outlined in Sec. 29.1.2 we derive the Boltzmann distribution by first taking the logarithm from (29.51) and then simplifying it using

Stirling's formula (31.1),

$$\ln W = \ln N! + \sum_j [n_j \ln g_j - \ln n_j!] \simeq \ln N! + \sum_j [n_j \ln \frac{g_j}{n_j} + n_j] \ , \tag{29.51}$$

then calculating the differential,

$$d \ln W = \sum_j \left(\frac{\partial \ln W}{\partial n_j} \right) dn_j = \sum_j \ln \frac{g_j}{n_j} dn_j \ . \tag{29.52}$$

introducing Lagrange multipliers α and β and minimizing the functional,

$$f(\{n_j\}) \equiv \ln W + \alpha(N - \sum_j n_j) + \beta(E - \sum_j \varepsilon_j n_j) \ , \tag{29.53}$$

Relating the condition,

$$0 = df(n_j) = d \ln W - \alpha \sum_j dn_j - \beta \sum_j \varepsilon_j dn_j = \sum_j \left(\ln \frac{g_j}{n_j} - \alpha - \beta \varepsilon_j \right) dn_j \tag{29.54}$$

via the Boltzmann hypothesis (29.16) to entropy,

$$dS = \frac{1}{T} dE + \frac{P}{T} dV - \frac{\mu}{T} dN = k_{\rm B} \beta \, dE + k_{\rm B} \alpha \, dN = k_{\rm B} \, d \ln W \ , \tag{29.55}$$

we identify the Lagrange multipliers,

$$\beta = \frac{1}{k_{\rm B} T} \qquad \text{and} \qquad \alpha = -\frac{\mu}{k_{\rm B} T} \ , \tag{29.56}$$

and finally obtain the Boltzmann distribution by setting the parenthesis in (29.54) to zero,

$$\boxed{n_j = \frac{g_j}{e^{\beta(\varepsilon_j - \mu)}}} \ . \tag{29.57}$$

29.2.2.2 Bosons

Boltzmann's fundamental equation (29.3) relates the thermodynamic entropy S to the logarithm of the number of microstates $W_{\{n_j\}}$. It was pointed out by Gibbs however, that the above expression (29.51) does not yield an extensive entropy, and is therefore faulty [6]. This problem is known as the *Gibbs paradox*. The problem is

[6] This can be seen as follows: Consider two identical systems, $r' = r$ and $g'_{j'} = g_j$, with atom numbers $N = \sum_j n_j$ and $N' = \sum_j n'_j$. The partition function for boltzons is not multiplicative,

$$(N + N')! \prod_{j=1}^{r} \frac{g_j^{n_j}}{n_j!} \neq N! \prod_{j=1}^{r} \frac{g_j^{n_j}}{n_j!} \times N'! \prod_{j=1}^{r} \frac{g_j^{n'_j}}{n'_j!}$$

while for fermions it is. To see this we set $n'_{j'} \equiv n_{r+j}$ for $j' = r + j$ and $j = 1, ..., r$. Then,

$$\prod_{j=1}^{2r} \binom{g_j}{n_j} = \prod_{j=1}^{r} \binom{g_j}{n_j} \times \prod_{j=1}^{r} \binom{g_j}{n'_j} \ .$$

The same argument holds for bosons. A critical discussion of the above statements can be read in [483].

that the particles considered by the above equation are *not indistinguishable*. In other words, for two particles (i and j) in two energy sublevels the population represented by $[i, j]$ is considered distinct from the population $[j, i]$, while for indistinguishable particles, they are not. Indeed, bosons have anti-symmetric wavefunctions, Fermions have symmetric ones. Boltzons have all wavefunctions as eigenfunctions. In the limit of high temperatures all particles behave like boltzons. Discretize the one-particle energies in small cells labeled j of constant energy ε_j. Let n_j be their number and g_j their degeneracy [see Fig. 29.3(b)].

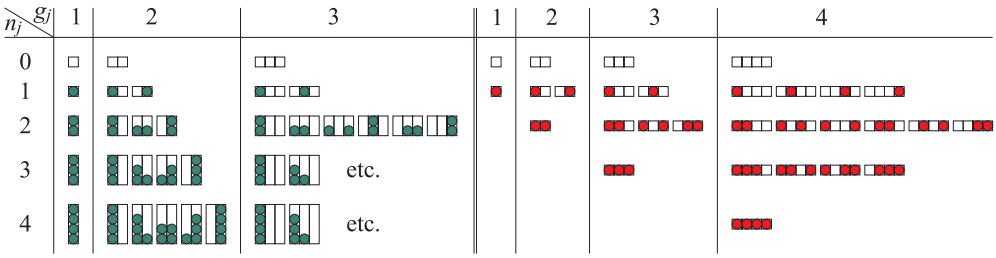

Figure 29.4: Distribution of n_j bosons (green) and fermions (red) over g_j boxes the number of possibilities being, respectively, $\binom{n_j+g_j-1}{n_j}$ and $\binom{g_j}{n_j}$.

For bosons, each level g_j can hold arbitrarily many of the n_j particles. If we carry out the argument for indistinguishable particles, we are led to the expression for the partition function for bosons [7],

$$\boxed{W_{\{n_j\}} = \prod_{j=1}^{r} \binom{n_j + g_j - 1}{n_j}} \,. \tag{29.58}$$

Analogously to (29.51) we calculate the logarithm using Stirling's formula,

$$\begin{aligned} \ln W &= \sum_j \left[\ln(n_j + g_j - 1)! - \ln n_j! - \ln(g_j - 1)!\right] \\ &\simeq \sum_j \left[n_j \ln \frac{g_j - 1 + n_j}{n_j} + (g_j - 1) \ln \frac{g_j - 1 + n_j}{g_j - 1} \right] \,, \end{aligned} \tag{29.59}$$

the differential,

$$d \ln W = \sum_j \left(\frac{\partial \ln W}{\partial n_j} \right) dn_j = \sum_j \ln \frac{n_j + g_j - 1}{n_j} dn_j \,, \tag{29.60}$$

and obtain the condition,

$$\begin{aligned} 0 = df(n_j) &= d \ln W - \alpha \sum_j dn_j - \beta \sum_j \varepsilon_j dn_j \\ &= \sum_j \left(\ln \frac{n_j + g_j - 1}{n_j} - \alpha \sum_j - \beta \sum_j \varepsilon_j \right) dn_j \end{aligned} \tag{29.61}$$

[7] Note that this partition function converges toward the one for boltzons for $g_j \gg n_j \gg 1$, which can be seen by simplifying it using the Stirling formula.

with the same Lagrange multipliers. This yields the Bose-Einstein distribution,

$$\boxed{n_j = \frac{g_j - 1}{e^{\beta(\varepsilon_j - \mu)} - 1}} \ . \tag{29.62}$$

The Boltzmann distribution follows from this Bose-Einstein distribution for temperatures well above absolute zero, implying that $g_j \gg 1$. The Boltzmann distribution also requires low density, implying that $g_j \gg n_j$. Under these conditions, we may use Stirling's approximation (31.1) for the factorial: $N! \approx N^N e^{-N}$.

29.2.2.3 Fermions

For fermions, each level g_j can hold at most one of the n_j particles, which implies that necessarily $g_j > n_j$ [see Fig. 29.3(b)]. Let us consider a single energy level j. The first of the n_j particles has the choice between g_j boxes. Since no box can be filled with more than one particle, the second particle has only $g_j - 1$ boxes at its disposal, and so on until all particles have been assigned. This corresponds to $g_j!/n_j!$ possible choices. However, we still need to respect the indistinguishability requirement. The overcounting can be removed by dividing by $(g_j - n_j)!$. The procedure is now repeated with all energy levels j, which leads to the partition function for fermions,

$$\boxed{W_{\{n_j\}} = \prod_{j=1}^{r} \binom{g_j}{n_j}} \ . \tag{29.63}$$

Again we calculate the logarithm using Stirling's formula,

$$\begin{aligned} \ln W &= \sum_j \left[\ln g_j! - \ln n_j! - \ln(g_j - n_j)!\right] \\ &\simeq \sum_j \left[n_j \ln \frac{g_j - n_j}{n_j} - g_j \ln \frac{g_j - n_j}{g_j}\right] \ , \end{aligned} \tag{29.64}$$

the differential,

$$d \ln W = \sum_j \left(\frac{\partial \ln W}{\partial n_j}\right) dn_j = \sum_j \ln \frac{g_j - n_j}{n_j} dn_j \ . \tag{29.65}$$

and obtain the condition,

$$\begin{aligned} 0 = df(n_j) &= d \ln W - \alpha \sum_j dn_j - \beta \sum_j \varepsilon_j dn_j \\ &= \sum_{j=1}^{r} \left(\ln \frac{g_j - n_j}{n_j} - \alpha - \beta \varepsilon_j\right) dn_j \ , \end{aligned} \tag{29.66}$$

with the same Lagrange multipliers. This yields the Fermi-Dirac distribution for $g_j \gg 1$,

$$\boxed{n_j = \frac{g_j}{e^{\beta(\varepsilon_j - \mu)} + 1}} \ . \tag{29.67}$$

Do the Exc. 29.2.6.1.

29.2.2.4 Thermodynamic potentials for bosons and fermions

Using the abbreviation $s = +1$ for bosons, $s = -1$ for fermions, and $s = 0$ for boltzons the distribution function can be expressed as,

$$\boxed{n_j = \frac{g_j}{e^{\beta(\varepsilon_j - \mu)} - s}} \ . \tag{29.68}$$

The chemical potential μ is fixed by the boundary conditions,

$$N = \sum_{j=1}^{r} n_j \qquad \text{and} \qquad E = \sum_{j=1}^{r} \varepsilon_j n_j \ , \tag{29.69}$$

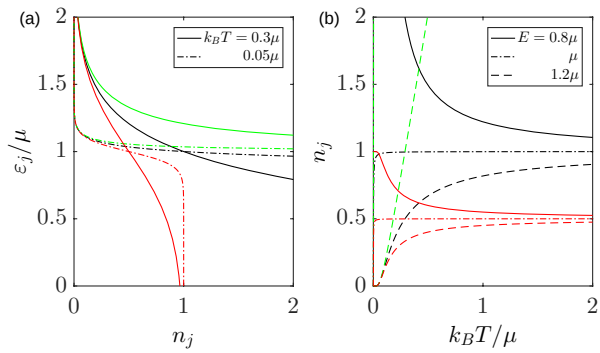

Figure 29.5: (code) Quantum statistical weight (29.49) for fermions (red dash-dotted line), bosons (green dashed line), and boltzons (black solid line). (a) Weight n_j as a function of level energy ε_j for two different temperatures (solid and dash-dotted lines). (b) Weight n_j as a function of temperature for various level energy ε_j (solid, dash-dotted, and dashed).

With this, knowing the energy spectrum ε_i and the distribution of states g_j of the system, we are able to calculate all thermodynamic potentials. E.g. the entropy reads,

$$\begin{aligned} S = k_\mathrm{B} \ln W_{\{n_j\}} &= k_\mathrm{B} \sum_j \left[n_j \ln\left(s + \frac{g_j}{n_j}\right) + s g_j \ln\left(1 + s\frac{n_j}{g_j}\right)\right] \\ &= k_\mathrm{B} \sum_j \left[\frac{s g_j \beta(\varepsilon_j - \mu)}{1 - s e^{-\beta(\varepsilon_j - \mu)}} + s g_j \ln\left(e^{\beta(\varepsilon_j - \mu)} - s\right)\right] \ . \end{aligned} \tag{29.70}$$

The Bose-Einstein and the Fermi-Dirac distribution both have many applications in quantum mechanics, e.g. for the explanation of the blackbody radiation, the heat capacity of metals, the laser, the Bose-Einstein condensation, and much more. In fact, these distributions must be used whenever quantum statistical effects are important. Prominent examples of systems where a quantum statistical treatment is crucial are electrons in metals and ultracold quantum gases. We will discuss the latter in Secs. 29.3 and 29.4.

29.2.3 Density-of-states in a trapping potential

An important boundary condition for the discussion of the quantum statistics of gases is that the atoms are often confined in trapping potentials. Suspended in space far from massive walls, they escape the perturbative influence of the environment. This however implies, that the system becomes inhomogeneous, which means that the number of states available to the atoms varies in space. In order to prepare subsequent evaluations of thermodynamic potentials, let us first characterize this spatial dependence by introducing the concept of the density-of-states.

In three dimensions the Hamiltonian of a trapped atoms is,

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla^2 + U(\mathbf{r}) \ . \tag{29.71}$$

As the wavefunction is localized, the spectrum of possible energies organizes into discrete levels, and the atoms are allocated in populations of these levels. Such multidimensional systems are often degenerate, which means that the same total energy can be realized with different sets of quantum numbers [8]. The way an atomic cloud accommodates itself inside a trapping potential is governed by the density of available states. We now introduce the *density-of-states* $\eta(\epsilon)$ for an arbitrary potential via,

$$\boxed{\int \eta(\varepsilon)d\varepsilon \equiv \frac{1}{(2\pi)^3}\int d^3r d^3k = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}\int d^3r \int d\varepsilon \sqrt{\varepsilon - U(\mathbf{r})}} \ , \tag{29.72}$$

with the substitution $k = \sqrt{\frac{2m}{\hbar^2}[\varepsilon - U(\mathbf{r})]}$.

As an example, let us consider a box potential of volume V. In this case, the expression (29.71) simply yields,

$$\boxed{\eta(\varepsilon) = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}\int_V d^3r\sqrt{\varepsilon} = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}V\sqrt{\varepsilon}} \qquad \text{(box potential)} \ . \tag{29.73}$$

In the following we derive the density-of-states for the case of an harmonic oscillator potential. More general potentials are discussed in the Excs. 29.2.6.2 and 29.2.6.3.

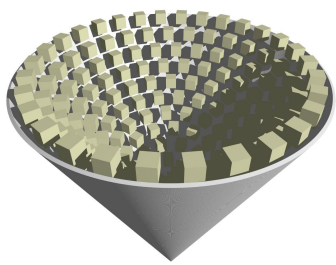

Figure 29.6: Artists's view of phase space cells in a trapping potential in two dimensions.

[8] This can be checked easily with separable potentials, such as the rectangular 3D box potential or the 3D harmonic oscillator, where the same energy $E = E_x + E_y + E_z$ can be reached with different combinations of E_x, E_y, and E_z.

Example 228 (*Density-of-states for a cylindrical harmonic oscillator potential*): Let us consider a cylindrical harmonic oscillator,

$$U(\mathbf{r}) = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 \qquad \text{where} \qquad r^2 = x^2 + y^2 \ , \tag{29.74}$$

which can also be given in the form,

$$U(\mathbf{r}) = \frac{m}{2}\omega_r^2 \rho^2 \qquad \text{where} \qquad \rho^2 = x^2 + y^2 + \lambda^2 z^2 \qquad \text{with} \qquad \lambda = \frac{\omega_z}{\omega_r} \ . \tag{29.75}$$

We also define the mean oscillation frequency,

$$\bar{\omega} = (\omega_r^2 \omega_z)^{1/3} = \lambda^{1/3}\omega_r \ . \tag{29.76}$$

The single-particle levels of this Hamiltonian are,

$$\varepsilon_{n_x n_y n_z} = \hbar\omega_x n_x + \hbar\omega_y n_y + \hbar\omega_z n_z \ , \tag{29.77}$$

where the coefficients n_j with $j = x, y, z$ are integer numbers. For the cylindrical

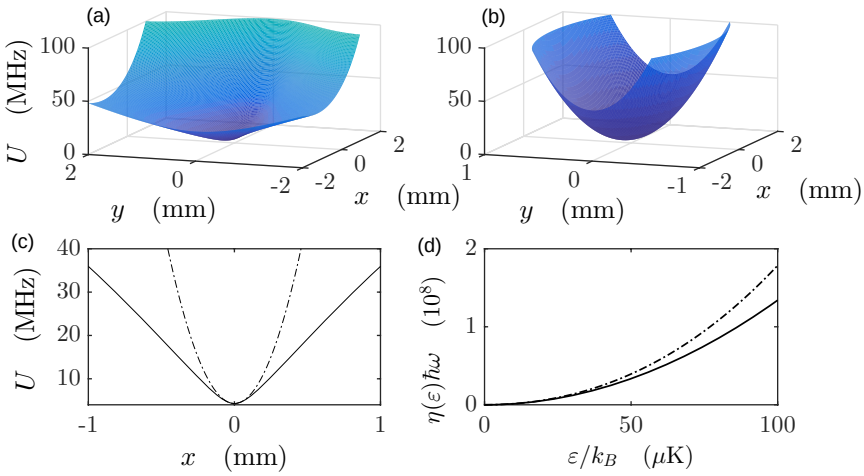

Figure 29.7: (code) (a) The figure shows two dimensions of a Ioffe-Pritchard type magnetic trapping potential (characterized by being approximately linear at large distances from the center and harmonic near the center). (b) Harmonic approximation (most experimentally feasible potentials are approximately harmonic near the center). (c) One-dimensional cut through the potential of (a,b). (d) Density-of-states for a harmonic (dotted line) and a Ioffe-Pritchard type potential (solid line).

harmonic trap defined in (29.73), we find with a little help from Dr. Bronstein [131],

$$\begin{aligned}\eta(\varepsilon) &= \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}\int d^3r\sqrt{\varepsilon - \frac{m}{2}\omega_r^2\rho^2} \\ &= \frac{1}{(2\pi)^2}\frac{8\varepsilon^2}{(\hbar\bar{\omega})^3}\int_{-1}^{1} d\tilde{x}\int_{-\sqrt{1-\tilde{x}^2}}^{\sqrt{1-\tilde{x}^2}} d\tilde{y}\int_{-\sqrt{1-\tilde{x}^2-\tilde{y}^2}}^{\sqrt{1-\tilde{x}^2-\tilde{y}^2}} d\tilde{z}\sqrt{1-\tilde{x}^2-\tilde{y}^2-\tilde{z}^2} \ .\end{aligned} \tag{29.78}$$

The resolution of the integral gives,

$$\boxed{\eta(\varepsilon) = \frac{\varepsilon^2}{2(\hbar\bar{\omega})^3}} \quad \text{(harmonic potential)} \ . \tag{29.79}$$

29.2.3.1 Application to the microcanonical partition function

Let us now come back to the distribution functions for ideal quantum gases introduced in Sec. 29.2.2. In the *thermodynamic limit*, $N \to \infty$, the distribution of states is assumed so dense, that it can be expressed by a continuous density,

$$\begin{array}{rcccl} & & \varepsilon_j & \longrightarrow & \varepsilon = \varepsilon_{\mathbf{r},\mathbf{p}} \\ & & g_j & \longrightarrow & \eta(\varepsilon) \\ & & \frac{1}{e^{\beta(\varepsilon_j-\mu)}-s} & \longrightarrow & \frac{1}{e^{\beta(\varepsilon-\mu)}-s} \equiv w_{T,\mu}(\varepsilon) \\ n_j & = & \frac{g_j}{e^{\beta(\varepsilon_j-\mu)}-s} & \longrightarrow & \eta(\varepsilon) w_{T,\mu}(\varepsilon) \\ & & \sum_j g_j & \longrightarrow & \int \eta(\varepsilon) d\varepsilon = \frac{1}{(2\pi)^3} \int d^3r d^3k \\ N & = & \sum_j n_j & \longrightarrow & \int \eta(\varepsilon) w_{T,\mu}(\varepsilon) d\varepsilon \\ E & = & \sum_j \varepsilon_j n_j & \longrightarrow & \int \varepsilon \eta(\varepsilon) w_{T,\mu}(\varepsilon) d\varepsilon \end{array} \tag{29.80}$$

where $s = 0$ stands for the 'Boltzmann', $s = -1$ for the 'Bose-Einstein', and $s = +1$ for the 'Fermi-Dirac' distributions derived in (29.57), (29.62), and (29.67). We also introduced the symbol $w_{T,\mu}$ to denote the statistical distribution function,

$$\boxed{w_{t\mu}(\mathbf{r},\mathbf{p}) d^3r d^3p = \eta(\varepsilon) w_{T,\mu}(\varepsilon) d\varepsilon} \ . \tag{29.81}$$

In the following sections we will calculate all system variables based on the expressions (29.90) in the thermodynamic limit.

29.2.4 Grand canonical ensembles of ideal quantum gases

Let us now derive the statistics for physical conditions satisfied by a *grand canonical ensemble*, which is a good model for many systems in which the particle number is not conserved. A deeper discussion of the relation to the *canonical ensemble* and the role of the chemical potential will be provided in the last part of this section.

Supposing that the particles of a system do *not interact*, it is possible to compute a series of single-particle stationary states, each of which represents a separable part that can be included into the total quantum state of the system. Let us call these single-particle stationary states 'orbitals' in order to avoid confusion with the total many-body state. Every orbital has a distinct set of quantum numbers and may be occupied by several particles or be empty. In this sense, each orbital forms a separate grand canonical ensemble by itself, one so simple that its statistics can be immediately derived. Focusing on just one orbital labeled m, the total energy for a microstate of

N particles in this orbital will be $E = N\varepsilon_m$, where ε_m is the characteristic energy level of that orbital. The grand potential for the orbital is given by [9],

$$\Omega = -k_{\rm B}T \ln \sum_{\rm microstates} e^{\beta(\mu N - E)} \ , \tag{29.82}$$

which is required for the microstates' probabilities to add up to 1, as already stated in (??).

In quantum mechanics the orbitals are understood as the eigenstates $|\psi_m\rangle$ of a single-particle Hamiltonian,

$$\hat{h}_m = \frac{\hat{\mathbf{p}}_m^2}{2m} + V_{\rm trap}(\hat{\mathbf{r}}_m) \ , \tag{29.83}$$

with $m = 1, \ldots, N$, whose spectrum is $\varepsilon_m = \langle\psi_m|\hat{h}_m|\psi_m\rangle$. That is, every single particle is completely characterized by the quantum number m [10]. A microstate $|\Psi_k\rangle$ is now identified as an eigenstate of the total many-particle Hamiltonian,

$$\hat{H} = \sum_{m=1}^{N} \hat{h}_m \qquad \text{with} \qquad |\Psi_k\rangle = \prod_{m=1}^{N} |\psi_m\rangle_k \ . \tag{29.84}$$

The request that the particles do not interact makes the system separable. The density operator and the grand canonical partition function are [209],

$$\boxed{\hat{\rho} = \frac{e^{-\beta(\hat{H}-\mu\hat{N})}}{\Xi_{\rm gc}} \qquad \text{and} \qquad \Xi_{\rm gc} = e^{-\beta\Omega} = \mathrm{Tr}\, e^{-\beta(\hat{H}-\mu\hat{N})}} \ , \tag{29.85}$$

obviously satisfying $\mathrm{Tr}\,\hat{\rho} = 1$. For the grand canonical ensemble the basis states of the total Hamiltonian $\hat{H}$ are all microstates composed of many particles, and the operators $\hat{N}$ and $\hat{\rho}$ can be expressed in the same basis.

We now migrate from the single-particle product state basis $\{|\Psi_k\rangle\}$ to a Fock state basis assigning a given number of particles n_j to every possible energy level ε_j, where $j = 1, \ldots, \infty$, as illustrated in Fig. 29.8,

$$|\Psi_k\rangle \longrightarrow |n_1, n_2, \ldots, n_j, \ldots\rangle \ . \tag{29.86}$$

I.e. we replace the distribution of microstates by a distribution of populations $\{n_j\}$ among the energy levels. Since the energy and particle numbers are separately conserved, the corresponding operators commute,

$$[\hat{H}, \hat{N}] = 0 \ , \tag{29.87}$$

and therefore it is possible to find a complete basis of simultaneous eigenstates,

$$\hat{H}|\ldots n_j \ldots\rangle = E|\ldots n_j \ldots\rangle \quad \text{with} \quad \hat{N}|\ldots n_j \ldots\rangle = N|\ldots n_j \ldots\rangle \tag{29.88}$$

[9] In case of multi-species ensembles, the potentials add up like $\mu_1 N_1 + \mu_2 N_2 + \ldots$.

[10] In practice, a set of several quantum numbers may be required.

with,

$$E = \sum_{j=0}^{\infty} \varepsilon_j n_j \qquad \text{and} \qquad N = \sum_{j=0}^{\infty} n_j \ . \tag{29.89}$$

This means that the number of particles is a conserved quantity and that $\hat{H}$ and $\hat{N}$ can be simultaneously diagonalized.

We can now evaluate the partition function (29.85),

$$\begin{aligned} \Xi_{\rm gc} &= \sum_{k\in\{\text{microstates}\}} \langle \Psi_k | e^{-\beta(\hat{H}-\mu\hat{N})} | \Psi_k \rangle \\ &= \sum_{\{n_j\}} \langle \ldots n_j \ldots | e^{-\beta(\hat{H}-\mu\hat{N})} | \ldots n_j \ldots \rangle = \sum_{\{n_j\}} e^{-\beta(E-\mu N)} \ . \end{aligned} \tag{29.90}$$

The density operator in this new basis is,

$$\hat{\rho} = \sum_{\{n_j\}} \frac{|\ldots n_j \ldots\rangle e^{-\beta(E-\mu N)} \langle \ldots n_j \ldots|}{\sum_{\{n_j\}} e^{-\beta(E-\mu N)}} \ . \tag{29.91}$$

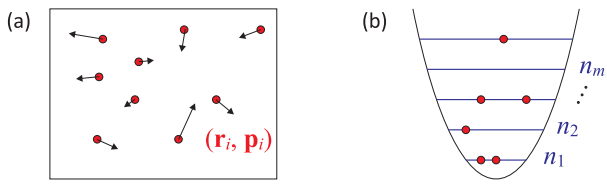

Figure 29.8: (a) Ensemble of N particles with different positions and velocities. (b) Distribution of the particles over the spectrum of allowed energies.

Using the conditions (29.89), the partition function becomes,

$$\begin{aligned} \Xi_{\rm gc} &= \sum_{n_1,n_2,\ldots} \langle \ldots n_j \ldots | e^{-\beta(\hat{H}-\mu\hat{N})} | \ldots n_j \ldots \rangle \\ &= \sum_{n_1} \langle n_1 | e^{-\beta(n_1\hat{h}_1 - n_1\mu)} | n_1 \rangle \sum_{n_2} \langle n_2 | e^{-\beta(n_2\hat{h}_2 - n_2\mu)} | n_2 \rangle \times \ldots \equiv \prod_{j=1}^{\infty} \Xi_j \ , \end{aligned} \tag{29.92}$$

where in the last step we defined a *partial* partition sum,

$$\Xi_j \equiv \sum_{n_j} e^{-\beta(\varepsilon_j n_j - \mu n_j)} \ , \tag{29.93}$$

accounting for all possible populations of a particular energy level ε_j. Analogously, the density operator becomes,

$$\begin{aligned} \hat{\rho} &= \frac{e^{-\beta(\hat{H}-\mu\hat{N})}}{\Xi_{\rm gc}} = \frac{1}{\Xi_{\rm gc}} e^{-\beta\left(\sum_{\{n_j\}}(\varepsilon_j-\mu)\hat{n}_j\right)} \\ &= \frac{1}{\Xi_{\rm gc}} e^{-\beta(\varepsilon_1-\mu)\hat{n}_1} e^{-\beta(\varepsilon_2-\mu)\hat{n}_2} \times \ldots = \prod_{j=1}^{\infty} \hat{\rho}_j \ . \end{aligned} \tag{29.94}$$

Note, that breaking down the exponential of a sum of operators, $e^{-\sum \hat{n}_j}$, into a product of exponentials of that operators, $\prod e^{-\hat{n}_j}$, is only possible because the operators commute, $[\hat{n}_k, \hat{n}_j] = 0$. In the last step we defined,

$$\hat{\rho}_j \equiv \frac{e^{-\beta(\varepsilon_j-\mu)\hat{n}_j}}{\Xi_j} = |n_j\rangle \frac{e^{-\beta(\varepsilon_j-\mu)}}{\Xi_j} \langle n_j| \ . \tag{29.95}$$

The problem with this expression is, that the global wavefunction $|\Psi\rangle$ has not yet been (anti-)symmetrized according the particles' bosonic or fermionic nature. For bosons, n_j may be any non-negative integer and each value of n_j counts as one microstate due to the indistinguishability of particles. For fermions, the Pauli exclusion principle allows only two microstates for the orbital (occupation of 0 or 1), giving a two-term series [11],

$$\Xi_j = \begin{cases} \sum_{n_j=0}^{\infty} e^{-\beta(n_j\varepsilon_j - n_j\mu)} = \frac{1}{1-e^{-\beta(\varepsilon_j-\mu)}} & \text{for bosons} \\ \sum_{n_j=0}^{1} e^{-\beta(n_j\varepsilon_j - n_j\mu)} = 1 + e^{-\beta(\varepsilon_j-\mu)} & \text{for fermions} \end{cases} \tag{29.96}$$

Hence,

$$\boxed{\Xi_{\text{gc}} = \prod_{j=1}^{\infty} (1 - s e^{-\beta(\varepsilon_j-\mu)})^{-s}} \ , \tag{29.97}$$

where $s = 1$ for bosons and $s = -1$ the lower for fermions.

The grand canonical potential per microstate becomes,

$$\Omega_j = -k_{\text{B}} T \ln \Xi_j = s k_{\text{B}} T \ln(1 - s e^{-\beta(\varepsilon_j-\mu)}) \ . \tag{29.98}$$

Considering again the entire system, the total Landau grand potential is found by adding up the Ω_j for all orbitals,

$$\Omega = \sum_{j=1}^{\infty} \Omega_j \ . \tag{29.99}$$

In any case the value [12]

$$\boxed{n_j = -\frac{\partial \Omega_j}{\partial \mu} = \frac{1}{e^{\beta(\varepsilon_j-\mu)} - s} \equiv w_{T,\mu}(\varepsilon_j)} \tag{29.100}$$

[11] Here, we introduce the statistics of indistinguishable particles *ad hoc*. The same result is obtained automatically introducing field operators satisfying bosonic or fermionic commutation rules, (see Exc. 30.2.4.1). Indeed, we can rewrite the Hamiltonian and the number operator of any non-interacting system like [953],

$$\hat{H} = \sum_{\{n_j\}} \varepsilon_j \hat{a}_j^\dagger \hat{a}_j \qquad \text{and} \qquad \hat{N} = \sum_{\{n_j\}} \hat{a}_j^\dagger \hat{a}_j \ ,$$

where $\hat{a}_j^\dagger$ and $\hat{a}_j$ are the particle creation and annihilation operators introduced in the occupation number representation, which will be fully developed in Sec. 30.2.2.

[12] Note the absence of the degeneracy factor g_j in comparison to the formula (29.68), which is simply due to the fact that here we only consider a potential with non-degenerate eigenstates. The degeneracy factor g_j can, however, simply added *ad hoc*.

gives the thermodynamic average number of particles on the orbital: the *Fermi-Dirac distribution* for fermions, and the *Bose-Einstein distribution* for bosons.

The problem is completely analogous to Planck's treatment of blackbody radiation, where the Bose-Einstein distribution function followed as a corollary from the Boltzmann statistics in thermal equilibrium and Planck's quantization hypothesis, $E = N\varepsilon_j$. See Excs. 37.2.4.4 and 37.2.4.5 and Sec. 23.2.3.

29.2.4.1 Grand potential and ensemble averages

Evaluating partial derivatives of the function $\Omega(\mu, V, T)$, looking up the relations (19.161), we find for the averages of numbers of particles, the Gibbs entropy, the average pressure, and the average energy,

$$\begin{aligned} 1 &= \mathrm{Tr}\,\hat{\rho} \\ N = \langle \hat{N} \rangle &= \mathrm{Tr}\,\hat{\rho}\hat{N} &&= -\left(\frac{\partial \Omega}{\partial \mu}\right)_{T,V} \\ S &= \mathrm{Tr}\,\hat{\rho}\ln\hat{\rho} &&= -\left(\frac{\partial \Omega}{\partial T}\right)_{\mu,V} \\ P & &&= -\left(\frac{\partial \Omega}{\partial V}\right)_{T,\mu} \\ E = \langle \hat{H} \rangle &= \mathrm{Tr}\,\hat{\rho}\hat{H} &&= TS + \mu N + \Omega \end{aligned} \quad . \tag{29.101}$$

We will derive Eq. (29.101)(iii) in Exc. 29.2.6.4.

Example 229 (*Calculation of ensemble averages*): Thermodynamic fluctuations can be calculated via the variances in energy and particle numbers. Starting from,

$$-\beta\Omega = \ln \Xi_{\mathrm{gc}} = \ln \mathrm{Tr}\, e^{-\beta(\hat{H}-\mu\hat{N})} \tag{29.102}$$

it is easy to show, that,

$$\begin{aligned} \frac{\partial \Xi_{\mathrm{gc}}}{\partial \mu} &= \beta \mathrm{Tr}\,\hat{N} e^{-\beta(\hat{H}-\mu\hat{N})} = \beta \Xi_{\mathrm{gc}} \langle \hat{N} \rangle \\ -\beta \frac{\partial \Omega}{\partial \mu} &= \frac{\mathrm{Tr}\,\hat{N} e^{-\beta(\hat{H}-\mu\hat{N})}}{\Xi_{\mathrm{gc}}} = \beta \langle \hat{N} \rangle \\ -\beta \frac{\partial^2 \Omega}{\partial \mu^2} &= \frac{\Xi_{\mathrm{gc}} \frac{\partial}{\partial \mu} \mathrm{Tr}\,\hat{N} e^{-\beta(\hat{H}-\mu\hat{N})} - \mathrm{Tr}\,\hat{N} e^{-\beta(\hat{H}-\mu\hat{N})} \frac{\partial}{\partial \mu} \Xi_{\mathrm{gc}}}{\Xi_{\mathrm{gc}}^2} = \beta(\langle \hat{N}^2 \rangle - \langle \hat{N} \rangle^2) \ . \end{aligned} \tag{29.103}$$

29.2.4.2 Meaning of chemical potential

The key behind second quantization is to remove the restriction that the number of particles is fixed. Instead, the theory is built around the idea of Fock space, where the number of particles is not fixed. This is highly advantageous when dealing with many-body systems. This same idea, when extended to finite temperatures, is what we call the grand canonical ensemble. What we want is to consider some finite temperature density matrix $\hat{\rho} \sim e^{-\beta\hat{H}}$, where the number of particles is not fixed, but can fluctuate [555].

However, we cannot let it fluctuate arbitrarily since that would make no physical sense. Instead, the basic idea of the grand canonical ensemble is to impose that the number of particles in the system is only fixed on average. That is, we impose that,

$$\langle \hat{N} \rangle = N \ . \tag{29.104}$$

In some systems, the number of particles does indeed fluctuate. This happens, for instance, in chemical solutions: if we look at a certain region of a liquid, the number of molecules there is constantly fluctuating due to molecules moving in and out from other regions. Of course, in many other systems, the number of particles is fixed. However, even in these cases, pretending it can fluctuate may still give good answers for large N (thermodynamic limit). The reason is that, as we have seen above, the variance of $\hat{N}$ scales as,

$$\Delta \hat{N} \propto \sqrt{N} \ , \tag{29.105}$$

which is small. Hence, when N is large, the grand canonical ensemble will give accurate answers, even if the number of particles is not actually allowed to fluctuate. This is the idea behind *ensemble equivalence*: we are allowed to use an ensemble where the number of particles fluctuates, even though it actually doesn't, because in the thermodynamic limit the fluctuations are small.

Because of $[\hat{H}, \hat{N}] = 0$ the eigenvalues of $\hat{N}$ are good quantum numbers alongside the eigenvalues of $\hat{H}$. We can now arrange the common eigenvectors of E and N in such a way as to sort the eigenvalue sets (N, E) by total atom numbers, such that $\hat{H}$ is divided in sectors with well-defined N. In other words, $\hat{H}$ is block diagonal, and there are no terms connecting sectors with different N. The eigenvalues E are thus labeled by two indices $E(N, m)$, where m labels the quantum states within each sector,

$$\hat{H} = \left(\begin{array}{cccc|cccc|c} E(N_1,1) & & & & & & & & \\ & E(N_1,2) & & & & & & & \\ & & \ddots & & & & & & \\ \hline & & & & E(N_2,1) & & & & \\ & & & & & E(N_2,2) & & & \\ & & & & & & \ddots & & \\ \hline & & & & & & & & \ddots \end{array}\right) \ . \tag{29.106}$$

Suppose now that the system is in thermal equilibrium with exactly N particles, which corresponds to a *canonical* ensemble. As resumed in Tab. 19.4, the conditions for equilibrium are then obtained minimizing the Helmholtz free energy, $dF = 0$, and the corresponding *canonical* density operator and partition function are,

$$\hat{\rho}_{\rm cn} = \frac{e^{-\beta \hat{H}}}{\Xi_{\rm cn}(N)} \quad , \quad \Xi_{\rm cn}(N) = \sum_{m \in \text{sector}} e^{-\beta E(N,m)} \quad , \quad F = -k_{\rm B} T \ln \Xi_{\rm cn}(N) \ . \tag{29.107}$$

This is a constrained sum, since we are only summing over that sector that has exactly N particles. This constraint makes it notoriously difficult to compute the sum in practice solving a Schrödinger equation with $\hat{H}$.

Instead, in the *grand canonical* ensemble we allow the number of particles to fluctuate but only fix them on average (29.104). To accomplish this we had to introduce a new parameter μ, called the chemical potential, so that the *grand canonical* equilibrium state is transformed to,

$$\rho_{\rm gc} = \frac{e^{-\beta(\hat{H}-\mu\hat{N})}}{\Xi_{\rm gc}} \quad , \quad \Xi_{\rm gc} = {\rm Tr}\, e^{-\beta(\hat{H}-\mu\hat{N})} \quad , \quad \Omega = -k_{\rm B}T\, \ln \Xi_{\rm gc} \ . \tag{29.108}$$

Apparently, the chemical potential enters by shifting the Hamiltonian,

$$\hat{H} \to \hat{H} - \mu\hat{N} \ . \tag{29.109}$$

As resumed in Tab. 19.4, in grand canonical ensembles the conditions for equilibrium are obtained minimizing the Landau energy, $d\Omega = d(F - \mu N) = 0$. To obtain the energy spectrum in the case of fluctuating particle numbers, we need to solve a many-body Schrödinger equation (such as the Gross-Pitaevski equation) with the Hamiltonian substituted by $\hat{\Omega} = \hat{H} - \mu\hat{N}$ [267].

The logic behind μ is twofold. When the number of particles is allowed to fluctuate, the value of μ is fixed externally (like the temperature). As a consequence the number of particles $\langle\hat{N}\rangle = N(\mu, T)$ is interpreted as a function of μ and T. Conversely, if the number of particles N is fixed, then $\mu = \mu(N, T)$ is to be interpreted as a function of N and T, which is to be determined as the solution of the implicit equation,

$$\langle\hat{N}\rangle = \frac{{\rm Tr}\, \hat{N} e^{-\beta(\hat{H}-\mu\hat{N})}}{{\rm Tr}\, e^{-\beta(\hat{H}-\mu\hat{N})}} = N \ . \tag{29.110}$$

Relevant cases in which the number of particles is not conserved are:

- Chemical reactions can convert one type of molecule to another; if reactions occur then the N_i must be defined such that they do not change during the chemical reaction.

- In high energy particle physics, ordinary particles can be spawned out of pure energy, if a corresponding antiparticle is created. Then, neither the number of particles nor antiparticles are conserved, only their difference.

- In a system composed of multiple compartments that share energy but do not share particles it is possible to set the chemical potentials separately for each compartment, for example, when a capacitor composed of two isolated conductors is charged by applying a difference in electron chemical potential.

- In some slow quasi-equilibrium situations it is possible to have distinct populations of the same kind of particle in the same location, which are each equilibrated internally but not with each other.

- The grand canonical ensemble is particularly useful for developing the *thermodynamics of large ideal trapped quantum gases*. While the phenomenon of BEC can be derived in any ensemble (in Sec. 29.2.2 we derived the bosonic partition function from the detailed balanced assumption using combinatorial arguments), when the dynamics of a condensate is the subject under study, it is often useful to consider it as a separate system being in thermal and chemical equilibrium with a reservoir. The role of a reservoir is played by the thermal cloud, which always coexists with the condensate and which exchanges particles and energy with it.

In order for a particle number to have an associated chemical potential, it must be conserved during the internal dynamics of the system, and only able to change when the system exchanges particles with an external reservoir. If the particles can be created out of energy during the dynamics of the system, then an associated μN term must not appear in the probability expression for the grand canonical ensemble, i.e. we require $\mu = 0$ for that kind of particle. Such is the case for *photons in a black cavity*, which can be annihilated or created due to absorption and emission on the cavity walls [13], see Exc. 29.2.6.5.

29.2.4.3 Summary on canonical ensembles

The *canonical ensemble* is used to represent the possible microstates of a mechanical system in thermal equilibrium with a heat bath at a fixed temperature. The system can exchange energy with the heat bath, so that the states of the system will differ in total energy. The principal thermodynamic variable of the canonical ensemble, determining the probability distribution of states, is the absolute temperature T. The ensemble typically also depends on mechanical variables, such as the number of particles N in the system and the system's volume V, each of which influence the nature of the system's internal states.

The canonical ensemble assigns a probability $\mathfrak{P}_{\rm cn}(E)$ to each distinct microstate given by the following exponential,

$$\boxed{\mathfrak{P}_{\rm cn}(E) = e^{\beta(F-E)} = \frac{1}{\Xi_{\rm cn}} e^{-E/(k_{\rm B}T)} \qquad \text{with} \qquad \Xi_{\rm cn} = e^{-F/(k_{\rm B}T)}} \,, \tag{29.111}$$

where E is the total energy of the microstate and $\Xi_{\rm cn}$ the canonical partition function.

In quantum mechanics the density operator and partition function are,

$$\boxed{\begin{aligned} \hat{\rho}_{\rm cn} &= e^{\beta(F-\hat{H})} = \frac{e^{-\beta\hat{H}}}{\Xi_{\rm cn}} = \frac{1}{\Xi_{\rm cn}} \sum_k |\psi_k\rangle e^{\beta(F-E_k)} \langle\psi_k| \\ \Xi_{\rm cn} &= \mathrm{Tr}\, e^{-\beta\hat{H}} = e^{-\beta F} = \sum_k e^{-\beta E_k} \end{aligned}} \,. \tag{29.112}$$

The Helmholtz free energy F is constant for the ensemble. However, the probabilities and F will vary if different N, V, T are selected. The free energy F serves two roles: first, it provides a normalization factor for the probability distribution (the

[13] Note that photons in a highly reflective cavity can be conserved and caused to have a non-zero chemical potential μ.

probabilities, over the complete set of microstates, must add up to one); second, many important ensemble averages can be directly calculated from the function $F(N, V, T)$.

The canonical ensemble is the ensemble that describes the possible states of a system that is in thermal equilibrium with a heat bath. It applies to systems of any size; while it is necessary to assume that the heat bath is very large (i.e. take a macroscopic limit), the system itself may be small or large.

The condition that the system is mechanically isolated is necessary in order to ensure it does not exchange energy with any external object besides the heat bath. In general, it is desirable to apply the canonical ensemble to systems that are in direct contact with the heat bath, since it is that contact that ensures the equilibrium. In practical situations, the use of the canonical ensemble is usually justified either (1) by assuming that the contact is mechanically weak, or (2) by incorporating a suitable part of the heat bath connection into the system under analysis, so that the connection's mechanical influence on the system is modeled within the system.

When the total energy is fixed but the internal state of the system is otherwise unknown, the appropriate description is not the canonical ensemble but the microcanonical ensemble. For systems where the particle number is variable (due to contact with a particle reservoir), the correct description is the grand canonical ensemble.

29.2.4.4 Summary on grand canonical ensembles

The *grand canonical ensemble* is used to represent the possible microstates of a system of particles that are in thermal and chemical equilibrium with a reservoir. The system is said to be open in the sense that the system can exchange energy and particles with a reservoir, so that various possible states of the system can differ in both their total energy and total number of particles. The system's volume, shape, and other external coordinates are kept the same in all possible states of the system.

The thermodynamic variables of the grand canonical ensemble are chemical potential μ and absolute temperature T. The ensemble is also dependent on mechanical variables such as volume V which influence the nature of the system's internal states. As each of these is assumed to be constant in the grand canonical ensemble, it is sometimes called the μVT ensemble.

The grand canonical ensemble assigns a probability $\mathfrak{P}_{\text{gc}}(E)$ to each distinct microstate given by the following exponential [14],

$$\boxed{\mathfrak{P}_{\text{gc}} = e^{\beta(\Omega+\mu N-E)} = \frac{1}{\Xi_{\text{gc}}} e^{\beta(\mu N-E)} \qquad \text{with} \qquad \Xi_{\text{gc}} = e^{-\beta\Omega}}\,, \tag{29.113}$$

where N is the number of particles in the microstate and E is the total energy of the microstate.

The quantum mechanics the density operator and partition function are,

$$\boxed{\begin{aligned} \hat{\rho}_{\text{gc}} &= e^{\beta(\Omega+\mu\hat{N}-\hat{H})} = \frac{e^{-\beta(\hat{H}-\mu\hat{N})}}{\Xi_{\text{gc}}} = \frac{1}{\Xi_{\text{gc}}} \sum_k |\psi_k\rangle e^{\beta(\Omega+\mu n_k-E_k)} \langle\psi_k| \\ \Xi_{\text{gc}} &= \operatorname{Tr} e^{-\beta(\hat{H}-\mu\hat{N})} = e^{-\beta\Omega} = \sum_k e^{\beta(\mu n_k-E_k)} \end{aligned}}\,. \tag{29.114}$$

[14] In the case where more than one kind of particle is allowed to vary in number, the probability expression generalizes to $\mathfrak{P}_{\text{gc}} = e^{\beta(\Omega+\mu_1 N_1+\mu_2 N_2+\cdots-E)}$, where μ_j is the chemical potential for the j-th kind of particles, N_j the number of that kind of particle in the microstate.

The grand potential Ω is constant for the ensemble. However, the probabilities and Ω will vary if different μ, V, T are selected. The grand potential Ω serves two roles: to provide a normalization factor for the probability distribution (the probabilities, over the complete set of microstates, must add up to one); second, many important ensemble averages can be directly calculated from the function $\Omega(\mu, V, T)$.

The grand canonical ensemble is the ensemble that describes the possible states of an isolated system that is in thermal and chemical equilibrium with a reservoir. The grand canonical ensemble applies to systems of any size, small or large; it is only necessary to assume that the reservoir with which it is in contact is much larger (i.e. to take the macroscopic limit).

The condition that the system is isolated is necessary in order to ensure it has well-defined thermodynamic quantities and evolution. In practice, however, it is desirable to apply the grand canonical ensemble to describe systems that are in direct contact with the reservoir, since it is that contact that ensures the equilibrium. The use of the grand canonical ensemble in these cases is usually justified either (1) by assuming that the contact is weak, or (2) by incorporating a part of the reservoir connection into the system under analysis, so that the connection's influence on the region of interest is correctly modeled. Alternatively, theoretical approaches can be used to model the influence of the connection, yielding an open statistical ensemble.

Another case in which the grand canonical ensemble appears is when considering a system that is large and thermodynamic (a system that is 'in equilibrium with itself'). Even if the exact conditions of the system do not actually allow for variations in energy or particle number, the grand canonical ensemble can be used to simplify calculations of some thermodynamic properties. The reason for this is that various thermodynamic ensembles (microcanonical, canonical) become equivalent in some aspects to the grand canonical ensemble, once the system is very large. Of course, for small systems, the different ensembles are no longer equivalent even in the mean. As a result, the grand canonical ensemble can be highly inaccurate when applied to small systems of fixed particle number, such as atomic nuclei [15].

Grand ensembles are apt for use when describing systems such as electrons in a conductor or photons in a cavity, where the shape is fixed but the energy and number of particles can easily fluctuate due to contact with a reservoir (e.g. an electrical ground or a dark surface, in these cases). The grand canonical ensemble provides a natural setting for an exact derivation of the Fermi-Dirac statistics or Bose-Einstein statistics for a system of non-interacting quantum particles.

29.2.4.5 Fluctuations

Fluctuations if the system can be readily calculated as well [555],

$$(\Delta\hat{H})^2 = \langle\hat{H}^2\rangle - \langle\hat{H}\rangle^2 = k_{\mathrm{B}}T^2\frac{\partial\langle\hat{H}\rangle}{\partial T} + k_{\mathrm{B}}T\mu\frac{\partial\langle\hat{H}\rangle}{\partial\mu} \tag{29.115}$$

$$(\Delta\hat{N})^2 = \langle\hat{N}^2\rangle - \langle\hat{N}\rangle^2 = k_{\mathrm{B}}T\frac{\partial\langle\hat{N}\rangle}{\partial\mu} \ .$$

[15] Note that even in the thermodynamic limit, in the presence of long range interactions, the ensembles may not be equivalent.

If different species are present, it is interesting to calculate correlations in fluctuations. The covariances of particle numbers and energy are then,

$$\langle N_1 N_2\rangle - \langle N_1\rangle\langle N_2\rangle = k_{\rm B}T\frac{\partial\langle\hat{N}_2\rangle}{\partial\mu_1} = k_{\rm B}T\frac{\partial\langle\hat{N}_1\rangle}{\partial\mu_2} \tag{29.116}$$
$$\langle\hat{N}_1\hat{H}\rangle - \langle\hat{N}_1\rangle\langle\hat{H}\rangle = k_{\rm B}T\frac{\partial\langle\hat{H}\rangle}{\partial\mu_1}\ .$$

From the above expressions, it can be seen that the function Ω has the *exact differential*,

$$d\Omega = -S\,dT - \langle\hat{N}\rangle d\mu - P\,dV\ . \tag{29.117}$$

Substituting the relationship (29.101)(v) for E into the exact differential of Ω, an equation similar to the *first law of thermodynamics* is found, except that some quantities only appear as averages,

$$d\langle\hat{H}\rangle = T\,dS + \mu\,d\langle\hat{N}\rangle - P\,dV\ . \tag{29.118}$$

29.2.5 Thermodynamic limit and Riemann's zeta function

The partition functions (29.58) resp. (29.63) for microcanonical and (29.97) for grand canonical ensembles are evaluated over discrete distributions of microstates. Also, in Sec. 29.2.3 we argued that, in view of the huge number of microstates, it is desirable to introduce continuous distribution functions,

$$\sum_{\mathbf{r},\mathbf{p}}\ldots \longrightarrow h^{-3}\int d^3r d^3p\ldots \longrightarrow h^{-3}\int d\varepsilon\eta(\varepsilon)\ldots\ , \tag{29.119}$$

which, for confined ensembles, can even be simplified using the concept of density-of-states $\eta(\varepsilon)$. As long as we are deep in the thermodynamic limit, $N\to\infty$, we expect to obtain reliable results. Let us now do this exercise for an ideal quantum gas confined in a *box potential* of volume V, whose density-of-states is given by (29.73).

We begin with the request that the chemical potential satisfies the normalization condition,

$$N = \int w_{T,\mu}(\varepsilon)\eta(\varepsilon)d\varepsilon = \frac{V\sqrt{2m}}{(2\pi)^2\hbar^3}\int_0^\infty \frac{\sqrt{\varepsilon}d\varepsilon}{e^{\beta(\varepsilon-\mu)}\mp 1}\ . \tag{29.120}$$

Introducing the *thermal de Broglie wavelength*,

$$\boxed{\lambda_{\rm th} \equiv \sqrt{\frac{2\pi\hbar^2}{mk_{\rm B}T}}}\ , \tag{29.121}$$

and defining the *fugacity*,

$$\boxed{Z \equiv e^{\beta\mu}}\ , \tag{29.122}$$

and we may also write,

$$N = \frac{V}{\lambda_{\rm th}^3}\int_0^\infty \frac{\sqrt{x}dx}{Z^{-1}e^x\mp 1}\ . \tag{29.123}$$

At this point, to simplify the notation, we introduce the *Bose function* and its integral representation,

$$g_\xi^+(Z) = \sum_{t=1}^{\infty} \frac{Z^t}{t^\xi} = \frac{1}{\Gamma(\xi)} \int_0^\infty \frac{x^{\xi-1}dx}{Z^{-1}e^x - 1} \equiv g_\xi(Z) \ , \tag{29.124}$$

where $\Gamma(\eta)$ denotes the Gamma function. Analogically, we can define the *Fermi function* via [16],

$$g_\xi^-(Z) = \sum_{t=1}^{\infty} -\frac{(-Z)^t}{t^\xi} = \frac{1}{\Gamma(\xi)} \int_0^\infty \frac{x^{\xi-1}dx}{Z^{-1}e^x + 1} \equiv f_\xi(Z) \ . \tag{29.125}$$

For classical particles,

$$g_\xi^0(Z) = \frac{1}{\Gamma(\xi)} \int_0^\infty \frac{x^{\xi-1}dx}{Z^{-1}e^x + 0} = Z \ . \tag{29.126}$$

That is, interestingly the classical function corresponding to the Bose or Fermi function is an *identity for all orders* of ξ. A particular value is the *Riemann zeta-function* defined as,

$$\zeta(\xi) = g_\xi^+(1) \ . \tag{29.127}$$

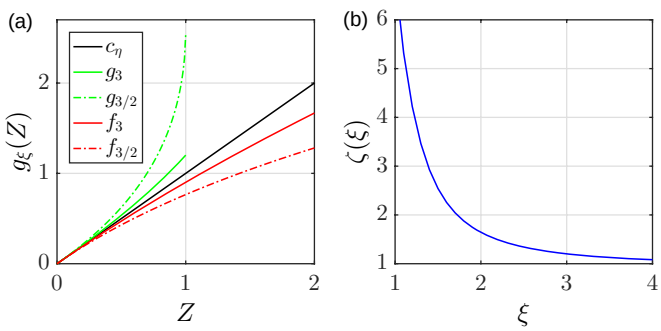

Figure 29.9: (code) (a) Bose and Fermi functions for box potentials ($g_{3/2}$ and $f_{3/2}$) and for harmonic potentials (g_3 and f_3). Also shown is the Boltzmann limit (29.126). (b) Riemann function.

Note that for $Z^{-1}e^x \gg 0$ all denominators in the expressions (29.125) ro (29.127) converge to the classical limit, which is to say, that for highly excited atoms, $\varepsilon - \mu \gg k_\mathrm{B}T$, all quantum statistical effects disappear.

With all these definitions we can now rewrite the expression (29.123),

$$\boxed{N = \frac{V}{\lambda_\mathrm{th}^3} g_{3/2}^{(s)}(Z)} \ , \tag{29.128}$$

[16] When the context is clear, we will use the shorter notations g_ξ and f_ξ for Bose and Fermi functions, respectively.

where $s = +$ for bosons, $s = -$ for fermions, and $s = 0$ for boltzons. Apparently, we can identify the Bose/Fermi function as the thermal phase space density of an ideal gas,

$$\rho_{\rm th} \equiv \frac{N}{V}\lambda_{\rm dB} = g^{(s)}_{3/2}(Z) \ . \tag{29.129}$$

In a similar way we could now derive analytic expressions for all other thermodynamic potentials. We will, however, see in the next Sec. 29.3, that for ideal bosonic gases the result (29.128) must be corrected. The reason is rooted in a momentous quality of the Bose function, which is that it diverges for $Z > 1$, which limits the chemical potential to negative values.

29.2.6 Exercises

29.2.6.1 Ex: Quantum statistics

n particles are distributed over $g > n$ different cells with the same probability. Calculate the probabilities
a. that there is exactly one particle in each one of the first n cells;
b. that there is no cell with more than one particle.
Use the three different assumptions that:
i. the particles are boltzon, i.e. they are identifiable and arbitrarily many particles can be assigned to each cell;
ii. the particles are bosons, i.e. they are NOT identifiable and arbitrarily many particles can be assigned to each cell;
iii. the particles are fermions, i.e. they are NOT identifiable and only a single particle may be assigned to each cell.

29.2.6.2 Ex: Density-of-states for non-harmonic potentials

Calculate the density-of-states for non-harmonic potentials, $\hat{H} = \frac{\hbar^2 k^2}{2m} + \left|\frac{x}{2\bar{x}}\right|^p + \left|\frac{y}{2\bar{y}}\right|^l + \left|\frac{z}{2\bar{z}}\right|^q$ using Ref. [51]. Apply the result to a quadrupolar potential.

29.2.6.3 Ex: Electron gas model

A simple model for the behavior of electrons in a metal is the *Fermi gas model*. In this model the electrons move in a square well potential, a mean-field approach accounts globally for the periodic lattice of ions and the influence of all other electrons. The density-of-states and the electron density are the same as for blackbody radiation,

$$\rho(\varepsilon)d\varepsilon = \frac{V(2m^3)^{1/2}}{\pi^2\hbar^3}\sqrt{\varepsilon}d\varepsilon \ ,$$
$$n(\varepsilon)\rho(\varepsilon)d\varepsilon = \frac{1}{e^{(\varepsilon-\varepsilon_{\rm F})/k_{\rm B}T}+1}\rho(\varepsilon)d\varepsilon \ .$$

Calculate the maximum energy at $T = 0$.

29.2.6.4 Ex: Entropy in the grand canonical ensemble

Derive the relationship $S = \mathrm{Tr}\,\hat{\rho}\ln\hat{\rho}$.

29.2.6.5 Ex: Black-body radiation

Derive the thermodynamics of the phenomenon of *black-body radiation*.
a. Which is the appropriate thermodynamic ensemble, and why?
b. For a single mode of a cavity, calculate the partition function, the density operator, the total energy, and the Helmholtz free energy.
c. Generalize the results for an arbitrary black-body.
d. Introducing the density-of-states, calculate the energy density in the cavity as a function of temperature.

29.3 Condensation of an ideal Bose gas

The clearest manifestation of quantum statistical effects is probably the phenomenon of Bose-Einstein condensation (BEC) predicted by Bose and Einstein in 1926 [117]. With the achievement of BEC in a dilute gas of atomic rubidium in 1995, Cornell *et al.* [194] confirmed the theory. Quantum degeneracy in Fermi gases was also observed a bit later [241, 699]. In this and the subsequent section, we will present a quantum statistical theory of *ideal* quantum gases for the cases of bosons, respectively, fermions. Clearly, the theory is unable to grasp many phenomena observed in BECs and linked to interatomic interactions, such as superfluidity. These will be discussed extensively in Chp. 50.

29.3.1 Condensation of a gas confined in a box potential

At very low temperatures approaching $T = 0$, according to the Bose-Einstein distribution (29.100), we expect the atoms to pile up in the lowest energy state $\varepsilon_j = 0$ of the trap,

$$n_j \stackrel{\varepsilon_j \to 0}{\longrightarrow} w_{T,\mu}(0) = \frac{1}{e^{-\beta\mu} - 1} = \frac{1}{1/Z - 1} = N \ , \tag{29.130}$$

where we used the definition of the fugacity (29.122). In the thermodynamic limit,

$$Z = \frac{1}{1 + 1/N} \stackrel{N \to \infty}{\longrightarrow} 1 \ , \tag{29.131}$$

we find that the fugacity approaches unity. Thus, $Z = 1$ is the condition for a macroscopic ground state population.

Let us now calculate the ground state population at finite temperatures. For a free gas with energy spectrum, $\varepsilon = p^2/2m$, we derived the density-of-states $\eta(\varepsilon)$ in (29.73) [17]. Using the occupation number $w_{T,\mu}(\varepsilon)$ for the Bose-Einstein distribution (29.100) in the thermodynamic limit, we express the total number of atoms as we already did in Eq. (29.128),

$$N = \int_0^\infty w_{T,\mu}(\varepsilon)\eta(\varepsilon)d\varepsilon = \frac{V}{\lambda_{\rm th}^3} g_{3/2}(Z) \ . \tag{29.132}$$

[17] We must, however, keep in mind that the state density approach is an approximation not valid for experiments with a limited number of atoms.

The problem with the expression (29.132) now is, that the thermal de Broglie wavelength diverges for $T \to 0$, while the phase space density $g_{3/2}(Z)$ is bounded between $g_{3/2}(0) = 0$ and $g_{3/2}(1) \approx 2.612$, which we realize after a quick inspection of Fig. 29.9(a). Hence, according to this formula, even taking the largest possible value of the fugacity, $Z \stackrel{T\to 0}{\longrightarrow} 1$, the number of atoms in the lowest energy state tends to 0,

$$N = \frac{V}{\lambda_{\rm th}^3} g_{3/2}(Z) < \left(\frac{mk_{\rm B}T}{2\pi\hbar^2}\right)^{3/2} V g_{3/2}(1) \stackrel{T\to 0}{\longrightarrow} 0 \ . \tag{29.133}$$

This is obviously in contrast to the expectation of a large ground state population for $T \to 0$.

The reason is, that in the process of converting the sum to an integral (29.119), the density-of-states disappears as we approach the ground state, thus removing the ground state from the spectrum of energies that can be occupied. Einstein's idea to resolve the problem, was to explicitly maintain a discrete term accounting for the ground state population N_c and to add it to the expression (29.132),

$$\boxed{N = N_c + \frac{V}{\lambda_{\rm th}^3} g_{3/2}(Z)} \ . \tag{29.134}$$

29.3.1.1 Critical temperature and condensed fraction

We can use Eq. (29.134) to calculate the critical temperature T_c for Bose-Einstein condensation. Above the phase transition, $T > T_c$, the population is distributed over all states, each individual state being weakly populated; in particular, practically no atoms are condensed, $N_c = 0$. The critical temperature T_c is the lowest temperature where there are still no condensed atoms.

Below the critical temperature, $T < T_c$, the chemical potential is fixed by $\mu = 0$, and the fugacity reaches its maximum value, $Z = 1$. Above and at the critical temperature all atoms occupy excited states,

$$N = \frac{V}{\lambda_{\rm th}^3} g_{3/2}(Z) = \frac{V}{\lambda_c^3} g_{3/2}(1) \qquad \text{for} \ \ T \geq T_c \ , \tag{29.135}$$

with $g_{3/2}(1) = 2.612$. The first part of Eq. (29.134) holds for $T \geq T_c$ and provides a mean of determining Z from temperature and total atom number. The second part of Eq. (29.134) holds at $T = T_c$. Resolving it by T_c we obtain,

$$k_{\rm B}T_c = \frac{2\pi\hbar^2}{m}\left(\frac{N}{V g_{3/2}(1)}\right)^{2/3} \ . \tag{29.136}$$

Below the critical temperature we need to add an additional term N_c. Resolving the full expression (29.134) by the fraction N_c/N of atoms condensed in the ground state and substituting N from (29.135), we obtain,

$$\frac{N_c}{N} = 1 - \frac{V}{N\lambda_{\rm th}^3} g_{3/2}(Z) = 1 - \frac{\lambda_c^3}{\lambda_{\rm th}^3}\frac{g_{3/2}(Z)}{g_{3/2}(1)} = \begin{cases} 1 - \frac{\lambda_c^3}{\lambda_{\rm th}^3} & \text{for} \ \ T \leq T_c \\ 0 & \text{for} \ \ T \geq T_c \end{cases} \tag{29.137}$$

The superscript (3/2) denotes the box potential shape of the trapping potential [18]. In summary we have,

$$\boxed{\frac{N_c}{N} = 1 - \left(\frac{\min(T, T_c^{(3/2)})}{T_c^{(3/2)}}\right)^{3/2} \qquad \text{with} \qquad k_\mathrm{B} T_c^{(3/2)} = \frac{2\pi\hbar^2}{m}\left(\frac{N}{V g_{3/2}(1)}\right)^{2/3}} \,. \tag{29.138}$$

The abrupt occurrence of a finite occupation in a single quantum state at temperature below $T_c^{(3/2)}$ indicates a spontaneous change in the system and a thermodynamic phase transition. Solve Exc. 29.3.4.1.

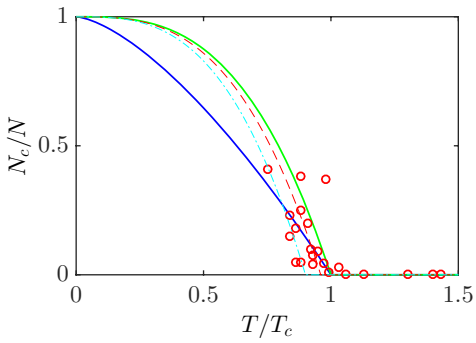

Figure 29.10: (code) Condensed fraction for an ideal Bose gas as a function of reduced temperature for a (blue) in a box potential and (green) in a harmonic trap. Red circles denote experimentally measured data points [412]. The red dashed line is a fit to the data. The cyan dash-dotted line is a theoretical curve taking into account finite size effects and interatomic interactions.

29.3.1.2 Thermodynamic potentials in a grand canonical ensemble

In order to calculate the density-of-states, state equation, mean values in the grand canonical ensemble, we start from the definitions of the partition sum Ξ_gc in Eq. (29.97) using the upper signs for bosons, the grand canonical potential Ω, the fugacity Z, the density operator $\hat{\rho}$, and the trace,

$$\Xi_\mathrm{gc} \equiv \prod_{j=1}^{\infty} (1 \mp Z e^{-\beta\varepsilon_j})^{\mp 1} \qquad \text{and} \qquad \Omega \equiv -k_\mathrm{B} T \ln \Xi_\mathrm{gc} \qquad \text{and} \qquad Z \equiv e^{\beta\mu}$$

$$\text{and} \qquad \hat{\rho} \equiv \frac{e^{-\beta(\hat{H}_N - \mu\hat{N})}}{\Xi_\mathrm{gc}} \qquad \text{and} \qquad \mathrm{Tr}\ldots \equiv \sum_j \langle\psi_j|\ldots|\psi_j\rangle \,. \tag{29.139}$$

The parameters μ, V, T are held fixed. As we have seen, for large systems in the thermodynamic limit, the sum can be replaced by an integral, which, in turn, may be expressed by the Riemann zeta-function (see Secs. 29.2.5 and 31.1.2). The thermodynamic potentials and their expressions are summarized in the following table [19].

[18] See Exc. 29.3.4.3 for an explanation of the notation.
[19] The red terms in {} brackets only hold for bosons, because the integrals diverge otherwise.

Table 29.1: Thermodynamic potentials for an ideal Bose gas (upper signs) or Fermi gas (lower signs) trapped in a box potential.

		$\mathrm{Tr}\,\hat{\rho}$	$\ln \Xi_{\mathrm{gc}}$	$\sum_{j=1}^{\infty}$	$\lim_{N\to\infty}$
Ω			$-\frac{1}{\beta}\ln \Xi_{\mathrm{gc}}$	$\sum_j \frac{\ln(1\mp Z e^{-\beta\varepsilon_j})}{\pm\beta}$	
μ				$\frac{1}{\beta}\ln Z$	
1		$\mathrm{Tr}\,\hat{\rho}$			
n_j	$-\left(\frac{\partial\Omega_j}{\partial\mu}\right)_{T,V}$	$w_{T,\mu}$	$-\frac{1}{\beta}\frac{\partial}{\partial\varepsilon_j}\ln \Xi_{\mathrm{gc}}$	$\frac{1}{e^{\beta\varepsilon_j}/Z\mp 1}$	
N	$-\left(\frac{\partial\Omega}{\partial\mu}\right)_{T,V}$	$\mathrm{Tr}\,\hat{N}\hat{\rho}$	$Z\frac{\partial}{\partial Z}\ln \Xi_{\mathrm{gc}}$	$\sum_j n_j$	$\frac{V}{\lambda_{\mathrm{th}}^3} g_{3/2}^{\pm} + \left\{\frac{1}{1/Z-1}\right\}$
S/k_{B}	$-\left(\frac{\partial\Omega}{k_{\mathrm{B}}\partial T}\right)_{\mu,V}$	$\mathrm{Tr}\,\hat{\rho}\ln\hat{\rho}$	$\ln \Xi_{\mathrm{gc}}$	$\pm\sum_j \ln\frac{n_j e^{\beta\varepsilon_j}}{Z}$	$\frac{5V}{2\lambda_{\mathrm{th}}^3} g_{5/2}^{\pm} - \{\ln Z\}$
P	$-\left(\frac{\partial\Omega}{\partial V}\right)_{T,\mu}$		$\frac{1}{\beta V}\ln \Xi_{\mathrm{gc}}$		$\frac{V}{\lambda_{\mathrm{th}}^3} g_{5/2}^{\pm} - \{N\ln(1-Z)\}$
E	$TS+\mu N+\Omega$	$\mathrm{Tr}\,\hat{H}\hat{\rho}$	$-\frac{\partial}{\partial\beta}\ln \Xi_{\mathrm{gc}}$	$\sum_j n_j\varepsilon_j$	$\frac{3k_{\mathrm{B}}TV}{2\lambda_{\mathrm{th}}^3} g_{5/2}^{\pm} \simeq \frac{3PV}{2}$
C_V	$\left(\frac{\partial E}{\partial T}\right)_{N,V}$				$\frac{15V}{4\lambda_{\mathrm{th}}^3} g_{5/2}^{\pm} - \left\{\frac{9N g_{3/2}^{\pm}}{4 g_{1/2}^{\pm}}\right\}$

With the particle number N we calibrate the chemical potential μ at a given temperature T via,

$$N = \frac{V}{\lambda_{\mathrm{th}}^3} g_{3/2}(Z) \Longrightarrow Z = g_{3/2}^{-1}\left(\lambda_{\mathrm{th}}^3 N/V\right) \ , \tag{29.140}$$

and knowing Z we can determine all thermodynamic potentials of the table 29.1. The internal energy with fixed volume is proportional to the pressure. Note that $\lim_{N\to\infty} S = 0$ and $\lim_{N\to\infty} C_V = 0$. Do the Exc. 29.3.4.2.

The Bose-Einstein phase transition occurs at some critical temperature T_c. At high temperature $T > T_c$ the ground state population vanishes. At low temperature $T < T_c$, we have to substitute in the above equations Z by 1. Since $g_{3/2}$ is limited for $Z = 0, .., 1$ the population balance must be equilibrated by an additional term describing the ground state population:

$$\begin{aligned} \frac{N}{V}\lambda_{\mathrm{th}}^3 &= \begin{cases} g_{3/2}^{+}(1) + \lambda_{\mathrm{th}}^3 \frac{N_c}{V} & \text{for} \quad T \le T_c \\ g_{3/2}^{+}(Z) & \text{for} \quad T \ge T_c \end{cases} \\ \frac{P}{k_{\mathrm{B}}T}\lambda_{\mathrm{th}}^3 &= \begin{cases} g_{5/2}^{+}(1) & \text{for} \quad T \le T_c \\ g_{5/2}^{+}(Z) & \text{for} \quad T \ge T_c \end{cases} \end{aligned} \tag{29.141}$$

In the thermal Bose-gas phase, $T \ge T_c$, we get from (29.141) the state equation,

$$\boxed{\frac{PV}{Nk_{\mathrm{B}}T} = \frac{g_{5/2}^{+}(Z)}{g_{3/2}^{+}(Z)} \overset{T\to\infty}{\longrightarrow} 1} \ . \tag{29.142}$$

In the classical limit, obtained by noticing $g^0_\xi(Z) = Z$, follows the well-known classical ideal gas equation. In the Bose-condensate phase, $T \leq T_c$, using the definition of the critical temperature, we recover from (29.141) the *equation of state* (29.138).

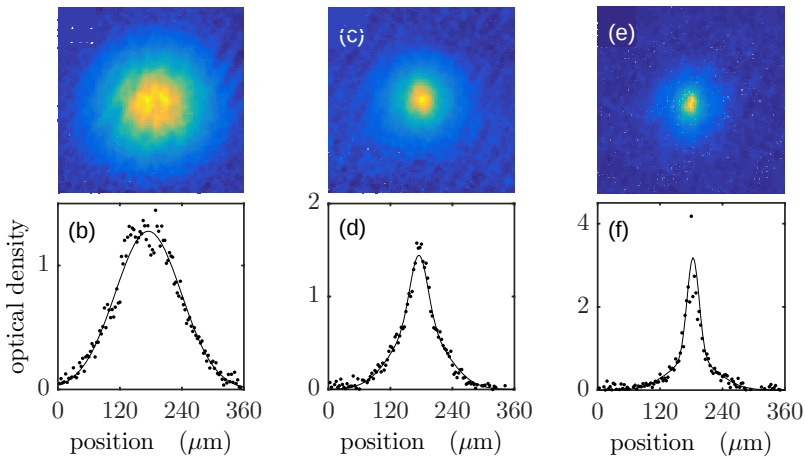

Figure 29.11: Ultracold ^{87}Rb gas at various temperatures (a,b) $T > T_c$, (c,d) $T \simeq T_c$, and (e,f) $T < T_c$ measured in experiment [412]. The figures (a,c,e) are two-dimensional false color images of the momentum distribution. The figures (b,d,f) are cuts through the images.

29.3.2 Condensation of a harmonically confined gas

The critical temperature T_c can be significantly altered, when the atoms are confined to a spatially inhomogeneous potential. The critical temperature depends on the general shape and the tightness of the potential. Let us consider N particles of an ideal Bose gas distributed over several quantum states of an arbitrary potential. The occupation number $w_{T,\mu}(\varepsilon)$ of particles at an energy level ε is still given by (29.118), the ground state energy is defined as zero. In the thermodynamic limit, the relation between the chemical potential and the total number of particles is still given by Eq. (29.140), with an adequate density-of-states $\eta(\varepsilon)$. The state density for an arbitrary confinement potential $U(\mathbf{r})$ can be found by generalizing the calculation to the free gas. The phase space volume between the energy surfaces ε and $\varepsilon + d\varepsilon$ is proportional to the number of states in this energy range. However, the external potential limits the space available for the gas. For a harmonic potential (29.75) with the mean secular frequency $\bar{\omega}$ the density-of-states $\eta(\varepsilon)$ has already been calculated in Eq. (29.79). With this, we can analogically to (29.140) and (29.138), calculate,

$$\begin{aligned} N &= N_c + \int_0^\infty w_{T,\mu}(\varepsilon)\eta(\varepsilon)d\varepsilon \\ &= N_c + \frac{1}{2(\hbar\bar{\omega})^3}\int_0^\infty \frac{\varepsilon^2 d\varepsilon}{e^{\beta(\varepsilon-\mu)}-1} = N_c + \left(\frac{k_\mathrm{B}T}{\hbar\bar{\omega}}\right)^3 g_3(Z)\ . \end{aligned} \tag{29.143}$$

In the same way as for a potential well we find for a harmonic potential,

$$N_{\rm th} = \left(\frac{k_{\rm B}T}{\hbar\bar{\omega}}\right)^3 g_3(1) = N\left(\frac{T}{T_c^{(3)}}\right)^3 , \tag{29.144}$$

with $g_3(1) = 1.202$. Since $N_c + N_{\rm th} = N$, the number of particles in the ground state is,

$$\boxed{\frac{N_c}{N} = 1 - \left(\frac{\min(T, T_c^{(3)})}{T_c^{(3)}}\right)^3 \qquad \text{with} \qquad k_{\rm B}T_c^{(3)} = \hbar\bar{\omega}\left(\frac{N}{g_3(1)}\right)^{1/3}} . \tag{29.145}$$

The superscript (3) indicates the harmonic shape of the trap.

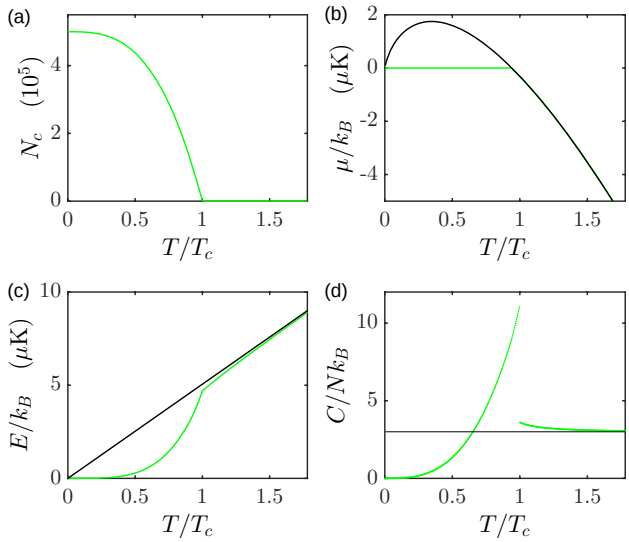

Figure 29.12: (code) Calculation of thermodynamic potentials as a function of temperature for a Bose gas of 500000 ^{88}Sr atoms trapped in a harmonic potential with secular frequency $\omega_{\rm ho}/2\pi = 416\,$Hz. (a) Chemical potential, (b) energy, (c) heat capacity per particle, and (d) total heat capacity. The critical temperature is $T_c = 1.7\,\mu$K.

Fig. 29.10 traces the condensed fraction N_c/N measured as a function of the reduced temperature $T/T_c^{(3)}$. Experiments [412, 297] confirm Bose's ideal gas theory in the thermodynamic limit. A particularity of inhomogeneous trapping potentials is, that the *condensed and the normal phase separate in momentum space*, simply because the condensed atoms occupy only the ground state, whose spatial extend is small, while thermal atoms are distributed over all energy levels. Fig. 29.11 shows a measurement of velocity distributions of a cloud of atoms close to the critical temperature.

We note that smaller trapping volumes (or tighter potentials) increase the critical temperature T_c, thus allowing for quantum degeneracy at higher temperatures, which can be advantageous in experimentation. Also, at a given temperature, a strongly

confining potential reduces the total minimum number of atoms required to reach condensation.

29.3.2.1 Energy and heat capacity

When the number of atoms is limited, $N < \infty$, we expect a slightly reduced critical temperature [390]. In addition, the interatomic interaction reduces the critical temperature [51]. As the effects are small, they are difficult to observe in experiments. However, measurements of other thermodynamic quantities such as energy and heat capacity [241, 297] showed significant deviations from the ideal gas behavior due to interaction effects.

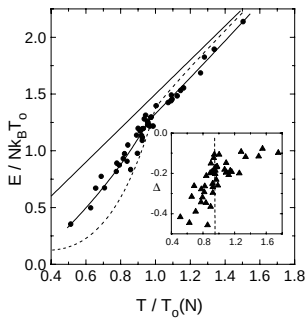

Figure 29.13: Measurement of the release energy [297].

The *heat capacity* quantifies the system's ability to secure its energy. In conventional systems, the heat capacity is typically either specified at constant volume or at constant pressure. With this specification heat capacities are extensive state variables. When crossing a phase transition, the temperature-dependent heat capacity measures the degree of change in the system above and below the critical temperature and provides valuable information about the general type of phase transition.

Using (29.81), the total energy per particle is given by,

$$\frac{E}{N} = \frac{\int \varepsilon w_{T,\mu}(\mathbf{r},\mathbf{p}) d^3r d^3p}{\int w_{T,\mu}(\mathbf{r},\mathbf{p}) d^3r d^3p} = \frac{\int \varepsilon \eta(\varepsilon)(e^{\beta(\varepsilon-\mu)}-1)^{-1} d\varepsilon}{\int \eta(\varepsilon)(e^{\beta(\varepsilon-\mu)}-1)^{-1} d\varepsilon} = 3k_{\mathrm{B}}T\frac{g_4(Z)}{g_3(Z)} \ . \tag{29.146}$$

For a confined gas, volume and temperature are interdependent, and the concept of pressure is somewhat vague. In this case, we can not refer to the heat capacity at constant volume or pressure. However, one can define the heat capacity for a fixed number of particles,

$$C(T) = \left(\frac{\partial E(T)}{\partial T}\right)_N \ . \tag{29.147}$$

Fig. 29.12 shows the temperature dependence of some thermodynamic potentials for a harmonically trapped ultracold Bose gas. The discontinuity of the heat capacity at the critical temperature is known as *λ-point*.

Calculating the second moments of the distributions obtained for the same density

by time-of-flight of absorption images, we obtain the kinetic energy,

$$E_{\rm kin} = \int \frac{p^2}{2m} n(\mathbf{p}) d^3p \ . \tag{29.148}$$

For confined ideal gases, the virial theorem ensures $E_{\rm kin}+E_{\rm pot} = 2E_{\rm kin}$. For real gases, the repulsive energy of the mean field adds to this energy, $E = E_{\rm kin} + E_{\rm pot} + E_{\rm self}$. The sudden extinction of the trapping potential before time-of-flight takes away the potential energy $E_{\rm pot}$ non-adiabatically. The kinetic energy and the self-energy of the condensate are fully converted into kinetic energy during ballistic expansion. It is this energy, $p^2/2m = E_{\rm kin} + E_{\rm self}$, which is sometimes called *release energy*, which is measured after ballistic expansion [20]. Fig. 29.13(right) shows a measurement of the release energy. Solve the Exc. 29.3.4.3.

29.3.2.2 Micro- and grand canonical Bose-condensates

The question which ensemble is the correct assumption depends on the experimental situation. The question is particularly interesting in the context of Bose-Einstein condensation: Here it is related to the question which state better describes a BEC: A Fock state characterized by a fixed atom number or a Glauber state, where the atom number is fluctuating.

The condensates experimentally produced in alkali gases consisted of relatively small atom numbers between 1000 to 10^7, so that the validity of the thermodynamic approximation and the use of the density-of-states approach has been questioned [390]. Also, the decision whether to use the grand canonical, the canonical or the micro-canonical ensemble for calculating the thermodynamic quantities noticeably influences the results. Herzog and Olshanii [438] have shown that for small atom numbers on the order of 100 the canonical and grand canonical statistics lead to predictions on the condensed fraction that differ by up to 10% [see Fig. 29.10(right)]. On the other hand, they give the same results if the particle numbers are large. Which canonical statistics is more appropriate is not a trivial question and depends on the experimental setup and in particular on the time scale of the measurements. If we look at the sample for short times, the number of condensed atoms will be fixed, and we can assume a canonical ensemble. For longer times, however, the atom number may be an equilibrium parameter depending on the contact of the sample with a reservoir, and the grand canonical statistics is better suited.

29.3.3 Density and momentum distribution for a Bose gas

Bose-Einstein condensates consist of atoms sharing a single quantum state. In inhomogeneous potentials, the condensate and the thermal fraction form spatially separated clouds, concentrated around the center of the potential and therefore very dense. For this reason, interatomic interaction effects generally dominate the density and momentum distribution of the condensed fraction. However, the non-condensed

[20] It is interesting to measure the heat capacity of a partially condensed cloud near the critical point and analyze the discontinuity, because it contains important information about interatomic interactions and finite-size effects ([197], Sec. 3.4). In addition, the classification of Bose-Einstein condensation as a phase transition depends very much on the behavior of the thermodynamic potential near the critical point [553, 458].

(or normal, or thermal) fraction is also subject to modifications due to the bosonic nature of the atoms. Since the density of the normal fraction is generally much smaller, these modifications are weak. In this section, we will only discuss these effects briefly, but we note that the calculations are analogous to the calculations for fermionic gases presented in Sec. 29.4.4.

For an ideal Bose gas the density and momentum distributions are expressed by Bose functions $g_{3/2}(Z)$ [197]. For example, as will be derived in Exc. 29.3.4.4, the density and momentum distributions are,

$$\boxed{\begin{aligned} n(\mathbf{x}) &= \frac{1}{\lambda_{\rm th}^3}\, g_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) \\ n(\mathbf{k}) &= \frac{a_{\rm ho}^6}{\lambda_{\rm th}^3}\, g_{3/2}(e^{\beta(\mu-\mathbf{p}^2/2m)}) \end{aligned}} \quad \text{(bosonic distribution functions)} \tag{29.149}$$

In the classical limit, we can calibrate the chemical potential by Eq. (29.140) for a box potential or by (29.143) for a harmonic potential,

$$g_{3/2}(e^{\beta\mu}) \to c_{3/2}(e^{\beta\mu}) = e^{\beta\mu} = \begin{cases} \frac{N}{V}\lambda_{\rm th}^3 & \text{(for a box potential)} \\ c_3(e^{\beta\mu}) = N\left(\frac{\hbar\bar{\omega}}{k_{\rm B}T}\right)^3 & \text{(for a harmonic potential)} \end{cases} \tag{29.150}$$

Hence, we obtain for the classical density distribution,

$$\begin{aligned} n(\mathbf{x}) &= \frac{1}{\lambda_{\rm th}^3} c_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) = \frac{e^{\beta\mu}}{\lambda_{\rm th}^3} e^{-\beta U(\mathbf{x})} \\ &= \begin{cases} \frac{N}{V}\Big|_{\mathbf{x}\in V} & \text{(for a box potential)} \\ N\sqrt{\frac{m\bar{\omega}^2}{2\pi k_{\rm B}T}}^{\,3}\, e^{-\beta m\bar{\omega}^2 x^2/2} & \text{(for a harmonic potential)} \end{cases} \end{aligned} \tag{29.151}$$

Similarly, the momentum density distribution is given by,

$$\begin{aligned} n(\mathbf{k}) &= \frac{a_{\rm ho}^6}{\lambda_{\rm th}^3} c_{3/2}(e^{\beta(\mu-p^2/2m)}) = \frac{a_{\rm ho}^6 e^{\beta\mu}}{\lambda_{\rm th}^3} e^{-\beta p^2/2m} \\ &= \begin{cases} \frac{N}{V} a_{\rm ho}^6\Big|_{\mathbf{x}\in V}\, e^{-\beta p^2/2m} & \text{(for a box potential)} \\ N\hbar^3\sqrt{\frac{1}{2\pi m k_{\rm B}T}}^{\,3}\, e^{-\beta p^2/2m} & \text{(for a harmonic potential)} \end{cases} \end{aligned} \tag{29.152}$$

where we used the spatial extend of the ground state of the harmonic oscillator $a_{\rm ho} = \sqrt{\hbar/m\omega}$. We see that we recover the Maxwell-Boltzmann velocity distribution, as seen in Fig. 29.14,

$$n(\mathbf{v}) = n(\mathbf{k})\frac{m^3}{\hbar^3} = N\sqrt{\frac{m}{2\pi k_{\rm B}T}}^{\,3}\, e^{-\beta m v^2/2}\,. \tag{29.153}$$

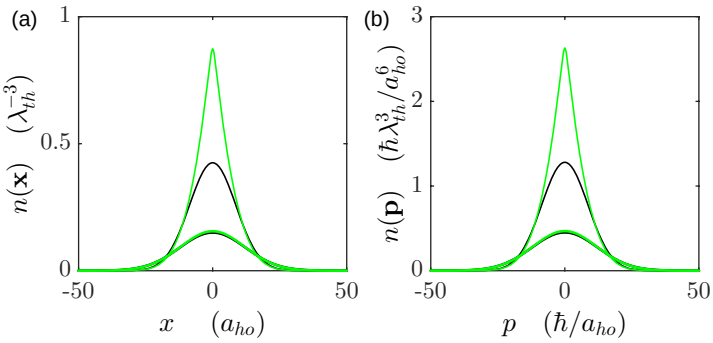

Figure 29.14: (code) (a) Density and (b) momentum distribution of a Bose gas (red) and a Boltzmann gas (green) at $T = 1.1T_c$ (solid line) and at $T = 2T_c$ (dotted line).

29.3.3.1 Ballistic expansion

To describe the density distribution of an ultracold Bose-gas after a time-of-flight we replace in the second Eq. (29.149): $\mathbf{k} = m\mathbf{r}/\hbar t_{\rm ToF}$. We obtain the density distribution,

$$n_{\rm ToF}(\mathbf{r}, t_{\rm ToF}) = \left(\frac{m}{\hbar t_{\rm ToF}}\right)^3 n(\mathbf{k} = m\mathbf{r}/\hbar t_{\rm ToF}) = \left(\frac{m}{\hbar t_{\rm ToF}}\right)^3 \frac{a_{\rm ho}^6}{\lambda_{\rm th}^3} g_{3/2}(e^{(\mu - mr^2/2t_{\rm ToF}^2)/k_{\rm B}T})$$
$$\stackrel{T\to\infty}{\longrightarrow} \left(\frac{m}{\hbar t_{\rm ToF}}\right)^3 N\hbar^3 \sqrt{\frac{1}{2\pi m k_{\rm B}T}}^{\,3} e^{-mr^2/2t_{\rm ToF}^2 k_{\rm B}T} = \frac{N}{(2\pi)^{3/2} r_{\rm rms}^3} e^{-r^2/2r_{\rm rms}^2} \ , \tag{29.154}$$

where we defined,

$$r_{\rm rms} \equiv \sqrt{\frac{k_{\rm B}T}{m}} t_{\rm ToF} \ . \tag{29.155}$$

This distribution does not directly depend on the potential $U(\mathbf{r})$, that is, the expansion is isotropic. In Exc. 29.3.4.4(b) we determine the time-of-flight density distribution of an ultracold Bose gas. For very long flight times (usually several 10 ms) the density resembles a Gaussian distribution [197]. Note however, that in interacting non-ideal gases the chemical potential does depend on the potential.

In a time-of-flight experiment, any deviation observed between the results (29.154) and (29.155) points towards an impact of quantum statistics. However, absorption images only record column densities, i.e. projections of the time-of-flight distribution on a plane, which tends to smear out the non-Gaussian features.

Example 230 (*Heat capacity measurement*): For an ideal Bose gas trapped in a harmonic potential the temperature dependence of the heat capacity at the threshold to condensation can easily be obtained as follows. The condensed fraction determines the chemical potential through,

$$N = N_0 + \left(\frac{k_{\rm B}T}{\hbar\omega}\right)^3 g_3(Z) \ , \tag{29.156}$$

where $Z(T) = e^{\mu/k_{\rm B}T}$ for a grand canonical ensemble and g_n denotes the Riemann zeta function. The condensed fraction vanishes above the critical

temperature, the chemical potential vanishes below the critical temperature. $(k_{\rm B}T/\hbar\omega)^3 = 2\pi(a_{\rm ho}/\lambda_{\rm th})^3$ denotes the normalized volume of a phase space cell. Knowing $Z(T)$ from equation (29.156), we can calculate the total energy, the heat capacity and all the other thermodynamic potentials:

$$C_N = 12k_{\rm B}\left(\frac{k_{\rm B}T}{\hbar\omega}\right)^3 g_4(Z) - 9k_{\rm B}N\frac{g_3(Z)}{g_2(Z)} \ . \tag{29.157}$$

For an interacting Bose-gas we expect that the Eqs. (29.156) and (29.157) are not scrupulously obeyed. Indeed, the abrupt discontinuous change in the heat capacity at the phase transition to BEC, expected for ideal gases, is smeared out by atomic collisions [51].

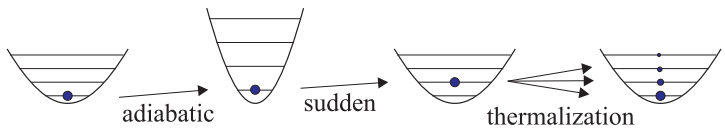

Figure 29.15: Population variation during a slow adiabatic compression followed by a sudden non-adiabatic decompression.

29.3.3.2 Adiabatic compression

Adiabaticity of a process means reversibility, while the atom number is unchanged $N = const$ and, hence, constant entropy $S - const$. This implies an unchanged population distribution $n_j = const$ and $\beta\varepsilon_j/T = const$ also we get $\beta\mu, \beta E = const$. Furthermore, the phase space density keeps unchanged $\rho = const$. The process of adiabatically compressing a harmonic trap therefore changes the temperature like $T' = T\omega'/\omega$. This is valid above and below the transition point. The measure is repeated twice: With and without adiabatic-sudden variation. The heat capacity then follows from equation (29.157).

29.3.4 Exercises

29.3.4.1 Ex: Monoatomic gas as a canonical ensemble

Consider a classical monoatomic gas made up of N non-interacting atoms of mass m confined in a container of volume V, at temperature T. The Hamiltonian corresponding to an atom is given by $\hat{H} = (\hat{p}_x^2 + \hat{p}_y^2 + \hat{p}_z^2)/2m$.
a. Show that the atomic canonical partition function is $\xi = V/\lambda_{\rm th}^3$, where $\lambda_{\rm th}$ is the thermal de Broglie wavelength defined in Eq. (29.117).
b. Using ξ of the previous item, obtain the system's partition function $\Xi_{\rm cn}$ and the Helmholtz free energy F. Also obtain the free energy per atom $f = F/N$ in the thermodynamic limit $N \longrightarrow \infty$, $V \longrightarrow \infty$, such that $v = N/V$ fixed.
c. Obtain internal energy E and the gas pressure p.
d. Calculate the chemical potential and entropy per atom in the thermodynamic limit, thus deriving the so-called *Sackur-Tetrode formula*.

29.3.4.2 Ex: Thermodynamic quantities for a Bose gas gas trapped in a box

Derive all expressions for the entropy and the pressure of Tab. 29.1.

29.3.4.3 Ex: Generalization for arbitrary potentials in reduced dimensions

The calculation of the thermodynamic potentials can be generalized to arbitrary trapping potentials and dimensions [117, 289, 232, 52, 995, 319, 53, 390, 438, 516, 509, 685, 553, 587, 297]. To do so, we consider a generic power law potential confining an ideal Bose gas in α dimensions,

$$U(\mathbf{r}) = \sum\nolimits_{i=1}^{\alpha} \left|\frac{x_i}{a_i}\right|^{t_i} ,$$

and define a parameter describing the confinement power of the potential,

$$\xi = \frac{\alpha}{2} + \sum\nolimits_{i=1}^{\alpha} \frac{1}{t_i} .$$

For example, for a three-dimensional potential, $\alpha = 3$. Now, for a 3D harmonic potential, $\xi = 3$, and for 3D box potential, $\xi = 3/2$.
a. Calculate the density-of-states η using the equation (29.71) employing Bose functions (29.124).
b. Prove the following expressions:

(bosonic potentials)

$$\boxed{\begin{aligned}
\frac{N_\mathrm{c}}{N} &= 1 - \left(\frac{\min(T,T_\mathrm{c})}{T_\mathrm{c}}\right)^{\xi} \\
\frac{E}{Nk_\mathrm{B}T} &= \xi\frac{g_{\xi+1}(Z)}{g_\xi(Z)}\left(\frac{\min(T,T_\mathrm{c})}{T_\mathrm{c}}\right)^{\xi} \\
\frac{S}{Nk_\mathrm{B}} &= 4\frac{g_{\xi+1}(Z)}{g_\xi(Z)} - \frac{2\mu}{k_\mathrm{B}T} \\
\frac{C}{Nk_\mathrm{B}} &= \xi(\xi+1)\frac{g_{\xi+1}(Z)}{g_\xi(Z)}\left(\frac{\min(T,T_\mathrm{c})}{T_\mathrm{c}}\right)^{\xi} - \xi^2\frac{g_\xi(Z)}{g_{\eta-1}(Z)}\frac{\max(T-T_\mathrm{c},0)}{T-T_\mathrm{c}} \\
\frac{C_{T>T_\mathrm{c}}}{Nk_\mathrm{B}} &= \xi(\xi+1)\frac{g_{\xi+1}(Z)}{g_\xi(Z)} - \xi^2\frac{g_\xi(Z)}{g_{\xi-1}(Z)} \quad , \quad \frac{C_{T<T_\mathrm{c}}}{Nk_\mathrm{B}} = \xi(\eta+1)\frac{g_{\xi+1}(1)}{g_\xi(1)} \\
\frac{\Delta C_{T_\mathrm{c}}}{Nk_\mathrm{B}} &= \frac{C_{T_\mathrm{c}^-} - C_{T_\mathrm{c}^+}}{Nk_\mathrm{B}} = \xi^2\frac{g_\xi(1)}{g_{\xi-1}(1)}
\end{aligned}} .$$

29.3.4.4 Ex: Time-of-flight distribution of a Bose-gas

a. Derive the formulae (29.149) describing the density and momentum distribution of an ultracold Bose-gas.
b. Calculate the time-of-flight distribution of a Bose-gas as a function of temperature (i) analytically for a harmonic potential and (ii) numerically for an arbitrary potential.

29.4 Quantum degeneracy of an ideal Fermi gas

Atoms are fermions or bosons, depending on whether their spin is integer or semi-integer. For example, ^{87}Rb atoms with their total integer spin of F are bosons, while ^{40}K atoms having a half-integer spin are fermions. At high phase space densities, atoms have to figure out how they will organize their coexistence. Bosons encourage each other to occupy the same phase space cell, in contrast to the reluctant fermions, which prefer to follow Pauli's exclusion principle. The different behavior is described by different quantum statistics that determine how the phase space (i.e., the available energy levels) has to be filled by the atoms. The Bose-Einstein distribution is valid for bosons, the distribution of Fermi-Dirac for fermions and both asymptotically approach the Boltzmann distribution at high temperatures. We have seen that bosons undergo a phase transition and condense in the ground state when the temperature is reduced below a critical threshold. On the other hand, the fermions organize their phase space, so that their energy levels are arranged like a ladder. The impact of fermionic quantum statistics on a cold cloud of atoms were observed experimentally by DeMarco and Jin [241, 699]. They cooled a two-components Fermi gas of 7×10^5 potassium atoms down to 300 nK, which corresponded to 60% of the atoms populating energy levels below the Fermi energy. The measured density distribution was found to deviate from the one expected for an ideal Boltzmann gas [21].

29.4.1 Chemical potential and Fermi radius for a harmonic trap

The phase space density for a *degenerate Fermi gas* in the thermodynamic limit has been derived in (29.125). We consider a cylindrically symmetric harmonic potential, as defined in (29.74), for which the density-of-states $\eta\varepsilon$ has been calculated in (29.79). In the same way as for a Bose gas, the chemical potential of the Fermi gas must satisfy the normalization condition,

$$N = \int w_{T,\mu}(\varepsilon)\eta(\varepsilon)d\varepsilon = \frac{1}{2(\hbar\bar{\omega})^3}\int_0^\infty \frac{\varepsilon^2 d\varepsilon}{e^{\beta(\varepsilon-\mu)}+1} = \left(\frac{k_\mathrm{B}T}{\hbar\bar{\omega}}\right)^3 f_3(Z)\ . \tag{29.158}$$

For low temperatures, $\beta\mu \gg 1$, we can use the Sommerfeld expansion of the Fermi function, which in first order gives $f_\xi(e^x) \simeq x^\xi/\Gamma(\xi+1)$, where x is a placeholder for $\beta\mu$, Γ is the Γ-function, and $\xi = 3$ for a harmonic potential. From this we immediately obtain the chemical potential at zero temperature defined as the *Fermi energy*,

$$\boxed{E_\mathrm{F} \equiv \mu(T=0) = \hbar\bar{\omega}(6N)^{1/3}}\ , \tag{29.159}$$

and from that the momentum of free particles and the Fermi radius,

$$K_\mathrm{F} \equiv \sqrt{\frac{2mE_\mathrm{F}}{\hbar^2}} \quad \text{and} \quad r_\mathrm{F} \equiv \sqrt{\frac{2E_\mathrm{F}}{m\omega_r^2}}\ , \quad z_\mathrm{F} = \sqrt{\frac{2E_\mathrm{F}}{m\omega_z^2}}\ . \tag{29.160}$$

[21] We note that meanwhile ultracold two-components Fermi gas have been demonstrated to form bosonic Cooper-pairs, similarly to the phenomena known as superconductivity in some metals and as superfluidity of the fermionic ^{3}He.

Using the second order of the Sommerfeld expansion,

$$f_\xi(e^x) \simeq \frac{x^\xi}{\Gamma(\xi+1)}\left(1+\frac{\pi^2\xi(\xi-1)}{6x^2}+...\right) , \tag{29.161}$$

we obtain for the chemical potential at finite temperature the equation, $0 = \mu^3 + (\pi k_\mathrm{B}T)^2\mu - E_\mathrm{F}^3$. The approximate solution of this equation, neglecting higher-order terms such as $4\pi^6 k_\mathrm{B}^6 T^6 \ll 27E_\mathrm{F}^6$, is

$$\mu = E_\mathrm{F}\left[1-\frac{\pi^2}{3}\left(\frac{k_\mathrm{B}T}{E_\mathrm{F}}\right)^2\right] . \tag{29.162}$$

For highly excited atoms, $\varepsilon-\mu \gg k_\mathrm{B}T$, the Fermi function approaches the identity, $f_\xi(Z) \overset{Z\to 0}{\longrightarrow} Z$ (see Fig. 29.9), so that,

$$N = \left(\frac{k_\mathrm{B}T}{\hbar\bar{\omega}}\right)^3 e^{\beta\mu} = \left(\frac{k_\mathrm{B}T}{\hbar\bar{\omega}}\right)^3 (1+\beta\mu+...) , \tag{29.163}$$

$$\mu = k_\mathrm{B}T\ln Z \simeq k_\mathrm{B}T\ln N\left[\left(\frac{\hbar\bar{\omega}}{k_\mathrm{B}T}\right)^3\right] = k_\mathrm{B}T\ln\frac{1}{6}\left(\frac{E_\mathrm{F}}{k_\mathrm{B}T}\right)^3 ,$$

where in the last step we substituted the definition of the Fermi energy. This means that highly excited fermions behave like a *Boltzmann gas*, which satisfies an ideal gas equation similar to that of classical particles in a box potential,

$$N = \left(\frac{k_\mathrm{B}T}{\hbar\bar{\omega}}\right)^3 . \qquad \text{(Boltzmann)} . \tag{29.164}$$

Fig. 29.16(a) shows calculations of the chemical potential for an ideal Fermi gas along with the chemical potentials of a Boltzmann gas and a Bose gas.

29.4.2 Energy

Using (29.81), the total energy per particle, $E/N \equiv N^{-1}\int \varepsilon w_{T\mu} d^3x d^3k$, is given by,

$$\frac{E}{N} = \frac{\int \varepsilon w_{T,\mu}(\mathbf{x},\mathbf{k})d^3x d^3k}{\int w_{T,\mu}(\mathbf{x},\mathbf{k})d^3x d^3k} = \frac{\int \varepsilon\eta(\varepsilon)\left(e^{\beta(\varepsilon-\mu)}+1\right)^{-1}d\varepsilon}{\int \eta(\varepsilon)\left(e^{\beta(\varepsilon-\mu)}+1\right)^{-1}d\varepsilon} = 3k_\mathrm{B}T\frac{f_4(Z)}{f_3(Z)} , \tag{29.165}$$

in analogy to the expression (29.146) holding for a Bose gas. Again using the Sommerfeld approximation, we see that for low temperatures, $T \to 0$, the energy is limited by [see Fig. 29.16(b)],

$$E = \frac{3}{\beta(\beta\hbar\bar{\omega})^3}f_4(e^{\beta\mu}) = \frac{3\mu^4}{4E_\mathrm{F}^3}\left(1+\frac{2\pi^2}{(\beta\mu)^2}+...\right) \overset{T\to 0}{\longrightarrow} \frac{3}{4}E_\mathrm{F} . \qquad \text{(Fermi)} \tag{29.166}$$

Hence, the total energy per fermion does not vanish for $T \to 0$. The reason is that the atoms are forced to adopt states in the outermost regions of the harmonic trap.

In the limit of high temperatures, $T \to \infty$, a classical gas has the energy per particle,

$$E = \frac{3}{\beta(\beta\hbar\bar{\omega})^3} f_4\left(f_3^{-1}\left(\frac{(\beta E_{\rm F})^3}{6}\right)\right) \simeq 3Nk_{\rm B}T \ . \qquad \text{(Boltzmann)} \tag{29.167}$$

which is seen by taking the high temperature limit $f_\eta(Z) \stackrel{Z\to 0}{\longrightarrow} Z$ and extrapolating to all Z. This implies, $E_1/E_{\rm F} \stackrel{T\to\infty}{\longrightarrow} 3k_{\rm B}T/E_{\rm F}$.

In comparison, for bosons we have,

$$E = 3Nk_{\rm B}T\frac{g_4(Z)}{g_3(Z)}\left(\frac{\min(T,T_c)}{T_c}\right)^3 \simeq 2.7Nk_{\rm B}T\left(\frac{T}{T_c}\right)^3 \ . \qquad \text{(Bose)} \tag{29.168}$$

Hence, the total energy per boson decreases very rapidly for $T \to 0$. The reason is that the atoms are bosonically encouraged to pile up in the inner region of the harmonic trap.

29.4.3 Entropy and heat capacity

The entropy per particle can be calculated from,

$$S = -k_{\rm B}\int \eta(\varepsilon)\left[w_{T,\mu}\ln w_{T,\mu} + (1-w_{T,\mu})\ln(1-w_{T,\mu})\right]d\varepsilon \tag{29.169}$$

and becomes,

$$S_1 = 4k_{\rm B}\frac{f_4(Z)}{f_3(Z)} - \frac{\mu}{T} = \frac{4E_1}{3T} - \frac{\mu}{T} \ . \tag{29.170}$$

The heat capacity per particle $C_1 = \left(\frac{\partial E_1}{\partial T}\right)_N$ is easily calculated using $Zf'_\eta(Z) = f_{\eta-1}(Z)$,

$$C_1 = 3k_{\rm B}\frac{f_4(Z)}{f_3(Z)} - \frac{3\mu}{T}\left(1 - \frac{f_4(Z)f_2(Z)}{f_3(Z)^2}\right) = \frac{E_1}{T} - \frac{3\mu}{T}\left(1 - \frac{f_4(Z)f_2(Z)}{f_3(Z)^2}\right) \ . \tag{29.171}$$

For fermions well below the Fermi temperature, $T \to 0$, using the Sommerfeld approximation, we calculate,

$$C_1 \stackrel{T\to 0}{\longrightarrow} \frac{3\pi^2}{2}\frac{k_{\rm B}T}{T_{\rm F}} \ . \qquad \text{(Fermi)} \tag{29.172}$$

For high temperature T

$$C_1 \approx 3k_{\rm B} \ . \qquad \text{(Boltzmann)} \tag{29.173}$$

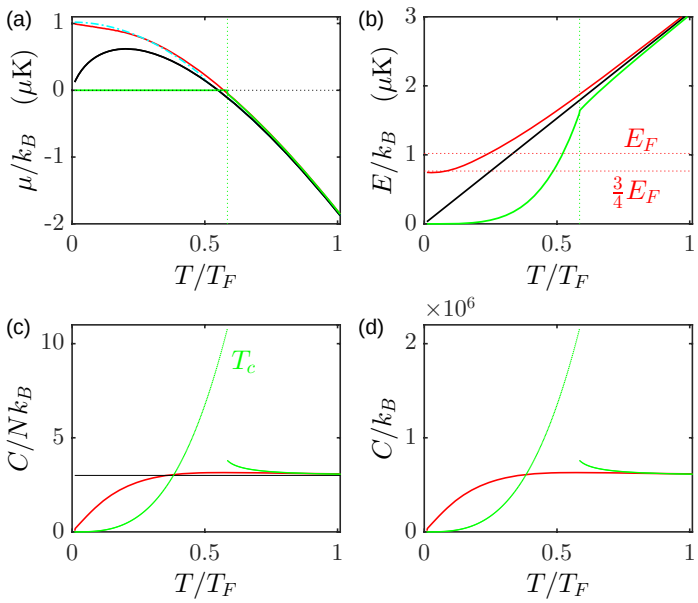

Figure 29.16: (code) Calculation of thermodynamic potentials for Bose (red), Fermi (green), and Boltzmann gases as a function of temperature for a given harmonic trapping potential. The gases are assumed to have same mass, same atom number $N = 200000$, and same trap frequencies $\omega_{\rm ho}/2\pi = 200\,$Hz. (a) Chemical potential, (b) energy, (c) heat capacity per particle, and (d) total heat capacity. The dotted magenta line in (a) shows the chemical potential calculated from the Sommerfeld approximation.

29.4.4 Density and momentum distribution for a Fermi gas

29.4.4.1 Spatial distribution

The density distribution is,

$$n(\mathbf{x}) = \int w_{T,\mu}(\mathbf{x},\mathbf{k})d^3k = \frac{1}{(2\pi)^2}\int \frac{2k^2dk}{e^{\beta[\hbar^2k^2/2m+U(\mathbf{x})-\mu]}+1} \tag{29.174}$$
$$= \frac{1}{(2\pi)^2}\left(\frac{2m}{\hbar^2}\right)^{3/2}\int \frac{\sqrt{\varepsilon}d\varepsilon}{e^{\beta[\varepsilon+U(\mathbf{x})-\mu]}+1} = \frac{1}{(2\pi)^2}\left(\frac{2m}{\beta\hbar^2}\right)^{3/2}\Gamma(3/2)f_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]})\ ,$$

such that,

$$\boxed{n(\mathbf{x}) = \lambda_{\rm th}^{-3}f_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]})} \qquad \text{(Fermi)}\ . \tag{29.175}$$

At low temperatures, $T \to 0$, we can apply the Sommerfeld expansion [144], which to first order gives $\mu \to E_{\rm F}$,

$$n(\mathbf{x}) \approx \frac{1}{(2\pi)^2}\frac{\Gamma(3/2)}{\Gamma(5/2)}\left(\frac{2m}{\hbar^2}[\mu - U(\mathbf{x})]\right)^{3/2} \tag{29.176}$$
$$= \frac{1}{(2\pi)^2}\frac{2}{3}\left(\frac{2m}{\hbar^2}\right)^{3/2}\left(E_{\rm F} - \frac{m}{2}\omega_r^2\rho^2\right)^{3/2} = \frac{8\lambda}{\pi^2}\frac{N}{R_{\rm F}^3}\left(1-\frac{\rho^2}{R_{\rm F}^2}\right)^{3/2}\ .$$

At high temperatures, $T \to \infty$, we should recover the Boltzmann gas situation,

$$n(\mathbf{x}) = \lambda_{\rm th}^{-3} f_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) \tag{29.177}$$
$$\approx \lambda_{\rm th}^{-3} N \left(\beta\hbar\bar{\omega}\right)^3 e^{-\beta U(\mathbf{x})} = \left(\frac{m\beta\bar{\omega}^2}{2\pi}\right)^{3/2} N e^{-\beta m(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 z^2)/2} \ .$$

It's easy to check, $\int n(\mathbf{x}) d^3\mathbf{x} = N$. Introducing the peak density n_0, we obtain,

$$\boxed{n(\mathbf{x}) = n_0 e^{-m\omega^2\rho^2/2k_{\rm B}T}} \qquad \text{(Boltzmann)} \ . \tag{29.178}$$

The *rms*-radius of the distribution is $\sigma_j = \sqrt{k_{\rm B}T/m\omega_j^2}$, which seems contrary to the above results, $\frac{m}{2}\omega_j^2 \left\langle x_j^2 \right\rangle = k_{\rm B}T$. In comparison,

$$\boxed{n(\mathbf{x}) = \lambda_{\rm th}^{-3} g_{3/2}\left[e^{\beta(\mu - U(\mathbf{x}))}\right]} \qquad \text{(Bose gas above } T_c\text{)} \ . \tag{29.179}$$

where $\lambda_{\rm th} = \sqrt{2\pi\hbar^2/mk_{\rm B}T}$ and $a_{\rm ho} = \sqrt{\hbar/m\bar{\omega}}$.

29.4.4.2 Momentum distribution

The momentum distribution is,

$$\tilde{n}(\mathbf{k}) = \int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3x = \frac{1}{(2\pi)^2} \int \frac{r dr dz}{e^{\beta[\varepsilon(k) + m\omega_r^2\rho^2/2 - \mu]} + 1} \tag{29.180}$$
$$= \frac{1}{(2\pi)^3} \int \frac{4\pi\rho^2 d\rho}{e^{\beta[\varepsilon + m\omega_r^2\rho^2/2 - \mu]} + 1}$$
$$= \frac{1}{(2\pi)^2} \left(\frac{2}{\beta m\omega_r^2}\right)^{3/2} \int \frac{\sqrt{t} dt}{e^{\beta[\varepsilon + t - \mu]} + 1} = \frac{1}{(2\pi)^2} \left(\frac{2}{\beta m\omega_r^2}\right)^{3/2} \Gamma(3/2) f_{3/2}(e^{\beta(\mu-\varepsilon)}) \ ,$$

such that,

$$\boxed{\tilde{n}(\mathbf{k}) = \lambda_{\rm th}^{-3} a_{\rm ho}^6 f_{3/2}(e^{\beta(\mu-\varepsilon)})} \qquad \text{(Fermi)} \ . \tag{29.181}$$

At low temperatures, $T \to 0$,

$$\tilde{n}(\mathbf{k}) \approx \frac{1}{(2\pi)^2} \left(\frac{2}{\beta m\omega_r^2}\right)^{3/2} \frac{\Gamma(3/2)}{\Gamma(5/2)} (\beta\left[\mu - \varepsilon\right])^{3/2} \tag{29.182}$$
$$\approx \frac{1}{(2\pi)^2} \left(\frac{2}{m\omega_r^2}\right)^{3/2} \frac{2}{3} \left(E_{\rm F} - \frac{\hbar^2 k^2}{2m}\right)^{3/2} = \frac{8}{\pi^2} \frac{N}{K_{\rm F}^3} \left(1 - \frac{k^2}{K_{\rm F}^2}\right)^{3/2} \ .$$

This can easily be integrated by dimensions,

$$\tilde{n}_{T\to 0}(k_z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \tilde{n}_{cl}(\mathbf{k}) dk_x dk_y = \frac{8}{\pi^2} \frac{N}{K_{\rm F}^3} \int\int_{|k| \le K_{\rm F}} \left(1 - \frac{k^2}{K_{\rm F}^2}\right)^{3/2} dk_x dk_y \tag{29.183}$$
$$= \frac{8}{\pi^2} \frac{N}{K_{\rm F}^3} \int_0^{2\pi} \int_0^{\sqrt{K_{\rm F}^2 - k_z^2}} \left(1 - \frac{k_z^2}{K_{\rm F}^2} - \frac{k_\rho^2}{K_{\rm F}^2}\right)^{3/2} k_\rho dk_\rho d\phi = \frac{16}{5\pi} \frac{N}{K_{\rm F}} \left(1 - \frac{k_z^2}{K_{\rm F}^2}\right)^{5/2} \ .$$

It is easy to check $\int_{-\infty}^{\infty} \tilde{n}_{T\to 0} dk_z = N$, with Maple.

At high temperatures, $T \to \infty$, we should recover the Boltzmann gas situation,

$$\boxed{\tilde{n}(\mathbf{k}) \approx \left(\frac{\hbar^2\bar{\omega}^2}{2\pi m\omega_r^2}\right)^{3/2} N e^{-\beta\varepsilon}} \qquad \text{(Boltzmann)} \ . \tag{29.184}$$

Since ε is the kinetic energy, the *rms*-radius $\sqrt{k^2}$ of this distribution is $\beta\hbar^2\langle k^2\rangle = m$. In comparison,

$$\boxed{\tilde{n}(\mathbf{k}) = \lambda_{\rm th}^{-3} a_{\rm ho}^6 \ g_{3/2}\left[e^{\beta\left(\mu - \mathbf{p}^2/2m\right)}\right]} \qquad \text{(Bose gas above } T_c\text{)} \ . \tag{29.185}$$

Example 231 (*Integrated momentum distribution of a Fermi gas*): To integrate the momentum distribution of finite temperature Fermi gas by dimensions,

$$\begin{aligned}
\tilde{n}(k_z) &= \frac{1}{(2\pi)^3}\left(\frac{2}{\beta m\tilde{\omega}_{\rm ho}^2}\right)^{3/2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_0^{\infty}\frac{4\pi\tilde{r}^2 d\tilde{r}}{e^{\beta\varepsilon-\beta\mu+\tilde{r}^2}+1}dk_y dk_x \qquad (29.186)\\
&= \frac{1}{(2\pi)^3}\left(\frac{2}{\beta m\tilde{\omega}_{\rm ho}^2}\right)^{3/2} 2\pi\int_0^{\infty}\int_0^{\infty}\frac{4\pi\tilde{r}^2 d\tilde{r}}{e^{\beta\hbar^2k_z^2/2m+\beta\hbar^2k_\rho^2/2m-\beta\mu+\tilde{r}^2}+1}k_\rho dk_\rho\\
&= \frac{1}{\pi}\left(\frac{2}{\beta m\tilde{\omega}_{\rm ho}^2}\right)^{3/2}\frac{2m}{\beta\hbar^2}\int_0^{\infty}\int_0^{\infty}\frac{\tilde{k}_\rho d\tilde{k}_\rho}{e^{\beta\hbar^2k_z^2/2m-\beta\mu+\tilde{r}^2+\tilde{k}_\rho^2}+1}\tilde{r}^2 d\tilde{r}\\
&= \frac{1}{\pi}\left(\frac{2}{\beta m\tilde{\omega}_{\rm ho}^2}\right)^{3/2}\frac{2m}{\beta\hbar^2}\frac{1}{2}\int_0^{\infty}\tilde{r}^2\ln\frac{1}{1+e^{-\beta\hbar^2k_z^2/2m+\beta\mu-\tilde{r}^2-k_\rho^2}}\Bigg|_0^{\infty}d\tilde{r}\\
&= \frac{2}{\pi\left(\beta\hbar\tilde{\omega}_{\rm ho}\right)^2}\left(\frac{2}{\beta m\tilde{\omega}_{\rm ho}^2}\right)^{1/2}\int_0^{\infty}\tilde{r}^2\ln\left(1+e^{\beta\mu-\beta\hbar^2k_z^2/2m-\tilde{r}^2}\right)d\tilde{r} \ .
\end{aligned}$$

29.4.4.3 Time-of-flight distribution

To describe time-of-flight images we substitute $\mathbf{k} = m\mathbf{r}/\hbar t$. We obtain the density distribution from a convolution,

$$\begin{aligned}
n_{\rm ToF}(\mathbf{x},t) &= \frac{1}{(2\pi)^3}\int d^3x_0 d^3k\frac{\delta^3(\mathbf{x}-\mathbf{x}_0-\mathbf{p}t/m)}{e^{\beta(\varepsilon(\mathbf{x}_0,\mathbf{p})-\mu)}+1} \qquad (29.187)\\
&= \frac{1}{(2\pi)^3}\int\frac{d^3k}{e^{\beta(\varepsilon(\mathbf{x}+\mathbf{p}t/m,\mathbf{p})-\mu)}+1}\\
&= \frac{1}{(2\pi)^3}\int\frac{dk_x dk_y dk_z}{e^{\beta\Sigma_j\left[\hbar^2k_j^2/2m+\frac{1}{2}m\omega_j^2(x_j+\hbar k_j t/m)^2\right]}/Z+1} \qquad \text{where} \quad j = x,y,z \ . \ .
\end{aligned}$$

We rewrite the exponent,

$$\begin{aligned}
\hbar^2k_j^2/2m + \tfrac{1}{2}m\omega_j^2\left(x_j+\hbar k_j t/m\right)^2 &= \hbar^2k_j^2/2m(1+\omega_j^2t^2) + \omega_j^2 t x_j\hbar k_j + \tfrac{1}{2}m\omega_j^2x_j^2\\
&= \left(\sqrt{\frac{\hbar^2k_j^2}{2m}(1+\omega_j^2t^2)} + \frac{\omega_j^2 t x_j\sqrt{2m}}{2\sqrt{1+\omega_j^2t^2}}\right)^2 + \frac{m\omega_j^2x_j^2}{2(1+\omega_j^2t^2)}\\
&= \xi_j + \frac{m}{2}\breve{\omega}_j^2x_j^2 \ . \qquad (29.188)
\end{aligned}$$

where we defined $\breve{\omega}_i \equiv \omega_i(1+\omega_i^2 t^2)^{-1/2}$. With the substitution $d\xi_j = dk_j\sqrt{\frac{2\hbar^2}{m}\xi_j\left(1+\omega_j^2 t^2\right)}$ we obtain

$$\begin{aligned} n_{\rm ToF}(\mathbf{x},t) &= \frac{1}{(2\pi)^3}\left(\frac{mk_{\rm B}T}{2\hbar^2}\right)^{3/2}\frac{1}{\prod_i\left(1+\omega_i^2t^2\right)}\int\frac{\beta^{3/2}\left(\xi_x\xi_y\xi_z\right)^{-1/2}d\xi_x d\xi_y d\xi_z}{e^{\beta\Sigma_j\left[\xi_j+\frac{m}{2}\breve{\omega}_j^2x_j^2\right]}/Z+1} \\ &= \frac{1}{2^3\pi^{3/2}}\frac{1}{\lambda_{\rm th}^3}\frac{\tilde{\omega}^3}{\bar{\omega}^3}\int\frac{\beta^{3/2}\xi^{-3/2}4\pi\xi^2 d\xi}{e^{\beta\Sigma_j\left[\xi+\frac{m}{2}\breve{\omega}_j^2x_j^2\right]}/Z+1}\ , \end{aligned} \tag{29.189}$$

where $\bar{\omega} \equiv (\omega_x\omega_y\omega_z)^{1/3}$ and $\breve{\omega} \equiv (\breve{\omega}_x\breve{\omega}_y\breve{\omega}_z)^{1/3}$.

$$\boxed{n_{\rm ToF}(\mathbf{x},t) = \frac{1}{\lambda_{\rm th}^3}\frac{\breve{\omega}^3}{\bar{\omega}^3}f_{3/2}\left(e^{\beta\mu-\frac{1}{2}\beta m\Sigma_j\breve{\omega}_j^2x_j^2}\right)}\ . \tag{29.190}$$

For long times-of-flight $t \gg \omega^{-1}$,

$$n_{\rm ToF}(\mathbf{x},t) = \frac{1}{\lambda_{\rm th}^3}\frac{1}{\bar{\omega}^2t^2}f_{3/2}\left(e^{\beta\left(\mu-m\mathbf{x}^2/2t^2\right)}\right) = \left(\frac{m}{\hbar t}\right)^3\tilde{n}(m\mathbf{x}/t)\ . \tag{29.191}$$

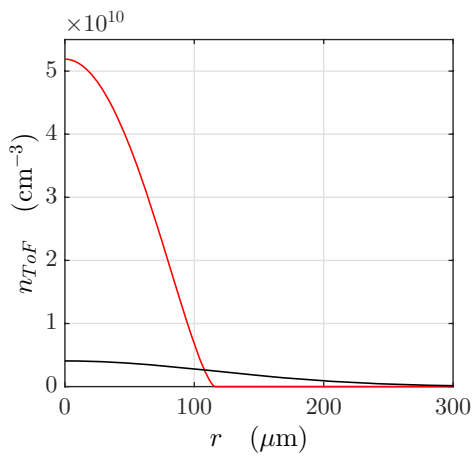

Figure 29.17: (code) Time-of-flight velocity distributions after $T_{\rm ToF} = 2\,$ms of (red) a Li Fermi gas at $T = 0$ with vanishing initial spatial distribution [144] and (black) a thermal gas at $T = T_{\rm F}$.

At low temperatures,

$$\begin{aligned} n_{\rm ToF}(\mathbf{x},t) &= \left(\frac{m}{\hbar t}\right)^3\frac{N}{K_{\rm F}^3}\frac{8}{\pi^2}\left(1-\frac{(m\mathbf{x}/\hbar t)^2}{K_{\rm F}^2}\right)^{3/2} \\ &= \left(\frac{m}{\hbar t}\right)^3\frac{R_{\rm F}^3}{6\pi^2\lambda}\left[1-\left(\frac{R_{\rm F}m\mathbf{x}/\hbar t}{(48N\lambda)^{1/3}}\right)^2\right]^{3/2} \end{aligned} \tag{29.192}$$

At high temperatures,

$$\begin{aligned} n_{\rm ToF}(\mathbf{x},t) &= \frac{1}{\lambda_{\rm th}^3}\frac{1}{\bar\omega^2 t^2} f_{3/2}(e^{\beta(\mu - m\mathbf{x}^2/2t^2)}) \\ &\approx \frac{1}{\lambda_{\rm th}^3}\frac{1}{\bar\omega^2 t^2} e^{\beta(\mu - m\mathbf{x}^2/2t^2)} \\ &\approx \left(\frac{mk_{\rm B}T}{2\pi\hbar^2}\right)^{3/2}\frac{1}{\bar\omega^2 t^2} N\left(\frac{\hbar\bar\omega}{k_{\rm B}T}\right)^3 e^{-\beta m\mathbf{x}^2/2t^2} \approx N\frac{\bar\omega}{t^2}\left(\frac{m}{2\pi k_{\rm B}T}\right)^{3/2} e^{-\beta m\mathbf{x}^2/2t^2} \ . \end{aligned} \tag{29.193}$$

A *rms*-width is,

$$\begin{aligned} \langle r_{\rm ToF}^2\rangle &= \int r^2 n_{\rm ToF}(\mathbf{x},t) d^3\mathbf{x} \\ &= \frac{1}{\lambda_{\rm th}^3}\frac{\check\omega^3}{\bar\omega^3}\int r^2 f_{3/2}\left(e^{\beta\mu - \frac{1}{2}\beta m\Sigma_j \check\omega_j^2 x_j^2}\right) d^3\mathbf{x} \\ &= \frac{2}{m\check\omega_r^2 N}\int \frac{\varepsilon g(\varepsilon) d\varepsilon}{e^{\beta(\varepsilon-\mu)}+1} = \frac{k_{\rm B}T}{m\check\omega_r^2}\frac{g_4(Z)}{g_3(Z)} \ . \end{aligned} \tag{29.194}$$

This shows that the width of the flight-of-time distribution can simply be obtained from the spatial distribution by substituting $\omega \to \omega/\sqrt{1+\omega^2 t^2}$. Of course this does not hold for condensed gases Bose.

Example 232 (*Equipartition theorem*): We find for harmonic traps,

$$\begin{aligned} E_{pot,1} &= \frac{\int U(\mathbf{x}) w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3\mathbf{k}}{\int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3\mathbf{k}} = \frac{1}{(2\pi)^3 N 2}\int \frac{m\omega^2 r^2 d^3\mathbf{x} d^3\mathbf{k}}{e^{\beta\left[\hbar^2 k^2/2m + m\omega^2 r^2/2 - \mu\right]}+1} \\ &= \frac{16}{\pi N \beta^4 (\hbar\omega)^3}\int \frac{u^4 v^2 du dv}{e^{u^2+v^2}/Z+1} \\ &= \frac{1}{(2\pi)^3 N 2m}\int \frac{\hbar^2 k^2 d^3\mathbf{x} d^3\mathbf{k}}{e^{\beta\left[\hbar^2 k^2/2m + m\omega^2 r^2/2 - \mu\right]}+1} = \frac{\int \hbar^2 k^2 w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3\mathbf{k}}{2m\int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3\mathbf{k}} = E_{kin,1} \ . \end{aligned} \tag{29.195}$$

This confirms the *equipartition theorem* for confined particles, which postulates,

$$E = E_{\rm kin} + E_{\rm pot} = 2E_{\rm kin} \ . \tag{29.196}$$

In flight time, however, $E_{\rm pot}$ suddenly vanishes.

29.4.4.4 Calibrating the number of atoms

Experimentally, to calibrate N, we can use either the measured value of $\langle k^2\rangle$ at $T=0$, which gives $\mu = E_{\rm F} = 4E/3$ and consequently,

$$N = \frac{32}{3}\left(\frac{\hbar^2\langle k^2\rangle}{6m\hbar\bar\omega}\right)^3 \ . \tag{29.197}$$

Or we determine the temperature T_g where the Boltzmann gas turns into a Fermi gas $3\mu/4 = 3k_{\rm B}T_g$,

$$N = \frac{32}{3}\left(\frac{k_{\rm B}T_g}{\hbar\bar\omega}\right)^3 \ . \tag{29.198}$$

29.4.5 Density and momentum distribution for anharmonic potentials

29.4.5.1 Width of momentum distribution for anharmonic potentials

If the potential is non-harmonic, the widths of Fermi distributions must in general be calculated numerically. I.e. first $\eta(\varepsilon)$ is determined by integrating for every value of ε the root $\sqrt{\varepsilon - U(\mathbf{x})}$ over the entire volume, where $U(\mathbf{x}) < \varepsilon$, i.e. in the case of cylindrical symmetry,

$$\eta(\varepsilon) = \frac{(2m)^{3/2}}{2\pi\hbar^3} \int \sqrt{\varepsilon - U(r,z)} r dr dz \ . \tag{29.199}$$

Second the chemical potential must also be calculated numerically from $N = \int \eta(\epsilon) \left(e^{\beta(\varepsilon-\mu)} + 1\right)^{-1} d\varepsilon$ by minimizing the function,

$$o(Z) = \left| \beta N - \int \frac{\eta(x/\beta) dx}{e^x/Z + 1} \right| \ . \tag{29.200}$$

Finally, the *rms*-momentum width of a degenerate Fermi-gas is calculated from,

$$\frac{\langle k^2 \rangle}{k_{\mathrm{F}}^2} = \frac{E_1}{E_{\mathrm{F}}} = \frac{1}{N E_{\mathrm{F}}} \int \frac{\varepsilon \eta(\varepsilon) d\varepsilon}{e^{\beta(\varepsilon-\mu)} + 1} \ . \tag{29.201}$$

It is important to note that the temperature cannot be obtained from $\hbar^2 \left\langle k^2 \right\rangle / 2m = 3Nk_{\mathrm{B}}T$ any more. Rather for a given $\langle k^2 \rangle$ the parameter β in the integral (29.199) must be fitted to satisfy the equation.

Alternatively, we may assume a polynomial potential for which the density-of-states can be described by $\eta(\varepsilon) \propto \varepsilon^n$. Then,

$$\frac{\langle k^2 \rangle}{k_{\mathrm{F}}^2} = \frac{1}{E_{\mathrm{F}}} \frac{\int \varepsilon \eta(\varepsilon) \left(e^{\beta(\varepsilon-\mu)} + 1\right)^{-1} d\varepsilon}{\int \eta(\varepsilon) \left(e^{\beta(\varepsilon-\mu)} + 1\right)^{-1} d\varepsilon} = \frac{T}{T_{\mathrm{F}}} \frac{(n+1) f_{n+2}(Z)}{f_{n+1}(Z)} \ , \tag{29.202}$$

For a harmonic potential we recover the energy formula,

$$\frac{\langle k^2 \rangle}{k_{\mathrm{F}}^2} = \frac{3T}{T_{\mathrm{F}}} \frac{f_4(Z)}{f_3(Z)} \ , \tag{29.203}$$

and for hot clouds the classical limit holds,

$$\frac{\langle k^2 \rangle}{k_{\mathrm{F}}^2} = \frac{n+1}{\beta E_{\mathrm{F}}} \ . \tag{29.204}$$

Must for a single dimension the value be divided by three? $\hbar^2 \langle k_j^2 \rangle = 2mk_{\mathrm{B}}T f_4(Z)/f_3(Z)$ setting $\varepsilon = \hbar^2 k^2/m$.

For a harmonic potential $\eta(\varepsilon) \propto \varepsilon^2$ and for a linear potential $\eta(\varepsilon) \propto \varepsilon^{7/2}$. Intermediate values are possible for non isotropic traps, which are linear in some directions and harmonic in others, e.g. for a radially quadrupolar and axially harmonic trap, we expect $\eta(\varepsilon) \propto \varepsilon^3$ and thus $E = 4Nk_{\mathrm{B}}T$. In general, we may have more complicated

situations, where the trap becomes non-harmonic beyond a certain distance from the origin. In those cases, the density-of-states may be approximated by series,

$$\eta(\varepsilon) \propto \varepsilon^2 + \varkappa\varepsilon^3 \ , \tag{29.205}$$

where η is a small parameter, so that,

$$\frac{\langle k^2\rangle}{k_{\rm F}^2} = \frac{1}{E_{\rm F}}\frac{\int(\varepsilon^3+\varkappa\varepsilon^4)(e^{\beta(\varepsilon-\mu)}+1)^{-1}d\varepsilon}{\int(\varepsilon^2+\varkappa\varepsilon^3)(e^{\beta(\varepsilon-\mu)}+1)^{-1}d\varepsilon} = \frac{T}{T_{\rm F}}\frac{3f_4(Z)+12\varkappa f_5(Z)}{f_3(Z)+3\varkappa f_4(Z)} \ , \tag{29.206}$$

which in the classical limit gives rise to energies $E = 3..4Nk_{\rm B}T$ depending on the value of $\varkappa$.

Such effects must be considered when the time-of-flight method is used for temperatures measurements. For example, if we underestimate $\eta(\varepsilon)$ by assuming a harmonic potential at all ε, although the potential is quadrupolar at large $\varepsilon \gg k_{\rm B}T$, we get a wrong estimate for the temperature $T_{wrng} = E/3Nk_{\rm B}$ instead of $T_{corr} = E/4Nk_{\rm B}$.

29.4.5.2 Width of the density distribution for anharmonic potentials

The result also permits to calculate the *rms* spatial width,

$$\sum\nolimits_{j=1}^{3}\frac{m}{2}\omega_j^2\langle x_j^2\rangle = 3k_{\rm B}T\frac{f_4(Z)}{f_3(Z)} \ . \tag{29.207}$$

Let us for simplicity assume $\omega_i = \omega_j$. So in the classical limit,

$$\frac{\langle x_j^2\rangle}{R_{\rm F}^2} = \frac{\langle \mathbf{x}^2\rangle}{3R_{\rm F}^2} = \frac{E_1}{3E_{\rm F}} = \frac{1..1.3T}{T_{\rm F}} \ . \tag{29.208}$$

If the potential is non-harmonic, the widths of Fermi distributions must in general be calculated numerically. We may use the same results for the density-of-states and the chemical potential as for the momentum width calculations. Then,

$$\frac{\langle x_j^2\rangle}{R_{\rm F}^2} = \frac{E_1}{3E_{\rm F}} = \frac{1}{3E_{\rm F}}\frac{\int\varepsilon\eta(\varepsilon)\left(e^{\beta(\varepsilon-\mu)}+1\right)^{-1}d\varepsilon}{\int\eta(\varepsilon)\left(e^{\beta(\varepsilon-\mu)}+1\right)^{-1}d\varepsilon} \ . \tag{29.209}$$

29.4.5.3 Momentum distribution for a classical gas

For high temperatures, $T\to\infty$, we should recover the ideal Boltzmann gas situation, $f_{3/2}\to id$,

$$\begin{aligned}\tilde{n}_{T\to\infty}(\mathbf{k}) &= \frac{1}{(2\pi)^3}\int\frac{4\pi\rho^2 d\rho}{e^{\beta\left[\varepsilon+m\omega_{\rm ho}^2\rho^2/2-\mu\right]}} = \frac{1}{2\pi^2}e^{-\beta(\varepsilon-\mu)}\int e^{-\beta m\omega_{\rm ho}^2\rho^2/2}\rho^2 d\rho \\ &= \left(\frac{1}{2\pi\beta m\omega_{\rm ho}^2}\right)^{3/2} e^{-\beta(\varepsilon-\mu)} = \lambda_{\rm th}^{-3}a_{\rm ho}^6\ e^{\beta(\mu-\varepsilon)} \ .\end{aligned} \tag{29.210}$$

Since the chemical potential satisfies the normalization, $\int\tilde{n}_{T\to\infty}(\mathbf{k})d^3\mathbf{k} = 1$,

$$\tilde{n}_{T\to\infty}(\mathbf{k}) = \left(\frac{1}{2\pi\beta m\omega_{\rm ho}^2}\right)^{3/2} N\left(\frac{\hbar\omega_{\rm ho}}{k_{\rm B}T}\right)^3 e^{-\beta\varepsilon} = N\sqrt{\frac{\hbar^2}{2\pi m k_{\rm B}T}}^{\,3}\ e^{-\hbar^2k^2/2mk_{\rm B}T} \ . \tag{29.211}$$

This is easy to integrate by dimensions, so that,

$$\tilde{n}_{T\to\infty}(k_z) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \tilde{n}_{T\to\infty}(\mathbf{k})dk_x dk_y = N\sqrt{\frac{\hbar^2}{2\pi m k_{\rm B}T}}e^{-\hbar^2 k_z^2/2mk_{\rm B}T} \ . \quad (29.212)$$

The rms-width of this distribution is,

$$\Delta k_z = \frac{\sqrt{mk_{\rm B}T}}{\hbar} \ . \quad (29.213)$$

29.4.6 Signatures for quantum degeneracy of a Fermi gas

Whether an atom is a *fermion* or a *boson* uniquely depends on its total spin. Halfinteger spin particles are fermions, integer spin particles are bosons. E.g. Rb atoms have in the ground state $J = 1/2, I = 7/2$, integer F, and are therefore bosons. Ca^+ ions have $J = 1/2$ and no hyperfine structure so that F is halfinteger, and are therefore fermions. ^{6}Li has half-integer F and is a boson.

For a *composite particle* the quantum statistical nature may depend on the interaction strength of the partners. For weak interaction, e.g. Feshbach the total spins of the partners will couple to a total total spin, which determines the nature of the composite particle. A fermion pairing with a fermion or a boson pairing with a boson will be bosons. A fermion pairing with a boson will be a fermion. Composite trimers may be either bosonic or fermionic depending on the coupling scheme. Can the quantum nature change with the tightness of the binding? What is the total spin of a deeply bound molecule? [767, 118, 360], [372, 445, 729]

29.4.6.1 Optical density of a Fermi gas

With the local density of a Fermi gas,

$$n_{loc} = \frac{k_{\rm F}^3}{3\pi^2} \quad (29.214)$$

the *optical density* is at $T = 0$,

$$\int \sigma n dy = \frac{8\sigma}{\pi^2}\frac{N}{R_{\rm F}^3}\int_{-R_{\rm F}}^{R_{\rm F}}\left(1 - \frac{x^2+y^2}{R_{\rm F}^2} - \frac{z^2}{Z_{\rm F}^2}\right)^{3/2} dy \quad (29.215)$$

$$= \frac{8\sigma}{\pi^2}\frac{N}{R_{\rm F}^3}\left(1 - \frac{x^2}{R_{\rm F}^2} - \frac{z^2}{Z_{\rm F}^2}\right)^{3/2}\int_{-R_{\rm F}}^{R_{\rm F}}\left(1 - \frac{y^2}{R_{\rm F}^2 - x^2 - R_{\rm F}^2 z^2/Z_{\rm F}^2}\right)^{3/2} dy \ .$$

Writing $a = R_{\rm F}/\sqrt{R_{\rm F}^2 - x^2 - R_{\rm F}^2 z^2/Z_{\rm F}^2}$,

$$\int \sigma n dy = \frac{8\sigma}{\pi^2}\frac{N}{R_{\rm F}^2 a^4}\int_{-a}^{a}(1-\tilde{y}^2)^{3/2}d\tilde{y} \quad (29.216)$$

$$= \frac{2\sigma}{\pi^2}\frac{N}{R_{\rm F}^2 a^4}\left(9a\sqrt{1-a^2} - 2a^3\sqrt{1-a^2} + 3\arcsin a\right) \ .$$

In the center, $a = 1$,

$$\int \sigma n dy = \frac{3N\sigma}{\pi R_{\rm F}^2} = \frac{9m\omega_r^2 N}{k_L^2 E_{\rm F}} \ , \quad (29.217)$$

such that for $E_{\rm F} \simeq 1\mu$K we expect $n_{loc} \simeq 4\times 10^{12}$ cm^{-3}.

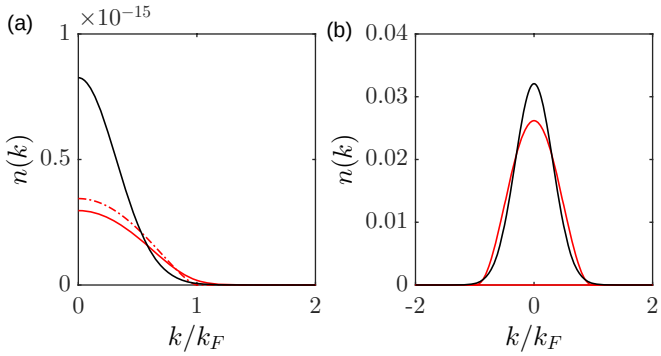

Figure 29.18: (code) (a) Radial momentum distribution and (b) distribution of momentum classes in the direction of k_z for a Fermi gas at $T/T_{\rm F} = 0.2\,\mu$K (red solid), a classical gas (black), and a Fermi gas at $T = 0$ (red dash-dotted).

29.4.6.2 'Pauli blocking' of sympathetic cooling

For a harmonic trap $U = \mu B = m\omega^2 r^2$ the *rms*-radius of a thermal cloud,

$$r_{\rm rms} = \sqrt{\frac{2k_{\rm B}T}{m\omega_r^2}} = \sqrt{\frac{k_{\rm B}T}{\mu\partial_r^2 B}}\,, \tag{29.218}$$

is independent on the atomic mass. This means that a Li and a Rb cloud in the same harmonic trap at the same temperature have the same radius. This ensures good overlap. E.g. at $T = 10\,\mu$K assuming the Rb secular frequencies $\omega_r \simeq 2\pi \times 300\,$Hz and $\omega_z \simeq 2\pi \times 30\,$Hz, we expect $r_{\rm rms} = 16\,\mu$m and $z_{\rm rms} = 160\,\mu$m. However below the temperature $0.5T_{\rm F}$, which is $T_{\rm F} \simeq 1\,\mu$K for $N_{\rm F} = 10^4$, the quantum pressure stops the reduction of the fermion cloud while cooling. This evtl. reduces the overlap with the boson cloud, disconnects the two clouds and stops the evaporative cooling. On the other hand, the interaction energy of the boson cloud also increases its size, when the Rb cloud approaches the critical temperature $T_c \simeq 0.6\,\mu$K for $N_{\rm B} = 10^6$.

The *Pauli blocking* of sympathetic cooling is a signature for the advent of quantum statistics [242, 382, 700]. It is due to a reduced mobility (or better reduced available phase space at collisions) of the atoms and not to be confused with the prohibition of s-wave collisions due to the *Pauli exlusion principle*. Furthermore, elastic collisions are suppressed [241], because atoms cannot be scattered into occupied trap levels [457, 927, 400, 402].

29.4.6.3 Superfluid suppression of sympathetic cooling

The fermions inside the bosonic cloud can be regarded as impurities. If they travel too slow, $v < c$, and if the condensed fraction is too large, the motion will be frictionless and thermalization stops. If they travel fast, quasiparticles are excited, which can be removed by evaporation. With the typical velocity of sound in the BEC $c = \hbar\sqrt{16\pi na}/2m_{\rm B} \approx 2\,$mm/s, or $\frac{m}{2}c^2 \approx k_{\rm B} \times 20\,$nK, we see that this is no real danger.

29.4.6.4 Component separation

If the interspecies interaction h is stronger than the inter-bosonic interaction, the components may separate [698]. Otherwise a small fermionic cloud stays inside the BEC.

29.4.6.5 Excess energy modifies 2nd moment

Independent on any model, just look deviation from Gaussian (interaction energy plays no role for the fermions). Also calculate the 2nd moment $E = \int E_{\text{kin}}(k)n(k)dk$, where $n(k)$ is measured in time-of-flight and $E_{\text{kin}} = \hbar^2 k^2/2m$.

29.4.6.6 Modification of light scattering

The unavailability of final momentum states inhibits scattering in a similar way as the Lamb-Dicke effect. Forward scattering is suppressed, because all small momentum states are occupied. Furthermore, spontaneous emission is suppressed like in photonic band gaps. However, here it is rather an atomic momentum band gap. Could it be that because scattering is suppressed, in-situ images of fermions are hampered?

A condition for this effect to play a role is $k_{\text{rec}} \ll k_{\text{F}}$. For Li the temperature must be $k_{\text{B}}T_{\text{F}} = \hbar^2 k_{\text{F}}^2/2m = \hbar\bar{\omega}(6N)^{1/3} \gg \hbar^2 k_L^2/2m \approx k_{\text{B}} \times 3\,\mu\text{K}$. I.e. we need quite large Fermi gases.

29.4.6.7 Hole heating

Loss processes that remove particles from an atom trap leave holes behind in the single particle distribution if the trapped gas is a degenerate fermion system. The appearance of holes increases the temperature, because of an increase in the energy share per particle if cold particles are removed. Heating is significant if the initial temperature is well below the Fermi temperature. Heating increases the temperature to $T > T_{\text{F}}/4$ after half of the systems lifetime, regardless of the initial temperature. The *hole heating* has important consequences for the prospect of observing Cooper pairing in atom traps.

29.4.7 Fermi gas in reduced dimensions

In n dimensions with the energy $\varepsilon = ap^s + br^t$ [575] we have to generalize the results of the last chapter,

$$N = g\frac{\Gamma\left(\frac{n}{s}+1\right)\Gamma\left(\frac{n}{t}+1\right)}{(2\hbar)^n a^{n/s} b^{n/t}\Gamma\left(\frac{n}{2}+1\right)^2}(k_{\text{B}}T)^{n/s+n/t} f_{n/s+n/t}(z)\ . \tag{29.219}$$

This gives for a harmonic trap where $\varepsilon = \frac{1}{2m}p^2 + \frac{m}{2}\omega^2 r^2$ and with the spin degeneracy factor $g = 1$,

$$N = \left(\frac{k_{\text{B}}T}{\hbar\omega}\right)^n f_n(z)\ . \tag{29.220}$$

The Fermi energy again follows from Sommerfeld's expansion,

$$E_{\text{F}} = (n!N)^{1/n}\hbar\omega\ . \tag{29.221}$$

We now assume a $1D$ potential $V = \frac{m}{2}\omega_z^2 r^2$ embedded in a $3D$ trap. A true $1D$ situation arises when the atoms occupy all low-lying axial levels with the lowest radial vibrational quantum number, i.e. $E_{\rm F} \ll \hbar\omega_r$ which gives,

$$N \ll \frac{\omega_r}{\omega_z} \ . \tag{29.222}$$

Such quantum degenerate $1D$ fermion gases realize the so-called *Luttinger liquid*. One of the hallmarks of Luttinger liquids is *spin-charge separation*.

Example 233 (*Estimations for 1D*): Let us consider a Fermi gas in a very elongated microtrap: $\omega_r = \sqrt{\frac{87}{7}}2\pi \times 1.4\,\text{kHz}$ and $\omega_z = \sqrt{\frac{87}{7}}2\pi \times 15\,\text{Hz}$ for Rb. With $N_{Li} = 10^5$ the Fermi temperature is as high as $T_{\rm F} \simeq 5\,\mu\text{K}$. However we need $N \ll 100$ to see $1D$ features.
Assume $\varepsilon = \frac{1}{2m}p^2 + \frac{m^2}{4}b^4 r^4$,

$$N = \frac{1}{(\hbar b)^n}\frac{\Gamma\left(\frac{n}{4}+1\right)}{\Gamma\left(\frac{n}{2}+1\right)}(k_{\rm B}T)^{3n/4} f_{3n/4}(z)$$
$$E_{\rm F} \approx (\hbar b)^{4/3}\left(N\frac{\Gamma\left(\frac{n}{2}+1\right)\Gamma(\frac{3n}{4}+1)}{\Gamma\left(\frac{n}{4}+1\right)}\right)^{4/3n} \ .$$

In $1D$,

$$N = \frac{1.02}{\hbar b}(k_{\rm B}T)^{3/4} f_{3/4}(z)$$
$$E_{\rm F} \approx 0.87(N\hbar b)^{4/3} \ .$$

29.4.7.1 Fermi degeneracy

A completely analogous treatment to the Bose-gas yield for the case of fermion

$$E = \frac{3}{2}k_{\rm B}TN\left(1 + 2^{-5/2}n\lambda_{\rm th}^3\right) + \dots \ . \tag{29.223}$$

Bosonic ^{4}He has a very different behavior than fermionic ^{3}He. It stays gaseous at very low temperatures and becomes a Fermi gas before becoming fluid. Fermi gases have a higher pressure then classically predicted.

Electrons in a solid are characterized by a high density and a low mass. Hence, $n\lambda_{\rm th}^3 \approx 10^3$. The interelectronic repulsion is canceled by atomic attraction, so that they may be considered an ideal gas. For the density-of-states we get the same formula as for bosons in a box multiplied with the factor 2 to account for the spin degree of freedom. Thus, from

$$N = \int_0^{E_{\rm F}} \rho f_{\rm FD} d\varepsilon \ , \tag{29.224}$$

we derive the Fermi energy $E_{\rm F} = \frac{h^2}{8m}(3N/\pi V)^(2/3)$. The free electron gas is deep in the Fermi regime, the classical statistics may only be used at temperatures above $T > 10^5\,\text{K}$. Hence the energy is temperature-independent and the heat capacity

vanishes, *i.e.* the electron gas does not contribute to the heat capacity of a metal. It is only at very low temperatures of a few K, when the heat capacity of the atomic lattice drops due to the underlying bosonic statistics, that the electrons contribute.

Now, make the metallic box potential having a finite depth. An electron can then leave the metal, if it surmounts the *exit work* $W = -V_{\mathrm{min}} - E_{\mathrm{F}} \simeq 10\,\mathrm{eV}$, which is the difference between the potential depth and the Fermi energy. At high temperatures, the tail of the Fermi-Dirac distribution can leak into the unbound regime, which gives rise to *thermoionic emission*. This feature explains the existence of *contact potentials*: Metals with different W and E_{F} brought into contact exchange charges until their Fermi level is at same height.

Chapter 30

Quantum theory of non-relativistic scalar particle fields

In the preceding sections we mostly restricted to single particles except in the context of the electron shell of atoms, where we presented the Pauli principle in Sec. 34.1. In the context of optical lattices [see Eq. (26.112)] we introduced particle creation and annihilation operators, which we only used to simplify the notation without considering the possible presence of several atoms per lattice site. On the other hand, in the context of the harmonic oscillator (Sec. 24.5), we allowed for large population of a quantum states by quasi-particles identified as phonon or photons (see Sec. 24.6.5). The commutation rule that the field operators of the quasi-particles had to obey was the expression of their bosonic nature.

The question now arises how to treat the presence of several massive particles. In quantum mechanics (differently from classical mechanics) there is no way of differentiating identical particles, and this feature has far-reaching consequences in the way of counting the number of possible microstates that a system may adopt. The field of physics preoccupied with this counting is *quantum statistics*[1].

The quantum mechanical state of a system is described by a global wavefunction, which must somehow be composed from the wavefunctions of all the particles of the system in such a way that the indistinguishability of particles is respected. In mathematical terms this means that the global wavefunction must satisfy some symmetry requirements upon particle exchange. We will show in Sec. 30.1.2 that the system's Hamiltonian must commute with the operator describing particle exchange, and consequently the eigenstates of the Hamiltonian must also be eigenstates of the particle exchange operator. We will find that only *two eigenstates are possible*: a symmetric and an antisymmetric one. Which one of the symmetries the system must exhibit depends on the nature of the particles: Particles behaving symmetrically under particle exchange are called *bosons*, particles behaving antisymmetrically are called fermions. Obviously, the symmetry requirement drastically limits the ways how the single-particle wavefunctions may be joined to a global wavefunction. We will see that bosons have increased probability to occupy the same quantum state, while fermions cannot occupy the same quantum state at all.

[1] See also the derivation of microcanonical partition function in Sec. 29.2.

The quantum statistical nature of particles has far-reaching consequences for the description of many-body problem; when the particles do not interact with each other and even more when interactions between the atoms couple the single-atom states. The formalism that rigorously enforces the exchange symmetry of the many-body wavefunction is known as the *second quantization method*, which will be introduced in Sec. 30.2, although a less confusing name would be occupation number (or Fock) representation. In Sec. 30.2.2 we introduce construction operators for the creation or annihilation of particles in properly symmetrized many-body states and show that the proper quantum statistics is enforced by an algebra defined through the commutation relations between the construction operators.

All this being said it is often not so obvious what is actually meant by *particle*. In most cases, the particles under study are composed from other particles bound together through strong forces. E.g. protons and neutrons bound together by nuclear forces form a nucleus, electrons bound to a nucleus by Coulomb forces form an atom, and atoms bound together by van der Waals forces form a molecule. The bosonic or fermionic nature of composite particles somehow depends on the nature of the components and on the way they interact. We consider a composite system as a *particle* as long it has a well-defined internal structure. If all particles of a system have the same internal structure they are called identical. When their structure brakes down, for instance, induced by strong inter-particle forces, new quantum numbers appear (related to the symmetries of the new structure), but the statistical nature under exchange of complete particles (e.g. all components of an atom) is conserved (see Sec. 30.1.2) [953].

30.1 Quantizing scalar fields

In the following, we will consider specifically consider atomic gases, although most findings can be translated to other systems, such as electrons in a metal.

30.1.1 Wavefunction (anti-)symmetrization for atom pairs

The physical situation under study is here an external potential $\mathfrak{U}(\mathbf{r})$ with the shape of a cubic box of length L and volume $V = L^3$. Introducing periodic boundary conditions, $\psi(x+L, y+L, z+L) = \psi(x, y, z)$, the Schrödinger equation for the spatial motion of a *single atom* in the box can be written as,

$$-\frac{\hbar^2}{2m}\nabla^2\psi_{\mathbf{k}}(\mathbf{r}) = \varepsilon_{\mathbf{k}}\psi_{\mathbf{k}}(\mathbf{r}) \ , \tag{30.1}$$

where the eigenfunctions and corresponding eigenvalues are given by

$$\psi_{\mathbf{k}}(\mathbf{r}) = \tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} \qquad \text{and} \qquad \varepsilon_{\mathbf{k}} = \frac{\hbar^2 k^2}{2m} \ . \tag{30.2}$$

The wavefunctions $\psi_k(\mathbf{r})$ represent *plane wave solutions*, normalized to the volume of the box, with $\mathbf{k}$ the wave vector of the atom, $k = |\mathbf{k}| = 2\pi/\lambda_{dB}$ the wave number, and λ_{dB} the de Broglie wavelength. The periodic boundary conditions give rise to a discrete set of wavenumbers, $k_\alpha = (2\pi/L)n_\alpha$ with $n_\alpha = 0, \pm1, \pm2, ...$ and $\alpha = x, y, z$.

The Hamiltonian for the motion of two atoms with interatomic interaction $\mathfrak{V}(\mathbf{r}_{12})$ and confined by the cubic box potential $\mathfrak{U}(\mathbf{r})$ defined above is given by,

$$\mathfrak{H} = \sum_{i=1,2} \left(-\frac{\hbar^2}{2m_i} \nabla_i^2 + \mathfrak{U}(\mathbf{r}_i) \right) + \mathfrak{V}(\mathbf{r}_{12}) \ . \tag{30.3}$$

When the interatomic interaction can be neglected, the Schrödinger equation takes the form [2],

$$\left(-\frac{\hbar^2}{2m_1} \nabla_1^2 - \frac{\hbar^2}{2m_2} \nabla_2^2 \right) \Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) = E_{\mathbf{k}_1,\mathbf{k}_2} \Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) \ . \tag{30.4}$$

In this limit, we have complete separation of variables so that the pair solution can be written in the form of a product wavefunction

$$\Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) = \tfrac{1}{V} e^{\imath \mathbf{k}_1 \cdot \mathbf{r}_1} e^{\imath \mathbf{k}_2 \cdot \mathbf{r}_2} \ , \tag{30.5}$$

with $\mathbf{k}_i$ the wavevector of atom i, quantized as $k_{i\alpha} = \frac{2\pi}{L} n_{i\alpha}$ with $n_{i\alpha} = 0, \pm 1, \pm 2, \ldots$. This wavefunction is normalized to unity (one pair). The energy and momentum eigenvalues are,

$$E_{\mathbf{k}_1,\mathbf{k}_2} = \frac{\hbar^2 k_1^2}{2m_1} + \frac{\hbar^2 k_2^2}{2m_2} \qquad \text{and} \qquad \mathbf{P} = \hbar \mathbf{k}_1 + \hbar \mathbf{k}_2 \ . \tag{30.6}$$

Hence, the total momentum is not affected by particle exchange, but the energy,

$$m_1 \neq m_2 \qquad \Longrightarrow \qquad E_{\mathbf{k}_1,\mathbf{k}_2} \neq E_{\mathbf{k}_2,\mathbf{k}_1} \qquad \text{for} \qquad \mathbf{k}_1 \neq \mathbf{k}_2 \ . \tag{30.7}$$

Importantly, only for pairs of *unlike* atoms the product wavefunctions (30.5) represent uniquely defined quantum mechanical eigenstates for the eigenvalues $E_{\mathbf{k}_1,\mathbf{k}_2}$. By unlike we mean that the atoms may be distinguished from each other because they are of different species. For *identical* atoms, i.e. atoms of the same species such that $m_1 = m_2$, the situation is fundamentally different. In this case the product wavefunctions (30.5) are degenerate with pair wavefunctions in which the atoms are exchanged,

$$m_1 = m_2 \qquad \Longrightarrow \qquad E_{\mathbf{k}_1,\mathbf{k}_2} = E_{\mathbf{k}_2,\mathbf{k}_1} \qquad \text{also for} \qquad \mathbf{k}_1 \neq \mathbf{k}_2 \ . \tag{30.8}$$

This is called exchange degeneracy (two states, one energy). This phenomenon shows that we cannot determine which atom is in which state by measuring the energy of the pair. Actually, it is fundamentally impossible to distinguish the atoms by any measurement because (by definition of being identical) the expectation values of all observables of the pair are invariant under exchange of the atoms. For identical atoms in the same state ($k_1 = k_2$) the exchange degeneracy is manifestly absent because there is nothing to be distinguished.

The exchange degeneracy implies that any linear combination of the type,

$$\Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) = \frac{1}{V} \frac{1}{\sqrt{|c_1|^2 + |c_2|^2}} (c_1 e^{\imath \mathbf{k}_1 \cdot \mathbf{r}_1} e^{\imath \mathbf{k}_2 \cdot \mathbf{r}_2} + c_2 e^{\imath \mathbf{k}_2 \cdot \mathbf{r}_2} e^{\imath \mathbf{k}_1 \cdot \mathbf{r}_1}) \tag{30.9}$$

[2] We use the letter Ψ to denote single-particle orbitals and the letter Ψ for many-particle orbitals.

represents a properly normalized energy eigenstate of the pair. For example, we can choose $c_1 = 1$ and $c_2 = \pm 1$, yielding,

$$\Psi^{\pm}_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2) = \frac{1}{V}\frac{1}{\sqrt{2}}(e^{\imath\mathbf{k}_1\cdot\mathbf{r}_1}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_2} \pm e^{\imath\mathbf{k}_2\cdot\mathbf{r}_2}e^{\imath\mathbf{k}_1\cdot\mathbf{r}_1}) \ . \tag{30.10}$$

These are called the symmetric and antisymmetric eigenstates of the pair. In the absence of exchange degeneracy (i.e. for $k_1 = k_2$) Eq. (30.5) represents the proper solution. This state is symmetric and unit normalized to start with, so there is no need for explicit symmetrization. Do the Exc. 30.1.3.1.

30.1.2 Identical particles and exchange operator

Linear combinations of the type (30.9) other than the symmetric or the antisymmetric one were never observed for pairs of identical particles. Pair states for particles of integral spin, i.e. *bosons*, are always symmetric and pair states for particles of half-integral spin, i.e. *fermions*, are always antisymmetric. Apparently, *nature does not allow us to neglect the internal degrees of freedom* when studying ensembles of identical particles, which is the essence of the *spin-statistics theorem*. Therefore, we repeat the discussion of the preceding section now including the spin, whose role is to *represent the internal structure of the particle*,

$$\Psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2) \ , \tag{30.11}$$

where $\mathbf{r}_1$ and $\mathbf{r}_2$ are the *position coordinates* and σ_1 and σ_2 the *spin coordinates* of the particles 1 and 2, respectively. The squared modulus of the wavefunction, $|\Psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2)|^2$, corresponds to the probability of observing particle 1 at position $\mathbf{r}_1$ in spin state σ_1 with particle 2 at position $\mathbf{r}_2$ in spin state σ_2. As before, two particles are called identical, if there is no physical way to establish whether or not they particles have been exchanged, a condition which is satisfied for particles with identical internal structure.

To describe the particle exchange, we introduce the *exchange operator* $\mathcal{P}$. For two identical particles in an arbitrary pair state $\Psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2)$ the operator $\mathcal{P}$ is defined by

$$\boxed{\mathcal{P}\Psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2) \equiv \Psi(\mathbf{r}_2,\sigma_2;\mathbf{r}_1,\sigma_1)} \ , \tag{30.12}$$

The effect of this operator is to exchange the particle labels. As *tracking* is impossible in quantum mechanics, we have no physical means to determine whether or not two identical particles have been exchanged, i.e. $|\Psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2)|^2 = |\Psi(\mathbf{r}_2,\sigma_2;\mathbf{r}_1,\sigma_1)|^2$.

Because $\mathcal{P}$ is a norm-conserving operator, $\langle\Psi|\mathcal{P}^\dagger\mathcal{P}|\Psi\rangle = 1$, we have

$$\mathcal{P}^\dagger\mathcal{P} = 1 \ . \tag{30.13}$$

Furthermore, exchanging the particles twice must leave the pair state unchanged. Therefore, we have,

$$\mathcal{P}^2 = 1 \ . \tag{30.14}$$

and writing $\mathcal{P} = \mathcal{P}^\dagger\mathcal{P}\mathcal{P} = \mathcal{P}$, we see that $\mathcal{P}^\dagger$ is *Hermitian*, i.e. the eigenvalues are real and have to ± 1 for the norm to be conserved.

Any pair state $\Psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2)$ can be written as the sum of a *symmetric* $(+)$ and an *antisymmetric* $(-)$ part, as we will demonstrate in Exc. 30.1.3.2. Therefore, the eigenstates of $\mathcal{P}$ span the full Hilbert space of the pair and $\mathcal{P}$ is not only Hermitian but also an *observable*. We do not deepen the discussion about the relation between spin and statistics and only mention that the bosons turn out to have *integral* total spin and the fermions *half-integral* total spin, so that the eigenvalues of the exchange operator are given by,

$$\mathcal{P}\Psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) = e^{-2\pi\imath s}\mathcal{P}\Psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) \ , \tag{30.15}$$

where s is the (semi-)integral spin of the particle. Apparently, for identical particles the *pair wavefunction has to be an eigenfunction of the exchange operator*, i.e. the exchange symmetry of the wavefunction is conserved in time and the pair Hamiltonian $\hat{H}$ is invariant under exchange of the two particles,

$$\boxed{[\mathcal{P}, \hat{H}] = 0} \ , \tag{30.16}$$

so that $\mathcal{P}$ and $\hat{H}$ share a complete set of eigenstates.

30.1.2.1 Fermions and the Pauli principle

Let us study the case of two fermions in the pair state $\Psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2)$. As we are dealing with fermions we know that $\mathcal{P}$ must have the eigenvalue -1. Exploiting the definition (30.12) we get,

$$\Psi(\mathbf{r}_2, \sigma_2; \mathbf{r}_1, \sigma_1) = \mathcal{P}\Psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) = -\Psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) \ . \tag{30.17}$$

For fermions in the same spin state $(\sigma_1 = \sigma_2 \equiv \sigma)$ and at the same position $(\mathbf{r}_1 = \mathbf{r}_2 \equiv \mathbf{r})$ this condition can only be satisfied, if $\Psi(\mathbf{r}, \sigma; \mathbf{r}, \sigma) = -\Psi(\mathbf{r}, \sigma; \mathbf{r}, \sigma)$. Hence, two fermions in the same spin state have *zero probability* to be found at the same position. Therefore, the fermions show correlated motion. Importantly, these *kinematic correlations* occur irrespective of the presence or absence of forces between the particles.

We first look at the symmetry of the spin states. A Clebsch-Gordan decomposition (see Sec. 25.4.1 and 25.4.4),

$$|S, M_S\rangle = \sum_{m_{S_1}, m_{S_2}} |s_1, m_{s_1}; s_2, m_{s_2}\rangle\langle s_1, m_{s_1}; s_2, m_{s_2}|S, M_S\rangle \tag{30.18}$$

yields for the $\frac{1}{2} \times \frac{1}{2}$ two fermion spin system,

$$\begin{aligned} &\left.\begin{aligned} |1,+1\rangle &= |\uparrow\uparrow\rangle \\ |1,0\rangle &= \sqrt{\tfrac{1}{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle) \\ |1,-1\rangle &= |\downarrow\downarrow\rangle \end{aligned}\right\} \quad (S=1) \\ &|0,0\rangle = \sqrt{\tfrac{1}{2}}(|\uparrow\downarrow\rangle - |\uparrow\downarrow\rangle) \qquad (S=0) \end{aligned} \tag{30.19}$$

with total wavefunction (see Sec. 34.1),

$$\Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) = \Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2)|S, M_S\rangle \ . \tag{30.20}$$

Hence, assuming the fermion to be in one of the symmetric spin states, $S = 1$, the orbital wavefunction must be antisymmetric,

$$\boxed{\Psi^A_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|1,M_S\rangle = \frac{1}{V}\sqrt{\frac{1}{2}}(e^{\imath\mathbf{k}_1\cdot\mathbf{r}_1}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_2} - e^{\imath\mathbf{k}_1\cdot\mathbf{r}_2}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_1})|1,M_S\rangle} \,. \tag{30.21}$$

If the fermions are in different orbital states ($\mathbf{k}_1 \neq \mathbf{k}_2$) this gives rise to the above mentioned *kinematic correlations*. For two fermions in the same orbital state ($\mathbf{k}_1 = \mathbf{k}_2 = \mathbf{k}$) the total wavefunction Eq. (30.20) vanishes and also its norm $|\Psi^-_{\mathbf{k},\mathbf{k}}(\mathbf{r}_1,\mathbf{r}_2)|^2$ is zero. Apparently two (identical) fermions cannot occupy the same state; such a coincidence is *entirely* destroyed by interference. This is the essence of *Pauli 's exclusion principle* which holds for all fermions. Starting from an antisymmetric spin state the orbital part should symmetric,

$$\boxed{\Psi^A_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|0,M_S\rangle = \frac{1}{V}\frac{1}{2}(e^{\imath\mathbf{k}_1\cdot\mathbf{r}_1}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_2} + e^{\imath\mathbf{k}_1\cdot\mathbf{r}_2}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_1})(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle)} \,. \tag{30.22}$$

In this case, no restriction is found for the relative positions of the fermions.

We found that the quantum mechanical *indistinguishability* of *identical* particles affects the distribution of particles over the single-particle states. Remarkably, these kinematic correlations happen in the complete absence of forces between the particles: it is a *purely quantum statistical effect*.

Example 234 (*Kinematic correlation in ortho and para isomers of the hydrogen and deuterium*): A consequence of such correlations can be observed in the rotational properties of homonuclear diatomic molecules: depending on the total spin of the molecules either the even or the odd rotational levels are observed. This is illustrated in Tab. 30.1 for the ortho and para isomers of hydrogen (bosonic atoms) and deuterium (fermionic atoms).

Table 30.1: In the ortho and para isomers of the hydrogen and deuterium molecule the distribution over the rotational levels is affected by quantum statistics (only even or odd levels) [953].

			symmetry				
species	J	I	Ψ_{nucl}	Ψ_{rot}	Ψ_{vib}	${}^1\Sigma^+_g$	Ψ_{tot}
ortho-H_2	$1,3,5,..$	1	S	A	S	A	S
ortho-D_2	$0,2,4,..$	1	A	S	S	A	A
para-H_2	$0,2,4,..$	0	A	S	S	A	S
para-D_2	$1,3,5,..$	$0,2$	S	A	S	A	A

30.1.2.2 Bosons and normalization

For bosons the energy eigenfunctions must be symmetric under exchange of the atoms. For spinless bosons (like ^{4}He atoms) or boson in symmetric spin states this suggests to use Eq. (30.9) in the form,

$$\boxed{\Psi^S_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2) = \frac{1}{V}\sqrt{\frac{1}{2}}(e^{\imath\mathbf{k}_1\cdot\mathbf{r}_1}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_2} + e^{\imath\mathbf{k}_1\cdot\mathbf{r}_2}e^{\imath\mathbf{k}_2\cdot\mathbf{r}_1})(|\uparrow\downarrow\rangle - |\uparrow\downarrow\rangle)} \,. \tag{30.23}$$

For $\mathbf{k}_1 \neq \mathbf{k}_2$ this form is appropriate because it is symmetric and also has the proper normalization of unity, $\langle \mathbf{k}_1, \mathbf{k}_2 | \mathbf{k}_1, \mathbf{k}_2 \rangle = 1$ (see Exc. 30.1.3.2). For $\mathbf{k}_1 = \mathbf{k}_2 = \mathbf{k}$ the situation is different. Eq. (30.23) yields norm 2 rather than the physically required value unity. In this case the properly symmetrized and normalized wavefunction is the product wavefunction,

$$\Psi_{\mathbf{k},\mathbf{k}}(\mathbf{r}_1, r_2) = \tfrac{1}{V} e^{\imath \mathbf{k}_1 \cdot \mathbf{r}_1} e^{\imath \mathbf{k}_2 \cdot \mathbf{r}_2} \ , \tag{30.24}$$

with $\langle \mathbf{k}, \mathbf{k} | \mathbf{k}, \mathbf{k} \rangle = 1$. Explicit symmetrization is superfluous because the product wavefunction is symmetrized to begin with. The general form (30.23) may still be used *provided the normalization is corrected for the degeneracy of occupation* (in this case we have to divide by an extra factor $\sqrt{2}$). For bosons in antisymmetric spin states we require the motional wavefunction to be also antisymmetric. Like in the fermion case this gives rise to kinematic correlations.

30.1.2.3 Spin orbitals and Slater determinants

Since internal and external degrees of freedom are related through the spin-statistics theorem it is important to treat them on equal footing by writing the wavefunction in the form of a multi-valued function called *spin orbital*. For an atom at position $|\mathbf{r}\rangle$ and in spin state $|\sigma\rangle$ the spin orbitals are $(2s+1)$-valued functions of the form,

$$\boxed{\psi_{\mathbf{k},s,m_s}(\mathbf{r}, \sigma) = \phi_{\mathbf{k}}(\mathbf{r}) \chi_{s,m_s}(\sigma) = \sqrt{\tfrac{1}{V}} e^{\imath \mathbf{k} \cdot \mathbf{r}} \chi_{s,m_s}(\sigma) \ .} \tag{30.25}$$

With this, Eq. (30.21) can be written in the form of a determinant. Taking, for instance, the spin state $|S, M_S\rangle = |\uparrow, \uparrow\rangle$, we write, introducing the abbreviation $(i) \equiv (\mathbf{r}_i, \sigma_i)$,

$$\Psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) | \uparrow, \uparrow \rangle = \sqrt{\tfrac{1}{2}} \begin{vmatrix} \psi_{\mathbf{k}_1 \uparrow}(1) & \psi_{\mathbf{k}_2 \uparrow}(1) \\ \psi_{\mathbf{k}_1 \uparrow}(2) & \psi_{\mathbf{k}_2 \uparrow}(2) \end{vmatrix} \ . \tag{30.26}$$

Example 235 (*Representation-free notation*): In Dirac's representation-free notation,

$$\phi_{\mathbf{k}}(\mathbf{r}_1) = \langle \mathbf{r}_1 | \mathbf{k} \rangle = \langle \mathbf{r} | \mathbf{k} \rangle_1 \qquad \text{and} \qquad \chi_{s,m_s}(\sigma_1) = \langle \sigma_1 | s, m_s \rangle = \langle \sigma | s, m_s \rangle_1$$

denote the spatial and the spin wavefunction of particle 1 in state $|\mathbf{k}, s, m_s\rangle$. Hence,

$$\psi_{\mathbf{k}}(\mathbf{r}_1, \sigma_1) = \phi_{\mathbf{k}}(\mathbf{r}_1) \chi_{s,m_s}(\sigma_1) = \langle \mathbf{r} | \mathbf{k} \rangle_1 \ \langle \sigma | s, m_s \rangle_1 = \langle \mathbf{r}, \sigma | \mathbf{k}, s, m_s \rangle_1$$

Also, for two particles in states $|\mathbf{k}_i, \mathbf{k}_j\rangle$,

$$\Psi_{\mathbf{k}_i,\mathbf{k}_j}(\mathbf{r}_1, \mathbf{r}_2) = \langle \mathbf{r}_1 | \langle \mathbf{r}_2 | \mathbf{k}_i, \mathbf{k}_j \rangle \ .$$

Hence,

$$\Theta_{\mathbf{k}_i,s_i,m_{si};\mathbf{k}_j,s_j,m_{sj}}(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) = \langle \mathbf{r}_1 | \langle \mathbf{r}_2 | \langle \sigma_1 | \langle \sigma_2 | \mathbf{k}_i, s_i, m_{si}; \mathbf{k}_j, s_j, m_{sj} \rangle \ .$$

Similarly, the symmetric spin state $|1,0\rangle$ in combination with the antisymmetric orbital state $\Psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)$ can be written as the sum of two determinants,

$$\Psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|1,0\rangle = \tfrac{1}{2}\begin{vmatrix}\psi_{\mathbf{k}_1\uparrow}(1) & \psi_{\mathbf{k}_2\downarrow}(1)\\ \psi_{\mathbf{k}_1\uparrow}(2) & \psi_{\mathbf{k}_2\downarrow}(2)\end{vmatrix} + \tfrac{1}{2}\begin{vmatrix}\psi_{\mathbf{k}_1\downarrow}(1) & \psi_{\mathbf{k}_2\uparrow}(1)\\ \psi_{\mathbf{k}_1\downarrow}(2) & \psi_{\mathbf{k}_2\uparrow}(2)\end{vmatrix}\ , \tag{30.27}$$

where $\psi_{\mathbf{k}_j\updownarrow}(i) = \psi_{\mathbf{k}_j}(\mathbf{r}_i)\chi_\updownarrow(\sigma_i)$ with $i = 1,2$. The two-body state (30.22) consisting of an antisymmetric spin state and a symmetric orbital state ($\mathbf{k}_1 = \mathbf{k}_2$) takes the form

$$\Psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|0,0\rangle = \sqrt{\tfrac{1}{2}}\begin{vmatrix}\psi_{\mathbf{k}_1\uparrow}(1) & \psi_{\mathbf{k}_2\uparrow}(1)\\ \psi_{\mathbf{k}_1\uparrow}(2) & \psi_{\mathbf{k}_2\uparrow}(2)\end{vmatrix}\ . \tag{30.28}$$

Indeed, the property of determinants to vanish when two columns or two rows are equal assures that the wavefunction vanishes when two fermions are in the same state α or share the same (position and spin) coordinates $(i) = (\mathbf{r}_i,\sigma_i)$, while exchanging two rows or two columns yields the minus sign required for antisymmetric wavefunctions. One can easily show that any two-body fermion state can be expressed as a linear combination of determinantal spin-orbital states.

Slater generalized this approach to antisymmetrize N-fermion systems,

$$\Psi_\alpha(\mathbf{r}_1,\sigma_1;...;\mathbf{r}_N,\sigma_N) = \sqrt{\tfrac{1}{N!}}\begin{vmatrix}\psi_{\alpha_1}(1) & \cdots & \psi_{\alpha_N}(1)\\ \vdots & \ddots & \vdots\\ \psi_{\alpha_1}(N) & \cdots & \psi_{\alpha_N}(N)\end{vmatrix}\ . \tag{30.29}$$

In this form the determinant is called a *Slater determinant*. It is the simplest generalization of the product wavefunction with the proper symmetry under interchange of any two fermions and consistent the Pauli principle. In Dirac notation the antisymmetrized form of N fermions in states $\alpha_1,...,\alpha_N$ is given by

$$|\alpha_1,...,\alpha_N\rangle \equiv \tfrac{1}{N!}\sum_P(-1)^p P|\alpha_1,...\alpha_N)\ , \tag{30.30}$$

where $|\alpha_1,...,\alpha_N) \equiv |\alpha_1\rangle_1 \otimes |\alpha_2\rangle_2 \otimes ...|\alpha_N\rangle_N$ is the N-body product state of the single-particle states $|\alpha_\kappa\rangle_i$, where $\kappa = 1,..,N$ is the *state index* and $i = 1,..,N$ is the *particle index*. The sum runs over all permutations P of the particles, p being the *parity* (number of transpositions; i.e., binary interchanges) required to realize the permutation starting from an initial ordering fixed by convention. As the sum runs over all permutations, it makes no difference whether we permute all particles or permute all states of the particles. We choose the permutation operator P to *act on the state index* (κ) *and not on the particle index* (i). With this choice, the interchange of the states of particles 1 and 2 is written as,

$$P|\alpha_1,...\alpha_N) = |\alpha_1,...\alpha_N) = |\alpha_1\rangle_1 \otimes ...|\alpha_N\rangle_N\ . \tag{30.31}$$

To assure a uniquely defined sign of the Slater determinants we shall adopt the standard ordering convention of atomic configurations (see below). The state labeling $\alpha_1,...\alpha_N$ represents both the orbital and the spin quantum numbers, e.g. $\psi_{\alpha_\kappa}(\mathbf{r}_i,\sigma_i) = \psi_{\mathbf{k}_1\uparrow}(\mathbf{r}_i,\sigma_i)$ and is called *spin orbital*.

30.1.3 Exercises

30.1.3.1 Ex: Norm of symmetrized wavefunctions

Show that $\psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)$ has the norm $N=1$ for $\mathbf{k}_1 \neq \mathbf{k}_2$, but $N=1$ for $\mathbf{k}_1=\mathbf{k}_2$.

30.1.3.2 Ex: Norm of symmetrized wavefunctions

Confirm that any pair state $\psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2)$ can be written as the sum of a *symmetric* and an *antisymmetric* part.

30.1.3.3 Ex: Symmetrization operators

Show that for $N>2$,

$$\mathcal{S}+\mathcal{A} \neq \mathcal{I} \ .$$

30.2 Occupation number representation

The notation of the previous section calls for simplification. This is realized by introducing construction operators which satisfy an algebra that enforces the quantum statistics. The first construction operators were introduced by Paul Dirac in 1927 [259]. Starting from Maxwell's equations, Dirac quantized the electromagnetic field by treating the eigenmodes of the field as independent harmonic oscillators. The excitation level of the oscillator represents the mode occupation of the field. The raising (lowering) operators of the oscillator serve to construct the field by creation (annihilation) of photons, the quanta of the radiation field, which occupy the modes. The commutation relations between the operators define the algebra that enforces the Bose statistics of the field. This marks the start of quantum field theory. In the same year Pascual Jordan and Oskar Klein showed that the method could be extended to describe quantum many-body systems of bosons satisfying the Schrödinger equation [491]. Adapting the algebra, Jordan and Wigner further extended the method to describe quantum many-body systems of interacting fermionic particles [492]. The above sequence of seminal papers is not complete without the name of Vladimir Fock, who emphasized in 1932 the use of field operators (construction operators for configuration space) [321]. This approach leads to an operator identity resembling the Schrödinger equation, which explains the unfortunate name second quantization for the construction operator formalism. In following sections we give a concise introduction in the construction operator formalism for quantum many-body systems [230, 953].

30.2.1 Number states in the N-body Hilbert space

The notation of the properly symmetrized states can be further compacted by listing only the occupations of the states,

$$|\tilde{n}_\gamma\rangle = |n_1,n_2,...,n_l\rangle \equiv |\underbrace{\mathbf{k}_1,\mathbf{k}_1,...}_{n_1},\underbrace{\mathbf{k}_2,\mathbf{k}_2,...}_{n_2},\underbrace{...,\mathbf{k}_l}_{n_l}\rangle \ , \tag{30.32}$$

where $\gamma = \{1, 1, ..., 2, 2, ..., n_l\}$ with $l \lesssim N$. In this way the states take the shape of *number states*, which are the basis states of the occupation number representation (see next section). For the case of N bosons in the same state $|\mathbf{k}_s\rangle$ the number state is given by $|n_s\rangle \equiv |\mathbf{k}_s, ..., \mathbf{k}_s\rangle$; for a single particle in state $|\mathbf{k}_s\rangle$ we have $|1_s\rangle \equiv |\mathbf{k}_s\rangle$. Note that the Bose symmetrization procedure puts no restriction on the value or order of the occupations $n_1, ..., n_l$ as long as they add up to the total number of particles, $n_1 + n_2 + ... + n_l = N$. For fermions the notation is the same but because the wavefunction changes sign under permutation the order in which the occupations are listed becomes subject to convention (for instance in order of growing energy of the states). Up to this point and in view of Eqs. (??) and (??) the number states (30.32) have normalization,

$$\langle n_1', n_2', ...|n_1, n_2, ...\rangle = \delta_{n_1',n_1}\delta_{n_2',n_2}... \tag{30.33}$$

and closure

$$\sum_{n_1,n_2,...}' |n_1, n_2, ...\rangle\langle n_1, n_2, ...| = \mathbb{I} \ , \tag{30.34}$$

where the prime indicates that the sum over all occupations equals the total number of particles, $n_1 + n_2 + ... + n_l = N$. This is called closure within $\mathcal{H}^N$.

30.2.2 Field operators

30.2.2.1 Position representation

Let us write the total number operator (7.98) in the position representation. Using the closure relation $\mathbb{I} = \int dr|\mathbf{r}\rangle\langle\mathbf{r}|$ we obtain,

$$\hat{N} = \int d^3r \sum_{s,s'} \hat{a}^\dagger_{s'}\langle s'|\mathbf{r}\rangle\langle\mathbf{r}|s\rangle\hat{a}_s = \int d^3r \sum_{s'} \phi^*_{s'}(\mathbf{r})\hat{a}^\dagger_{s'} \sum_{s,s'} \phi_s(\mathbf{r})\hat{a}_s \ , \tag{30.35}$$

where the $\mathbf{r}|s\rangle = \psi_s(\mathbf{r})$ are the wavefunctions of an arbitrary single-particle basis $\{|s\rangle\}$. With this transformation we introduced two operator densities,

$$\boxed{\hat{\psi}(\mathbf{r}) \equiv \sum_s \psi(\mathbf{r})\hat{a}_s \qquad \text{and} \qquad \hat{\psi}^\dagger(\mathbf{r}) \equiv \sum_s \psi^*(\mathbf{r})\hat{a}^\dagger_s} \ , \tag{30.36}$$

which are called field operators in view of their dependence on position. In terms of these field operators the total number operator takes the form,

$$\hat{N} = \int d^3r\hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r}) = \int d^3r\hat{n}(\mathbf{r}) \ , \tag{30.37}$$

where we defined the density operator $\hat{n}(\mathbf{r})$ as the diagonal part of the density matrix operator. The field operators are construction operators that create or annihilate particles at a given position. Let us demonstrate this for $\hat{\psi}(\mathbf{r})$: This field operator is a creation operator because it is defined in terms of creation operators,

$$\hat{\psi}^\dagger(\mathbf{r})|0\rangle = \sum_s \psi^*_s(\mathbf{r})\hat{a}^\dagger_s|0\rangle = \sum_s |s\rangle\langle s|\mathbf{r}\rangle = |\mathbf{r}\rangle \ . \tag{30.38}$$

Using the closure relation, we found that $\hat{\psi}^\dagger(\mathbf{r})$ creates from the vacuum a particle in state $|\mathbf{r}\rangle$; i.e., a particle at position $\mathbf{r}$. Similarly we can show that $\hat{\psi}(\mathbf{r})$ is the corresponding annihilation operator,

$$\hat{\psi}(\mathbf{r})|0\rangle = |0\rangle \ . \tag{30.39}$$

The field operators are important quantities because (at least in principle) the positions of the particles can be measured to arbitrary accuracy in any many-body system, also when the concept of stationary single-particle states has lost meaning due to coupling by the interactions. Do the Exc. 30.2.4.2.

Example 236 (*Atom annihilation in a number state*): Consider the number state $|N_0\rangle$ representing N_0 bosons in the single-particle ground state $|\psi_0(\mathbf{r})\rangle$. In this case, the following relation holds,

$$\langle N_0 - 1|\hat{\psi}(\mathbf{r})|N_0\rangle = \sqrt{N_0}\psi(\mathbf{r}) \ .$$

This expression follows immediately from Eq. (30.36). As only a single single-particle state is occupied, only a single term contributes. If in contrast, $|\Psi_N\rangle = |\tilde{n}_\gamma\rangle$ is a pure number state of the single-particle representation $\{|s\rangle\}$, with many single-particle states are occupied, the expression is replaced by the linear combination,

$$\langle \Psi_{N-1}|\hat{\psi}(\mathbf{r})|\Psi_N\rangle = \sum_s \sqrt{n_s}\psi_s(\mathbf{r}) \ .$$

30.2.2.2 Commutation relations for field operators

It is straightforward to show (see Exc. 30.2.4.3) that the field operators $\hat{\psi}(\mathbf{r})$ and $\hat{\psi}^\dagger(\mathbf{r})$ satisfy commutation relations very similar to those of the construction operators $\hat{a}_s$ and $\hat{a}_s^\dagger$ (see Sec. 30.3),

$$[\hat{\psi}(\mathbf{r}), \hat{\psi}^\dagger(\mathbf{r}')]_\pm = \delta(\mathbf{r}-\mathbf{r}') \qquad \text{and} \qquad [\hat{\psi}(\mathbf{r}), \hat{\psi}(\mathbf{r}')]_\pm = 0 = [\hat{\psi}^\dagger(\mathbf{r}), \hat{\psi}^\dagger(\mathbf{r}')]_\pm \ . \tag{30.40}$$

Like previously, the commutators $(-)$ refer to to case of bosons and the anti-commutators $(+)$ to the case of fermions. Further we have for both bosons and fermions,

$$[\hat{n}(\mathbf{r}), \hat{\psi}^\dagger(\mathbf{r}')]_\pm = \hat{\psi}^\dagger(\mathbf{r})\delta(\mathbf{r}-\mathbf{r}') \qquad \text{and} \qquad [\hat{n}(\mathbf{r}), \hat{\psi}(\mathbf{r}')]_\pm = -\hat{\psi}(\mathbf{r})\delta(\mathbf{r}-\mathbf{r}') \ . \tag{30.41}$$

Using the expression (30.37) for the total number operator the latter commutation relation leads to,

$$[\hat{\psi}^\dagger(\mathbf{r}'), \hat{N}]_\pm = \hat{\psi}(\mathbf{r}) \ . \tag{30.42}$$

30.2.2.3 Number densities

For a many-body system in the state $|\Psi_N\rangle$ the number-density is given by $\langle\Psi_N|\hat{n}(\mathbf{r})|\Psi_N\rangle$. Using the definitions (30.36) the density operator can be expressed in the occupation number representation of the single-particle representation $\{|s\rangle\}$,

$$\hat{n}(\mathbf{r}) = \sum_s \varphi_s^*(\mathbf{r})\hat{a}_s^\dagger \sum_t \varphi_t(\mathbf{r})\hat{a}_t = \sum_s |\varphi_s(\mathbf{r})|^2 \hat{a}_s^\dagger \hat{a}_s + \sum_{s,t\neq s} \varphi_s^*(\mathbf{r})\varphi_t(\mathbf{r})\hat{a}_s^\dagger\hat{a}_t \ . \tag{30.43}$$

We separated the operators into a sum of two contributions: (i) a part diagonal in the number representation of $\{|s\rangle\}$: For pure number states, $|\Psi_N\rangle = |\tilde{n}_\gamma\rangle$, we calculate,

$$\langle\Psi_N|\hat{n}(\mathbf{r})|\Psi_N\rangle = \sum_s |\varphi_s(\mathbf{r})|^2\langle\tilde{n}_\gamma|\hat{n}_s|\tilde{n}_\gamma\rangle = \sum_s |\varphi_s(\mathbf{r})|^2|\hat{n}_s = \bar{n}(\mathbf{r}) \ . \tag{30.44}$$

which corresponds to an eigenvalue equal to the quantum mechanical average (probability density). (ii) the cross terms in this representation,

$$\sum_{s,t\neq s} \varphi_s^*(\mathbf{r})\varphi_t(\mathbf{r})\hat{a}_s^\dagger\hat{a}_t = \hat{n}(\mathbf{r}) - \sum_s |\varphi_s(\mathbf{r})|^2|\hat{n}_s \ . \tag{30.45}$$

For pure number states the cross term contribution vanishes. For linear combinations of number states the cross terms correspond to *density fluctuations* about the average.

30.2.2.4 Hamiltonian expressed by field operators

It is instructive to write the matrix elements $\langle s'|\mathcal{H}_0|s\rangle$ and $\langle s',t'|\mathcal{V}_{int}|s,t\rangle$ in the position representation,

$$\hat{H}_0 = \sum_{s,s'} \int \dots \ . \tag{30.46}$$

30.2.3 Correlations

30.2.4 Exercises

30.2.4.1 Ex: Quantum statistics

Show that the Fermi-Dirac statistics and the Bose-Einstein statistics directly follow from the fermionic, respectively, bosonic commutation rules.

30.2.4.2 Ex: Annihilation operator

Show that $\hat{\psi}(\mathbf{r})|\mathbf{r}\rangle = 0$.

30.2.4.3 Ex: Annihilation operator

Verify the commutation rules (30.40).

30.2.4.4 Ex: Construction operators and occupation number representation

Many body quantum systems are described by symmetrized or antisymmetrized wavefunctions. To keep the calculations manageable this is done in the occupation number representation. Below follows a series of questions with regard to the properties of construction operators. We presume that the standard ordering is represented by the alphabetic ordering of the state indices.
1. For an arbitrary normalized one-body eigenstate $|s\rangle$, i.e. $\langle s'|s\rangle = \delta_{s,s'}$, we have by definition $|s\rangle \equiv |1_s\rangle \equiv |\bar{1}_s\rangle = \hat{a}_s^\dagger|0\rangle$. Comment of the differences of notation.
2. Give the definition of the creation operator $\hat{a}_s^\dagger$ acting on the number state $|n_s, n_t, ..., n_l\rangle$

for bosons.
3. Give the definition of the annihilation operator $\hat{a}_s$ acting on the number state $|n_s, n_t, ..., n_l\rangle$ for bosons.
4. Evaluate $\hat{a}_s^\dagger|0_q, 0_s, ...\rangle$ for fermions.
5. Evaluate $\hat{a}_s^\dagger|1_q, 0_s, ...\rangle$ for fermions.
6. Evaluate $\hat{a}_s^\dagger|1_q, 1_s, ...\rangle$ for fermions.
7. Show that also the vacuum state $|0\rangle$ is normalized.
8. Calculate the norm $\langle 2_s|2_s\rangle$ for bosons and fermions without using the fermion rule $\hat{a}_s^\dagger|1_q, 1_s, ...\rangle = 0$.
9. Derive $[\hat{a}_q^\dagger, \hat{a}_s^\dagger] = 0$ for bosons.
10. Derive $[\hat{a}_q^\dagger, \hat{a}_s^\dagger]_+ = 0$ for fermions.
11. Derive $[\hat{a}_q, \hat{a}_s^\dagger]_+ = \delta_{q,s}$ for fermions.
12. Show that $[\hat{n}_q, \hat{a}_s^\dagger]_\pm = +\hat{a}_s^\dagger\delta_{q,s}$ for both bosons and fermions.

30.2.4.5 Ex: Important commutation relations for boson field operators

Consider a many-body system of particles confined by on external potential $\mathfrak{U}(\mathbf{r})$. At sufficiently low densities this system may be described by the Hamiltonian for a pairwise interacting system,

$$\mathfrak{H} = \sum_i \mathfrak{H}^{(i)} + \tfrac{1}{2}\sum_{i,j} \mathfrak{H}^{(i,j)} \ ,$$

where

$$\mathfrak{H}^{(i)} = \frac{\mathbf{p}_i^2}{2m} + \mathfrak{U}(\mathbf{r}_i)$$

is the free particle contribution of particle i and $\mathfrak{H}^{(i,j)} = \mathfrak{V}(\mathbf{r}_i, \mathbf{r}_j)$ represents the potential energy of interaction between the particles i and j. At sufficiently low temperatures this potential may be approximated by the expression

$$\mathfrak{V}(\mathbf{r}_i, \mathbf{r}_j) = g\delta(\mathbf{r}_i - \mathbf{r}_j) \ ,$$

where $g = (4\pi\hbar^2/m)a$ and a is called the s-wave scattering length. In the occupation number representation for a system of identical particles the Hamiltonian takes the form

$$\hat{H} = \hat{H}^{(1)} + \hat{H}^{(2)} \ ,$$

where

$$\hat{H}^{(1)} = \sum_{s,s'} \hat{a}_{s'}^\dagger \langle s'|\mathfrak{H}^{(1)}|s\rangle \hat{a}_s \ ,$$

and

$$\hat{H}^{(2)} = \tfrac{1}{2}\sum_{t,t'}\sum_{s,s'} \hat{a}_{s'}^\dagger \hat{a}_{t'}^\dagger \langle s', t'|\mathfrak{H}^{(1,2)}|s, t\rangle \hat{a}_t \hat{a}_s \ ,$$

Here $|s\rangle, |s'\rangle \in \{|s\rangle\}$, and $|t\rangle, |t'\rangle \in \{|t\rangle\}$ represent single particle eigenstates of the Hamiltonians $\mathfrak{H}^{(1)}$ and $\mathfrak{H}^{(2)}$, respectively. Rewriting the Hamiltonian in terms of field operators we obtain

$$\hat{H}^{(1)} = \int d\mathbf{r}\hat{\psi}^\dagger(\mathbf{r})\mathfrak{H}_0\hat{\psi}(\mathbf{r})$$

with $\mathcal{H}_0 = p^2/2m + \mathfrak{U}(\mathbf{r})$ and

$$\hat{H}^{(2)} = \tfrac{1}{2}\int d\mathbf{r}d\mathbf{r}'\hat{\psi}^\dagger(\mathbf{r})\hat{\psi}^\dagger(\mathbf{r}')\mathfrak{V}(\mathbf{r},\mathbf{r}')\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r}) \ .$$

Here $\mathbf{r}$ is the position coordinate of a single particle and $\mathbf{r},\mathbf{r}'$ are the position coordinates of a pair of particles. The total number operator is defined as the integral over the density operator

$$\hat{N} = \int d\mathbf{r}\hat{n}(\mathbf{r}) \ .$$

Three commutation relations for boson field operators are crucial for the understanding of the ground state of an interacting bosonic superfluid:

$$\begin{aligned}[\hat{\psi}(\mathbf{r}), \hat{H}^{(1)}] &= \mathfrak{H}_0(\mathbf{p},\mathbf{r})\hat{\psi}(\mathbf{r}) \\ [\hat{\psi}(\mathbf{r}), \hat{H}^{(2)}] &= g\hat{n}(\mathbf{r})\hat{\psi}(\mathbf{r}) \\ [\hat{\psi}(\mathbf{r}), \hat{N}] &= \hat{\psi}(\mathbf{r}) \ .\end{aligned}$$

Derive the above commutation relations.

30.2.4.6 Ex: Amplitude and phase of the order parameter

To analyze the deviations from the stationary state we write the order parameter in a form separating the fluctuations of the amplitude from those of the phase,

$$\Psi(\mathbf{r},t) = |\Psi(\mathbf{r},t)|e^{-\imath\mu t/\hbar + \imath\Phi(\mathbf{r},t)} \ .$$

Using the Bogolubov ansatz the amplitude takes the form

$$|\Psi(\mathbf{r},t)| = \sqrt{n_0(\mathbf{r},t)} \ .$$

The overall phase $\phi(\mathbf{r},t)$ is a real quantity defined as

$$\phi(\mathbf{r},t) \equiv \mu t - \Phi(\mathbf{r},t) \ .$$

The phase $\Phi(\mathbf{r},t)$ is called the *fluctuating phase* and represents the *deviation* from the dynamical phase evolution $\mu t/\hbar$ of the stationary state $\Psi_0(\mathbf{r},t)$. The current density is defined as

$$\mathbf{j}(\mathbf{r},t) = \frac{\imath\hbar}{2m}(\Psi\nabla\Psi^* - \Psi^*\nabla\Psi) \ .$$

a. Derive the following expression for the current density,

$$\mathbf{j}(\mathbf{r},t) = \frac{\hbar}{m}n_0(\mathbf{r},t)\nabla\Phi(\mathbf{r},t) \ .$$

b. Show that the time dependence of the phase of the order parameter can be expressed in the form,

$$-\hbar\frac{\partial\phi}{\partial t} = \frac{\hbar^2}{2m}(\nabla\Phi)^2 + \mathcal{U}(\mathbf{r}) + g|\Psi|^2 - \frac{\hbar^2}{2m}\frac{1}{|\Psi|}\nabla^2|\Psi| \ .$$

Hint: Use the difference of time-dependent GP equation and its complex conjugate.

30.3 Quantum statistics

To describe the time evolution of an isolated quantum gas, in principle, all we need to know is the many-body wavefunction plus the hamiltonian operator. Of course, in practice, these quantities will be known only to limited accuracy. Therefore, just as in the case of classical gases, we have to rely on statistical methods to describe the properties of a quantum gas. This means that we are interested in the occupation probability of quantum many-body states. In view of the convenience of the occupation number representation we ask in particular for the occupation probability P_γ of the number states $|\tilde{n}_\gamma\rangle$. The canonical ensemble introduced in Sec. ?? is not suited for this purpose because it presumes a fixed number of atoms N, whereas the ensemble of number states $\{|\tilde{n}_\gamma\rangle\}$ is defined in grand Hilbert space in which the number of atoms is not fixed. This motivates us to introduce an important variant of the canonical ensemble which is known as the grand canonical ensemble, which has already been extensively discussed in Sec. 29.2.

30.3.1 Exercises

Chapter 31

Appendices to 'Statistical Physics'

31.1 Quantities and formulas in statistical physics

31.1.1 Statistical formulas

Stirling's formula is,

$$\boxed{\ln n! = n \ln n - n + O(\ln n)} \qquad \text{or} \qquad n! \simeq \sqrt{2\pi n} n^n e^{-n} \ . \tag{31.1}$$

Note that $O(\ln n) = \frac{\ln n + \ln 2\pi}{2 \ln 2} + O(\frac{1}{n})$.

31.1.2 Polylogarithm

The polylogarithm (or Joncquière's function) is a function defined as,

$$Li_\eta(Z) \equiv \sum_{t=1}^{\infty} \frac{Z^t}{t^\eta} = \frac{1}{\Gamma(\eta)} \int_0^\infty \frac{x^{\eta-1} dx}{Z^{-1} e^x - 1} \ . \tag{31.2}$$

It serves to express the Bose and Fermi functions used in quantum statistics,

$$g_\eta^{(\pm)}(Z) = \pm Li_\eta(\pm Z) \ . \tag{31.3}$$

The upper sign holds for bosons, the lower for fermions.

31.1.2.1 Riemann zeta-function

The definition of the *Riemann zeta-function* is,

$$g_\xi(1) = \zeta(\xi) \ . \tag{31.4}$$

31.1.2.2 Bose/Fermi function

According to (31.3) the Bose-Fermi functions are given by,

$$g_\xi^{\pm}(Z) = \frac{1}{\Gamma(\xi)} \int_0^\infty \frac{x^{\xi-1} dx}{Z^{-1} e^x \mp 1} = \sum_{\ell=0}^{\infty} \frac{(\pm Z)^\ell}{\ell^\xi} \ , \tag{31.5}$$

where the second equation represents an expansion. The derivative satisfies a useful relationship,

$$\frac{\partial g_\xi^\pm(Z)}{\partial Z} = \sum_{\ell=0}^{\infty} \frac{\partial}{\partial Z} \frac{(\pm Z)^\ell}{\ell^\xi} = \sum_{\ell=1}^{\infty} \frac{\pm(\pm Z)^{\ell-1}}{\ell^{\xi-1}} = \frac{1}{Z} \sum_{\ell=1}^{\infty} \frac{(\pm Z)^\ell}{\ell^{\xi-1}} = \frac{g_{\xi-1}^\pm(Z)}{Z} \ . \tag{31.6}$$

The relationship can also be derive via partial integration exploiting,

$$\frac{d}{dx} \frac{-Z}{Z^{-1}e^x + 1} = \frac{e^x}{(e^x/Z \mp 1)^2} \ . \tag{31.7}$$

We calculate,

$$\frac{\partial g_\xi^\pm(Z)}{\partial Z} = \frac{1}{\Gamma(\xi)} \int_0^\infty \frac{-x^{\xi-1} \frac{\partial}{\partial Z}(Z^{-1}e^x \mp 1)}{(Z^{-1}e^x \mp 1)^2} dx = \frac{1}{Z^2\Gamma(\xi)} \int_0^\infty x^{\xi-1} \frac{e^x}{(Z^{-1}e^x \mp 1)^2} dx \tag{31.8}$$

$$= \frac{x^{\xi-1}e^x}{(e^x/Z \mp 1)^2}\bigg|_0^\infty - \frac{1}{Z^2\Gamma(\xi)} \int_0^\infty (\xi-1)x^{\xi-2} \frac{-Z}{Z^{-1}e^x \mp 1} dx$$

$$= 0 + \frac{1}{Z\Gamma(\xi-1)} \int_0^\infty \frac{x^{\xi-2}}{Z^{-1}e^x \mp 1} dx = \frac{g_{\xi-1}^\pm(Z)}{Z} \ .$$

Another useful relationship is the *Sommerfeld expansion*, which holds for Fermi functions,

$$\int_0^\infty \frac{\eta(x)dx}{e^{x-y}+1} = \int_0^y \eta(x)dx + \int_0^\infty \frac{\eta(y+x)^{\xi-1}dx}{e^x+1} - \int_0^x \frac{\eta(y-x)^{\xi-1}dx}{e^x+1} \tag{31.9}$$

$$\approx \int_0^y \eta(x)dx + \frac{\pi^2}{6}\eta'(x) + ...$$

holds for $z \gg 1$ and yields,

$$f_\xi(e^y) \approx \frac{x^\xi}{\Gamma(\xi+1)} \left(1 + \frac{\pi^2\xi(\xi-1)}{6x^2} + \frac{7\pi^4\xi(\xi-1)(\xi-2)(\xi-3)}{360x^4} + ...\right) \ . \tag{31.10}$$

For small z both functions converge towards,

$$c_\xi(z) = \frac{1}{\Gamma(\xi)} \int_0^\infty \frac{x^{\xi-1}dx}{z^{-1}e^x} = c_{\xi-1}(z) = z \ . \tag{31.11}$$

31.2 Special topic: Microcanonical ensembles

The *microcanonical ensemble* is used to represents the possible microstates of a mechanical system whose total energy E is exactly specified. The system is assumed to be isolated in the sense that it cannot exchange energy or particles with its environment, so that the energy of the system does not change with time. The primary macroscopic variables of the microcanonical ensemble are the total number of particles N in the system, the system's volume V, as well as the total energy E in the system.

In the microcanonical ensemble an equal probability $\rho_{\rm mc}(E)$ is assigned to every microstate whose energy falls within a range centered at E. All other microstates are given a probability of zero. Since the probabilities must add up to 1, the probability is the inverse of the number of microstates W within the range of energy,

$$\boxed{\rho_{\rm mc} = W^{-1}} \ . \tag{31.12}$$

The range of energy ΔE is then reduced in width until it is infinitesimally narrow, still centered at E. The microcanonical ensemble is obtained in the limit of this process. For a given mechanical system (fixed N, V) and a given range of energy, the uniform distribution of probability $\rho_{\rm mc}$ over microstates maximizes the ensemble average $-\langle \ln \rho_{\rm mc} \rangle$.

31.2.1 Density of states

We consider an isolated system with N particles and energy E in a volume V. By definition, such a system exchanges neither particles nor energy with the surroundings. The assumption, that thermal equilibrium implies that the distribution function $\rho_{\rm mc}(q,p)$ of the system is a function of its energy [1],

$$\rho_{\rm mc}(r,p) = \rho(H(r,p)) \qquad , \qquad \frac{d}{dt}\rho_{\rm mc}(r,p) = \frac{\partial \rho}{\partial H}\dot{E} \equiv 0 \ , \tag{31.13}$$

leads to to a constant $\rho_{\rm mc}(r,p)$, which is manifestly consistent with the ergodic hypothesis and the postulate of a priori equal probabilities, i.e. a uniform distribution of microstates.

Now, we consider a small but finite energy shell $[E, E+\Delta E]$ close to the energy surface. The microcanonical ensemble is then defined by,

$$\rho_{\rm mc}(r,p) = \frac{1}{W(E,V,N)} f\left(\tfrac{H(r,p)-E}{\Delta E}\right) \qquad \text{with} \qquad f(x) = \theta(\tfrac{1}{2} - |x|) \ . \tag{31.14}$$

In this expression,

$$\begin{aligned} W(E,V,N) &= \int_{2|H(r,p)-E|<\Delta E} d^{3N}r d^{3N}p \\ &\overset{\Delta E \to 0}{\longrightarrow} \int \delta(E - H(r,p)) \Delta E d^{3N}r d^{3N}p \equiv \eta(E)\Delta E \end{aligned} \tag{31.15}$$

is the phase space volume occupied by the microcanonical ensemble, that is, the volume of the shell bounded by the two energy surfaces with energies E and $E+\Delta E$. The dependence on the spatial volume V comes from the limits of the integration over dr_i,

$$\eta(E) \equiv \int \delta(E - H(r,p)) d^{3N}r d^{3N}p \ . \tag{31.16}$$

[1] See e.g. Lecture by C. Gros.

31.2.2 Entropy

The expectation value of a classical observable $O(q,p)$ can be obtained by averaging over the probability density $\rho(q,p)$ of the microcanonical ensemble,

$$\langle O\rangle = \int \rho_{\rm mc}(r,p)O(r,p)d^{3N}rd^{3N}p = \frac{1}{W(E,V,N)}\int_{2|H(r,p)-E|<\Delta E} O(r,p)d^{3N}rd^{3N}p \ . \tag{31.17}$$

The entropy can, however, not be obtained as an average of a classical observable. It is instead a function of the overall number of available states.

The entropy is, according to ***Boltzmann's postulate***, proportional to the logarithm of the number of available states included in the phase space volume W,

$$S = k_{\rm B}\ln\frac{W(E,V,N)}{W_0(N)} \ . \tag{31.18}$$

Note that the normalization constant $W_0(N)$ introduced above cancels the dimensions of $W(E,V,N)$. Also, the number of particles N being one of the fundamental thermodynamic variables, the functional dependence of $W_0(N)$ on N is important. Let us now discuss the ramification of this postulate.

31.2.2.1 Incompleteness of classical statistics

Importantly, $W_0(N)$ *cannot correctly be derived within classical statistics.* In quantum statistics we will derive later,

$$W_0(N) = h^{3N}N! \ . \tag{31.19}$$

We consider this value also for classical statistics, noting that the factor h^{3N} defines the reference measure in phase space and that $N!$ is the counting factor for states obtained by permuting particles supposed to be indistinguishable. Even though one may be in a range of temperature and density where the motion of molecules can be treated to a very good approximation by classical mechanics, one cannot go so far as to disregard the essential indistinguishability of the molecules; one cannot observe and label individual atomic particles as though they were macroscopic billiard balls.

We will discuss later the Gibbs paradox, which arises when one regards the constituent particles as distinguishable. In this case there would be no factor $N!$ in $W_0(N)$.

31.2.2.2 Entropy as an expectation value

We rewrite the definition (31.18) of the entropy as,

$$S = -k_{\rm B}\int_{2|H(r,p)-E|<\Delta E} \rho_{\rm mc}(r,p)\ln[W_0(N)\rho_{\rm mc}(r,p)]d^{3N}rd^{3N}p \ , \tag{31.20}$$

where we have used that $\rho_{\rm mc}(q,p) = W(E,V,N)^{-1}$ within the energy shell and that

$$\int \rho_{\rm mc}(r,p)d^{3N}rd^{3N}p = \frac{1}{W(E,V,N)}\int_{2|H(r,p)-E|<\Delta E} d^{3N}rd^{3N}p = 1 \ . \tag{31.21}$$

We hence have [2],

$$S = -k_{\rm B} \ln \langle W_0(N) \rho(r,p) \rangle \ . \tag{31.22}$$

31.2.2.3 Thermodynamic consistency of the entropy definition

Since we have introduced the entropy definition in an ad-hoc way, we need to convince ourselves that it describes the thermodynamic entropy as a state function. The entropy must therefore fulfill the requirements of (1) additivity, (2) consistency with the definition of the temperature, (3) consistency with the second law of thermodynamics, and (4) adiabatic invariance.

(1) **Additivity, Gibbs' paradox.** The classical Hamiltonian $H(r,p) = H_{\rm kin}(p) + H_{\rm int}(r)$ is the sum of the kinetic energy and of the particle-particle interaction. The condition,

$$E < H_{\rm kin}(p) + H_{\rm int}(r) < E + \Delta E \tag{31.23}$$

limiting the available phase space volume $W(E,V,N)$ on the energy shell, as defined by (31.15) could then be fulfilled by a range of combinations of $H_{\rm kin}(p)$ and $H_{\rm int}(r)$.

The law of large numbers, which we will discuss in Sec. 31.2.5, implies however that both the kinetic and the interaction energies take well defined values for large particle numbers N.

The interaction between particles involves only pairs of particles, with the remaining $N-2 \simeq N$ particles moving freely within the available volume V. This consideration suggest together with an equivalent argument for the kinetic energy that the *phase space volume of the energy shell scales like*

$$\int_{E<H(r,p)<E+\Delta E} d^{3N}r d^{3N}p = W(E,V,N) \sim V^N w^N(E/N, V/N) \ . \tag{31.24}$$

We will verify this relation in Sec. 31.2.5 for the classical ideal gas. This assumption may not hold in the presence of long range interactions.

Using scaling relation (31.24) for the volume of the energy shell and the assumption that $W_0(N) = h^{3N} N!$ we then find that the entropy defined by (31.18) is extensive,

$$S = k_{\rm B} \ln \frac{V^N w^N(E,V,N)}{h^{3N} N!} = k_{\rm B} N \left(\ln \frac{V}{N} \frac{w}{h^3} + 1 \right) \equiv k_{\rm B} N \, s(E/N, V/N) \ , \tag{31.25}$$

where we have used the Stirling formula (31.1). The *extensivity of the entropy* result in (31.25) from the fact that $V^N/N! \simeq (V/N)^N$. Without the factor $N!$ in $W_0(N)$, which is however not justifiable within classical statistics, the entropy would not be extensive. This is the *Gibbs paradox*.

[2] The entropy coincides hence with Shannon's information-theoretical definition of the entropy, apart from the factors $k_{\rm B}$ and $W_0(N)$.

Two subsystems with particle numbers N_1 and N_2 have identical thermodynamic properties, if their intensive variables are the same, via temperature T, pressure P, particle density N/V, and energy density E/N [see illustration in Fig. 31.1(a)]. It then follows directly from (31.25) that,

$$S(E,V,N) = k_{\rm B}(N_1+N_2)s(E/N,V/N) = S(E_1,V_1,N_1) + S(E_2,V_2,N_2) \ . \tag{31.26}$$

That is, in the case of *identical thermodynamic states the entropy is additive.*

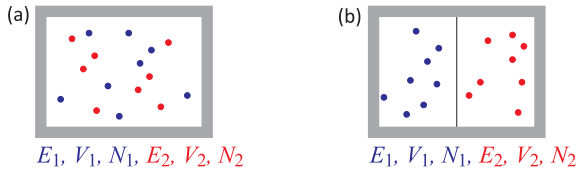

Figure 31.1: (a) Two subsystems sharing the same volume. (b) Two subsystems in thermal contact.

Two systems defined by E_1, V_1, N_1 and respectively E_2, V_2, N_2 in thermal contact may allow energy such that the total energy $E = E_1 + E_2$ is constant [see illustration in Fig. 31.1(b)]. For the argument of the entropy we have then,

$$\frac{W(E,V,N)}{W_0(N)} = \sum_{E_1} \frac{W(E_1,V_1,N_1)}{W_0(N_1)} \frac{W(E-E_1,V_2,N_2)}{W_0(N_2)} \ . \tag{31.27}$$

The law of large numbers tells us that the right-hand-side is sharply peaked at its maximum value $E_1 = E_{\rm max}$ and that the width of the peak has a width scaling with $\sqrt{E_{\rm max}}$. We hence have,

$$S(E_{\rm max}) < S(E,N,V) < k_{\rm B} \ln \sqrt{E_{\rm max}} + S(E_{\rm max}) \ , \tag{31.28}$$

where the first inequality is due to the fact that a single term is smaller than the sum of positive terms. The second inequality in (31.28) results when when one replaces the sum on the r.h.s. of (31.27) by the product of the width $\sqrt{E_{\rm max}}$ of the peak and its height. We have defined in (31.28)

$$S(E_{\rm max}) = k_{\rm B} \ln \frac{W(E_{\rm max},V_1,N_1)}{W_0(N_1)} \frac{W(E-E_{\rm max},V_2,N_2)}{\Gamma_0(N_2)} \ , \tag{31.29}$$

from which follows that the *entropy for two systems in thermal contact is additive* $S(E,V,N) = S(E_1,V_1,N_1) + S(E_2,V_2,N_2)$. Note that the entropy $S(E_{\rm max})$ is extensive and that the term $\sim \ln(E_{\rm max})$ in (31.28) is hence negligible in the thermodynamic limit $N \to \infty$.

(2) **Consistency with the definition of the temperature.** Two systems with entropies $S_1 = S(E_1,V_1,N_1)$ and $S_2 = S(E_2,V_2,N_2)$ in thermal contact may exchange energy in the form of heat, with the total entropy,

$$0 = dS = \frac{\partial S_1}{\partial E_1} dE_1 + \frac{\partial S_2}{\partial E_2} dE_1 \quad , \quad dE_1 = -dE_2 \ , \tag{31.30}$$

becoming stationary at equilibrium. Note that the total energy $E_1 + E_2$ is constant. The equilibrium condition (31.30) implies that there exists a quantity T, denoted temperature, such that

$$\frac{\partial S_1}{\partial E_1} = \frac{1}{T} = \frac{\partial S_2}{\partial E_2} \ . \tag{31.31}$$

The possibility to define the temperature, as above, is hence a direct consequence of the conservation of the total energy. From the microcanonical definition of the entropy one only needs that the entropy is a function only of the internal energy, via the volume $\Gamma(E, V, N)$ of the energy shell, and not of the underlying microscopic equation of motion.

(3) **Consistency with the second law of thermodynamics.** The statistical entropy defined by (31.18) need to satisfy the second law of thermodynamics saying that, '*if an isolated system undergoes a process between two states at equilibrium, the entropy of the final state cannot be smaller than that of the initial state.*'

Both the energy E and the number of particle N stay constant during a *free expansion*, defined by the absence of external heat transfer,

$$\delta Q = 0 \ . \tag{31.32}$$

According to (31.24), the phase space volume $W(E, V, N)$ of the energy shell increases when the volume increases from V_i to V_f. Since according to (31.18) the entropy increases with the phase space volume, while the normalization factor $W_0(N)$ remains constant, we have [3],

$$S(E, V_\mathrm{f}, N) > S(E, V_\mathrm{i}, N) \ . \tag{31.33}$$

(4) **Thickness of the energy shell.** The definition of the entropy (31.18) involves the volume in state space $W(E, V, N)$ of a shell of width ΔE centered around the energy E. It seems therefore that the entropy $S = S_{\Delta E}(E, V, N)$ depends on an unspecified parameter ΔE. The question then arises whether the entropy then not uniquely specified.

For small ΔE we may use the approximation

$$W(E, V, N) \simeq \eta(E)\Delta E \ , \tag{31.34}$$

where $\eta(E)$ is the density of states, as defined previously in (31.16). In order to decide whether a given ΔE is small or large, we compare it to some *reference energy* ΔE_0. One may take e.g. $\Delta E_0 \sim k_\mathrm{B}T$, which corresponds in order of magnitude to the thermal energy of an individual particle.

The entropy involves the logarithm of $W(E, V, N)$,

$$\ln \frac{W(E, V, N)}{W_0} = \ln \frac{\eta(E)\Delta E \Delta E_0}{W_0 \Delta E_0} = \underbrace{\ln \frac{\eta(E)\Delta E_0}{W_0}}_{\propto N} + \ln(\Delta E/\Delta E_0) \ , \tag{31.35}$$

[3] Dynamical constraints (viz bouncing from the wall) are mitigated when the volume is increased. The second law is *equivalent* to saying that the entropy rises when dynamical constraints are eliminated.

where we have taken care that the arguments of the logarithms are dimensionless. The key insight resulting from this representation is that the exact value of both ΔE and ΔE_0 is irrelevant in the *thermodynamic limit* $N \to \infty$ as long as [4],

$$|\ln(\Delta E/\Delta E_0)| \ll N \ . \tag{31.36}$$

We may also consider the limit of large ΔE to the extend that we may substitute the phase space volume $W(E, V, N)$ of the energy shell by the phase space volume of the sphere ,

$$\Phi(E) \equiv \sum_E W(E) = \int_0^E \eta(E) dE \ . \tag{31.37}$$

Now, the volume and surface of a phase space sphere with radius R of dimension $3N$ scale respectively like R^{3N} and R^{3N-1} (see Eq. (31.48) below). This scaling leads to,

$$\ln \Phi(E) \sim \ln R^{3N} = 3N \ln R \tag{31.38}$$

$$\ln W(E, V, N) \sim \ln R^{3N-1}\Delta = (3N-1)\ln R + \ln \Delta \sim 3N \ln R \sim 3N \ln R \ . \tag{31.39}$$

Hence,

$$\ln W(E, V, N) \simeq \ln \Phi(E) \ , \tag{31.40}$$

where we have disregarded the normalization factor W_0, did not perform here an analysis of the units involved, and neglected in particular the reference energy Δ_0.

31.2.3 Calculating with the microcanonical ensemble

In order to perform calculations in statistical physics one proceeds through the following steps:

1. Formulation of the Hamilton function $H(r, p) = H(r_1, ..., r_{3N}, p_1, ..., p_{3N}, z)$, where z is some external parameter, e.g. volume V. $H(r, p)$ specifies the microscopic interactions.

2. Determination of the phase space $W(E, V, N)$ and calculation of the density of states,

$$\rho(E, V, N) = \int d^{3N}r \int d^{3N}p \delta(E - H(r, p)) \ . \tag{31.41}$$

3. Calculation of the entropy from the volume $\Phi(E)$ of the energy sphere via

$$S(E, V, N) = k_{\mathrm{B}} \ln \frac{\Phi(E)}{W_0} \ . \tag{31.42}$$

[4] In quantum statistics this condition is ensured by energy quantization.

4. Calculation of P, T, and μ,

$$\frac{1}{T} = \left(\frac{\partial S}{\partial E}\right)_{V,N} \quad , \quad -\frac{\mu}{T} = \left(\frac{\partial S}{\partial N}\right)_{E,V} \quad , \quad \frac{P}{T} = \left(\frac{\partial S}{\partial V}\right)_{E,N} \quad . \tag{31.43}$$

5. Calculation of the internal energy,

$$E = \langle H \rangle = E(S, V, N) \ . \tag{31.44}$$

6. Calculation of other thermodynamic potentials and their derivatives by application of the Legendre transformation,

$$\begin{aligned} F(T, V, N) &= E - TS \\ H(S, P, N) &= E + PVG(T, P, N) \qquad = E + PV - TS \ . \end{aligned} \tag{31.45}$$

7. One can calculate other quantities than the thermodynamic potentials, for instance, probability distribution functions of certain properties of the system, e.g., momenta/velocity distribution functions. If the phase space density of a system of N particles is given by,

$$\rho_{\rm mc}(r, p) = \rho_{\rm mc}(\mathbf{r}_1, ..., \mathbf{r}_N, \mathbf{p}_1, ..., \mathbf{p}_N) \ , \tag{31.46}$$

then the probability of finding particle i with momentum $\mathbf{p}$ is,

$$\begin{aligned} \rho_{i,{\rm mc}(\mathbf{p})} &= \langle \delta(\mathbf{p} - \mathbf{p}_i) \rangle \\ &= \int d^3q_1 ... d^3q_N d^3p_1 ... d^3p_N \rho_{\rm mc}(\mathbf{r}_1, ..., \mathbf{r}_N, \mathbf{p}_1, ..., \mathbf{p}_i, ..., \mathbf{p}_N) \delta(\mathbf{p} - \mathbf{p}_i) \ . \end{aligned} \tag{31.47}$$

Example 237 (*Hyperspheres*): Let us calculate for later purposes the volume,

$$\Omega_n(R) = \int_{\sum_{i=1}^n x_i^2 < R^2} d^n x = R^n \Omega_n(1) \tag{31.48}$$

of a hypersphere of n dimensions and radius R (see Exc. 9.3.8.8). We notice that the volume $\Omega_n(1)$ of the sphere with unity radius enters the determinant of the Jacobian when transforming *Euclidean to spherical coordinates* via,

$$d^n x = dx_1 ... dx_n = \Omega_n(1) n R^{n-1} dR \ . \tag{31.49}$$

This transformation is valid if the integrand depends exclusively on the radius R.
In order to evaluate (31.48) we make use of the fact that we can rewrite the *Gaussian integral*,

$$\int_{\mathbb{R}^3} e^{-(x_1^2 + ... + x_N^2)} dx_1 ... dx_n = \pi^{n/2} \tag{31.50}$$

as

$$\begin{aligned} \pi^{n/2} &= \int_0^\infty e^{-R^2} \Omega_n(1) n R^{n-1} dR \\ &= n\Omega_n(1) \int_0^\infty e^{-y} y^{(n-1)/2} \frac{dy}{2\sqrt{y}} = \tfrac{n}{2} \Omega_n(1) \int_0^\infty e^{-y} y^{n/2-1} dy \ , \end{aligned} \tag{31.51}$$

where we have used $\sum_i x_i^2 = R^2 \equiv y$ and $2RdR = dy$. With the definition,

$$\Gamma(z) = \int_0^\infty x^{z-1} e^{-x} dx \ , \tag{31.52}$$

of the Γ-function, comparing (31.50) and (31.50) we obtain,

$$\Omega_n(1) = \frac{\pi^{n/2}}{(n/2)\Gamma(n/2)} \ . \tag{31.53}$$

Note that we evaluated the volume of a hypersphere for formally dimensionless variables x_i.

31.2.4 Classical ideal gas

We consider now the steps given in the last section in order to analyze an ideal gas of N particles in a volume V, defined by the Hamilton function,

$$H(r,p) = \sum_{i=1}^N \frac{\mathbf{p}_i^2}{2m} \ , \tag{31.54}$$

where m is the mass of the particles.

We will make use of (31.40), namely that the volume $W(E,V,N)$ of the energy shell $E < H < E + \Delta E$ can be replaced by the volume of the energy sphere,

$$\Phi(E) = \iint\limits_{\sum_{i=1}^N p_i^2 \leq 2mE} d^{3N}r d^{3N}p = V^N \int_{\sum_{i=1}^N p_i^2 \leq 2mE} d^{3N}r = V^N W_{3N}(\sqrt{2mE}) \ , \tag{31.55}$$

when it comes to calculating the entropy in the thermodynamic limit. We have identified the last integral in (31.55) as the volume of a $3N$-dimensional sphere with radius $\sqrt{2mE}$. Using (31.48) and (31.51),

$$W_{3N}(\sqrt{2mE}) = \sqrt{2mE}^{3N} W_{3N}(1) \qquad \text{with} \qquad W_{3N}(1) = \frac{\pi^{3N/2}}{(3N/2)\Gamma(3N/2)} \ , \tag{31.56}$$

we obtain,

$$\Phi(E) = V^N W_{3N}(1) \sqrt{2mE}^{3N} \ . \tag{31.57}$$

31.2.4.1 Entropy

Using (31.57) we find,

$$S(E,V,N) = k_\mathrm{B} \ln \frac{\Phi(E)}{h^{3N} N!} = k_\mathrm{B} \ln \frac{V^N W_{3N}(1) \sqrt{2mE}^{3N}}{h^{3N} N!} \tag{31.58}$$

for the entropy of a classical gas. It is easy to check, that the argument of the logarithm is dimensionless as it should be.

For large $N \gg 1$, one may use the Stirling formula (31.1), to expand the Γ-function for integer argument as,

$$\ln \Gamma(N) = \ln(N-1)! \simeq (N-1)\ln(N-1) - (N-1) \simeq N \ln N - N \ , \tag{31.59}$$

in order to simplify the expression for $S(E,V,N)$. Using (8.19) we perform the following algebraic transformations to $W_{3N}(1)$,

$$\begin{aligned}\ln W_{3N}(1) &= \ln \frac{\pi^{3N/2}}{(3N/2)\Gamma(3N/2)} = \tfrac{3N}{2}\ln\pi - \left[\tfrac{3N}{2}\ln\tfrac{3N}{2} - \tfrac{3N}{2}\right] \\ &= N\left[\left(\tfrac{2\pi}{3N}\right)^{3/2} + \tfrac{3}{2} + O(\tfrac{\ln N}{N})\right] .\end{aligned} \tag{31.60}$$

We insert this expression in Eq. (31.58) and obtain,

$$S = k_{\mathrm{B}}N\left[\ln\frac{B(2mE)^{3/2}}{h^3} + \ln\left(\frac{2\pi}{3N}\right) + \frac{3}{2} - \underbrace{(\ln N - 1)}_{\ln N!/N}\right] . \tag{31.61}$$

Rewriting (31.61) as,

$$S = \mathrm{B}N\left\{\ln\left[\left(\frac{4\pi mE}{3h^2N}\frac{V}{N}\right)^{3/2}\right] + \frac{5}{2}\right\} , \tag{31.62}$$

we obtain the *Sackur-Tetrode equation*.

Now we can differentiate the Sackur-Tetrode equation to obtain the *caloric equation of state* (19.149) for the ideal gas,

$$\frac{1}{T} = \left(\frac{\partial S}{\partial E}\right)_{V,N} = Nk_{\mathrm{B}}\frac{3}{2}\frac{1}{E} \quad , \quad E = \tfrac{3}{2}Nk_{\mathrm{B}}T , \tag{31.63}$$

as well as the *thermal equation of state* for the ideal gas,

$$\frac{P}{T} = \left(\frac{\partial S}{\partial V}\right)_{E,T} = \frac{k_{\mathrm{B}}N}{V} \quad , \quad PV = Nk_{\mathrm{B}}T . \tag{31.64}$$

Example 238 (*'Classical' Sackur-Tetrode equation*): Note that, if we hadn't considered the factor $N!$ when working out the entropy, then one would obtain,

$$S_{\mathrm{classical}} = k_{\mathrm{B}}N\left\{\ln\left[\left(\frac{4\pi mE}{3h^2N}V\right)^{3/2}\right] + \frac{3}{2}\right\} , \tag{31.65}$$

With this definition, the entropy is non-additive, i.e.,

$$S(E,V,N) \neq Ns(\tfrac{E}{N},\tfrac{V}{N}) , \tag{31.66}$$

as mentioned previously. This was realized by *Gibbs paradox*, who introduced the factor $N!$ and attributed it to the fact that the particles are indistinguishable.

31.2.5 Quantum statistics

The quantum mechanics the microcanonical density operator and partition function are given by,

$$\boxed{\begin{aligned}\hat{\rho}_{\mathrm{mc}} &= \tfrac{1}{\Xi_{\mathrm{mc}}}\textstyle\sum_k |\psi_k\rangle f(\tfrac{E-\varepsilon_k}{\Delta E})\langle\psi_k| \\ \Xi_{\mathrm{mc}} &= \textstyle\sum_k f(\tfrac{E-\varepsilon_k}{\Delta E}) \qquad \text{with} \qquad f(x) = \theta(\tfrac{1}{2} - |x|)\end{aligned}} . \tag{31.67}$$

31.2.5.1 Applicability

Because of its connection with the elementary assumptions of equilibrium statistical mechanics (particularly the postulate of a priori equal probabilities), the microcanonical ensemble is an important conceptual building block in the theory and is sometimes considered to be the fundamental distribution of equilibrium statistical mechanics. It is also useful in some numerical applications, such as molecular dynamics. On the other hand, most nontrivial systems are mathematically cumbersome to describe in the microcanonical ensemble, and there are also ambiguities regarding the definitions of entropy and temperature. For these reasons, other ensembles are often preferred for theoretical calculations.

The applicability of the microcanonical ensemble to real-world systems depends on the importance of energy fluctuations, which may result from interactions between the system and its environment as well as uncontrolled factors in preparing the system. Generally, fluctuations are negligible if a system is macroscopically large, or if it is manufactured with precisely known energy and thereafter maintained in near isolation from its environment. In such cases the microcanonical ensemble is applicable. Otherwise, different ensembles are more appropriate, such as the canonical ensemble (fluctuating energy) or the grand canonical ensemble (fluctuating energy and particle number).

31.2.5.2 Phase transitions and thermodynamic analogies

Under their strict definition, phase transitions correspond to non-analytic behavior in the thermodynamic potential or its derivatives. Using this definition, phase transitions in the microcanonical ensemble can occur in systems of any size. This contrasts with the canonical and grand canonical ensembles, for which phase transitions can occur only in the thermodynamic limit– i.e. in systems with infinitely many degrees of freedom. Roughly speaking, the reservoirs defining the canonical or grand canonical ensembles introduce fluctuations that 'smooth out' any non-analytic behavior in the free energy of finite systems. This smoothing effect is usually negligible in macroscopic systems, which are sufficiently large that the free energy can approximate non-analytic behavior exceedingly well. However, the technical difference in ensembles may be important in the theoretical analysis of small systems.

The volume entropy S_{vol} and associated temperature T_{vol} form a close analogy to thermodynamic entropy and temperature. It is possible to show exactly that,

$$dE = T_{\text{vol}} dS_{\text{vol}} - \langle P \rangle dV \ , \tag{31.68}$$

where $\langle P \rangle$ is the ensemble average pressure, as expected for the first law of thermodynamics. A similar equation can be found for the surface entropy and its associated temperature T_{sur}, however the 'pressure' in this equation is a complicated quantity unrelated to the average pressure.

The microcanonical T_{vol} and T_{sur} are not entirely satisfactory in their analogy to temperature. Outside of the thermodynamic limit, a number of artefacts occur.

- Nontrivial result of combining two systems: Two systems, each described by an independent microcanonical ensemble, can be brought into thermal contact

and be allowed to equilibriate into a combined system also described by a microcanonical ensemble. Unfortunately, the energy flow between the two systems cannot be predicted based on the initial T's. Even when the initial T's are equal, there may be energy transferred. Moreover, the T of the combination is different from the initial values. This contradicts the intuition that temperature should be an intensive quantity, and that two equal-temperature systems should be unaffected by being brought into thermal contact.

- Strange behavior for few-particle systems: Many results, such as the microcanonical equipartition theorem acquire a one- or two-degree of freedom offset when written in terms of T_{sur}. For a small systems this offset is significant, and so if we make S_{sur} the analogue of entropy, several exceptions need to be made for systems with only one or two degrees of freedom.

- Spurious negative temperatures: A negative T_{sur} occurs whenever the density of states decreases with energy. In some systems the density of states is not monotonic in energy, and so T_{sur} can change sign multiple times as the energy is increased. The preferred solution to these problems is to avoid using the microcanonical ensemble. In many realistic cases a system is thermostatted to a heat bath so that the energy is not precisely known. Then, a more accurate description is the canonical ensemble or grand canonical ensemble, both of which have complete correspondence to thermodynamics.

31.2.6 Exercises

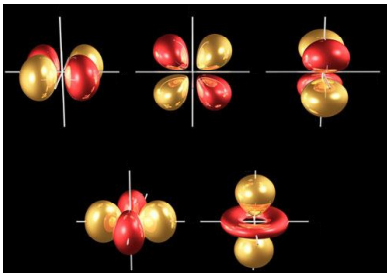
31.2.6.1 Ex: Ideal gas in a uniform gravitational field in the microcanonical description

Calculate the microcanonical phase space volume, the velocity distribution, and the kinetic temperature explicitly for an ideal gas in a uniform gravitational field.

Part VI

Atomic and Molecular Physics

Preface to the part *Atomic and Molecular Physics*



In quantum mechanics (see Chp. 25) we have learned how to handle rotationally symmetric systems and deduced Bohr's atom model for the case of Coulombian potentials. Real atoms are of course much more complicated and exhibit a complex energy level structure, which necessitates a deepening of the theory of atomic physics.

Important corrections arise from relativistic effects, such as the fact that electrons have a spin. These corrections will be presented in chapter 32. In Chp. 33 we will discuss the impact of external electric and magnetic fields on the atomic level structure. When several electrons are present in the shell, their mutual interaction and quantum statistical effects (already introduced in Chp. 29) must be accounted for, as will be shown in 34. Interactions between atoms may lead to the formation of molecules, rudimentarily discussed in Chp. 35 or collisions discussed in Chp. 36.

Chapter 32

Electron spin and the atomic fine structure

The energy structure of hydrogen calculated by Bohr's model from the non-relativistic Hamiltonian agrees very well with the experimental measurements. However, in high-resolution experiments, small deviations were observed as energy shifts and splittings of spectral lines. These deviations, called *fine structure*, were not predicted by theory, which suggests that there are weak additional effects that do not strongly affect the position of the spectral lines but remove the energy degeneracy of the orbital quantum number ℓ: $E = E_{n,\ell}$.

As a possible explanation we have the fact that the electrons present relativistic mass and momentum. In order to estimate the relevance of relativistic corrections let us estimate the electron velocity in the fundamental hydrogen states given by $E_1 = -\hbar^2/2m_e a_{\mathrm{B}}^2$. Using the definitions of the Bohr radius, $a_{\mathrm{B}} = 4\pi\varepsilon_0\hbar^2/(m_e e^2)$, and the *fine structure constant*

$$\alpha \equiv \frac{e^2}{4\pi\epsilon_0\hbar c} \simeq \frac{1}{137} \ , \tag{32.1}$$

we obtain,

$$v = \sqrt{\frac{2E_1}{m_e}} = \frac{\hbar}{m_e a_{\mathrm{B}}} = \frac{e^2}{4\pi\varepsilon_0\hbar} = \alpha c \ , \tag{32.2}$$

which shows that the electron velocity is very high and that relativistic effects may indeed be *non negligible*.

32.1 The Dirac equation

32.1.1 The Klein-Gordon equation for bosons

The Schrödinger equation for a free particle is based on the non-relativistic energy-momentum dispersion relation,

$$E = \frac{p^2}{2m_e} \ . \tag{32.3}$$

and the definitions of the quantum operators for energy and momentum,

$$\hat{E} = \imath\hbar\frac{\partial}{\partial t} \qquad \text{and} \qquad \hat{\mathbf{p}} = -\imath\hbar\nabla \ . \tag{32.4}$$

As already discussed in Sec. 23.3.2 we can, in order to find a relativistic wave equation, try the approach of inserting the quantum operators into the relativistic energy-momentum relation [1].

$$E^2 = c^2p^2 + m_e^2c^4 \ . \tag{32.5}$$

We obtain,

$$\boxed{\left[\frac{1}{c^2}\frac{\partial^2}{\partial t^2} - \nabla^2 + \left(\frac{m_e c}{\hbar}\right)^2\right]\psi = 0} \ . \tag{32.6}$$

This is the *Klein-Gordon equation*. The stationary solution of this equation is a spherical wave,

$$\psi = \psi_0 \frac{1}{r} e^{-2\pi r/\lambda_C} \ , \tag{32.7}$$

where $\lambda_C = h/m_e c$ is the *Compton wavelength*. We show this in Exc. 32.1.5.1. For example, in the case of heavy bosonic particles, such as a field of π-mesons, ψ is the *Yukawa potential*.

In the framework of the *standard model*, it is believed that matter is composed of two fundamental types of particles, bosons and fermions. Bosons are exchanged between fermions conveying the interaction between them. A typical example is the one of two electrons whose Coulomb interaction is mediated by the exchange of photons. Bosons obey the Klein-Gordon equation, fermions the Dirac equation derived in the following section.

32.1.2 The Dirac equation for fermions

In 1928 Paul Dirac, at the age of 26, developed an approach to a relativistic wave equation which differed from the Klein-Gordon equation. Motivated by the observation that the photon, being the relativistic particle *par excellence*, obeys a linear energy-momentum relation of the form $\omega = ck$, he attempted to derive a linear dispersion relation in E and p for heavy particles via the following ansatz:

$$E = \alpha_0 m_e c^2 + \alpha_1 c p_x + \alpha_2 c p_y + \alpha_3 c p_z \ . \tag{32.8}$$

Replacing energy and momentum with their respective operators [2],

$$\imath\hbar\frac{\partial}{\partial t}\phi = \alpha_0 m_e c^2 \phi - \imath c\hbar\left(\alpha_1\frac{\partial}{\partial x} + \alpha_2\frac{\partial}{\partial y} + \alpha_3\frac{\partial}{\partial z}\right)\phi \ . \tag{32.9}$$

We must now ensure that the relativistic energy-momentum condition (32.5) be satisfied.

Example 239 (*Derivation of the Dirac equation*): Taking the square on the right-hand side of the equation (32.9),

$$\begin{aligned}
&[\alpha_0 m_e c^2 - \imath c\hbar(\alpha_1\partial_x + \alpha_2\partial_y + \alpha_3\partial_z)][\alpha_0 m_e c^2 - \imath c\hbar(\alpha_1\partial_x + \alpha_2\partial_y + \alpha_3\partial_z)] \\
&= m_e^2c^4\alpha_0^2 - \imath c\hbar m_e c^2[(\alpha_0\alpha_1 + \alpha_1\alpha_0)\partial_x + (\alpha_0\alpha_2 + \alpha_2\alpha_0)\partial_y + (\alpha_0\alpha_3 + \alpha_3\alpha_0)\partial_z] \\
&\quad - c^2\hbar^2[\alpha_1^2\partial_x^2 + \alpha_2^2\partial_y^2 + \alpha_3^2\partial_z^2] \\
&\quad - c^2\hbar^2[(\alpha_1\alpha_2\partial_x\partial_y + \alpha_2\alpha_1\partial_y\partial_x) + (\alpha_2\alpha_3\partial_y\partial_z + \alpha_3\alpha_2\partial_z\partial_y) + (\alpha_3\alpha_1\partial_z\partial_x + \alpha_1\alpha_3\partial_x\partial_z)] \ .
\end{aligned}$$

[1] Using the covariant notation with $p_\mu \equiv (E/c, \mathbf{p})$: $p_\mu p^\mu = E^2/c^2 - p^2 = m_e^2c^2$ is a Lorentz invariant.

[2] We introduce the abbreviation $\partial_k \equiv \frac{\partial}{\partial x_k}$

For this expression to be identical to the relativistic energy-momentum condition (32.5),

$$m_e^2c^4 - c^2\hbar^2[\partial_x^2 + \partial_y^2 + \partial_z^2] \ ,$$

we need to postulate for all $i = 0, .., 3$, that $\alpha_i\alpha_j + \alpha_j\alpha_i = 2\delta_{ij}$.

Obviously, the condition

$$[\alpha_i, \alpha_j]_+ = 2\delta_{ij} \tag{32.10}$$

can not be satisfied if the α_i are numbers. The idea of Dirac was to interpret the variables α_i as matrices. These matrices act as operators on appropriate states, which are no longer scalar wavefunctions but vectors. Each component of the vector is a wavefunction in the usual sense. The Hilbert space is extended to be the product space of the usual spatial wavefunctions and a finite-dimensional vector space.

Example 240 (*Calculation with matrices of operator*): To give an idea of how the algebra works we consider a general situation. As the operator we choose the product,

$$\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \frac{\partial}{\partial x}$$

and as the wavefunction vector we choose,

$$\begin{pmatrix} e^{\imath k_1 x} \\ e^{\imath k_2 x} \end{pmatrix} \ .$$

Applying the operator on the state vector we get,

$$\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \frac{\partial}{\partial x} \begin{pmatrix} e^{\imath k_1 x} \\ e^{\imath k_2 x} \end{pmatrix} = \begin{pmatrix} 0 & \frac{\partial}{\partial x} \\ \frac{\partial}{\partial x} & 0 \end{pmatrix} \begin{pmatrix} e^{\imath k_1 x} \\ e^{\imath k_2 x} \end{pmatrix} = \begin{pmatrix} 0 + \frac{\partial}{\partial x} e^{\imath k_2 x} \\ \frac{\partial}{\partial x} e^{\imath k_1 x} + 0 \end{pmatrix} = \begin{pmatrix} \imath k_2 e^{\imath k_2 x} \\ \imath k_1 e^{\imath k_1 x} \end{pmatrix} \ .$$

The matrices α_i must satisfy the condition (32.10). It is possible to show that this requires at least four-dimensional matrices of the following form:

$$\alpha_0 = \begin{pmatrix} -\mathbb{I} & 0 \\ 0 & \mathbb{I} \end{pmatrix} \qquad \text{and} \qquad \alpha_j = \begin{pmatrix} 0 & \sigma_j \\ \sigma_j & 0 \end{pmatrix} \ , \tag{32.11}$$

where $j = x, y, z = 1, 2, 3$. In this notation the components of the matrices are themselves matrices, i.e. the *Pauli spin matrices* defined in (23.154). The state vector must also have four dimensions,

$$\vec{\Phi}(\mathbf{r}, t) = \begin{pmatrix} \vec{\phi}(\mathbf{r}, t) \\ \vec{\chi}(\mathbf{r}, t) \end{pmatrix} \quad \text{with} \quad \vec{\phi}(\mathbf{r}, t) = \begin{pmatrix} \phi_1(\mathbf{r}, t) \\ \phi_2(\mathbf{r}, t) \end{pmatrix} \quad \text{and} \quad \vec{\chi}(\mathbf{r}, t) = \begin{pmatrix} \chi_1(\mathbf{r}, t) \\ \chi_2(\mathbf{r}, t) \end{pmatrix} \ . \tag{32.12}$$

ϕ_j are called *large components*, χ_j are called *small components*. This designation is explained later. Combining the matrices α_j to a three-dimensional vector $\vec{\alpha}$, we can now write the Dirac equation (32.9) like,

$$\boxed{\imath\hbar\partial_t\vec{\Phi}(\mathbf{r}, t) = \left(m_e c^2\alpha_0 + c\vec{\alpha} \cdot \hat{\mathbf{p}}\right)\vec{\Phi}(\mathbf{r}, t)} \ . \tag{32.13}$$

Or, using the notation (32.11) and combining the Pauli matrices σ_j to a three-dimensional vector $\vec{\sigma}$, we can write the Dirac equation as:

$$\boxed{\imath\hbar\frac{\partial}{\partial t}\begin{pmatrix}\vec{\phi}\\ \vec{\chi}\end{pmatrix} = \left[m_e c^2\begin{pmatrix}-\mathbb{I} & 0\\ 0 & \mathbb{I}\end{pmatrix} + c\begin{pmatrix}0 & \vec{\sigma}\cdot\hat{\mathbf{p}}\\ \vec{\sigma}\cdot\hat{\mathbf{p}} & 0\end{pmatrix}\right]\begin{pmatrix}\vec{\phi}\\ \vec{\chi}\end{pmatrix}} \ . \tag{32.14}$$

The non-diagonal matrix,

$$\begin{pmatrix}0 & \vec{\sigma}\cdot\hat{\mathbf{p}}\\ \vec{\sigma}\cdot\hat{\mathbf{p}} & 0\end{pmatrix} \tag{32.15}$$

couples large and small components.

Example 241 (*Covariant and relativistically invariant form of Dirac's equation*): To demonstrate its relativistic invariance it is useful to rewrite the Dirac equation in a way in which time and space appear on equal footings. For this we introduce new matrices,

$$\gamma^0 \equiv \alpha_0 \qquad \text{and} \qquad \gamma^k = \gamma^0\alpha_k \ . \tag{32.16}$$

We obtain,

$$\gamma^0 = \begin{pmatrix}-\mathbb{I} & 0\\ 0 & \mathbb{I}\end{pmatrix} \qquad \text{and} \qquad \gamma^k = \begin{pmatrix}0 & \sigma_k\\ -\sigma_k & 0\end{pmatrix} \ . \tag{32.17}$$

We also define another important matrix by,

$$\gamma_5 \equiv \imath\gamma_0\gamma_1\gamma_2\gamma_3 = \begin{pmatrix}0 & \mathbb{I}\\ \mathbb{I} & 0\end{pmatrix} \ . \tag{32.18}$$

With this, using Einstein's notation [3], the Dirac equation (32.12) adopts the form,

$$\imath\hbar\gamma^\mu\partial_\mu\psi - m_e c\psi = 0 \ . \tag{32.19}$$

The complete system is summarized in the Minkowski metrics of time-space in the form,

$$[\gamma^\mu, \gamma^\nu]_+ = 2\eta^{\mu\nu} \ , \tag{32.20}$$

for $\mu, \nu = 0, .., 5$, that is, all matrices γ_k anticommute.
The Dirac equation can now be interpreted as an eigenvalue equation, where the rest mass is proportional to the eigenvalue of a momentum quadrivector, the proportionality constant being the speed of light:

$$\hat{p}_{\text{op}}\psi = m_e c\psi \ , \tag{32.21}$$

Using $\partial\!\!\!/$ in the Feynman slash notation, which includes the γ-matrices, as well as a summation over the components of the spinor in the derivative, the Dirac equation becomes:

$$\imath\hbar\partial\!\!\!/\psi - m_e c\psi = 0 \ . \tag{32.22}$$

A fundamental theorem states that, if two distinct sets of matrices are given, which both satisfy Clifford's relations, then they are connected to each other by a similarity transformation:

$$\gamma'^\mu = S^{-1}\gamma^\mu S \ . \tag{32.23}$$

[3] $\partial_0 \equiv \frac{1}{c}\partial_t$

If, in addition, the matrices are all unitary, as is the case of Dirac's set, then S is unitary,

$$\gamma'^{\mu} = \mathcal{U}^{\dagger}\gamma^{\mu}\mathcal{U} \ . \tag{32.24}$$

32.1.2.1 Anti-particles

Disregarding for a moment the non-diagonal matrix, the Dirac equation separates into two independent equations,

$$\imath\hbar\frac{\partial\vec{\phi}}{\partial t} = m_e c^2\vec{\phi} \qquad \text{and} \qquad \imath\hbar\frac{\partial\vec{\chi}}{\partial t} = -m_e c^2\vec{\chi} \ . \tag{32.25}$$

These are eigenenergy equations with the eigenvalues $m_e c^2$ and $-m_e c^2$. The state with negative energy is interpreted as *anti-particle*. Therefore, the non-diagonal matrix mixes particles and anti-particles. We will study in Exc. 32.1.5.2 the so-called *Zitterbewegung* as a solution of the Dirac equation.

32.1.2.2 Particles and anti-particles in the non-relativistic limit

To reduce the Dirac equation to the non-relativistic Schrödinger equation, we first need to get rid of the rest energy. To do so, we separate a fast oscillation, whose frequency corresponds to the rest mass of the electron via the following ansatz, where $\mathbf{u}$ and $\mathbf{v}$ vary slowly in time:

$$\vec{\vec{\Phi}}(\mathbf{r},t) = e^{-\imath\omega_0 t}\begin{pmatrix}\mathbf{u}(\mathbf{r},t)\\ \mathbf{v}(\mathbf{r},t)\end{pmatrix} \qquad , \qquad \hbar\omega_0 = m_e c^2 \ , \tag{32.26}$$

with the temporal derivative,

$$\imath\hbar\dot{\vec{\vec{\Phi}}} = \left[m_e c^2\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix} + \imath\hbar\begin{pmatrix}\dot{\mathbf{u}}\\ \dot{\mathbf{v}}\end{pmatrix}\right]e^{-\imath\omega_0 t} \ . \tag{32.27}$$

We insert this into the Dirac equation,

$$\left[m_e c^2\begin{pmatrix}\mathbf{u}\\ \mathbf{v}\end{pmatrix} + \imath\hbar\begin{pmatrix}\dot{\mathbf{u}}\\ \dot{\mathbf{v}}\end{pmatrix}\right]e^{-\imath\omega_0 t} = \left[m_e c^2\begin{pmatrix}\mathbf{u}\\ -\mathbf{v}\end{pmatrix} + c\vec{\sigma}\cdot\hat{\mathbf{p}}\begin{pmatrix}\mathbf{v}\\ \mathbf{u}\end{pmatrix}\right]e^{-\imath\omega_0 t} \tag{32.28}$$

finally obtaining,

$$\imath\hbar\dot{\mathbf{u}} = c(\vec{\sigma}\cdot\hat{\mathbf{p}})\mathbf{v} \qquad , \qquad \imath\hbar\dot{\mathbf{v}} = c(\vec{\sigma}\cdot\hat{\mathbf{p}})\mathbf{u} - 2m_e c^2\mathbf{v} \ . \tag{32.29}$$

Since $\mathbf{u}$ and $\mathbf{v}$ only vary slowly in time, the derivatives on the left-hand side are small quantities. However, the condition that both derivatives must vanish is too strong, because it leads to the trivial solution $\mathbf{u} = 0$ and $\mathbf{v} = 0$. We find the first non-trivial solution by the condition $\dot{\mathbf{v}} = 0$. The second equation then becomes,

$$\mathbf{v} = \frac{1}{2m_e c}(\vec{\sigma}\cdot\hat{\mathbf{p}})\mathbf{u} \ . \tag{32.30}$$

Inserted into the first equation,

$$\imath\hbar\dot{\mathbf{u}} = c\frac{(\vec{\sigma}\cdot\hat{\mathbf{p}})^2}{2m_e c}\mathbf{u}\ . \tag{32.31}$$

We need, therefore, to evaluate the expression $(\vec{\sigma}\cdot\hat{\mathbf{p}})^2$,

$$\vec{\sigma}\cdot\hat{\mathbf{p}} = \begin{pmatrix} -\hat{p}_z & \hat{p}_x + \imath\hat{p}_y \\ \hat{p}_x - \imath\hat{p}_y & \hat{p}_z \end{pmatrix} \qquad \text{and} \qquad (\vec{\sigma}\cdot\hat{\mathbf{p}})^2 = \hat{\mathbf{p}}^2\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}\ . \tag{32.32}$$

Inserted into the differential equation (32.31) for $\mathbf{u}$ we obtain precisely the Schrödinger equation for a free particle,

$$\boxed{\imath\hbar\dot{\mathbf{u}} = \frac{\hat{\mathbf{p}}^2}{2m_e}\mathbf{u}}\ . \tag{32.33}$$

Let us return to the question, why we call $\mathbf{u}$ the *strong* component. We have from the equation (32.30),

$$\mathbf{v}^\dagger\mathbf{v} = \frac{1}{(2m_e c)^2}(\vec{\sigma}\cdot\hat{\mathbf{p}})^2\mathbf{u}^\dagger\mathbf{u} = \frac{1}{2m_e c^2}\frac{\hat{\mathbf{p}}^2}{2m_e}\mathbf{u}^\dagger\mathbf{u}\ , \tag{32.34}$$

and since $\frac{\hat{\mathbf{p}}^2}{2m_e} \ll m_e c^2$ follows immediately $\mathbf{v}^\dagger\mathbf{v} \ll \mathbf{u}^\dagger\mathbf{u}$.

In this non-relativistic approximation the components $\mathbf{u}$ are much larger than the components $\mathbf{v}$. The mixture between particles and antiparticles only matters when $\frac{\hat{\mathbf{p}}^2}{2m_e} \simeq m_e c^2$, resp., $\frac{1}{2}m_e v^2 \simeq m_e c^2$ or $|v| \simeq c$. The electron only receives small positronic contributions as it approaches the speed of light. In the ground state of the hydrogen atom the electron has a velocity of of $v = \alpha c \simeq c/137$. That is, the contribution of the weak components is small, but present.

Example 242 (*Vanishing rest mass*): Let us note that for the case of vanishing rest mass, $m_e = 0$, the Dirac equation (32.14) dramatically simplifies. Taking the time derivative of the upper equation (32.14) and inserting the lower equation (32.14), we find,

$$\frac{1}{c^2}\frac{\partial^2}{\partial t^2}\vec{\phi} = \frac{1}{c^2}\frac{c\vec{\sigma}\cdot\hat{\mathbf{p}}}{\imath\hbar}\frac{\partial}{\partial t}\vec{\chi} = -\frac{(\vec{\sigma}\cdot\hat{\mathbf{p}})^2}{\hbar^2}\vec{\phi} = -\frac{\hat{\mathbf{p}}^2}{\hbar^2}\vec{\phi} = \nabla^2\vec{\phi}\ . \tag{32.35}$$

I.e. we recover a Helmholtz type wave equation.

32.1.2.3 The spin

We consider the operator defined by [260, 261],

$$\hat{\mathbf{S}} \equiv \tfrac{\hbar}{2}\hat{\vec{\sigma}}\ , \tag{32.36}$$

and we calculate the commutation relations between its components. From the definitions of the Pauli matrices (23.154) we obtain the rule,

$$[\hat{S}_x, \hat{S}_y] = \tfrac{\hbar^2}{4}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 0 & \imath \\ -\imath & 0 \end{pmatrix} - \tfrac{\hbar^2}{4}\begin{pmatrix} 0 & \imath \\ -\imath & 0 \end{pmatrix}\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \frac{\hbar^2}{4}\begin{pmatrix} -2\imath & 0 \\ 0 & 2\imath \end{pmatrix} = \imath\hbar\hat{S}_z\ . \tag{32.37}$$

In general terms the following holds true: $[\hat{S}_i, \hat{S}_j] = \epsilon_{ijk}\imath\hbar\hat{S}_k$. It is interesting to compare this with the commutation relation for the orbital angular momentum $[\hat{L}_i, \hat{L}_j] = \epsilon_{ijk}\imath\hbar\hat{L}_k$. The coincidence suggests a generalization of the concept of angular momentum: We now call *angular momentum operator* every three-dimensional vector operator satisfying this commutation relation [4]. We consider the eigenvalue equation for $\hat{s}_z$, which is incorporated in the Dirac equation,

$$\hat{S}_z\vec{\phi} = \tfrac{\hbar}{2}\begin{pmatrix}-1 & 0\\ 0 & 1\end{pmatrix}\begin{pmatrix}\phi_1\\ \phi_2\end{pmatrix} = M_S\hbar\begin{pmatrix}\phi_1\\ \phi_2\end{pmatrix} \ . \tag{32.38}$$

The eigenvalues are obviously $M_S = \pm\frac{1}{2}$. The angular momentum related to the matrices $\hat{\mathbf{S}}$ is obviously half-integer. We are dealing here with a new type of angular momentum, which is not included in the usual definition of *orbital* angular momentum $\hat{\mathbf{L}} = \mathbf{r}\times\hat{\mathbf{p}}$. The new angular momentum is called *intrinsic* angular momentum or *spin* of the particle. The spin represents a new structure or dimension additional to space comparable to the polarization of light. The photons of a circularly polarized light beam also contribute to an intrinsic angular momentum, which however in this case is integer.

In Exc. 32.1.5.3 we will see that neither $\hat{L}_z$ nor $\hat{S}_z$ are constants of motion of the Hamiltonian (32.14), but the sum $\hat{J}_z \equiv \hat{L}_z + \hat{S}_z$,

$$[\hat{J}_z, \hat{H}] = 0 \ . \tag{32.39}$$

32.1.2.4 The stationary Dirac equation

By a similar treatment as in the Schrödinger equation one can deduce a stationary Dirac equation (32.13) via a separation of the time variable. Making for the time an exponential ansatz,

$$\vec{\phi}(\mathbf{r},t) = \vec{\phi}(\mathbf{r})e^{-\imath Et/\hbar} \qquad \text{and} \qquad \vec{\chi}(\mathbf{r},t) = \vec{\chi}(\mathbf{r})e^{-\imath Et/\hbar} \ , \tag{32.40}$$

we obtain coupled stationary equations for the large and small components,

$$(E - m_ec^2)\vec{\phi}(\mathbf{r}) = c\sigma\cdot\hat{\mathbf{p}}\vec{\chi}(\mathbf{r}) \qquad \text{and} \qquad (E + m_ec^2)\vec{\chi}(\mathbf{r}) = c\sigma\cdot\hat{\mathbf{p}}\vec{\phi}(\mathbf{r}) \ . \tag{32.41}$$

32.1.3 The relativistic electron in a central Coulomb field

32.1.3.1 Minimal coupling

In atomic physics we are mainly interested in electrons bound to a potential (e.g., generated by an atomic nucleus), that is, we must introduce electromagnetic forces into the Dirac equation. Therefore, we now consider the interaction of a charged particle with an electromagnetic field given by the vector potential $\mathbf{A}$ and by the electrostatic potential U, such that the electric and magnetic fields,

$$\vec{\mathcal{E}} = -\nabla U - \frac{\partial\mathbf{A}}{\partial t} \qquad \text{and} \qquad \vec{\mathcal{B}} = \nabla\times\mathbf{A} \ , \tag{32.42}$$

[4] This concept can be derived from the requirement of symmetry under rotation of space as discussed in Sec. 23.7.

allow to calculate the Coulomb-Lorentz force. In the Hamiltonian formulation of electrodynamics the interaction can be described simply by the transition [5],

$$\boxed{\hat{\mathbf{p}} \longrightarrow \hat{\mathbf{p}} - q\mathbf{A} \equiv \vec{\pi} \qquad \text{and} \qquad \hat{H} \longrightarrow \hat{H} + qU} \ . \tag{32.43}$$

called the *minimal coupling*. We briefly mentioned this already in Sec. 23.7.4, and the rules will be derived in Sec. 33.1. In addition to the substitution of the momentum, we must add the scalar potential qU, and we obtain the Dirac equation for a particle inside an applied electromagnetic field,

$$\imath\hbar\dot{\vec{\vec{\Phi}}} = \left(m_e c^2 \alpha_0 + c\vec{\alpha}\cdot\vec{\pi} + qU\right)\vec{\vec{\Phi}} \ , \tag{32.44}$$

in generalization of Eq. (32.13).

32.1.3.2 Solving the stationary Dirac equation

Let us, for now, disregard external magnetic fields, $\mathbf{A} = 0$. Then, the stationary Dirac equation (32.41) becomes,

$$\begin{aligned} [E - qU(\mathbf{r}) - m_e c^2]\vec{\phi}(\mathbf{r}) &= c\sigma\cdot\hat{\mathbf{p}}\vec{\chi}(\mathbf{r}) \\ [E - qU(\mathbf{r}) + m_e c^2]\vec{\chi}(\mathbf{r}) &= c\sigma\cdot\hat{\mathbf{p}}\vec{\phi}(\mathbf{r}) \ . \end{aligned} \tag{32.45}$$

For the Coulomb potential,

$$qU(r) = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r} \tag{32.46}$$

the Dirac equation can be solved algebraically [262, 383, 389, 329] [6]. The calculation is more complicated than the resolution of the Schrödinger equation for hydrogen derived in Secs. 25.1.4 and 25.2.1 and will be sketched in the following.

Example 243 (*Dirac equation in spherical coordinates*): The goal of the following calculation is to express the Dirac equation for an electron in a central Coulomb field in spherical coordinates, i.e. r and $\hat{p}_r = -\imath\hbar\partial_r$ instead of $\hat{\mathbf{p}}$. The starting point is the Dirac equation (32.14),

$$\imath\hbar\partial_t\vec{\vec{\Phi}}(\mathbf{r},t) = \hat{H}\vec{\vec{\Phi}}(\mathbf{r},t) \ , \tag{32.47}$$

with the Hamiltonian in the minimal coupling (32.43),

$$\begin{aligned} \hat{H} &\equiv m_e c^2\alpha_0 + c\vec{\alpha}\cdot[\hat{\mathbf{p}} - q\mathbf{A}(\mathbf{r})] + qU(\mathbf{r}) \\ &\text{with} \qquad \mathbf{A} = 0 \qquad \text{and} \qquad U(\mathbf{r}) = -\frac{e^2}{4\pi\varepsilon_0 r} \ . \end{aligned} \tag{32.48}$$

We adopt the standard procedure from non-relativistic physics, which consists in rewriting the Hamiltonian in terms of observables, which commute with the Hamiltonian [7].

[5] In quadrivetorial notation: $\pi_\mu = p_\mu - qA_\mu$ with $p_\mu = \begin{pmatrix} E/c \\ \hat{\mathbf{p}} \end{pmatrix}$ and $A_\mu = \begin{pmatrix} U/c \\ \mathbf{A} \end{pmatrix}$.

[6] See also http://einstein.drexel.edu/~bob/Term_Reports/Whitehead_3.pdf

[7] Typical examples are the Hamiltonian of the harmonic oscillator (24.84) written in terms of $\hat{n} \equiv \hat{a}^\dagger\hat{a}$ or the Hamiltonian of the hydrogen atom (25.34) written in terms of $\mathbf{L}^2$.

The goal is to calculate the quantity $\vec{\alpha}\cdot\hat{\mathbf{p}}$ appearing in the above Hamiltonian. As a first steps we define the following quantities,

$$\boxed{\begin{aligned}
\hat{\mathbf{L}} &\equiv \mathbf{r}\times\hat{\mathbf{p}} \qquad \text{satisfying} \qquad \hat{\mathbf{L}}\times\hat{\mathbf{L}} = \imath\hbar\hat{\mathbf{L}} \\
\hat{\mathbf{S}} &\equiv \tfrac{\hbar}{2}\vec{\varsigma} \equiv \tfrac{\hbar}{2}\gamma_5\vec{\alpha} \\
\hat{\mathbf{J}} &\equiv \hat{\mathbf{L}}+\hat{\mathbf{S}} \\
\hbar j' &\equiv \alpha_0(\gamma_5\vec{\alpha}\cdot\hat{\mathbf{L}}+\hbar) \\
r\varepsilon &\equiv \vec{\alpha}\cdot\mathbf{r}
\end{aligned}} \quad . \tag{32.49}$$

remembering that $\gamma_5 = -\imath\alpha_1\alpha_2\alpha_3 = \begin{pmatrix} 0 & \mathbb{I} \\ \mathbb{I} & 0 \end{pmatrix}$ is the transformation exchanging particles and anti-particles. The first important relationship we have to derive is,

$$(\vec{\alpha}\cdot\mathbf{B})(\vec{\alpha}\cdot\mathbf{C}) = (\mathbf{B}\cdot\mathbf{C}) + \imath\gamma_5\vec{\alpha}\cdot(\mathbf{B}\times\mathbf{C}) \ . \tag{32.50}$$

It holds for $[\vec{\alpha},\mathbf{B}] = 0 = [\vec{\alpha},\mathbf{C}]$ and will be proven in 32.1.5.4. Exploiting this relationship, we see that the scalar quantity ε satisfies,

$$\varepsilon^2 = \frac{1}{r^2}(\vec{\alpha}\cdot\mathbf{r})^2 = \frac{1}{r^2}[\mathbf{r}\cdot\mathbf{r} + \imath\vec{\alpha}\cdot(\mathbf{r}\times\mathbf{r})] = 1 \ . \tag{32.51}$$

Furthermore, with the definition of j' we show,

$$\begin{aligned} r\varepsilon\vec{\alpha}\cdot\hat{\mathbf{p}} = (\vec{\alpha}\cdot\mathbf{r})(\vec{\alpha}\cdot\hat{\mathbf{p}}) &= \mathbf{r}\cdot\hat{\mathbf{p}} + \imath\gamma_5\vec{\alpha}\cdot(\mathbf{r}\times\hat{\mathbf{p}}) \\ &= \mathbf{r}\cdot\hat{\mathbf{p}} + \imath\gamma_5\vec{\alpha}\cdot\mathbf{L} = r\hat{p}_r + \imath\alpha_0\hbar j' - \imath\hbar \ , \end{aligned} \tag{32.52}$$

where the relationship $\mathbf{r}\cdot\hat{\mathbf{p}} = r\hat{p}_r$ is verified in Exc. 32.1.5.5(c). Hence,

$$\vec{\alpha}\cdot\hat{\mathbf{p}} = \varepsilon\left(\hat{p}_r + \frac{\imath\hbar(\alpha_0 j' - 1)}{r}\right) \ , \tag{32.53}$$

The final radial Hamiltonian is,

$$\boxed{\hat{H} = m_e c^2\alpha_0 + c\varepsilon\left(p_r - \imath\frac{\hbar}{r}\right) + \frac{\imath c\varepsilon\alpha_0\hbar j'}{r} - \frac{e^2}{4\pi\varepsilon_0 r}} \ . \tag{32.54}$$

For now the choice of the quantities ε and j' must seem arbitrary, so we will have to discover their properties. We will see that j' is a non-zero integer related to the total angular momentum j. The following properties will be proven in Exc. 32.1.5.5(a) and (b),

$$\begin{aligned} (\hbar j')^2 &= \mathbf{J}^2 + \tfrac{\hbar^2}{4} \\ [\hbar j', \hat{H}]_- = [\varepsilon, \hat{H}]_- &= [\alpha_0, \hat{H}]_- = 0 \ . \end{aligned} \tag{32.55}$$

Hence, we got a collection of radial variables being constants of motion of the Dirac Hamiltonian.

Example 244 (*Resolving the spherical Dirac equation*): We will now search a solution to the spherical Dirac equation with the Hamiltonian (32.54). Noticing that the matrix α_0 is diagonal and the matrix ε counter-diagonal (just

like the Dirac matrices $\vec{\alpha}$), we may break down the stationary radial Dirac equation into 2 by 2 matrices. Using the fact that ε commutes with all other terms and anti-commutes with α_0 and that $\varepsilon^{-1} = \varepsilon^\dagger$ is a unitary transformation, we may go to a new basis via,

$$\begin{pmatrix} m_e c^2 - \frac{e^2}{4\pi\varepsilon_0 r} & -\imath c p_r - c\frac{\hbar}{r} - c\frac{\hbar j'}{r} \\ \imath c p_r + c\frac{\hbar}{r} - c\frac{\hbar j'}{r} & -m_e c^2 - \frac{e^2}{4\pi\varepsilon_0 r} \end{pmatrix} \begin{pmatrix} \vec{\phi} \\ \varepsilon\vec{\chi} \end{pmatrix} = E \begin{pmatrix} \vec{\phi} \\ \varepsilon\vec{\chi} \end{pmatrix} . \tag{32.56}$$

Substituting $\alpha = \frac{e^2}{4\pi\varepsilon_0 \hbar c}$ and $a_\pm \equiv \frac{\hbar}{m_e c \mp E/c}$ (that is, $\pm m_e c^2 - E \equiv \pm\frac{\hbar c}{a_\pm}$), we find,

$$\begin{pmatrix} \frac{1}{a_+} - \frac{\alpha}{r} & -\frac{d}{dr} - \frac{j'+1}{r} \\ \frac{d}{dr} - \frac{j'-1}{r} & -\frac{1}{a_-} - \frac{\alpha}{r} \end{pmatrix} \begin{pmatrix} \vec{\phi} \\ \varepsilon\vec{\chi} \end{pmatrix} = 0 . \tag{32.57}$$

Assuming the existence of solutions of the form,

$$\begin{pmatrix} \vec{\phi} \\ \varepsilon\vec{\chi} \end{pmatrix} = \frac{e^{-r/a}}{r} \begin{pmatrix} \vec{f} \\ \vec{g} \end{pmatrix} , \tag{32.58}$$

where $a \equiv \sqrt{a_+ a_-} = \hbar\left(m_e^2 c^2 - \frac{E^2}{c^2}\right)^{-1}$ [that is, $\frac{d}{dr}\frac{e^{-r/a}}{r} = \frac{e^{-r/a}}{r}\left(-\frac{1}{a} - \frac{1}{r}\right)$], we find,

$$\begin{pmatrix} \frac{1}{a_+} - \frac{\alpha}{r} & -\frac{d}{dr} - \frac{1}{a} - \frac{j'}{r} \\ \frac{d}{dr} - \frac{1}{a} - \frac{j'}{r} & -\frac{1}{a_-} - \frac{\alpha}{r} \end{pmatrix} \begin{pmatrix} \vec{f} \\ \vec{g} \end{pmatrix} = 0 . \tag{32.59}$$

Next we expand the unknown function $\vec{f}$ and $\vec{g}$ as series,

$$\vec{f}(r) = \sum_{s=-\infty}^{\infty} f_s r^s \qquad \text{and} \qquad \vec{g}(r) = \sum_{s=-\infty}^{\infty} g_s r^s . \tag{32.60}$$

These are then substituted into our system of equations. In order for the equation to go to zero as required, each term in the resulting series must separately go to zero. The coefficient of the r_s terms are,

$$\begin{aligned} \frac{f_s}{a_+} - \alpha f_{s+1} - (s+1+j')g_{s+1} + \frac{g_s}{a} &= 0 \\ \frac{g_s}{a_-} - \alpha g_{s+1} - (s+1-j')f_{s+1} + \frac{f_s}{a} &= 0 . \end{aligned} \tag{32.61}$$

These can be combined by multiplying the first equation (32.61) by a and and the second by a_- and then subtracting the former from the latter. Exploiting $\frac{a}{a_+} = \frac{a_-}{a}$, this gives us an expression directly relating the f_s coefficients with the g_s coefficients,

$$[\alpha a - a_+(s-j')]f_s + [\alpha a_- + a(s+j')]g_s = 0 . \tag{32.62}$$

To obtain the values of the coefficients we consider the boundary conditions. The functions $\vec{f}(r)$ and $\vec{g}(r)$ must go to zero at $r = 0$, because the functions $\vec{\phi}$ and $\vec{\chi}$ would otherwise diverge there due to the r^{-1} term. This means that there is some smallest s below which the series does not continue. We call this s_0, and it has the property,

$$f_{s_0-1} = g_{s_0-1} = 0 . \tag{32.63}$$

Plugging this into the equations (32.61), we find,

$$\begin{aligned} \alpha f_{s_0} + (s_0 + j')g_{s_0} &= 0 \\ \alpha g_{s_0} - (s_0 - j')f_{s_0} &= 0 \ . \end{aligned} \tag{32.64}$$

Combining these equations we can write the value s_0 in a very simple form,

$$s_0 = \sqrt{j'^2 - \alpha^2} \ . \tag{32.65}$$

This places a lower bound on the series. Note that this bound becomes imaginary if $\alpha > j'$. This will be discussed in more detail shortly.
The upper bound of the series is also useful. It can be shown that the series must terminate if the energy eigenvalue is to be less than $m_e c^2$ [262]. The implication of this result is that if the series terminates at index s_1 such that,

$$f_{s_1+1} = g_{s_1+1} = 0 \ . \tag{32.66}$$

Then, using equations (32.61) and (32.62), we have,

$$\frac{s_1}{a} = \frac{1}{2}\left(\frac{1}{a_-} - \frac{1}{a_+}\right)\alpha = \frac{E}{\hbar c}\alpha \ , \tag{32.67}$$

where we have used the definitions of the coefficients $a_\pm$ to expand them. Squaring this expression and expanding a using its definition, we get,

$$s_1^2\left(m_e c^2 - \frac{E^2}{c^2}\right) = \alpha^2 \frac{E^2}{c^2} \ . \tag{32.68}$$

This can be solved for the energy eigenvalues,

$$E = \pm m_e c^2 \left(1 + \frac{\alpha^2}{s_1^2}\right)^{-1/2} \ . \tag{32.69}$$

Note that the 'negative energy' solution corresponds to positron energy levels. From here forward, we drop the negative root and look only at the electron solution.
The two end points of the series, the indices s_0 and s_1 are separated by an integer number of steps. Calling this integer n' we can write,

$$s_1 = n' + s_0 = n' + \sqrt{j'^2 - \alpha^2} \ . \tag{32.70}$$

Plugging this into (32.69) gives a result for the energy eigenvalues in terms of only the two quantum numbers n' and j',

$$E_{n',j'} = m_e c^2 \left[1 + \frac{\alpha^2}{\left(n' + \sqrt{j'^2 - \alpha^2}\right)^2}\right]^{-1/2} \ .$$

This is the final result quoted for the energy eigenvalues of the hydrogenic atom by Dirac [262]. It turns out that later developments in the field [383, 389] prefer to use an equivalent set of quantum numbers that maps more closely to the familiar ones. The number j' is closely related to the total angular momentum quantum number j. j' has the range 1, 2, 3, while j has the range $\frac{1}{2}$, $\frac{3}{2}$, $\frac{5}{2}$. It is natural, and in fact correct, to make the identifications,

$$j' = j + \tfrac{1}{2} \ , \tag{32.71}$$

and

$$n' = n - j' = n - j - \tfrac{1}{2} \ , \tag{32.72}$$

for the principal quantum number n [383]. Combining these two adjustments with equation (32.71), we get the *Sommerfeld fine-structure formula*,

$$\boxed{E_{n,j} = m_e c^2 \left[1 + \frac{\alpha^2}{\left(n - j - \frac{1}{2} + \sqrt{(j+\frac{1}{2})^2 - \alpha^2} \right)^2} \right]^{-1/2}} \ , \tag{32.73}$$

with $j = \left| \ell \pm \frac{1}{2} \right|$ and $\ell = 0, 1, \ldots$ The derivation of the form of the actual wave functions $\vec{\phi}(r)$ and $\vec{\chi}(r)$ is very tedious [383] and will not be reproduced here.

The energy predicted by the Sommerfeld fine-structure formula (32.73) depends on two quantum numbers. The degeneracy of the orbital angular momentum $\mathbf{j}$ is lifted, and the new quantum number besides the main quantum number n is that of the total angular momentum j. The intransparent expression can be expanded by α,

$$\boxed{E_{n,j} \simeq m_e c^2 \left[1 - \frac{\alpha^2}{2n^2} - \frac{\alpha^4}{2n^3} \left(\frac{1}{j+1/2} - \frac{3}{4n} \right) \right]} \ . \tag{32.74}$$

The second term reproduces the energy of Bohr's model, but there are correction terms proportional to α^4. We will show in Secs. 32.1.4, that the energy levels, called *fine structure*, result from several relativistic corrections of different origins.

In the expression (32.74) for the electron energy in the Coulomb potential, the last term is positive and proportional to $1/n^4$. It describes relaxation of the binding due to the contribution of weak components. The term containing the quantum number j is called the spin-orbit coupling. To better understand this contribution we must first analyze more deeply the matrices $\vec{\sigma}$.

32.1.3.3 Dirac's Hamiltonian in the sub-relativistic limit

Defining the energy $E' = E - m_e c^2$, the stationary Dirac equation (32.45) for an electron of charge $q = -e$ in an external electrostatic potential $U(\mathbf{r})$ can be written,

$$[E' - qU(\mathbf{r})]\vec{\phi} = c\vec{\sigma} \cdot \hat{\mathbf{p}}\vec{\chi} \qquad \text{and} \qquad [E' - qU(\mathbf{r}) + 2m_e c^2]\vec{\chi} = c\vec{\sigma} \cdot \hat{\mathbf{p}}\vec{\phi} \ . \tag{32.75}$$

resolving the second equation for the wavefunction $\vec{\chi}$ and substituting it into the first,

$$\boxed{E'\vec{\phi} = qU(\mathbf{r})\vec{\phi} + \vec{\sigma} \cdot \hat{\mathbf{p}} \frac{1}{2m_e} \left(1 + \frac{E' - qU(\mathbf{r})}{2m_e c^2} \right)^{-1} \vec{\sigma} \cdot \hat{\mathbf{p}}\vec{\phi}} \ . \tag{32.76}$$

In the non-relativistic limit,

$$E' - qU \simeq \frac{\hat{\mathbf{p}}^2}{2m_e} \ll m_e c^2 \ , \tag{32.77}$$

we get by Taylor expansion of the second term in the bracket,

$$E'\vec{\phi} \simeq qU(\mathbf{r})\vec{\phi} + \vec{\sigma} \cdot \hat{\mathbf{p}} \frac{1}{2m_e} \left(1 - \frac{E' - qU(\mathbf{r})}{2m_e c^2} \right) \vec{\sigma} \cdot \hat{\mathbf{p}}\vec{\phi} \ . \tag{32.78}$$

Now, $\vec{\sigma}\cdot\hat{\mathbf{p}}$ is an operator entity, which acts on the subsequent operators and wave-functions. We thus have to apply the product rule, $(\vec{\sigma}\cdot\hat{\mathbf{p}})U(\mathbf{r})\psi = U(\mathbf{r})(\vec{\sigma}\cdot\hat{\mathbf{p}})\psi + [(\vec{\sigma}\cdot\hat{\mathbf{p}})U(\mathbf{r})]\psi$, in equation (32.78),

$$E'\vec{\phi} \simeq qU(\mathbf{r})\vec{\phi} + \tfrac{1}{2m_e}\left(1 - \tfrac{E'-qU(\mathbf{r})}{2m_ec^2}\right)(\vec{\sigma}\cdot\hat{\mathbf{p}})^2\,\vec{\phi} + \tfrac{q}{4m_e^2c^2}[(\vec{\sigma}\cdot\hat{\mathbf{p}})U(\mathbf{r})](\vec{\sigma}\cdot\hat{\mathbf{p}})\vec{\phi}\ . \quad (32.79)$$

In the following we will make use of a general relationship which is similar to (32.50),

$$(\vec{\sigma}\cdot\mathbf{B})(\vec{\sigma}\cdot\mathbf{C}) = (\mathbf{B}\cdot\mathbf{C}) + \imath\vec{\sigma}\cdot(\mathbf{B}\times\mathbf{C})\ . \quad (32.80)$$

It holds for $[\vec{\sigma},\mathbf{B}] = 0 = [\vec{\sigma},\mathbf{C}]$ and will be demonstrated in Exc. 32.1.5.4. The relationship yields,

$$(\vec{\sigma}\cdot\hat{\mathbf{p}})^2 = \hat{\mathbf{p}}^2 \qquad \text{and} \qquad [\vec{\sigma}\cdot\hat{\mathbf{p}}U(\mathbf{r})](\vec{\sigma}\cdot\hat{\mathbf{p}}) = \hat{\mathbf{p}}U(\mathbf{r})\cdot\hat{\mathbf{p}} + \imath\vec{\sigma}\cdot[\hat{\mathbf{p}}U(\mathbf{r})\times\hat{\mathbf{p}}]\ , \quad (32.81)$$

so that expressing the momentum operator by $\mathbf{p} = -\imath\hbar\nabla$ wherever it acts on the potential,

$$E'\vec{\phi} \simeq qU(\mathbf{r})\vec{\phi} + \tfrac{1}{2m_e}\left(1 - \tfrac{E'-qU(\mathbf{r})}{2m_ec^2}\right)\hat{\mathbf{p}}^2\vec{\phi} - \tfrac{\hbar^2 q}{4m_e^2c^2}\nabla U(\mathbf{r})\cdot\nabla\vec{\phi} + \tfrac{\hbar}{4m_e^2c^2}\vec{\sigma}\cdot[\nabla U(\mathbf{r})\times\hat{\mathbf{p}}]\vec{\phi}\ . \quad (32.82)$$

Also, with $U(\mathbf{r}) = U(r)$,

$$\nabla U(r) = \frac{\partial U}{\partial r}\nabla r = \frac{\partial U}{\partial r}\frac{\mathbf{r}}{r} \qquad \text{and} \qquad \nabla U(r)\cdot\nabla = \frac{\partial U}{\partial r}\hat{\mathbf{e}}_r\cdot\nabla = \frac{\partial U}{\partial r}\frac{\partial}{\partial r}\ . \quad (32.83)$$

We get,

$$\begin{aligned} E'\vec{\phi} &= qU(\mathbf{r})\vec{\phi} + \frac{1}{2m_e}\left(1 - \frac{E'-qU(\mathbf{r})}{2m_ec^2}\right)\hat{\mathbf{p}}^2\vec{\phi} - \frac{\hbar^2}{4m_e^2c^2}\frac{\partial qU}{\partial r}\frac{\partial}{\partial r}\vec{\phi} + \frac{\hbar q}{4m_e^2c^2}\vec{\sigma}\cdot\left[\frac{1}{r}\frac{\partial U}{\partial r}\mathbf{r}\times\hat{\mathbf{p}}\vec{\phi}\right] \\ &\simeq \left(\frac{\hat{\mathbf{p}}^2}{2m_e} + qU(r) - \frac{\hat{\mathbf{p}}^4}{8m_e^3c^2} + \frac{q}{2m_e^2c^2}\frac{1}{r}\frac{\partial U}{\partial r}\mathbf{s}\cdot\mathbf{l} - \frac{\hbar^2 q}{4m_e^2c^2}\frac{\partial U}{\partial r}\frac{\partial}{\partial r}\right)\vec{\phi}\ . \end{aligned} \quad (32.84)$$

where we again applied the non-relativistic approximation (32.77) in the second line and made use of the definitions $\hat{\mathbf{S}} = \frac{\hbar}{2}\vec{\sigma}$ and $\hat{\mathbf{L}} = \mathbf{r}\times\hat{\mathbf{p}}$. The term in the bracket can be used as the Hamiltonian allowing to calculate the fine structure as first-order perturbations to the non-relativistic energy levels obtained from non-relativistic theory,

$$\boxed{\hat{H} \simeq \frac{\hat{\mathbf{p}}^2}{2m_e} - \frac{1}{4\pi\varepsilon_0}\frac{e^2}{r} - \frac{\hat{\mathbf{p}}^4}{8m_e^3c^2} - \frac{e}{2m_e^2c^2}\frac{1}{r}\frac{\partial U}{\partial r}\hat{\mathbf{S}}\cdot\hat{\mathbf{L}} - \frac{\hbar^2 e}{4m_e^2c^2}\frac{\partial U}{\partial r}\frac{\partial}{\partial r}}\ . \quad (32.85)$$

The first two terms are those arising from Bohr's atom model, the third one is a correction due to the relativistic velocity of the electron, the forth comes from the electron's spin-orbit coupling, and the fifth is called the Darwin term. All contributions represent perturbations to the non-relativistic Schrödinger theory of Bohr's atom and will be discussed extensively in Secs. 32.2. We will show in 32.1.5.6 that $\hat{\mathbf{L}}^2$, $\hat{\mathbf{S}}^2$, and $\hat{\mathbf{J}}^2$ are constants of motion of the above Hamiltonian.

32.1.4 The Pauli equation

When we calculated the electron's energy in the Coulomb potential (32.85), we only considered the electrostatic potential of the nucleus, letting the potential vector $\mathbf{A}$ be zero. As long as we do not apply an external magnetic field this is correct, because the internal magnetism of the atom is already completely enclosed in the Dirac equation. On the other hand, we know that the atom contains moving charges, that is, currents which generate magnetic fields [8]. Furthermore, the spins of the electron and of the proton produce magnetic moments, which ought to interact with the magnetic fields. Hence, the existence of magnetic effects in an atom is to be expected.

These magnetic effects can be discussed in a more transparent way applying a Schrödinger-like equation with minimal coupling to electromagnetic fields (32.43) to a two-component spinor $\vec{\phi}$. This Schrödinger-like equation can be obtained from Dirac's equation (32.75) via a stronger non-relativistic approximation, which consists in completely neglecting the weak component $[E' - qU(\mathbf{r})]\vec{\chi}$. On the other hand, we allow for the existence of magnetic fields via the substitution $\hat{\mathbf{p}} \to \vec{\pi}$. The equation for the strong component (32.76) then becomes,

$$\boxed{E'\vec{\phi} = qU(\mathbf{r})\vec{\phi} + \frac{(\vec{\sigma}\cdot\vec{\pi})^2}{2m_e}\vec{\phi}} \,. \tag{32.86}$$

We can again apply the formula (32.80) to calculate,

$$\begin{aligned}(\vec{\sigma}\cdot\vec{\pi})^2\psi &= \vec{\pi}^2\psi + \imath\vec{\sigma}\cdot(\vec{\pi}\times\vec{\pi})\psi = \vec{\pi}^2\psi + \imath q\vec{\sigma}\cdot[-\mathbf{p}\times\mathbf{A}(\mathbf{r}) - \mathbf{A}(\mathbf{r})\times\hat{\mathbf{p}}]\psi \\ &= \vec{\pi}^2\psi - \hbar q\vec{\sigma}\cdot\{\nabla\times[\mathbf{A}(\mathbf{r})\psi] + \mathbf{A}(\mathbf{r})\times\nabla\psi\} \\ &= \vec{\pi}^2\psi - \hbar q\vec{\sigma}\cdot[\nabla\times\mathbf{A}(\mathbf{r})]\psi = [\mathbf{p} - q\mathbf{A}(\mathbf{r})]^2\psi - \hbar q\vec{\sigma}\cdot\vec{\mathcal{B}}(\mathbf{r})\psi \,.\end{aligned} \tag{32.87}$$

In the case of an electron ($e = -q$) we obtain the so-called *Pauli equation*,

$$E'\vec{\phi} = \left[\frac{1}{2m_e}\left(-\imath\hbar\nabla + e\mathbf{A}\right)^2 + \frac{e\hbar}{2m_e}\vec{\sigma}\cdot\vec{\mathcal{B}} - eU(\mathbf{r})\right]\vec{\phi} \,, \tag{32.88}$$

which corresponds to a Schrödinger-like equation for a two-component spinor $\vec{\phi}$ with the Hamiltonian,

$$\boxed{\hat{H} \simeq \frac{\hat{\mathbf{p}}^2}{2m_e} - \frac{1}{4\pi\varepsilon_0}\frac{e^2}{r} - \frac{\imath\hbar e}{2m_e}(\nabla\cdot\mathbf{A} + \mathbf{A}\cdot\nabla) + \frac{e}{m_e}\mathbf{S}\cdot\vec{\mathcal{B}}} \,, \tag{32.89}$$

neglecting terms in $\mathbf{A}^2$. Note however, that the kinetic energy is calculated with the *momentum projected onto the spin*, $\vec{\sigma}\cdot\vec{\pi}$. The third term can be simplified within the Coulomb gauge $\nabla\cdot\mathbf{A} = 0$ yielding,

$$\hat{H}_{\text{int}} = \frac{e}{m_e}(\mathbf{A}\cdot\hat{\mathbf{p}}) \,. \tag{32.90}$$

The Pauli equation serves for a classical (non-relativistic) approach to the electron's spin-orbit coupling, as we will see below and in the discussion of the fine structure in Sec. 32.2.2.

[8] The spin of the electron does not generate a magnetic field, in contrast to the angular momentum caused by its *orbital motion*. It only interacts with the environment through the requirement of symmetrization for being a fermion.

32.1.4.1 Dipole moment of the orbital angular momentum

The rotational motion of a charge, $-e$, creates a current I, corresponding to a current density,

$$\mathbf{j}(\mathbf{r}') = I\hat{\mathbf{e}}_\phi \delta(r-r')\delta(z') = -e\frac{\mathbf{v}}{2\pi r}\delta(r-r')\delta(z') \ . \tag{32.91}$$

Hence, the dipole moment caused by the circular motion of an electron is,

$$\begin{aligned}\vec{\mu}_\ell &= \frac{1}{2}\int_V \mathbf{r}\times\mathbf{j}(\mathbf{r}')d^3r' \qquad (32.92)\\ &= \frac{1}{4\pi}\mathbf{r}\times\int_0^{2\pi}d\phi'\int_{-\infty}^{\infty}dz'\int_0^\infty r'dr'\frac{-e\mathbf{v}}{r}\delta(r-r')\delta(z') = \tfrac{-1}{2}e\mathbf{r}\times\mathbf{v} = \frac{-e}{2m_e}\mathbf{L} \ ,\end{aligned}$$

with the angular momentum $\mathbf{L} = \mathbf{r}\times m_e\mathbf{v}$. The quotient $\gamma_e \equiv -e/2m_e$ is called *gyromagnetic ratio* of the electron. We often use the *Bohr magneton*, $\mu_\mathrm{B} \equiv \hbar e/2m_e$, which represents the elementary unit of spin,

$$\boxed{\frac{\vec{\mu}_\ell}{\mu_\mathrm{B}} = -g_\ell\frac{\hat{\mathbf{L}}}{\hbar}} \ . \tag{32.93}$$

The *g-factor* of a system having any angular momentum $\hat{\mathbf{L}}$ is defined as a proportionality constant between the normalized dipole moment and the normalized angular momentum. $g_\ell \equiv \frac{\mu_\ell}{\ell\mu_\mathrm{B}} = 1$ takes into account possible corrections between our classical derivation and quantum mechanics.

32.1.4.2 Pauli's model of spin-orbit coupling

The aim of this section is to demonstrate the relationship between the spin-orbit coupling term in Dirac's Hamiltonian (32.85) and the spin-magnetic field coupling term in Pauli's Hamiltonian (32.89).

A comparison of Pauli's expression with the energy of a magnetic moment in the field $\vec{\mathcal{B}}$,

$$\hat{H}_{\ell s} = -\vec{\mu}_s\cdot\vec{\mathcal{B}} \ , \tag{32.94}$$

suggests the following connection between the spin and the magnetic moment:

$$-\vec{\mu}_s\cdot\vec{\mathcal{B}} = \frac{e\hbar}{2m_e}\vec{\sigma}\cdot\vec{\mathcal{B}} = \frac{e}{m_e}\hat{\mathbf{S}}\cdot\vec{\mathcal{B}} \ . \tag{32.95}$$

We conclude, that the electron carries, besides mass, charge and spin, also a magnetic dipole moment,

$$\boxed{\frac{\vec{\mu}_s}{\mu_\mathrm{B}} = -\frac{e}{m_e\mu_\mathrm{B}}\hat{\mathbf{S}} = -2\frac{\hat{\mathbf{S}}}{\hbar}} \ , \tag{32.96}$$

For the g-factor of the electron, we obtain $g_e = 2$ [9]. Neutron and proton are also fermions with spin $\frac{1}{2}$, but they do not obey the Dirac equation! Their g-factors are

[9] The exact value is $g_e \equiv \frac{\mu_s}{s\mu_\mathrm{B}} = 2.002319314...$ The deviation $g_e - 2 \simeq \frac{\alpha}{\pi} - 0.164\frac{\alpha^2}{\pi^2}$ is due to the coupling of the spin to the fluctuations of the electromagnetic vacuum. We need to use quantum electrodynamical methods to calculate the corrections.

$g_{proton} = 5.5858$ and $g_{neutron} = -3.8261$. The large deviation from $g = 2$ points to the existence of an internal structure.

The rapid motion of the electron within the electrostatic field $\vec{\mathcal{E}}$ of the nucleus produces, following the theory of relativity, in the electron's reference frame a magnetic field $\vec{\mathcal{B}}'$ with which the electronic spin can interact. As we will show in Exc. 32.1.5.7, the field seen by the electron can be approximated in first order in v/c by,

$$\vec{\mathcal{B}}' \simeq \frac{\mathbf{v}}{c^2} \times \vec{\mathcal{E}} \,. \tag{32.97}$$

With this the interaction energy (32.94) becomes,

$$\begin{aligned} \hat{H}_{\ell s} &= -\vec{\mu}_s \cdot \vec{\mathcal{B}}' = \frac{e}{m_e c^2} \mathbf{s} \cdot (\mathbf{v} \times \vec{\mathcal{E}}) = -\frac{e}{m_e^2 c^2} \mathbf{s} \cdot (\hat{\mathbf{p}} \times \nabla U) \\ &= -\frac{e}{m_e^2 c^2} \mathbf{s} \cdot \left(\hat{\mathbf{p}} \times \frac{\mathbf{r}}{r} \frac{\partial U}{\partial r} \right) = -\frac{1}{m_e^2 c^2 r} \hat{\mathbf{S}} \cdot \hat{\mathbf{L}} \frac{\partial V(r)}{\partial r} \,, \end{aligned} \tag{32.98}$$

with $V(r) = -eU(r)$.

The resulting interaction energy coincides, apart from a factor $\frac{1}{2}$ [911], with the one obtained in the from Dirac's equation (32.85). The deviation, called *Thomas factor*, is due to the necessity to transform back into the inertial system of the nucleus. This transformation, called *Thomas precession*, must be done by a Lorentz transformation, which is not trivial with electron continuously changing its propagation direction on its circular orbit. The transformation introduces the additional factor of $\frac{1}{2}$ [10].

32.1.5 Exercises

32.1.5.1 Ex: Yukawa potential

Show, that Yukawa's potential satisfies the Klein-Gordon equation.

32.1.5.2 Ex: Zitterbewegung

Zitterbewegung is a hypothetical rapid motion of elementary particles, in particular electrons, that obey the Dirac equation. The existence of such motion was first proposed by Erwin Schrödinger in 1930 as a result of his analysis of the wave packet solutions of the Dirac equation for relativistic electrons in free space, in which an interference between positive and negative energy states produces what appears to be a fluctuation (at the speed of light) of the position of an electron around the median, with a frequency of $2m_e c^2/\hbar$, or approximately $1.6 \cdot 10^{21}$ rad/s. For the hydrogen atom, the Zitterbewegung produces the Darwin term which plays the role in the fine structure as a small correction of the energy level of the s-orbitals.
Use the Heisenberg equation to derive, from Dirac's Hamiltonian, equations of motion for the position operator $\hat{\mathbf{r}}$ and the 'velocity operator' $\hat{\vec{\alpha}}$. Solve the equation of motion and identify the Zitterbewegung.
Zitterbewegung of a free relativistic particle has never been observed. However, it has been simulated in experiments engineered to obey equations similar to Dirac's. First,

[10] This is a kinematic effect in space-time: the Lorentz transformations for systems moving with non-collinear velocities can not simply be concatenated, but must be rotated, too [329, 473].

with a trapped ion, by putting it in an environment such that the non-relativistic Schrödinger equation for the ion has the same mathematical form as the Dirac equation (although the physical situation is different) [351]. Then, in 2013, it was simulated in a setup with Bose-Einstein condensates [560].

32.1.5.3 Ex: Constants of motion of Dirac's Hamiltonian 1

Show that $\hat{L}_z$ with $\hat{\mathbf{L}} \equiv \mathbf{r} \times \hat{\mathbf{p}}$ and $\hat{S}_z$ with $\hat{\mathbf{S}} \equiv \frac{\hbar}{2}\gamma_5\vec{\alpha}$ defining $\gamma_5 \equiv -\imath\alpha_1\alpha_2\alpha_3$ are not constants of motions, but $\hat{\mathbf{J}} = \hat{\mathbf{L}} + \hat{\mathbf{S}}$, that is,

$$[\hat{H}, \hat{J}_z] = [\hat{H}, \hat{L}_z + \hat{S}_z] = 0 \ . \tag{32.99}$$

32.1.5.4 Ex: Calculating with Dirac matrices

a. Prove that, if $[\mathbf{B}, \vec{\sigma}] = 0 = [\mathbf{C}, \vec{\sigma}]$ where $\vec{\sigma}$ are the Pauli matrices, then,

$$(\vec{\sigma} \cdot \mathbf{B})(\vec{\sigma} \cdot \mathbf{C}) = \mathbf{B} \cdot \mathbf{C} + \imath\vec{\sigma} \cdot (\mathbf{B} \times \mathbf{C}) \ . \tag{32.100}$$

b. Prove that, if $[\mathbf{B}, \vec{\alpha}] = 0 = [\mathbf{C}, \vec{\alpha}]$ where $\vec{\alpha}$ are the Dirac matrices, then,

$$(\vec{\alpha} \cdot \mathbf{B})(\vec{\alpha} \cdot \mathbf{C}) = \mathbf{B} \cdot \mathbf{C} + \imath\gamma_5\vec{\alpha} \cdot (\mathbf{B} \times \mathbf{C}) \ . \tag{32.101}$$

c. Show that the spin defined as,

$$\mathbf{S} = \tfrac{\hbar}{2}\vec{\varsigma} \qquad \text{where} \qquad \vec{\varsigma} \equiv \gamma_5\vec{\alpha} = \mathbb{I} \otimes \vec{\sigma} \tag{32.102}$$

obeys different commutation rules than the Dirac matrices.
d. Conclude that,

$$(\vec{\varsigma} \cdot \mathbf{B})(\vec{\varsigma} \cdot \mathbf{C}) = \mathbf{B} \cdot \mathbf{C} + \imath\vec{\varsigma} \cdot (\mathbf{B} \times \mathbf{C}) \ . \tag{32.103}$$

32.1.5.5 Ex: Constants of motion of Dirac's Hamiltonian 2

In this exercise we will prove the relationships (32.55):
a. Prove,

$$(\hbar j')^2 = \hat{\mathbf{J}}^2 + \tfrac{\hbar^2}{4} \ . \tag{32.104}$$

b. Prove,

$$[\hbar j', \hat{H}]_- = 0 \ . \tag{32.105}$$

c. Prove,

$$\mathbf{r} \cdot \hat{\mathbf{p}} = -\imath\hbar r \frac{\partial}{\partial r} \ . \tag{32.106}$$

d. Prove,

$$[\varepsilon, \hat{H}]_- = 0 \ . \tag{32.107}$$

32.1.5.6 Ex: Constants of motion in the $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$-coupling

Consider a particle of mass μ described by the Hamiltonian $\hat{H} = -\frac{\hbar^2}{2\mu}\nabla^2 + V(r) + \xi(r)\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$, being $V(r)$ a central potential, $\hat{\mathbf{L}}$ and $\hat{\mathbf{S}}$ its orbital angular momentum and spin.
a. Obtain the commutation relations $[\hat{\mathbf{L}}, \hat{H}]$, $[\hat{\mathbf{S}}, \hat{H}]$ and $[\hat{\mathbf{L}}+\mathbf{S}, \hat{H}]$ for the cases without and with spin-orbit interaction $\xi(r)\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$ introduced by relativistic corrections.
b. Calculate $[\hat{\mathbf{L}}^2, \hat{H}]$, $[\hat{\mathbf{S}}^2, \hat{H}]$ and $[\hat{\mathbf{J}}^2, \hat{H}]$.

32.1.5.7 Ex: Magnetic field generated by the orbiting proton at the location of the electron

Calculate the magnetic field generated by the orbiting proton as it is perceived by the electron.

32.2 Fine structure of hydrogen-like atoms via TIPT

The wave equation that simultaneously satisfies the requirements of quantum mechanics and special relativity is the *Dirac equation*. In free space including electromagnetic interactions it describes all massive particles of semi-integer spin with parity as a symmetry, such as electrons and quarks. It was the first theory to fully explain special relativity in the context of quantum mechanics. The Dirac equation describes the fine structure of the hydrogen spectrum in a completely rigorous manner. The equation also implied the existence of a new form of matter, antimatter, previously unsuspected and unobserved. The equation also justifies a posteriori the introduction of spinors, that is, of the vector wavefunctions introduced by Pauli in a heuristic way. We have seen in the last section that, in the limit of high but non-relativistic velocities, the Dirac equation adopts the form of a Schrödinger equation with the modified Hamiltonian (32.85) [11],

$$\begin{aligned}\hat{H} &= \hat{H}_0 + \hat{H}_{\text{rel}} + \hat{H}_{\ell s} + \hat{H}_{\text{dw}} + \hat{H}_{\text{lamb}} \\ &= \left(\frac{\hat{p}^2}{2m_e} - \frac{Ze^2}{4\pi\varepsilon_0 r}\right) - \frac{\hat{p}^4}{8m_e^3c^2} + \frac{1}{2m_e^2c^2}\frac{1}{r}\frac{dV}{dr}\hat{\mathbf{L}} \cdot \hat{\mathbf{S}} + \frac{\pi\hbar^2}{2m_e^2c^2}\frac{Ze^2}{4\pi\varepsilon_0}\delta^3(\mathbf{r}) + \hat{H}_{\text{lamb}} \ .\end{aligned} \tag{32.108}$$

We will discuss the various terms in the following sections. Note that the expression for the Darwin term differs from that of (32.85). We will see in Exc. 32.2.6.1, that they are, in fact, equivalent.

32.2.1 Correction for relativistic velocities

The first correction in the expression, $\hat{H}_{\text{rel}}$ in Eq. (32.108), comes from the expansion of the relativistic energy for small velocities up to second order,

$$E_{\text{kin}} = \sqrt{p^2c^2 + m_e^2c^4} \simeq m_ec^2 + \frac{p^2}{2m_e} - \frac{p^4}{8m_e^3c^2} + \dots \ . \tag{32.109}$$

[11] From now in we will frequently drop the 'hat' on quantum operators, when their nature is clear in the context.

The correction is of the order of magnitude,

$$\frac{H_{\rm rel}}{H_0} = \frac{\frac{p^4}{8m_e^3c^2}}{\frac{p^2}{2m_e}} = \frac{v^2}{4c^2} \simeq \frac{\alpha^2}{4} \approx 0.01\% \ . \tag{32.110}$$

Due to the degeneracy of these states, it would be appropriate to use perturbation theory with degenerate states. However, as $\hat{H}_{\rm rel}$ only depends on spatial coordinates commuting with $\mathbf{l}$ and $\mathbf{s}$ (see Exc. 32.1.5.6), the degeneracy is not very important, since $\hat{H}_{\rm rel}$ is already diagonal in the base $|n,\ell,m\rangle$, that is, $\langle n,\ell,m|n',\ell',m'\rangle = \delta_{\ell\ell'}\delta_{mm'}$. Starting from,

$$\begin{aligned}\hat{H}_{\rm rel} &= -\frac{\hat{p}^4}{8m_e^3c^2} = -\frac{1}{2m_ec^2}\left(\frac{\hat{p}^2}{2m_e}\right)^2 = -\frac{1}{2m_ec^2}\left(\hat{H}_0 + \frac{Ze^2}{4\pi\varepsilon_0 r}\right)^2 \\ &= -\frac{1}{2m_ec^2}\left(\hat{H}_0 - \frac{2E_n n^2}{\tilde{r}}\right)^2 \ ,\end{aligned} \tag{32.111}$$

with $\tilde{r} \equiv \frac{Zr}{a_{\rm B}}$ and using as an abbreviation the energies of hydrogen following Bohr's model,

$$E_n = \langle n,\ell|\hat{H}_0|n,\ell\rangle = -\frac{Z^2e^2}{4\pi\varepsilon_0}\frac{1}{2a_{\rm B}n^2} = -\frac{m_ec^2}{2}\frac{Z^2\alpha^2}{n^2} \ . \tag{32.112}$$

We have

$$\begin{aligned}\Delta E_{\rm rel} &= \langle n,\ell|\hat{H}_{\rm rel}|n,\ell\rangle \\ &= -\frac{1}{2m_ec^2}\left[\langle n,\ell|\hat{H}_0^2|n,\ell\rangle - \langle n,\ell|\frac{4E_n n}{\tilde{r}}\hat{H}_0|n,\ell\rangle + \langle n,\ell|\left(\frac{2E_n n}{\tilde{r}}\right)^2|n,\ell\rangle\right] \\ &= \frac{Z^2\alpha^2}{4E_n n^2}\left[E_n^2 - 4E_n^2n^2\frac{1}{n^2} + 4E_n^2n^4\frac{1}{n^3(\ell+\frac{1}{2})}\right] \ ,\end{aligned} \tag{32.113}$$

using the eigenvalues calculated in (25.53). Finally, we obtain the following relativistic correction,

$$\boxed{\Delta E_{\rm rel} = E_n(Z\alpha)^2\left[\frac{1}{n(\ell+\frac{1}{2})} - \frac{3}{4n^2}\right]} \ . \tag{32.114}$$

Obviously, the degeneracy with respect to the angular momentum ℓ is lifted by this correction.

32.2.2 Correction due to spin-orbit coupling

The second correction, $\hat{H}_{\ell s}$ in the expression (32.108), called *spin-orbit interaction*, is a relativistic correction due to the fact that the electron moves rapidly within the electrostatic field $\vec{\mathcal{E}}$ generated by the nucleus. Considering the fundamental orbit and the fact that the angular momenta are of the order of $\hbar$ we can estimate the importance of this effect,

$$\frac{H_{\ell s}}{H_0} = \frac{\frac{1}{2m_e^2c^2}\frac{1}{r}\frac{e^2}{4\pi\varepsilon_0 r^2}\mathbf{l}\cdot\mathbf{s}}{\frac{p^2}{2m_e}} \simeq \frac{\frac{1}{2m_e^2c^2}\frac{e^2}{4\pi\varepsilon_0}\frac{1}{a_{\rm B}^3}\hbar^2}{\frac{e^2}{4\pi\varepsilon_0 a_{\rm B}}} = \frac{1}{2m_e^2c^2}\frac{\hbar^2}{a_{\rm B}^2} = \frac{\alpha^2}{2} \approx 0.01\% \ . \tag{32.115}$$

Example 245 (*Classical derivation of the spin-orbit interaction*): In the following, we will derive the expression (32.98) for the spin-orbit interaction energy from classical arguments borrowed from electrodynamic theory. Seen from the rest system of the electron being at position $\mathbf{x} = 0$, it is the proton that orbits around the electron. This orbit creates a current, $-\mathbf{j}(\mathbf{r}')$, which generates a magnetic field. Following the *Biot-Savart's law* the potential vector and the amplitude of the field are,

$$\mathbf{A}(\mathbf{x}) = \frac{\mu_0}{4\pi}\int_V \frac{-\mathbf{j}(\mathbf{r}')d^3r'}{|\mathbf{x}-\mathbf{r}'|} \ , \tag{32.116}$$

respectively,

$$\begin{aligned}\vec{\mathcal{B}}(\mathbf{x}) = \nabla_{\mathbf{x}}\times\mathbf{A}(\mathbf{x}) &= \frac{\mu_0}{4\pi}\int_V \frac{(\mathbf{x}-\mathbf{r}')\times\mathbf{j}(\mathbf{r}')}{|\mathbf{x}-\mathbf{r}'|^3}d^3r' \\ &= -\frac{\mu_0}{4\pi}\int_{-\infty}^{\infty}dz'\int_0^{\infty}r'dr'\int_0^{2\pi}d\phi\frac{(\mathbf{x}-\mathbf{r}')\times\mathbf{v}}{|\mathbf{x}-\mathbf{r}'|^3}\frac{Ze}{2\pi r}\delta(r-r')\delta(z') \\ &= \frac{Ze\mu_0}{4\pi}\frac{(\mathbf{x}-\mathbf{r})\times\mathbf{v}}{|\mathbf{x}-\mathbf{r}|^3} \ ,\end{aligned} \tag{32.117}$$

where we replaced the expression for the current density (32.91). With the expression for the *Coulomb potential* between the electron and the proton and its radial derivative,

$$V(r) = \frac{-Ze^2}{4\pi\varepsilon_0 r} \quad , \quad \frac{1}{r}\frac{dV(r)}{dr} = \frac{Ze^2}{4\pi\varepsilon_0 r^3} \ , \tag{32.118}$$

we have at the position of the electron,

$$\begin{aligned}\vec{\mathcal{B}}(\mathbf{0}) &= \frac{Ze\mu_0}{4\pi}\frac{-\mathbf{r}\times\mathbf{v}}{r^3} = -\frac{\varepsilon_0\mu_0}{e}\frac{\mathbf{r}\times\mathbf{v}}{r}\frac{dV(r)}{dr} \\ &= -\frac{1}{ec^2}\frac{\mathbf{r}\times\mathbf{v}}{r}\frac{dV(r)}{dr} = -\frac{1}{em_ec^2r}\frac{dV(r)}{dr}\mathbf{L} \ .\end{aligned} \tag{32.119}$$

The advantage of maintaining the general potential V in the formula is, that this expression also holds for more complicated atoms with many electrons, where the potential may deviate considerably from the Coulombian potential. Note, that the magnetic field is very strong, $B \simeq \xi(a_{\mathrm{B}})\hbar/\mu_{\mathrm{B}} \approx 5\,\mathrm{T}$. Inserting the magnetic field into Pauli's expression (32.94) together with the magnetic moment of the spin (32.96) we arrive at,

$$\hat{H}_{\ell s} = -\vec{\mu}_s\cdot\vec{\mathcal{B}}(\mathbf{0}) = \frac{1}{m_e^2c^2}\mathbf{S}\cdot\mathbf{L}\frac{1}{r}\frac{dV(r)}{dr} \ . \tag{32.120}$$

where we still have to apply the corrective *Thomas factor* of $\frac{1}{2}$.

The interaction operator can be written,

$$\hat{H}_{\ell s} = \xi(r)\hat{\mathbf{L}}\cdot\hat{\mathbf{S}} \ , \tag{32.121}$$

with the abbreviation,

$$\xi(r) \equiv \frac{-1}{2m_e^2c^2r}\frac{dV}{dr} = -\frac{Ze^2}{8\pi\varepsilon_0 m_e^2c^2}\frac{1}{r^3} = \frac{E_nZ^2\alpha^2n^2}{\hbar^2}\frac{1}{\tilde{r}^3} \ , \tag{32.122}$$

with $\tilde{r} \equiv Zr/a_{\rm B}$ and using the formulas (25.53).

After the introduction of the spin, the Hilbert space of the particles' wavefunctions must be extended. The wavefunctions are now products of spatial wavefunctions and spin eigenvectors:

$$|n, \ell, m_\ell, m_s\rangle = R_{n\ell}(r) Y_{\ell m}(\theta, \phi) \begin{pmatrix} s_1 \\ s_2 \end{pmatrix} \ . \tag{32.123}$$

The new Hilbert space is the tensorial product of position space and spin space. The *radial* Hamiltonian for the hydrogen atom including the centrifugal term and the spin-orbit coupling now takes the form:

$$\hat{H} = \frac{p^2}{2m} + V(r) + \frac{\hat{\mathbf{L}}^2}{2m_e r^2} + \xi(r) \hat{\mathbf{L}} \cdot \hat{\mathbf{S}} \ . \tag{32.124}$$

We may again consider the energy term $V_{\ell s}$ as a small perturbation, and calculate it using unperturbed wavefunctions,

$$\begin{aligned} \Delta E_{\ell s} &= \langle n, \ell, s, m_\ell, m_s | V_{\ell s} | n, \ell, s, m_\ell, m_s \rangle \\ &= \langle n, \ell | \xi(r) | n, \ell \rangle \langle \ell, s, m_\ell, m_s | \hat{\mathbf{S}} \cdot \hat{\mathbf{L}} | \ell, s, m_\ell, m_s \rangle \ . \end{aligned} \tag{32.125}$$

Assuming a Coulombian potential, we first look at the radial part (32.122), which can easily be calculated using the formulae (25.53),

$$\langle n, \ell | \xi(r) | n, \ell \rangle = \frac{E_n Z^2 \alpha^2 n^2}{\hbar^2} \frac{1}{n^3 \ell (\ell + \frac{1}{2})(\ell + 1)} \ . \tag{32.126}$$

To diagonalize the angular part of the Hamiltonian, we need the common wavefunctions of $\hat{\mathbf{L}}^2$ and $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$. We can rewrite the coupling term as:

$$\hat{\mathbf{L}} \cdot \hat{\mathbf{S}} = \tfrac{1}{2}(\hat{\mathbf{J}}^2 - \hat{\mathbf{L}}^2 - \hat{\mathbf{S}}^2) \ . \tag{32.127}$$

In the common eigensystem of $\hat{\mathbf{J}}^2$, $\hat{\mathbf{L}}^2$, and $\hat{\mathbf{S}}^2$ the Hamiltonian, therefore, is diagonal. We know the basis of this system from the theory of the addition of angular momenta. The states of the basis are linear combinations of the functions $|n, \ell, m_\ell, m_s\rangle$. Since the spins precess around each other, $\hat{L}_z$ and $\hat{S}_z$ are not good observables, the non-coupled basis is not appropriate. But $\hat{\mathbf{S}}^2$, $\hat{\mathbf{L}}^2$, and $\hat{\mathbf{J}}^2$ are good observables. In the coupled basis $\{n, (\ell, s) j, m_j\}$,

$$\langle n, (\ell, s) j, m_j | \hat{\mathbf{S}} \cdot \hat{\mathbf{L}} | n, (\ell, s) j, m_j \rangle = \tfrac{\hbar^2}{2} [j(j+1) - \ell(\ell+1) - s(s+1)] \ . \tag{32.128}$$

Since $j = \ell \pm 1/2$, we find that every level splits into two levels, one with the energy $E_{n\ell} + \ell \zeta_{n\ell}$ and the degeneracy $2\ell + 2$ and the other with the degeneracy $E_{n\ell} - (\ell+1)\zeta_{n\ell}$ with the degeneracy 2ℓ, where we introduced the abbreviation,

$$\zeta_{n\ell} \equiv \tfrac{\hbar^2}{2} \langle \xi(r) \rangle \ . \tag{32.129}$$

All in all, we get an energy correction due to the spin-orbit interaction of,

$$\boxed{\Delta E_{\ell s} = -E_n (Z\alpha)^2 \frac{j(j+1) - \ell(\ell+1) - \frac{3}{4}}{2n\ell(\ell + 1/2)(\ell+1)}} \ . \tag{32.130}$$

Note, that the coupling $\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}$ lifts the degeneracy with respect to $\hat{\mathbf{L}}$, but not with respect to $\hat{L}_z$ (see Fig. 32.1). As we have already seen in Exc. 32.1.5.6, in the presence of an energy associated with the $\mathbf{L} \cdot \mathbf{S}$ coupling, only the total angular momentum $\mathbf{L} + \mathbf{S}$ is a constant of motion.

32.2.3 Non-local electron-core interaction

Let us now discuss the third correction in the expression (32.108). The electron-nucleus interaction that we have considered so far is *local*, that is, the interaction at the point $\mathbf{r}$ sensed by the electron depends essentially on the field at that point in space. However, when relativistic theory is correctly applied, the electron-nucleus interaction becomes *non-local*, and the electron is then affected by all values of the nuclear field in a region around $\mathbf{r}$ [12]. The size of this region is of the order of the *Compton wavelength* of the electron, $\lambda_C/2\pi \equiv \hbar/m_e c$. This correction was introduced by *Sir Charles Galton Darwin* through a substitution in the Dirac equation that solved the problem of normalization of the wavefunction.

Imagine that instead of the potential $V(\mathbf{r})$, the potential of the electron is given by the integral,

$$\int f(r')V(\mathbf{r}+\mathbf{r}')d^3r' \ , \tag{32.131}$$

where $f(r')$ is a radially symmetric and normalized density-type function that takes significant values only in the vicinity of $\mathbf{r}$ within a volume $(\lambda_C/2\pi)^3$ centered at $\mathbf{r}' = 0$. Expanding the potential $V(\mathbf{r}+\mathbf{r}')$ near the origin,

$$V(\mathbf{r}+\mathbf{r}') = V(\mathbf{r}) + [\mathbf{r}' \cdot \nabla_r]V(\mathbf{r}) + \tfrac{1}{2!}[\mathbf{r}' \cdot \nabla_r]^2 V(\mathbf{r}) + \dots \ , \tag{32.132}$$

and inserting into the integral,

$$\begin{aligned} &\int f(r')V(\mathbf{r}+\mathbf{r}')d^3r' \\ &= V(\mathbf{r})\int f(r')d^3r' + \int \mathbf{r}' f(r')d^3r' \cdot \nabla_r V(\mathbf{r}) + \tfrac{1}{2!}\int r'^2 f(r')[\hat{\mathbf{e}}_{r'} \cdot \nabla_r]^2 d^3r' V(r) + \dots \\ &= V(\mathbf{r}) + 0 + \tfrac{1}{2!}\int r'^2 f(r')d^3r' \nabla^2 V(r) + \dots \ . \end{aligned} \tag{32.133}$$

The second term is null due to the parity of $f(r')$ and the third produces the Darwin correction using $V(\mathbf{r}) = V(r)$. Letting the function be constant within the volume, $f(\mathbf{r}) \simeq f_0$, and with the normalization,

$$1 = \int_{-\hbar/2m_e c}^{\hbar/2m_e c}\int_{-\hbar/2m_e c}^{\hbar/2m_e c}\int_{-\hbar/2m_e c}^{\hbar/2m_e c} f(r)dxdydz = f_0\left(\frac{\hbar}{m_e c}\right)^3 \ , \tag{32.134}$$

we get the integral

$$\int r^2 f(r)d^3r = \int_{-\hbar/2m_e c}^{\hbar/2m_e c}\int_{-\hbar/2m_e c}^{\hbar/2m_e c}\int_{-\hbar/2m_e c}^{\hbar/2m_e c} f(r)r^2 dxdydz = \left(\frac{\hbar}{2m_e c}\right)^2 \ . \tag{32.135}$$

[12] The smearing out of the electron's position is also known as *Zitterbewegung*. See Exc. 32.1.5.2.

Also,

$$\nabla^2 V(\mathbf{r}) = -e\nabla^2 \frac{Ze}{4\pi\varepsilon_0 r} = -e\frac{\varrho(\mathbf{r})}{\varepsilon_0} = -\frac{Ze^2\delta^3(\mathbf{r})}{\varepsilon_0} \ . \tag{32.136}$$

Hence,

$$\int f(r')V(\mathbf{r}+\mathbf{r}')d^3r' = -\frac{Ze^2}{4\pi\varepsilon_0 r} + \frac{\pi\hbar^2}{2m_e^2c^2}\frac{Ze^2}{4\pi\varepsilon_0}\delta^3(\mathbf{r}) + \dots \ , \tag{32.137}$$

which is precisely the electrostatic energy with the Darwin correction in the expressions (32.85) and (32.108).

To estimate the importance of this effect we inserting the wavefunctions (25.52) evaluated at the origin,

$$\begin{aligned}\langle \hat{H}_{\rm dw}\rangle &= \int d^3r \psi^*_{n\ell m}(\mathbf{r})\frac{\pi\hbar^2}{2m_e^2c^2}\frac{Ze^2}{4\pi\varepsilon_0}\delta^3(\mathbf{r})\psi_{n\ell m}(\mathbf{r}) \\ &= \frac{\pi\hbar^2}{2m_e^2c^2}\frac{Ze^2}{4\pi\varepsilon_0}|\psi_{n00}(0)|^2\delta_{\ell 0}\delta_{m0} = \frac{\pi\hbar^2}{2m_e^2c^2}\frac{Ze^2}{4\pi\varepsilon_0}\frac{Z^3}{\pi n^3 a_{\rm B}^3}\delta_{\ell 0} \ .\end{aligned} \tag{32.138}$$

We obtain,

$$\frac{H_{\rm dw}}{H_0} = \frac{\frac{\pi\hbar^2}{2m_e^2c^2}\frac{Ze^2}{4\pi\varepsilon_0}\frac{1}{\pi a_{\rm B}^3}}{\frac{e^2}{4\pi\varepsilon_0 a_{\rm B}}} = \frac{\hbar^2}{2m_e^2c^2}\frac{Z}{a_{\rm B}^2} = \frac{\alpha^2}{2} \approx 0.01\% \ . \tag{32.139}$$

Darwin's correction vanishes for angular momentum $\ell > 0$, such that,

$$\boxed{\Delta E_{\rm dw} = \langle \hat{H}_{\rm dw}\rangle = -E_n\frac{(Z\alpha)^2}{n}\delta_{\ell 0} \ .} \tag{32.140}$$

32.2.4 Summary of the corrections

Combining the $\mathbf{l}\cdot\mathbf{s}$ and relativistic corrections, we obtain,

$$\begin{aligned}\Delta E_{\rm fs} &= \Delta E_{\rm rel} + \Delta E_{\ell s} + \Delta E_{\rm dw} \\ &= E_n(Z\alpha)^2\left[\frac{1}{n(\ell+\frac{1}{2})} - \frac{3}{4n^2}\right] - E_n(Z\alpha)^2\frac{j(j+1)-\ell(\ell+1)-\frac{3}{4}}{2n\ell(\ell+\frac{1}{2})(\ell+1)} - E_n(Z\alpha)^2 \\ &= E_n(Z\alpha)^2\begin{cases}\frac{1}{nj} - \frac{3}{4n^2} - \frac{j(j+1)-(j-\frac{1}{2})(j+\frac{1}{2})-\frac{3}{4}}{2n(j-\frac{1}{2})j(j+\frac{1}{2})} - 1 & \text{para} \quad \ell = j-\frac{1}{2} \\ \frac{1}{n(j+1)} - \frac{3}{4n^2} - \frac{j(j+1)-(j+\frac{1}{2})(j+\frac{3}{2})-\frac{3}{4}}{2n(j+\frac{1}{2})(j+1)(j+\frac{3}{2})} - 1 & \text{para} \quad \ell = j+\frac{1}{2}\end{cases} \\ &= E_n(Z\alpha)^2\left[\frac{1}{n(j+\frac{1}{2})} - \frac{3}{4n^2} - 1\right] \ .\end{aligned} \tag{32.141}$$

That is, the levels are now degenerate in j (see Fig. 32.1) [13]. Obviously the levels which are most affected by relativistic corrections are those with low values of n and ℓ.

The levels are labeled by $n\ell_j$. For example, the state $3d_{5/2}$ has the main quantum number $n = 3$, the orbital angular momentum $\ell = 2$, and the total angular momentum

[13] It is interesting that the quantum treatment presented here, including relativistic corrections, coincidentally agrees with the corrections of *Arnold Johannes Wilhelm Sommerfeld*.

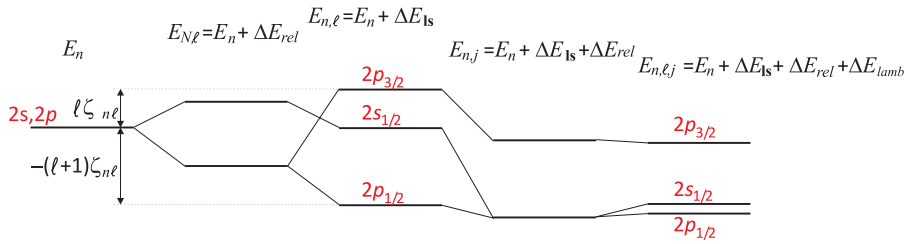


Figure 32.1: Hydrogen levels in the presence of various combinations of relativistic corrections.

$j = 5/2$. For large n or j the fine structure disappears. The new energy scheme is shown in Fig. 32.1. We note that, taking into account all relativistic corrections (but without the Lamb shift), we still have a partial degeneracy of the quantum number j. For example, the states ${}^2s_{1/2}$ and ${}^2p_{1/2}$ have the same energy. This is a particularity of the hydrogen atom.

32.2.5 Lamb shift

Only remains to discuss the fourth correction, $\hat{H}_{\text{lamb}}$ in the expression (32.6). The origin of the *Lamb shift* lies in quantum electrodynamics. Being due to the quantum nature of the electromagnetic field, this correction is not predicted within the Dirac equation.

We may imagine the Coulomb force between charged particles being mediated by a continuous exchange of virtual photons. But each isolated charge also continuously emits and reabsorbs virtual photons, with the result that the position of the electron is smeared over a region of 0.1 fm. This reduces the overlap between the electronic orbits and the nucleus. Hence, the Lamb shift causes corrections that are stronger for small n and small ℓ. For example in hydrogen, the $2p_{1/2}$ is $4.4 \cdot 10^{-6}$ eV $= 1$ GHz below the $2s_{1/2}$ (see Fig. 32.1).

32.2.6 Exercises

32.2.6.1 Ex: The Darwin term

Show that the expressions for the Darwin correction (32.85) and (32.108) are equivalent.

32.3 Hyperfine structure

Rutherford's measurements suggested a point-like and infinitely heavy atomic nucleus. In fact, the mass is finite and the nuclear charge is distributed over a finite volume and often in a non-isotropic manner, which leads to multipolar interactions with the electrons. In addition, many nuclei have a spin that can interact with the magnetic moment of the electrons. The energy corrections due to these effects are

called *hyperfine structure* [14].

Because many of the following considerations will remain valid for many-electron systems to be discussed later, we will switch to a notation denoting by $\hat{\mathbf{L}}$ the total orbital angular momentum of the electronic shell, $\hat{\mathbf{S}}$ the total spin of the electronic shell, and $\hat{\mathbf{J}}$ the total angular momentum of the electronic shell, remembering that for hydrogen $\hat{\mathbf{S}} = \frac{\hbar}{2}\hat{\vec{\sigma}}$.

32.3.1 Coupling to the nuclear spin

32.3.1.1 Dipole moment of the nuclear spin

The nucleus may also have an angular momentum interacting with the angular momentum of the electrons. However, the momentum depends inversely on the masses. That is, the angular momentum of the nucleus is $\mu_{\mathrm{N}}/\mu_{\mathrm{B}} = m_e/m_p \simeq 10^{-3}$ times smaller, where $\mu_{\mathrm{N}} = \hbar e/2m_p$ is an abbreviation called *nuclear magneton*. Thus, we can assume that the interaction between the nucleus and the electron will not interfere with the $\mathbf{L}\cdot\mathbf{S}$-coupling between the orbital angular momentum and the spin of the electron. The spin of the nucleus will be oriented along the total momentum of the electrons $\hat{\mathbf{J}}$. However, this interaction will have the ability to lift the hydrogen degeneracy, even though the *splitting* will only be *hyperfine*. Indeed, the order of magnitude of *hyperfine splitting* is 10^{-6} eV.

Analogously to the expressions (32.93) and (32.96), we write the dipole moment of the nucleus,

$$\boxed{\frac{\vec{\mu}_I}{\mu_{\mathrm{N}}} = \frac{e}{2m_p\mu_{\mathrm{N}}} g_p \hat{\mathbf{I}} = g_p \frac{\hat{\mathbf{I}}}{\hbar}} \,, \tag{32.142}$$

where $g_p \equiv \mu_I/I$ is once again a factor taking into account possible corrections between the classical derivation and quantum mechanics [15].

32.3.1.2 Hyperfine splitting

In the derivation of the Pauli equation (32.89) from the Dirac equation (32.76) we discarded non-relativistic terms and reintroduced electronic spin-orbit coupling by hand allowing for $\mathbf{A}(\mathbf{r},t) \neq 0$. By an analogous calculation directly applied to the Dirac equation we may unravel the *hyperfine structure*. Instead of setting the vector potential to $\mathbf{A}(\mathbf{r},t) = 0$, as we did in (32.45), we now generalize the Dirac equation (32.76),

$$E'\vec{\phi} = qU(\mathbf{r})\vec{\phi} + \vec{\sigma}\cdot\vec{\pi}\frac{1}{2m_e}\left(1 + \frac{E' - U(\mathbf{r})}{2m_e c^2}\right)^{-1} \vec{\sigma}\cdot\vec{\pi}\vec{\phi} \,. \tag{32.143}$$

Assuming $\langle q\mathbf{A}\rangle \ll \langle \mathbf{p}\rangle$, we may only retain terms to the lowest order in $\mathbf{A}$ and neglect terms containing $q\mathbf{A}\frac{E'-U(\mathbf{r})}{2m_e c^2}$. Using the result of the calculation (32.87),

$$(\vec{\sigma}\cdot\vec{\pi})(\vec{\sigma}\cdot\vec{\pi}) = [\mathbf{p} - q\mathbf{A}]^2 - \hbar q\vec{\sigma}\cdot\vec{\mathcal{B}} \,, \tag{32.144}$$

[14] See [184] p. 1229 and [935] p. 23 for further reading.

[15] In fact, the proton factor g is anomalous, $g_p = 5.58$, which reduces the fraction μ_l/μ_I. For the neutron we have: $g_n = -3.83$

we find the generalization of the total energy (32.85),

$$\hat{H} \simeq \frac{[\hat{\mathbf{p}} - q\mathbf{A}(\mathbf{r})]^2}{2m_e} - \frac{1}{4\pi\varepsilon_0}\frac{e^2}{r} - \frac{\hat{\mathbf{p}}^4}{8m_e^3c^2} - \frac{e}{2m_e^2c^2}\frac{1}{r}\frac{\partial U}{\partial r}\hat{\mathbf{S}}\cdot\hat{\mathbf{L}} - \frac{\hbar^2 e}{4m_e^2c^2}\frac{\partial U}{\partial r}\frac{\partial}{\partial r} - \frac{\hbar q}{2m_e}\vec{\sigma}\cdot\vec{\mathcal{B}}(\mathbf{r}) \ , \tag{32.145}$$

and expanding the bracket

$$[\mathbf{p} - q\mathbf{A}]^2 \simeq \mathbf{p}^2 - q\mathbf{p}\cdot\mathbf{A} - q\mathbf{A}\cdot\mathbf{p} = \mathbf{p}^2 - 2q\mathbf{A}\cdot\mathbf{p} \tag{32.146}$$

in the Coulomb gauge, we see that two new terms are added to the energy called the hyperfine structure,

$$\boxed{\begin{array}{rrcl} & \hat{H} & = & \hat{H}_B + \hat{H}_{\rm fs} + \hat{H}_{\rm hfs} \\ \text{with} & \hat{H}_{\rm hfs} & = & \hat{H}_{LI} + \hat{H}_{SI} = \frac{e}{m_e}\mathbf{A}(\mathbf{r})\cdot\hat{\mathbf{p}} + \frac{2\mu_{\rm B}}{\hbar}\hat{\mathbf{S}}\cdot\vec{\mathcal{B}}(\mathbf{r}) \end{array}} \ , \tag{32.147}$$

with $\vec{\mu}_S = -\frac{e}{m_e}\hat{\mathbf{S}}$.

Up to now we did not say anything about the origin of the magnetic field. We only notice that any magnetic field will interact with the electron's orbit and with its spin. We now make use of our knowledge that the proton has a spin of its own which produces, at the position of the electrons, a magnetic vector potential,

$$\mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi}\frac{\vec{\mu}_I \times \mathbf{r}}{r^3} \ , \tag{32.148}$$

interacting with the angular momentum of the electron $\hat{\mathbf{L}}$ in the form,

$$\begin{aligned} \hat{H}_{LI} &= \frac{e}{m_e}\mathbf{A}\cdot\hat{\mathbf{p}} = \frac{e}{m_e}\frac{\mu_0}{4\pi r^3}(\vec{\mu}_I \times \mathbf{r})\cdot\hat{\mathbf{p}} \\ &= \frac{e}{m_e}\frac{\mu_0}{4\pi r^3}\frac{\mu_{\rm N}}{\hbar}g_p(\hat{\mathbf{I}}\times\mathbf{r})\cdot\hat{\mathbf{p}} = \frac{\mu_0}{2\pi r^3}\frac{\mu_{\rm B}}{\hbar}\frac{\mu_{\rm N}}{\hbar}g_p\hat{\mathbf{L}}\cdot\hat{\mathbf{I}} \ , \end{aligned} \tag{32.149}$$

using the definition of Bohr's magneton.

In addition, the potential vector (32.148) generated by the nuclear spin produces a magnetic field [473],

$$\vec{\mathcal{B}} = \nabla\times\mathbf{A} = \frac{\mu_0}{4\pi r^3}\left[3(\vec{\mu}_I\cdot\hat{\mathbf{e}}_r)\hat{\mathbf{e}}_r - \vec{\mu}_I\right] + \tfrac{2}{3}\mu_0\vec{\mu}_I\delta^3(\mathbf{r}) \ , \tag{32.150}$$

as will be shown in Exc. 32.3.3.1. This field interacts with the spin of the electron $\hat{\mathbf{S}}$ in the form,

$$\begin{aligned} \hat{H}_{SI} &= -\vec{\mu}_S\cdot\vec{\mathcal{B}} = -\frac{\mu_0}{4\pi r^3}\left[3(\vec{\mu}_I\cdot\hat{\mathbf{e}}_r)(\vec{\mu}_S\cdot\hat{\mathbf{e}}_r) - (\vec{\mu}_S\cdot\vec{\mu}_I)\right] - \tfrac{2}{3}\mu_0\vec{\mu}_S\cdot\vec{\mu}_I\delta^3(\mathbf{r}) \\ &= \frac{\mu_0}{4\pi r^3}\frac{\mu_{\rm B}}{\hbar}g_e\frac{\mu_{\rm N}}{\hbar}g_p\left[3(\hat{\mathbf{I}}\cdot\hat{\mathbf{e}}_r)(\hat{\mathbf{S}}\cdot\hat{\mathbf{e}}_r) - (\hat{\mathbf{S}}\cdot\hat{\mathbf{I}})\right] + \tfrac{2}{3}\mu_0 g_e\mu_{\rm B}\frac{\hat{\mathbf{S}}}{\hbar}\cdot g_p\mu_{\rm N}\frac{\hat{\mathbf{I}}}{\hbar}\delta^3(\mathbf{r}) \ , \end{aligned} \tag{32.151}$$

inserting the expressions (32.96) and (32.142). The first term gives the energy of the nuclear dipole in the field due to the electronic orbital angular momentum. The second term gives the energy of the 'finite distance' interaction of the nuclear dipole with the field due to the electron spin magnetic moments. The final term, often known as the *Fermi contact term* relates to the direct interaction of the nuclear dipole with the spin dipoles and is only non-zero for states with a finite electron spin density at the position of the nucleus (those with unpaired electrons in s-subshells).

We now discuss the two cases in which $\ell = 0$ or $\ell \neq 0$ separately in the following subsections [184, 801, 473].

32.3.1.3 Orbital angular momentum $\ell = 0$

For vanishing orbital angular momenta, $\ell = 0$, we only need to consider the contribution $\hat{H}_{SI}$. Furthermore, this contribution will be dominated by the Dirac term, because the s-orbitals have a high probability at the nuclear region, but fall off quickly at larger distances. Hence,

$$\hat{H}_{SI} \simeq \tfrac{2}{3}\mu_0 g_e \mu_{\mathrm{B}} \frac{\hat{\mathbf{S}}}{\hbar} \cdot g_p \mu_{\mathrm{N}} \frac{\hat{\mathbf{I}}}{\hbar} \delta^3(\mathbf{r}) \ . \tag{32.152}$$

Defining the complete total angular momentum of the atom,

$$\hat{\mathbf{F}} \equiv \hat{\mathbf{I}} + \hat{\mathbf{S}} \ , \tag{32.153}$$

we calculate from (32.151),

$$\begin{aligned}
\Delta E_{\mathrm{hfs}}^{\ell=0} &= \langle (S,I)F, m_F | \hat{H}_{SI} | (S,I)F, m_F \rangle = \frac{2\mu_0 g_e g_p \mu_{\mathrm{B}} \mu_{\mathrm{N}}}{3\hbar^2} \langle \mathbf{S}\cdot\mathbf{I}\rangle \langle \delta^3(\mathbf{r})\rangle \qquad (32.154)\\
&= \tfrac{2}{3}\mu_0 g_e g_p \mu_{\mathrm{B}} \mu_{\mathrm{N}} [F(F+1) - I(I+1) - S(S+1)] \int \psi^*_{n00}(\mathbf{r}) \delta^3(\mathbf{r}) \psi_{n00}(\mathbf{r}) d^3r \\
&= \tfrac{2}{3}\mu_0 g_e g_p \mu_{\mathrm{B}} \mu_{\mathrm{N}} [F(F+1) - I(I+1) - S(S+1)] \left| \tfrac{1}{\sqrt{\pi}} \left(\tfrac{Z}{n a_{\mathrm{B}}}\right)^{3/2} \right|^2 \ .
\end{aligned}$$

As an example consider the hyperfine structure of the state $1s_{1/2}$ of the hydrogen atom. With $J = I = \frac{1}{2}$ and $Z = n = 1$ we obtain (see Exc. 32.3.3.2),

$$\begin{aligned}
\Delta E_{\mathrm{hfs}}^{\ell=0}(F=1) - \Delta E_{\mathrm{hfs}}^{\ell=0}(F=0) &= \tfrac{2}{3}\mu_0 g_e \mu_{\mathrm{B}} g_p \mu_{\mathrm{N}} \ 2 \ \tfrac{1}{\pi} \left(\tfrac{Z}{n a_{\mathrm{B}}}\right)^3 \qquad (32.155)\\
&= \frac{2 g_e g_p m_e^2 c^2}{3 m_p} \alpha^4 \approx (2\pi\hbar) \cdot 1.420\,\mathrm{GHz} \ .
\end{aligned}$$

The experimental value is 1.4204057518 GHz. This frequency corresponds to the spectral line used in radio astronomy, where the measurement of the angular distribution of this radiation allows the mapping of the spatial distribution of interstellar hydrogen.

32.3.1.4 Orbital angular momenta $\ell \neq 0$

In the case $\ell \neq 0$ both contributions, $\hat{H}_{SI}$ and $\hat{H}_{LI}$ have to be considered, however, we may neglect the Dirac term, because the orbitals with orbital angular momentum have vanishing probabilities at the nuclear region. Combining the two terms (32.149) and (32.151), we obtain,

$$\begin{aligned}
\hat{H}_{JI} = \hat{H}_{LI} + \hat{H}_{SI} &= \frac{\mu_0}{4\pi r^3} \frac{\mu_{\mathrm{B}}}{\hbar} g_e \frac{\mu_{\mathrm{N}}}{\hbar} g_p \left[3(\hat{\mathbf{I}}\cdot\hat{\mathbf{e}}_r)(\mathbf{S}\cdot\hat{\mathbf{e}}_r) + \mathbf{L}\cdot\hat{\mathbf{I}} - \hat{\mathbf{S}}\cdot\hat{\mathbf{I}} \right] \qquad (32.156)\\
&= \frac{\mu_0}{4\pi r^3} \frac{\mu_{\mathrm{B}}}{\hbar} g_e \frac{\mu_{\mathrm{N}}}{\hbar} g_p \hat{\mathbf{N}} \cdot \hat{\mathbf{I}} \ ,
\end{aligned}$$

introducing $\hat{\mathbf{N}}$ as a quantity that only depends on the electronic shell:

$$\hat{\mathbf{N}} \equiv 3(\hat{\mathbf{S}}\cdot\hat{\mathbf{e}}_r)\hat{\mathbf{e}}_r + \hat{\mathbf{L}} - \hat{\mathbf{S}} \ . \tag{32.157}$$

Generalizing the complete total angular momentum of the atom (32.153),

$$\hat{\mathbf{F}} \equiv \hat{\mathbf{I}} + \hat{\mathbf{J}} \ , \tag{32.158}$$

is useful for calculating the coupling $\hat{\mathbf{I}} \cdot \hat{\mathbf{J}} = \frac{1}{2}(\hat{\mathbf{F}}^2 - \hat{\mathbf{I}}^2 - \hat{\mathbf{J}}^2)$. Now, as the $\mathbf{L} \cdot \mathbf{S}$-coupling is strong, we project the two angular momenta onto the total electronic angular momentum $\hat{\mathbf{J}}$,

$$\hat{\mathbf{N}} \longrightarrow \frac{\hat{\mathbf{N}} \cdot \hat{\mathbf{J}}}{|\mathbf{J}|} \frac{\hat{\mathbf{J}}}{|\mathbf{J}|} \quad , \quad \hat{\mathbf{I}} \longrightarrow \frac{\hat{\mathbf{I}} \cdot \hat{\mathbf{J}}}{|\mathbf{J}|} \frac{\mathbf{J}}{|\mathbf{J}|} \ . \tag{32.159}$$

We get for the coupling between the projected spins (32.159) of the electronic layer and the nucleus,

$$\hat{\mathbf{N}} \cdot \hat{\mathbf{I}} \longrightarrow \frac{(\hat{\mathbf{N}} \cdot \hat{\mathbf{J}})(\hat{\mathbf{I}} \cdot \hat{\mathbf{J}})}{|\mathbf{J}|^2} = \frac{(\hat{\mathbf{N}} \cdot \hat{\mathbf{J}})(\hat{\mathbf{F}}^2 - \hat{\mathbf{I}}^2 - \hat{\mathbf{J}}^2)}{2|\mathbf{J}|^2} \ . \tag{32.160}$$

We calculate

$$\begin{aligned} \Delta E_{\text{hfs}}^{\ell \neq 0} &= \langle ((L,S)J,I)F, m_F | \hat{H}_{JI} | ((L,S)J,I)F, m_F \rangle \\ &= \frac{\mu_0}{4\pi} \frac{\mu_{\text{B}}}{\hbar} g_e \frac{\mu_{\text{N}}}{\hbar} g_p \left\langle \frac{\hat{\mathbf{N}} \cdot \hat{\mathbf{I}}}{r^3} \right\rangle \\ &\longrightarrow \frac{\mu_0}{4\pi} \frac{\mu_{\text{B}}}{\hbar} g_e \frac{\mu_{\text{N}}}{\hbar} g_p \frac{\mathbf{N} \cdot \mathbf{J}[F(F+1) - I(I+1) - J(J+1)]}{2J(J+1)} \left(\frac{Z}{a_{\text{B}}} \right)^3 \frac{n}{n^4 L(L+\frac{1}{2})(L+1)} \ . \end{aligned} \tag{32.161}$$

Introducing the *interval factor*,

$$A_J \equiv \frac{\mu_0}{4\pi} \frac{\mu_{\text{B}}}{\hbar} g_e \frac{\mu_{\text{N}}}{\hbar} g_p \left(\frac{Z}{a_{\text{B}}} \right)^3 \frac{\mathbf{N} \cdot \mathbf{J}}{2J(J+1)} \frac{n}{n^4 L(L+\frac{1}{2})(L+1)} \ , \tag{32.162}$$

as a quantity that only depends on the electronic shell, we can write

$$\boxed{\Delta E_{\text{hfs}}^{\ell \neq 0} = \frac{A_J}{2} [F(F+1) - J(J+1) - I(I+1)]} \ . \tag{32.163}$$

This formula includes the case $\ell = 0$ with the interval factor calculated from (32.154).

Note, that the $\mathbf{J} \cdot \mathbf{I}$-coupling breaks the degeneracy of $\hat{\mathbf{J}}$ in the hydrogen atom, but not of $\hat{J}_z$. We can derive the following *interval rule*,

$$\Delta E_{F+1} - \Delta E_F = A_J (F+1) \ . \tag{32.164}$$

Besides the magnetic interaction between the angular momenta of the nucleus and the electronic shell there is an interaction between the nucleus, when it is not spherically symmetric, and the shell. This interaction causes deviations from the interval rule and an additional splitting of the hyperfine states.

32.3.2 Electric quadrupole interaction

The fact that the nucleus is not perfectly spherical gives rise to new electron-nucleus corrections that are called *quadrupolar interaction*. The starting point is,

$$\hat{H}_{\text{quad}} = -\frac{1}{4\pi\varepsilon_0}\frac{e^2}{|\mathbf{r}_e - \mathbf{r}_N|} - \frac{1}{4\pi\varepsilon_0}\frac{e^2}{|\mathbf{r}_e|} \ , \tag{32.165}$$

where $\mathbf{r}_e$ is the electronic coordinate and $\mathbf{r}_N$ is the nuclear coordinate, both having their origin in the center mass of the nucleus. For $\mathbf{r}_e > \mathbf{r}_N$ this interaction can be obtained after several mathematical steps as [626],

$$\hat{H}_{\text{quad}} = B_J \frac{3(\hat{\mathbf{I}}\cdot\hat{\mathbf{J}})(2\hat{\mathbf{I}}\cdot\hat{\mathbf{J}}+1) - 2\hat{\mathbf{I}}^2\hat{\mathbf{J}}^2}{2I(I-1)2J(J-1)} \ , \tag{32.166}$$

where B_J is called the *constant of the quadrupolar electron-nucleus interaction*. With this expression we can calculate,

$$\Delta E_{\text{quad}} = \langle IJKm_K|\hat{H}_{\text{quad}}|IJKm_K\rangle = B_J \frac{\frac{3}{2}K(K+1) - 2I(I+1)J(J+1)}{2I(2I-1)2J(2J-1)} \ , \tag{32.167}$$

where $K \equiv 2\langle\hat{\mathbf{J}}\cdot\hat{\mathbf{I}}\rangle = F(F+1) - I(I+1) - J(J+1)$. It is important to remember that a nucleus with $I = 0$ or $I = \frac{1}{2}$ has no quadrupole moment, $B_J = 0$. Also for $J = \frac{1}{2}$ there will be no contribution.

Joining the contributions $\hat{\mathbf{J}}\cdot\hat{\mathbf{I}}$ of Eq. (32.163) and the quadrupolar contribution (32.167), the hyperfine structure can be described by,

$$\begin{aligned}\Delta E_{\text{hfs}} &= \Delta E_{JI} + \Delta E_{\text{quad}} \\ &= \frac{A_J}{2}K + \frac{B_J}{8IJ(2I-1)(2J-1)}[3K(K+1) - 4I(I+1)J(J+1)] \ ,\end{aligned} \tag{32.168}$$

where the constants A_J and B_J depend on the atom and the total electronic angular momentum.

Table 32.1: List of atomic data [879] showing the natural linewidth of the D_2 line, frequencies of the D_1 and D_2 lines, and the hyperfine splitting.

In Excs. 32.3.3.3 and 32.3.3.4 we determine the hyperfine structures of sodium and rubidium atoms.

32.3.3 Exercises

32.3.3.1 Ex: Field of a magnetic moment

a. Calculate the vector potential $\mathbf{A}(\mathbf{r})$ and the magnetic dipole moment $\vec{\mu}$ produced by an orbiting electron by Biot-Savart's law using the expansion of $|\mathbf{r}-\mathbf{r}'|^{-1}$ in Legendre polynomials.
b. Calculate the magnetic field $\vec{\mathcal{B}}(\mathbf{r})$.

32.3.3.2 Ex: Probability for finding the electron near the nucleus

Calculate the expectation value $\langle\delta^{(3)}(\mathbf{r})\rangle_{n\ell m}$ for encountering the electron of a hydrogen atom close to the nucleus.

32.3.3.3 Ex: Hyperfine structure of sodium

Determine the hyperfine structure of the ^2S and ^2P states of the sodium atom including energy shifts. See Tab. 39.1 for the hyperfine constants A_J and B_J.

Table 32.2: Hyperfine constants of some alkaline atoms.

atom	n	$A_J(n^2S_{1/2})$	$A_J(n^2P_{1/2})$	$A_J(n^2P_{3/2})$	$B_J(n^2P_{3/2})$
		[MHz·h]	[MHz·h]	[MHz·h]	[MHz·h]
^{1}H, $I=\frac{1}{2}$	1	1420	46.17	−3.07	−0.18

^{87}Rb, $I=\frac{3}{2}$	5	3417.3	409.1	84.852	12.510
	6	809.1	132.5	27.70	3.947

32.3.3.4 Ex: Hyperfine structure of rubidium

Given the following energy distances $\nu_{F,F'}$ of the hyperfine levels of the rubidium isotopes ^{87}Rb and ^{85}Rb [67],

$$\begin{array}{lll}
^{87}\mathrm{Rb}, S_{1/2} & \text{splits into} & \nu_{1,2} = 6834.7\,\mathrm{MHz} \\
^{87}\mathrm{Rb}, P_{3/2} & \text{splits into} & \nu_{0,1} = 72.3\,\mathrm{MHz}, \nu_{1,2} = 157.1\,\mathrm{MHz}, \nu_{2,3} = 267.2\,\mathrm{MHz} \\
^{85}\mathrm{Rb}, S_{1/2} & \text{splits into} & \nu_{1,2} = 3035.7\,\mathrm{MHz} \\
^{85}\mathrm{Rb}, P_{3/2} & \text{splits into} & \nu_{1,2} = 29.4\,\mathrm{MHz}, \nu_{2,3} = 63.4\,\mathrm{MHz}, \nu_{3,4} = 120.7\,\mathrm{MHz}
\end{array},$$

calculate the positions of the barycenters.

32.3.3.5 Ex: Two particles

Consider a two-particle system of masses μ_1 and μ_2, exposed to a central potential $V(r)$ and an interaction potential $V(|\mathbf{r}_1 - \mathbf{r}_2|)$ which only depends on the distance between the particles. The Hamiltonian of the system in the interaction representation is $H = H_1 + H_2 + V(|\mathbf{r}_1 - \mathbf{r}_2|)$ with $H_\ell = -\frac{\hbar^2}{2\mu_\ell}\nabla_\ell^2 + V(r_\ell)$, $\ell = 1, 2, ...$ Show that the individual angular momenta $\mathbf{L}_\ell$ are not, in general, constants of the motion, unlike the *total* angular momentum $\mathbf{L} = \mathbf{L}_1 + \mathbf{L}_2$.

32.4 Exotic atoms

'Normal' atoms consist of a nucleus made of protons and neutrons and an electronic shell. But other two-particle systems are possible, e.g. where the nucleus or electron is replaced by another hadron or lepton (anti-proton, positron, muon, etc.). Such a system is called *exotic atom*. Atoms in Rydberg states also belong to this category.

32.4.1 Positronium and muonium

Positronium (e^+e^-) is a hydrogen-like system consisting of leptons, that is, an electron and a positron, which is the antiparticle of the electron. The muonium (μ^+e^-) is similar to positronium, except that here the positron is replaced by a muon whose mass is $m_{\mu^+} = 207m_e$. Leptons are, according to the present understanding, particles without internal structure. Both systems are unstable: the two particles annihilate each other producing γ-photons. The energy levels and orbits of the two particles are similar to that of the hydrogen atom. However, because of the reduced mass, the frequencies of the spectral lines are less than half of the corresponding hydrogen lines.

The fundamental state of positronium, like that of hydrogen, has two possible configurations depending on the relative orientation of the electron and positron spins. The singlet state with antiparallel spins ($S = 0$, $M_s = 0$) is known as para-positronium (p-Ps) and denoted by $^1S_0$. It has an average lifetime of

$$\tau = \frac{2\hbar}{m_e c^2 \alpha^5} = 124.4\,\text{ps} \tag{32.169}$$

and decays preferably in two gamma rays with energy of 511 keV each (in the center-of-mass). The triplet state with parallel spins ($S = 1, M_s = -1, 0, 1$) is known as ortho-positronium (o-Ps) and denoted as $^3S_1$. It has an average life of 138.6 ns, and the most common form of decay produces three photons. Other forms of decay are negligible. For example, the decay channel producing five photons is 10^{-6} times less likely. Measurements of these lifetimes and the positronium energy levels have been used in precision tests of quantum electrodynamics.

While the precise calculation of the positronium energy levels is based on the Bethe-Salpeter equation, the similarity between positronium and hydrogen allows for an approximate estimate. In this approach, the energy levels are suppodsed to be different from those of hydrogen because of the difference in the value of the reduced mass μ, used in the energy equation. Since $\mu = m_e/2$ for positronium, we have

$$E_n = -\frac{\mu q_e^4}{8h^2\varepsilon_0^2}\frac{1}{n^2} = -\frac{1}{2}\frac{m_e q_e^4}{8h^2\varepsilon_0^2}\frac{1}{n^2} = \frac{-6.8\,\text{eV}}{n^2}\ . \tag{32.170}$$

A di-positronium molecule, that is, a system of two bound positronium atoms, has already been observed. Positronium in high energy states has been conjectured to become the dominant form of atomic matter in the universe in the very distant future if the proton decay becomes tangible.

32.4.2 Hadronic atoms

In contrast to *leptons* (such as the electron e^-, the positron e^+ and the muons μ^+ and μ^-) that participate only in electromagnetic interactions and weak interactions, *hadrons* also participate in strong (nuclear type) interactions. There are two types of hadrons, *baryons* (such as the proton p and antiproton $\bar{p}$, the neutron n and antineutron $\bar{n}$, hyperons Σ, Ξ, ...) that have semi-integer spin and behave like fermions and *mesons* (like the π-meson, K-meson, ...) that have an integer spin. Every negatively charged hadron can be used to form a hydrogen-type *hadronic atom*. These systems contain a nucleus and negative hyperon and are known as hyperonic atoms. All of

these are unstable and due to the fact that they have a sufficiently long lifetime, some of their spectral lines have now been observed.

Since the hadrons interact strongly with the nucleus, the theory developed for hydrogen systems (in which only exist Coulomb interaction) can not be directly applied. In this way the values shown in Tab. 32.3 give only an estimate of the 'radius' and the ionization potential of the hadronic atoms $p\pi^-$, $p\kappa^-$, $p\bar{p}$ and $p\Sigma^-$.

Table 32.3: *Main features of some exotic atoms.*

system	reduced mass	radius a_μ	I_p
pe^-	$1836/1837 \approx 1$	$\approx a_\mathrm{B} = 1$	$e^2/2a_\mathrm{B} \approx 0.5$
e^+e^-	0.5	2	0.25
μ^+e^-	$207/208 \approx 1$	1	0.5
$p\mu^-$	≈ 186	$5.4 \cdot 10^{-3}$	93
$p\pi^-$	≈ 238	$4.2 \cdot 10^{-3}$	119
$p\kappa^-$	≈ 633	$1.6 \cdot 10^{-3}$	317
$p\bar{p}$	≈ 928	$1.1 \cdot 10^{-3}$	459
$p\Sigma^-$	≈ 1029	$9.7 \cdot 10^{-3}$	515

32.4.3 Muonic hydrogen

The muon mass is $m_\mu = 207 m_e$. When a muon is attached to a proton we have *muonic hydrogen*. Its size is smaller because of the reduced mass $a_\mu = a_\mathrm{B} \frac{1/m_e}{1/m_\mu + 1/m_p}$ and the binding energy and the energies of excitation are greater for the same reason. F.ex. while for $H = p^+e^-$ the transition $2S - 2P_{1/2}$ is at 10 eV $\triangleq$ 121 nm, for $p^+\mu^-$ it is at 1900 eV. Muonic atoms are interesting because they have amplified Lamb shifts, hyperfine interactions, and quantum electrodynamical corrections. Therefore, the displacement due to the finite distribution of charges in the proton $r_p = 0.8$ fm should influence the spectrum. While in p^+e^- the $2S$ level is shifted upward by the Lamb shift by a value of 4.4×10^{-6} eV, in $p^+\mu^-$ it is shifted down by a value of 0.14 eV. In Exc. 32.4.5.2 we calculate the spectrum of the muonic hydrogen and in Exc. 27.1.3.3 we compare the energy corrections due to the finite extension of the nuclei for muonic and for standard hydrogen in first order TIPT.

32.4.4 Rydberg atoms

An atom excited to a state whose main quantum number is very high is called *Rydberg atom*. These atoms have a number of peculiar properties, including high sensitivity to electric and magnetic fields, long decay times, and wavefunctions that approximate classical electron orbits. The inner electrons protect the outer electron from the electric field of the nucleus such that, from a distance, the electric potential looks identical to that seen by the electron of a hydrogen atom.

Despite its flaws, Bohr's atom model is useful in explaining these properties. In Exc. 23.1.6.6 we derive Bohr's expression for the orbital radius in terms of the principal

quantum number n:

$$r = \frac{4\pi\varepsilon_0 n^2\hbar^2}{e^2 m} \ . \tag{32.171}$$

Thus, it is clear why Rydberg atoms have peculiar properties: the radius goes as n^2 (such that for example the state with $n = 137$ of hydrogen has a radius of $\sim 1\,\mathrm{mm}$) and the geometric cross section goes as n^4. Thus, Rydberg atoms are extremely large, with loosely bound valence electrons that are easily perturbed or ionized by collisions or external fields.

Since the binding energy of a Rydberg electron is proportional to $1/r$, and therefore falls as $1/n^2$, the spacing between energy levels falls as

$$\Delta E = E_1\left(\frac{1}{(n+1)^2} - \frac{1}{n^2}\right) \overset{n\to\infty}{\longrightarrow} E_1\left(-\frac{2}{n^3} + \frac{3}{n^4} + ...\right) \tag{32.172}$$

leading to less and less spaced levels. These Rydberg states form the *Rydberg series*.

32.4.4.1 Correspondence principle in Rydberg atoms

To calculate the oscillation frequency of an electron confined to a proton, we use the classical planetary model,

$$m\omega_n^2 = \frac{e^2}{4\pi\varepsilon_0 r} \qquad \text{and} \qquad m\omega r^2 = n\hbar \ . \tag{32.173}$$

Eliminating r,

$$\omega_n = \frac{me^4}{(4\pi\varepsilon_0)^2 n^3\hbar^3} \ . \tag{32.174}$$

Radiation of this frequency will be emitted by an atomic antenna. On the other hand, the Bohr model predicts frequencies between orbitals,

$$\omega_n = \frac{E_{n+1} - E_n}{\hbar} = \frac{me^4}{2(4\pi\varepsilon_0)^2\hbar^2}\left(\frac{1}{(n+1)^2} - \frac{1}{n^2}\right) \overset{n\to\infty}{\longrightarrow} \frac{me^4}{2(4\pi\varepsilon_0)^2\hbar^2}\frac{2}{n^3} \ . \tag{32.175}$$

32.4.4.2 Production of Rydberg atoms

In the hydrogen atom only the ground state ($n = 1$) is actually stable. Other states must be excited by various techniques such as electron impact or charge exchange. In contrast to these methods, which produce a distribution of excited atoms at various levels, the optical excitation method allows to produce specific states, but only for alkali metals whose transitions fall into frequency regimes which are accessible to lasers.

32.4.4.3 Potential in a Rydberg atom

The valence electron in a Rydberg atom with Z protons in the nucleus and $Z - 1$ electrons in closed layers sees a spherically symmetric Coulomb potential:

$$U_\mathrm{C} = -\frac{e^2}{4\pi\varepsilon_0 r} \ . \tag{32.176}$$

The similarity of the effective potential 'seen' by the outer electron and the authentic hydrogen potential suggests a classical treatment within the planetary model. There are three notable exceptions:

- An atom can have two (or more) electrons in highly excited states with comparable orbital radii. In this case, the electron-electron interaction gives rise to a significant deviation from the hydrogen potential. For an atom in a multiple Rydberg state the additional term U_{ee} includes a sum over each pair of highly excited electrons:
$$U_{ee} = \frac{e^2}{4\pi\varepsilon_0} \sum_{i<j} \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} \ . \tag{32.177}$$
- If the valence electron has very low angular momentum (interpreted classically as an extremely eccentric elliptical orbit), it can pass close enough to the nucleus to polarize it, giving rise to an additional term,
$$U_{\text{pol}} = -\frac{e^2 \alpha_d}{(4\pi\varepsilon_0)^2 r^4} \ . \tag{32.178}$$
- If the outer electron penetrates the inner electronic shells, it *sees* more of the charge of the nucleus and therefore feels a larger force. In general, the modification of the potential energy is not simple to calculate and should be based on some knowledge of the nucleus' geometry.

In hydrogen the binding energy is given by:
$$E_{\text{B}} = -\frac{E_1}{n^2} \ . \tag{32.179}$$
The binding energy is weak at high values of n, which explains the fragility of the Rydberg states that can easily be ionized, e.g. by collisions.

Additional terms modifying the potential energy of a Rydberg state require the introduction of a *quantum defect*, $\delta\ell$, in the expression for the binding energy:
$$E_{\text{B}} = -\frac{E_1}{(n - \delta_\ell)^2} \ . \tag{32.180}$$

The long lifetimes of Rydberg states with high orbital angular momentum can be explained in terms of overlapping wavefunctions. The wavefunction of an electron in a state with high ℓ (large angular momentum, 'circular orbit') has little overlap with the wavefunctions of the internal electrons and therefore stays relatively unperturbed. Also, the small energy difference between adjacent Rydberg states decreased the decay rate according to the result (39.40).

32.4.4.4 Rydberg atoms in external fields

The large distance between the electron and ionic nucleus in a Rydberg atom gives rise to an extremely large electric dipole moment d. There is an energy associated with the presence of an electric dipole in an electric field $\vec{\mathcal{E}}$, known as *Stark shift*,
$$E_{\text{S}} = -\mathbf{d} \cdot \vec{\mathcal{E}} \ . \tag{32.181}$$

Depending on the sign of the projection of the dipole moment onto the vector of the local electric field, the energy of a state increases or decreases with the intensity of the field. The narrow spacing between adjacent levels n in the Rydberg series means that the states can approach degeneracy even for relatively weak fields. Theoretically, the force of the field in which a level crossing would occur (assuming no coupling between the states) is given by the *Inglis-Teller limit*,

$$F_{\mathrm{IT}} = \frac{e}{12\pi\varepsilon_0 a_0^2 n^5} \ . \tag{32.182}$$

In hydrogen the pure Coulomb potential does not couple the Stark states of an n level, which results in a *real crossover*. In other elements, deviations from the ideal $1/r$-potential allow for *avoided crossings*.

32.4.5 Exercises

32.4.5.1 Ex: Positronium

Calculate and compare the fine and hyperfine structure of positronium.

32.4.5.2 Ex: Muonic hydrogen

Muonic hydrogen consists of a proton and a negatively charged muon. Calculate the binding energy of the ground state of muonic hydrogen in eV and write down the ground state's wavefunction.

Chapter 33

Atoms with spin in external fields

The atomic fine structure was derived in the last chapter under the assumption that all electric and magnetic fields arise from the motion and spin of the electrons in the atomic shell and the nuclear spin. In this chapter, we will extend the treatment to include the reaction of the electrons to external electrostatic or electromagnetic fields. In this context, we will discuss the Zeeman and the Stark effect.

33.1 Charged particles in electromagnetic fields

33.1.1 Lagrangian and Hamiltonian of charged particles

A charge subject to an electromagnetic field feels the Lorentz force,

$$\mathbf{F} = q\vec{\mathcal{E}} + q\dot{\mathbf{r}} \times \vec{\mathcal{B}} \ , \tag{33.1}$$

where

$$\vec{\mathcal{E}} = -\nabla\Phi - \frac{\partial \mathbf{A}}{\partial t} \qquad \text{and} \qquad \vec{\mathcal{B}} = \nabla \times \mathbf{A} \ , \tag{33.2}$$

where Φ and $\mathbf{A}$ are called scalar and vector potential, respectively.

It is important to realize here, that the momentum $\mathbf{p}$ not only involves the momentum of the particle $m\mathbf{v}$, but the field also carries a momentum $q\mathbf{A}(\mathbf{r})$. As we learned in electrodynamics it is possible to derive the Lorentz force from a Lagrangian for the electronic motion,

$$\boxed{\mathcal{L}(r_i, \dot{r}_i) = \frac{m}{2}\dot{\mathbf{r}}^2 - q\Phi(\mathbf{r}) + q\dot{\mathbf{r}} \cdot \mathbf{A}(\mathbf{r})} \ . \tag{33.3}$$

With this aim we first determine the momentum by,

$$p_i = \frac{\partial \mathcal{L}}{\partial \dot{r}_i} = m\dot{r}_i + qA_i \ , \tag{33.4}$$

and the Hamiltonian by,

$$\mathcal{H} = \sum\nolimits_i p_i \dot{r}_i - \mathcal{L}(r_i, \dot{r}_i) = (m\mathbf{v} + q\mathbf{A}) \cdot \dot{\mathbf{r}} - \frac{m}{2}\dot{\mathbf{r}}^2 + q\Phi - q\dot{\mathbf{r}} \cdot \mathbf{A} = \frac{m}{2}\mathbf{v}^2 + q\Phi \ . \tag{33.5}$$

That is,

$$\boxed{\mathcal{H}(r_i, p_i) = \frac{1}{2m}(\mathbf{p} - q\mathbf{A})^2 + q\Phi} \ . \tag{33.6}$$

The following equations hold,

$$\dot{r}_i = \frac{\partial \mathcal{H}}{\partial p_i} \qquad \text{and} \qquad \dot{p}_i = -\frac{\partial \mathcal{H}}{\partial r_i} \ . \tag{33.7}$$

The first equation is easily verified by inserting the Hamiltonian (33.5). The second leads to the Lorentz force,

$$F_i = m\dot{v}_i = \dot{p}_i - q\dot{A}_i = -\frac{\partial \mathcal{H}}{\partial r_i} - q\dot{A}_i = q\mathcal{E}_i + q(\mathbf{v} \times \vec{\mathcal{B}})_i \ , \tag{33.8}$$

where the last step of the derivation will be shown in the Exc. 33.1.3.1 using the Coulomb gauge $\nabla \cdot \mathbf{A} = 0$.

33.1.2 Minimal coupling

Note that the same result (33.6) can be obtained by a canonical substitution,

$$m\mathbf{v} \longrightarrow \mathbf{p} - q\mathbf{A} \qquad \text{and} \qquad \mathcal{H} \longrightarrow \mathcal{H} + q\Phi \ . \tag{33.9}$$

This substitution rule, called *minimal coupling*, can be applied in quantum mechanics,

$$m\hat{\mathbf{v}} \longrightarrow -\imath\hbar\nabla - q\mathbf{A} \qquad \text{and} \qquad \hat{H} \longrightarrow \hat{H} + q\Phi \ . \tag{33.10}$$

In the case of the electron ($q = -e$) trapped in a central Coulomb potential $q\Phi = -\frac{Ze^2}{4\pi\varepsilon_0 r}$ and in the presence of any magnetic potential $\mathbf{A}$, we thus obtain,

$$\boxed{\hat{H} = \frac{m_e}{2}\hat{\mathbf{v}}^2 + q\Phi = \frac{-\hbar^2}{2m_e}\nabla^2 - \frac{\imath\hbar e}{2m_e}\mathbf{A}\cdot\nabla - \frac{\imath\hbar e}{2m_e}\nabla\cdot\mathbf{A} + \frac{e^2\mathbf{A}^2}{2m_e} + q\Phi} \ . \tag{33.11}$$

The fourth term called *diamagnetic term* is quadratic in $\mathbf{A}$ and usually so small that it can be neglected. The second and third terms describe the interaction of the electron through its momentum $\hat{\mathbf{p}}$ with the potential vector $\mathbf{A}$ produced by magnetic moments inside the atom or outer magnetic fields. Within the Coulomb gauge we have $(\nabla\cdot\mathbf{A})\psi = (\mathbf{A}\cdot\nabla)\psi + \psi(\nabla\cdot\mathbf{A}) = (\mathbf{A}\cdot\nabla)\psi$, such that,

$$\boxed{\hat{H}_{\text{int}} = \tfrac{e}{m_e}\mathbf{A}\cdot\hat{\mathbf{p}}} \ . \tag{33.12}$$

Example 246 (*Interaction Hamiltonian in dipolar approximation*): Note that the Hamiltonian (33.11) is not the only one correctly describing the system, since we may apply a unitary gauge transformation, as shown in (23.331). With the particular choice for the gauge field,

$$\chi(\mathbf{r}, t) \equiv -\mathbf{A}(\mathbf{r}, t)\cdot\mathbf{r} \ ,$$

assuming that the potential only weakly varies in space, such that,

$$\nabla\chi(\mathbf{r}, t) \simeq -\mathbf{A}(\mathbf{r}, t) \qquad \textit{and} \qquad \frac{\partial\chi(\mathbf{r}, t)}{\partial t} = -\mathbf{r}\cdot\frac{\partial\mathbf{A}(\mathbf{r}, t)}{\partial t} = -\mathbf{r}\cdot\vec{\mathcal{E}}(\mathbf{r}, t) \ ,$$

we get with $\mathbf{d} \equiv q\mathbf{r}$,

$$\begin{aligned}\hat{H} &= \frac{1}{2m_e}(\hat{\mathbf{p}} - q\mathbf{A} + \nabla\chi)^2 + q\Phi + q\frac{\partial\chi(\mathbf{r},t)}{\partial t} \\ &\simeq \frac{\hat{\mathbf{p}}^2}{2m_e} + q\Phi - \mathbf{d}\cdot\vec{\mathcal{E}}(\mathbf{r},t)\ .\end{aligned} \tag{33.13}$$

This is the interaction Hamiltonian in the dipolar approximation.

33.1.3 Exercises

33.1.3.1 Ex: Lagrangian of an electron in the electromagnetic field

a. Show that the Lagrangian (33.3) reproduces the Lorentz force (33.1).
b. Show that the Hamiltonian (33.5) reproduces the Lorentz force (33.1).

33.1.3.2 Ex: Atom-field coupling

We determine here the coupling Hamiltonian for an atom in a classical field under two equivalent forms (we have only considered the quantum case in the course). We consider the case of the simplest hydrogen atom, with a single electron (reduced mass m, charge $q = -e$) bound to a proton by the Coulomb potential Φ. This atom interacts also with a laser wave, whose potential and scalar vectors are $V(\mathbf{r},t)$ and $\mathbf{A}(\mathbf{r},t)$.
1. Derive the complete classical Hamiltonian of the atom from the standard form of the classical Lagrangian of a charge in a field: $\mathcal{L} = T - q(V+\Phi) + q\mathbf{v}\cdot\mathbf{A}$. What is the link between the electron's velocity and its momentum (conjugate with its position)?
2. Show that the quantum Hamiltonian is thus:

$$\hat{H} = \frac{1}{2m}(\mathbf{P} - q\mathbf{A}(\mathbf{R},t))^2 + q\Phi(\mathbf{R}) + qV(\mathbf{R})\ .$$

3. Show that in the Coulomb gauge, $\nabla\cdot\mathbf{A} = 0$, V can be set to zero without loss of generality.
4. Show that in the Coulomb gauge, $\mathbf{A}\cdot\mathbf{P} = \mathbf{P}\cdot\mathbf{A}$. Develop accordingly the full Hamiltonian.
5. Under which hypotheses does $\hat{H}$ reduce to $\hat{H} = \hat{H}_0 - (q/m)\mathbf{P}\cdot\mathbf{A}(0,t)$, where $\hat{H}_0$ is the free atomic Hamiltonian?
We now transform the Hamiltonian under the more standard dipole form using the Göppert-Mayer transformation. We restart from the full Hamiltonian, with all terms including $V(\mathbf{r},t)$.
6. We neglect the terms quadratic in $\mathbf{A}$. The atom being small compared to the optical wavelength, give the Hamiltonian obtained by expanding $\mathbf{A}$ and $\mathbf{V}$ to the lowest relevant order. Use the notation $\mathbf{D} = q\mathbf{R}$.
7. Show that a proper gauge transformation cancels $\mathbf{A}(0,t)$.
8. Show that in this new gauge, the Hamiltonian reads $\hat{H} = \hat{H}_0 - \mathbf{D}\cdot\vec{\mathcal{E}}(0)$. Is this result gauge-dependent?

33.2 Interaction with magnetic fields

33.2.1 Normal Zeeman effect of the fine structure

The dipole moments of atoms can interact with external magnetic fields. The interaction leads to a shift of levels, which depends on the magnetic quantum number. Thus, the ultimate degeneracy in the energetic structure of the atom is lifted. This is called *Zeeman splitting*. We consider a uniform magnetic field $\vec{\mathcal{B}} = \mathcal{B}\hat{\mathbf{e}}_z$ with the potential vector,

$$\mathbf{A} = \tfrac{1}{2}\vec{\mathcal{B}} \times \mathbf{r} = -\tfrac{\mathcal{B}}{2}(-y\hat{\mathbf{e}}_x + x\hat{\mathbf{e}}_y) \ . \tag{33.14}$$

Thus the interaction energy between the electron and the field is given by the Hamiltonian (33.12),

$$\begin{aligned}\hat{V}_{\text{Zeem}}(\mathcal{B}) &= -\frac{\imath\hbar e}{m_e}\mathbf{A}\cdot\nabla = -\frac{\imath\hbar e}{2m_e}(\vec{\mathcal{B}}\times\mathbf{r})\cdot\nabla = -\frac{\imath\hbar e}{2m_e}\vec{\mathcal{B}}\cdot(\mathbf{r}\times\nabla) \\ &= -\frac{e}{2m_e}\vec{\mathcal{B}}\cdot\hat{\mathbf{L}} = -\frac{\mu_{\text{B}}}{\hbar}g_L\hat{\mathbf{L}}\cdot\vec{\mathcal{B}} = -\vec{\mu}_L\cdot\vec{\mathcal{B}} = -\frac{\mu_{\text{B}}}{\hbar}\hat{L}_z\mathcal{B} \ ,\end{aligned} \tag{33.15}$$

with $g_L = 1$ using the relation (32.93), $\vec{\mu}_L = \frac{e}{2m_e}\mathbf{L}$, between the angular momentum of the electron and the resulting magnetic moment. This relationship holds for an atom without spin (two electrons can couple their spins to a singlet state) and no hyperfine structure (or an unresolved hyperfine structure). The energies are therefore,

$$\boxed{\Delta E_{\text{Zeem}}(\mathcal{B}) = -\frac{\mu_{\text{B}}}{\hbar}\mathcal{B}\langle n, L, m_L|\hat{L}_z|n, L, m_L\rangle = -\mu_{\text{B}}m_L\mathcal{B}} \ . \tag{33.16}$$

In the Excs. 33.2.7.1 and 33.2.7.2 we represent the interaction between an atomic angular momentum and a magnetic field in different bases characterized by different quantization axes.

33.2.2 Anomalous Zeeman effect

The anomalous Zeeman effect occurs when the ensemble of electrons has a spin. Using the already known expressions for the dipole moments of the orbital momentum and the spin of the electron, we obtain for the magnetic dipole moment,

$$\hat{\vec{\mu}}_J = \hat{\vec{\mu}}_L + \hat{\vec{\mu}}_S = \frac{\mu_{\text{B}}}{\hbar}g_L\hat{\mathbf{L}} + \frac{\mu_{\text{B}}}{\hbar}g_S\hat{\mathbf{S}} = \frac{\mu_{\text{B}}}{\hbar}(\hat{\mathbf{L}} + 2\hat{\mathbf{S}}) \ , \tag{33.17}$$

with $g_L = 1$ and $g_S = g_e = 2$. We can see that the dipole moment of the atom is not parallel to the total momentum, $\hat{\mathbf{J}} = \hat{\mathbf{L}} + \hat{\mathbf{S}}$.

When the magnetic field is weak, $\hat{V}_{\ell s} \gg \hat{V}_{\text{Zeem}}(\mathcal{B})$, the total momentum $\hat{\mathbf{J}}$ will be a good observable. Therefore, we must first project the momenta $\hat{\mathbf{L}}$ and $\hat{\mathbf{S}}$ onto $\hat{\mathbf{J}}$,

$$\hat{\mathbf{L}} \longrightarrow \left(\hat{\mathbf{L}}\cdot\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|}\right)\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|} \qquad \text{and} \qquad \hat{\mathbf{S}} \longrightarrow \left(\hat{\mathbf{S}}\cdot\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|}\right)\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|} \ , \tag{33.18}$$

before projecting the result onto the $\vec{\mathcal{B}}$-field. The potential is,

$$\begin{aligned}\hat{V}_{\rm Zeem}(\mathcal{B}) &= -\hat{\vec{\mu}}_J\cdot\vec{\mathcal{B}} = -\frac{\mu_{\rm B}}{\hbar}(\hat{\mathbf{L}}+2\hat{\mathbf{S}})\cdot\vec{\mathcal{B}} \longrightarrow -\frac{\mu_{\rm B}}{\hbar}\left[\left(\hat{\mathbf{L}}\cdot\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|}\right)\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|}\cdot\vec{\mathcal{B}}+2\left(\hat{\mathbf{S}}\cdot\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|}\right)\tfrac{\hat{\mathbf{J}}}{|\hat{\mathbf{J}}|}\cdot\vec{\mathcal{B}}\right]\\ &= -\frac{\mu_{\rm B}}{\hbar|\mathbf{J}|^2}\left[\hat{\mathbf{L}}\cdot\hat{\mathbf{J}}+2\hat{\mathbf{S}}\cdot\hat{\mathbf{J}}\right]\hat{\mathbf{J}}\cdot\vec{\mathcal{B}} = -\frac{\mu_{\rm B}}{\hbar|\mathbf{J}|^2}\frac{1}{2}\left[\hat{\mathbf{J}}^2+\hat{\mathbf{L}}^2-\hat{\mathbf{S}}^2+2(\hat{\mathbf{J}}^2+\hat{\mathbf{S}}^2-\hat{\mathbf{L}}^2)\right]\hat{\mathbf{J}}\cdot\vec{\mathcal{B}}\\ &= -\frac{\mu_{\rm B}}{\hbar}\frac{1}{2}\frac{3\hat{\mathbf{J}}^2-\hat{\mathbf{L}}^2+\hat{\mathbf{S}}^2}{|\hat{\mathbf{J}}|^2}\hat{\mathbf{J}}\cdot\vec{\mathcal{B}}\,. \end{aligned} \tag{33.19}$$

And the energy is,

$$\Delta E_{\rm Zeem}(\mathcal{B}) = \left\langle\frac{\mu_{\rm B}}{\hbar}\left(1+\frac{J(J+1)-L(L+1)+S(S+1)}{2J(J+1)}\right)\hat{\mathbf{J}}\cdot\vec{\mathcal{B}}\right\rangle\,. \tag{33.20}$$

Introducing the *Landé factor*,

$$g_J \equiv 1+\frac{J(J+1)+S(S+1)-L(L+1)]}{2J(J+1)}\,, \tag{33.21}$$

we can write

$$\boxed{\Delta E_{\rm Zeem}(\mathcal{B}) = -\frac{\mu_{\rm B}}{\hbar}g_J\langle\hat{J}_z\rangle\mathcal{B} = -\mu_{\rm B}g_J m_J\mathcal{B}}\,. \tag{33.22}$$

This expression describes the *anomalous Zeeman effect*, for which $S\neq 0$. For the *normal Zeeman effect*, for which the spin is zero, we find again $g_J=1$.

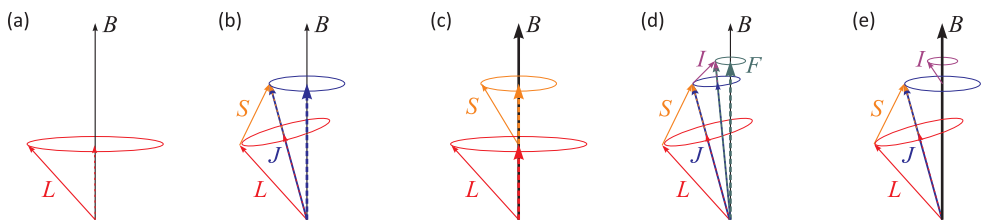

Figure 33.1: Coupling angular moments for the effect (a) Normal Zeeman effect, (b) anomalous Zeeman effect, (c) Paschen-Back effect, (d) Zeeman effect of the hyperfine structure, and (e) Paschen-Goudsmith effect.

33.2.3 Paschen-Back effect and intermediate magnetic fields

A very strong external magnetic field (>1 T), such that $\hat{V}_{\ell s}\ll\hat{V}_{\rm Zeem}(\mathcal{B})$, can break the $\hat{\mathbf{L}}\cdot\hat{\mathbf{S}}$-coupling. Both spins $\hat{\mathbf{L}}$ and $\hat{\mathbf{S}}$ now couple separately to the field,

$$\hat{\mathbf{L}}\longrightarrow\left(\hat{\mathbf{L}}\cdot\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right)\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\qquad\text{and}\qquad\hat{\mathbf{S}}\longrightarrow\left(\hat{\mathbf{S}}\cdot\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right)\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\,. \tag{33.23}$$

Therefore,

$$\hat{V}_{\rm PB}(\mathcal{B}) = -\frac{\mu_{\rm B}}{\hbar}(\hat{\mathbf{L}}+2\hat{\mathbf{S}})\cdot\vec{\mathcal{B}}\longrightarrow-\frac{\mu_{\rm B}}{\hbar}\left[\left(\hat{\mathbf{L}}\cdot\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right)\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}+2\left(\hat{\mathbf{S}}\cdot\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right)\tfrac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right]\cdot\vec{\mathcal{B}}\,, \tag{33.24}$$

such that

$$\boxed{\Delta E_{\rm PB}(\mathcal{B}) = -\mu_{\rm B}(m_L+2m_S)\mathcal{B}}\,. \tag{33.25}$$

This is the *Paschen-Back effect*.

33.2.3.1 Fine structure in the intermediate magnetic field regime

The derivations we have made so far have focused on simple situations well described by CSCOs in various coupling schemes. The projections on the different quantization axes [the total spin (33.18) in the Zeeman case or the applied magnetic field (33.23) in the Paschen-Back case] ensure that the Hamiltonians $\hat{V}_{\ell s}$ and $\hat{V}_{\text{Zeem}}(\mathcal{B})$ in these CSCOs are described by diagonal matrices. However, in regimes *intermediate* between Zeeman and Paschen-Back, $\hat{V}_{\ell s} \simeq \hat{V}_{\text{Zeem}}(\mathcal{B})$, it is generally not possible to find a diagonal representation.

In order to calculate the energy spectrum in intermediate regimes we must, therefore, determine all the components of the matrix,

$$\hat{V}_{\ell s} + \hat{V}_{\text{Zeem}}(\mathcal{B}) = \xi(r)\hat{\mathbf{L}} \cdot \hat{\mathbf{S}} + \frac{\mu_{\text{B}}}{\hbar}(\hat{\mathbf{L}} + 2\hat{\mathbf{S}}) \ . \tag{33.26}$$

Using $\hat{L}_\pm \equiv \hat{L}_x \pm \imath \hat{L}_y$ and $\hat{S}_\pm \equiv \hat{S}_x \pm \imath \hat{S}_y$, we can easily rewrite the energy in the following way,

$$\hat{V}_{\ell s} + \hat{V}_{\text{Zeem}}(\mathcal{B}) = \xi(r)\left(\hat{L}_z\hat{S}_z + \tfrac{1}{2}\hat{L}_+\hat{S}_- + \tfrac{1}{2}\hat{L}_-\hat{S}_+\right) + \frac{\mu_{\text{B}}}{\hbar}(\hat{\mathbf{L}} + 2\hat{\mathbf{S}}) \cdot \vec{\mathcal{B}} \ . \tag{33.27}$$

This operator acts on the uncoupled states,

$$\begin{aligned}
&\Delta E_{\ell s} + \Delta E_{\text{Zeem}}(\mathcal{B}) \qquad (33.28)\\
&= \langle L' m'_L; S' m'_S | \xi_{nl}(\hat{L}_z\hat{S}_z + \tfrac{1}{2}\hat{L}_+\hat{S}_- + \tfrac{1}{2}\hat{L}_-\hat{S}_+) + \mu_{\text{B}}(\hat{L}_z + 2\hat{S}_z)\mathcal{B} | L m_L; S m_S\rangle\\
&= \hbar^2 \xi_{nl}\left(m_L m_S \delta_{m_L,m'_L}\delta_{m_S,m'_S} + \tfrac{1}{2}L_+S_-\delta_{m_L,m'_L-1}\delta_{m_S-1,m'_S} + \tfrac{1}{2}L_-S_+\delta_{m_L-1,m'_L}\delta_{m_S,m'_S-1}\right)\\
&\quad + \hbar\mu_{\text{B}}(m_L + 2m_S)\mathcal{B}\delta_{m_L,m'_L}\delta_{m_S,m'_S} \ ,
\end{aligned}$$

with the abbreviations $L_\pm \equiv \sqrt{L(L+1) - m_L(m_L \pm 1)}$. The energies are now the eigenvalues of this matrix. The factor ξ_{nl} is usually determined experimentally by letting $\mathcal{B} = 0$. In Exc. 33.2.7.3 we calculate the re-coupling of the spins of two electrons in an external magnetic field.

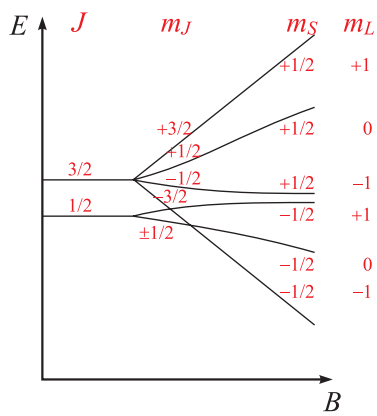

Figure 33.2: Transition between the Zeeman regime and the Paschen-Back regime for the case $L = 1$ and $S = 1/2$.

33.2.4 Zeeman effect of the hyperfine structure

When the energy of the interaction with the magnetic field is comparable to the hyperfine interactions, but much weaker than that of the fine interactions, the fields do not disturb the coupling between the total electronic momentum $\hat{\mathbf{J}}$ and the spin of the nucleus $\hat{\mathbf{I}}$. Hence, J, I, F, and m_F are good quantum numbers. Therefore, to calculate the interaction energy,

$$\hat{V}_{\rm hfs} + \hat{V}_{\rm Zeem}(\mathcal{B}) = \hat{V}_{\rm hfs} - \hat{\vec{\mu}}_F \cdot \vec{\mathcal{B}} \,, \tag{33.29}$$

where $\hat{\vec{\mu}}_F$ is the total magnetic momentum,

$$\hat{\vec{\mu}}_F = \hat{\vec{\mu}}_J + \hat{\vec{\mu}}_I = -\frac{\mu_{\rm B}}{\hbar} g_J \hat{\mathbf{J}} + \frac{\mu_{\rm N}}{\hbar} g_p \hat{\mathbf{I}} \,. \tag{33.30}$$

we project the nuclear spin and the total electronic momentum separately in the direction of $\hat{\mathbf{F}}$,

$$\hat{\mathbf{J}} \longrightarrow \left(\hat{\mathbf{J}} \cdot \frac{\hat{\mathbf{F}}}{|\mathbf{F}|}\right) \frac{\hat{\mathbf{F}}}{|\mathbf{F}|} \qquad \text{and} \qquad \hat{\mathbf{I}} \longrightarrow \left(\hat{\mathbf{I}} \cdot \frac{\hat{\mathbf{F}}}{|\mathbf{F}|}\right) \frac{\hat{\mathbf{F}}}{|\mathbf{F}|} \,. \tag{33.31}$$

Note the negative sign in (33.30) due to the negative charge of the electron. The Landé factor g_J [see (33.21)] is the one caused by the coupling of the orbital angular momentum $\hat{\mathbf{L}}$ and the electron spin $\hat{\mathbf{S}}$ and depends on the state under consideration. Thereby,

$$\begin{aligned} \hat{V}_{\rm Zeem}(\mathcal{B}) &= \left[-\frac{\mu_{\rm B}}{\hbar} g_J \left(\hat{\mathbf{J}} \cdot \frac{\hat{\mathbf{F}}}{|\mathbf{F}|}\right) \frac{\hat{\mathbf{F}}}{|\mathbf{F}|} + \frac{\mu_{\rm N}}{\hbar} g_p \left(\hat{\mathbf{I}} \cdot \frac{\hat{\mathbf{F}}}{|\mathbf{F}|}\right) \frac{\hat{\mathbf{F}}}{|\mathbf{F}|}\right] \vec{\mathcal{B}} \\ &= \left(-\frac{\mu_{\rm B}}{\hbar |\hat{\mathbf{F}}|^2} g_J \hat{\mathbf{J}} \cdot \hat{\mathbf{F}} + \frac{\mu_{\rm N}}{\hbar |\hat{\mathbf{F}}|^2} g_p \hat{\mathbf{I}} \cdot \hat{\mathbf{F}}\right) (\mathcal{B} \cdot \hat{F}_z) \,. \end{aligned} \tag{33.32}$$

Using $\hat{\mathbf{J}} \cdot \hat{\mathbf{F}} = \frac{1}{2}(\hat{\mathbf{F}}^2 + \hat{\mathbf{J}}^2 - \hat{\mathbf{I}}^2)$ and $\hat{\mathbf{I}} \cdot \hat{\mathbf{F}} = \frac{1}{2}(\hat{\mathbf{F}}^2 - \hat{\mathbf{J}}^2 + \hat{\mathbf{I}}^2)$ we write,

$$\hat{V}_{\rm Zeem}(\mathcal{B}) = -\frac{\mu_{\rm B}}{\hbar} g_J \frac{\hat{\mathbf{F}}^2 + \hat{\mathbf{J}}^2 - \hat{\mathbf{I}}^2}{2|\mathbf{F}|^2} \mathcal{B} \hat{F}_z + g_p \frac{\mu_{\rm N}}{\hbar} \frac{\hat{\mathbf{F}}^2 - \hat{\mathbf{J}}^2 + \hat{\mathbf{I}}^2}{2|\hat{\mathbf{F}}|^2} \mathcal{B} \hat{F}_z \,, \tag{33.33}$$

such that

$$\boxed{\Delta E_{\rm hfs} + \Delta E_{\rm Zeem}(\mathcal{B}) \simeq \Delta E_{\rm hfs} + \mu_{\rm B} g_F m_F \mathcal{B}} \,, \tag{33.34}$$

using the *Landé factor* g_F for the state F,

$$g_F \simeq g_J \frac{F(F+1) + J(J+1) - I(I+1)}{2F(F+1)} - g_p \frac{\mu_{\rm N}}{\mu_{\rm B}} \frac{F(F+1) - J(J+1) + I(I+1)}{2F(F+1)} \,, \tag{33.35}$$

where the second term can be neglected.

The splitting of electronic states with the momentum $\hat{\mathbf{F}}$ into $2F+1$ sublevels $m_F = -F, .., F$ is called *Zeeman effect of the hyperfine structure*. The result (33.32) only applies to weak magnetic fields. For strong fields the Zeeman splitting becomes a Paschen-Back splitting of the hyperfine structure.

33.2.5 Paschen-Back effect of the hyperfine structure

When the interaction with the magnetic field exceeds the hyperfine interaction, the nuclear spin $\hat{\mathbf{I}}$ decouples from the total momentum $\hat{\mathbf{J}}$, and both couple separately to the external magnetic field,

$$\hat{\mathbf{J}} \longrightarrow \left(\hat{\mathbf{J}} \cdot \frac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right) \frac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|} \qquad \text{and} \qquad \hat{\mathbf{I}} \longrightarrow \left(\hat{\mathbf{I}} \cdot \frac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|}\right) \frac{\vec{\mathcal{B}}}{|\vec{\mathcal{B}}|} \ . \tag{33.36}$$

The Zeeman effect of the hyperfine structure becomes a hyperfine structure of the Zeeman effect, also called *Paschen-Back effect of the hyperfine structure* or *Paschen-Goudsmith effect*. We can diagonalize the potential on a basis, where I, m_I, J, and m_J are good quantum numbers. Using the expression (32.168) but disregarding the quadrupolar contribution to the hyperfine interaction, $B_J \simeq 0$, we obtain,

$$\begin{aligned} \hat{V}_{\text{hfs}} + \hat{V}_{\text{Zeem}}(\mathcal{B}) &= \hat{V}_{\text{hfs}} - (\hat{\vec{\mu}}_J + \cancelto{\simeq 0}{\hat{\vec{\mu}}_I}) \cdot \vec{\mathcal{B}} \simeq \frac{A_J}{\hbar^2} \hat{\mathbf{J}} \cdot \hat{\mathbf{I}} - \hat{\vec{\mu}}_J \cdot \vec{\mathcal{B}} \\ &\longrightarrow \frac{A_J}{\hbar^2} \left(\hat{\mathbf{J}} \cdot \frac{\vec{\mathcal{B}}}{\mathcal{B}}\right) \frac{\vec{\mathcal{B}}}{\mathcal{B}} \cdot \left(\hat{\mathbf{I}} \cdot \frac{\vec{\mathcal{B}}}{\mathcal{B}}\right) \frac{\vec{\mathcal{B}}}{\mathcal{B}} - \mu_{J_z} \mathcal{B} = \frac{A_J}{\hbar^2} \hat{J}_z \hat{I}_z + \frac{\mu_{\text{B}}}{\hbar} g_J \hat{J}_z \mathcal{B} \ , \end{aligned} \tag{33.37}$$

where we neglect the interaction of the dipole moment of the nucleus with the external magnetic field, $\vec{\mu}_I \simeq 0$. We obtain for strong magnetic fields,

$$\boxed{\Delta E_{\text{hfs}} + \Delta E_{\text{Zeem}}(\mathcal{B}) \simeq A_J m_J m_I + \mu_{\text{B}} g_J m_J \mathcal{B}} \ . \tag{33.38}$$

The re-coupling of the state $|F m_F\rangle$ to $|m_I m_J\rangle$ in strong magnetic fields is described by Clebsch-Gordan coefficients,

$$|F m_F\rangle = \sum\nolimits_{m_I + m_J = m_F} |m_I m_J\rangle \langle m_I m_J | F m_F\rangle \ . \tag{33.39}$$

Example 247 (*Nuclear magnetic resonance*): In Eq. (33.37) we have neglected the nuclear dipole moment for being small in comparison to the electronic one. Taking it into account, we get an additional term $\hat{V}_{\text{nmr}}$,

$$\hat{V}_{\text{hfs}} + \hat{V}_{\text{Zeem}} + \hat{V}_{\text{nmr}} = \frac{A_J}{\hbar^2} \hat{\mathbf{J}} \cdot \hat{\mathbf{I}} + \vec{\mu}_J \cdot \vec{\mathcal{B}} + \vec{\mu}_I \cdot \vec{\mathcal{B}} = \frac{A_J}{\hbar^2} \hat{J}_z \hat{I}_z + \mu_{J_z} \mathcal{B} + \mu_{I_z} \mathcal{B} \ . \tag{33.40}$$

Considering a hydrogen atom ^{1}H in a $\vec{\mathcal{B}} = 10\,\text{T}$ strong magnetic field, we have the following hierarchy of energies:

$$\begin{aligned} \Delta E_{\text{Zeem}}(\mathcal{B}) &= \mu_{\text{B}} g_e m_J \simeq h \cdot 140\,\text{GHz} \\ \Delta E_{\text{hfs}}(\mathcal{B}) &\simeq h \cdot 1.4\,\text{GHz} \\ \Delta E_{\text{nmr}}(\mathcal{B}) &= \mu_{\text{N}} g_p m_I \simeq h \cdot 213\,\text{MHz} \ , \end{aligned} \tag{33.41}$$

where $g_e = 2.002..$ is the g-factor of the electron and $g_p = 5.586..$ of the proton. Now, in large molecules the most electrons are paired, such that $\hat{\mathbf{J}} = 0$. In that case, we are left with the interaction between the nuclear spin and the applied magnetic field,

$$\Delta E_{\text{nmr}}(\mathcal{B}) = \mu_{\text{N}} g_I m_I \mathcal{B} \ , \tag{33.42}$$

where the g-factor of the nucleus g_I must be looked up in data tables. This is the regime where *nuclear magnetic resonances* (NMR) can be excited with a large variety of applications in spectroscopy and imaging.

33.2.5.1 Hyperfine structure in the intermediate field regime

Knowing the dipolar magnetic A_J and quadrupolar B_J interval factors, it is possible to calculate the Zeeman shift of the hyperfine structure in magnetic fields intermediate between the Zeeman and Paschen-Back regimes. For this, we must determine all the components of the matrix $\hat{V}_{\rm hfs}+\hat{V}_{\rm Zeem}(\mathcal{B})$ and calculate the eigenvalues. The relevant terms of the Eqs. (32.168) and the Eq. (33.36) are,

$$\hat{V}_{\rm hfs}+\hat{V}_{\rm Zeem}(\mathcal{B})=\frac{A_J}{\hbar^2}\hat{\mathbf{I}}\cdot\hat{\mathbf{J}}+\frac{B_J}{\hbar^2}\frac{6(\hat{\mathbf{I}}\cdot\hat{\mathbf{J}})^2+3\hat{\mathbf{I}}\cdot\hat{\mathbf{J}}-2\hat{\mathbf{J}}^2\hat{\mathbf{I}}^2}{2I(2I-1)2J(2J-1)}+g_J\mu_{\rm B}\vec{\mathcal{B}}\cdot\hat{\mathbf{J}}-g_I\mu_{\rm N}\vec{\mathcal{B}}\cdot\hat{\mathbf{I}}\ . \tag{33.43}$$

We develop the complete matrix representation of this Hamiltonian within the uncoupled base, where m_J, m_I are good quantum numbers, introducing the abbreviations

$$I_\pm\equiv\sqrt{I(I+1)-m_I(m_I\pm1)}\qquad\text{and}\qquad I_{\pm\pm}\equiv\sqrt{I(I+1)-(m_I\pm1)(m_I\pm2)}\ . \tag{33.44}$$

The SU(2) algebra provides useful expressions, $\hat{\mathbf{I}}\cdot\hat{\mathbf{J}}=\hat{I}_z\hat{J}_z+\frac{1}{2}(\hat{I}_+\hat{J}_-+\hat{I}_-\hat{J}_+)$. The elements of the matrix are,

$$\begin{aligned}
&\langle m_I'm_J'|H_{\rm hfs}+H_B|m_Im_J\rangle=\left[A_J+\tfrac{3B_J}{2I(2I-1)2J(2J-1)}\right]\times \\
&\times\left\{m_Im_J\delta_{m_I'\ m_I}\delta_{m_J'\ m_J}+\tfrac{1}{2}I_+J_-\delta_{m_I'\ m_I+1}\delta_{m_J'\ m_J-1}+\tfrac{1}{2}I_-J_+\delta_{m_I'\ m_I-1}\delta_{m_J'\ m_J+1}\right\} \\
&+\tfrac{6B_J}{2I(2I-1)2J(2J-1)}\langle m_I'm_J'|\left(\tfrac{\mathbf{I}\cdot\mathbf{J}}{\hbar}\right)^2|m_Im_J\rangle \\
&+\left[-\tfrac{B_J2I(I+1)J(J+1)}{2I(2I-1)2J(2J-1)}+(g_Jm_J-g_I\mu_{\rm N}m_I)\mu_{\rm B}\mathcal{B}\right]\delta_{m_I'\ m_I}\delta_{m_I'\ m_I}
\end{aligned} \tag{33.45}$$

where

$$\begin{aligned}
\langle m_I'm_J'|\left(\tfrac{\hat{\mathbf{I}}\cdot\hat{\mathbf{J}}}{\hbar}\right)^2|m_Im_J\rangle=&\left[(m_Im_J)^2+\tfrac{1}{4}I_-^2J_+^2+\tfrac{1}{4}I_+^2J_-^2\right]\delta_{m_I'\ m_I}\delta_{m_J'\ m_J}+ \\
&+\tfrac{1}{2}\left(m_I'm_J'+m_Im_J\right)I_+J_-\delta_{m_I'\ m_I+1}\delta_{m_J'\ m_J-1}+ \\
&+\tfrac{1}{2}\left(m_I'm_J'+m_Im_J\right)I_-J_+\delta_{m_I'\ m_I-1}\delta_{m_J'\ m_J+1}+ \\
&+\tfrac{1}{4}I_+J_-I_{++}J_{--}\delta_{m_I'\ m_I+2}\delta_{m_J'\ m_J-2}+ \\
&+\tfrac{1}{4}I_-J_+I_{--}J_{++}\delta_{m_I'\ m_I-2}\delta_{m_J'\ m_J+2}\ .
\end{aligned} \tag{33.46}$$

The matrix $\langle m_I'm_J'|H_{\rm hfs}+H_B|m_Im_J\rangle$ is divided into $2F+1$ diagonal blocks, each labeled m_F. The total number of levels is,

$$\sum_{F=|I-J|,..,I+J}2F+1=(2I+1)(2J+1)=\sum_{m_F=|-F,..,F|}\left(\sum_{m_I=|-I,..,I|,\ m_J=|-J,..,J|,\ m_I+m_J=m_F}1\right)\ .$$

In this form the matrix can be programmed, e.g. using computational software such as MATLAB, and all eigenvalues of the Hamiltonian for any state ${}^{2S+1}X_J$ and nuclear spin I can be calculated numerically. Obviously, the eigenvalues follow from a diagonalization of the matrix and do not depend on the chosen base. Fig. 33.3 shows the result obtained for ^{6}Li ($I=1$) in the states $2s\ {}^2S_{1/2}$ and $2s\ {}^2P_{3/2}$ (see Tab. 39.1).

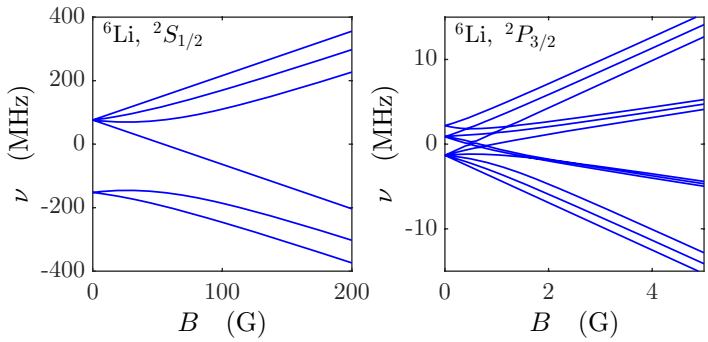

Figure 33.3: (code) Hyperfine and Zeeman structure of the states $2s\ ^2S_{1/2}$ and $2s\ ^2P_{3/2}$ of ^{6}Li, which has the nuclear spin $I = 1$.

Example 248 (*Fully stretched states*): It is interesting to analyze the so-called *fully stretched Zeeman states* defined by $F = I + J$ and $|m_F| = F$. For these states, the spin K defined in (32.167) becomes,

$$\begin{aligned} K \equiv 2\langle \hat{\mathbf{J}} \cdot \hat{\mathbf{I}} \rangle &= F(F+1) - I(I+1) - J(J+1) \\ &= (I+J)(I+J+1) - I(I+1) - J(J+1) = 2JI \ , \end{aligned}$$

and the hyperfine structure (32.168) becomes,

$$\Delta E_{\rm hfs} = \frac{A_J}{2} K + \frac{B_J}{8I(2I-1)J(2J-1)} [3K(K+1) - 4I(I+1)J(J+1)] = A_J IJ + \tfrac{B_J}{4} \ .$$

That is, the hyperfine structure does not depend on the F quantum number at any $\mathcal{B}$-field amplitude, which means that the m_J, m_I, and m_F will be good quantum numbers at arbitrary $\mathcal{B}$-field strengths. So see this, we calculate the Landé-factor (33.35),

$$g_F = g_J \frac{J}{F} - g_J \frac{\mu_{\rm N}}{\mu_{\rm B}} \frac{I}{F} \ ,$$

and consider the particular Zeeman state $m_F = F$, $m_J = J$, and $m_I = I$,

$$\begin{aligned} \hat{V}_{\rm hfs} + \hat{V}_{\rm Zeem}(\mathcal{B}) &= A_J IJ + \tfrac{B_J}{4} + g_J \mu_{\rm B} \vec{\mathcal{B}} \cdot \hat{\mathbf{J}} - g_I \mu_{\rm N} \vec{\mathcal{B}} \cdot \hat{\mathbf{I}} \\ &= A_J IJ + \tfrac{B_J}{4} + \mu_{\rm B} g_F m_F \mathcal{B} = A_J IJ + \tfrac{B_J}{4} + (\mu_{\rm B} g_J J - \mu_{\rm N} g_J I)\mathcal{B} \ . \end{aligned}$$

The energy displacement of the fully stretched states is always linear in the magnetic field. We can also look at the matrix elements $I_+ = 0$ and $I_- = \sqrt{2I}$ and note that all non-diagonal terms vanish.

When one of the spins, J or I, is equal to 1/2 only two possible hyperfine states exist: $F = I \pm J$. For this case there is an approximate analytic formula called the *Breit-Rabi formula* [56], which will be derived in Exc. 33.2.7.4,

$$\begin{aligned} \Delta E_{\rm hfs} + \Delta E_{\rm Zeem}(\mathcal{B}) &= \langle \tfrac{A_J}{\hbar^2} \hat{\mathbf{I}} \cdot \hat{\mathbf{J}} + g_J \mu_{\rm B} \vec{\mathcal{B}} \cdot \hat{\mathbf{J}} - g_I \mu_{\rm N} \vec{\mathcal{B}} \cdot \hat{\mathbf{I}} \rangle \\ &= -\frac{A_J}{4} + \mu_{\rm N} g_N m_F \mathcal{B} \pm \frac{A_J(I+\frac{1}{2})}{2} \sqrt{1 + \frac{4m_F}{2I+1} x + x^2} \ , \end{aligned} \tag{33.47}$$

with the abbreviation $x \equiv \frac{2(\mu_{\rm B} g_J - \mu_{\rm N} g_I)\mathcal{B}}{A_J}$. Resolve also Exc. 33.2.7.5.

Atoms with paired electrons have no spin and therefore no magnetic dipole moment. For example, helium or strontium in their ground state $^1S_0$. These systems are diamagnetic due to the Hamiltonian term (33.11) being quadratic in $\vec{\mathcal{B}}$, as we shall see in Exc. 33.2.7.6.

33.2.6 Landau levels in two-dimensional systems subject to magnetic fields

Magnetic field can also have interesting effects in *artificial atoms*, e.g. quantum dots. An important example is the formation of *Landau levels*. We consider a two-dimensional system of non-interacting particles with charge q and spin S confined to an area $A = L_x L_y$ in the xy plane. We apply a uniform magnetic field,

$$\vec{\mathcal{B}} = \mathcal{B}\hat{\mathbf{e}}_z \tag{33.48}$$

along the z axis. The Hamiltonian of this system is,

$$\hat{H} = \tfrac{1}{2m}(\hat{\mathbf{p}} - q\hat{\mathbf{A}})^2 \ , \tag{33.49}$$

where $\hat{\mathbf{p}}$ is the operator of the canonical momentum and $\hat{\mathbf{A}}$ is the potential vector, related to the magnetic field by $\vec{\mathcal{B}} = \nabla \times \hat{\mathbf{A}}$. The vector potential,

$$\mathbf{A} = \tfrac{1}{2}\begin{pmatrix} -\mathcal{B}y \\ \mathcal{B}x \\ 0 \end{pmatrix} \tag{33.50}$$

reproduces the field (33.48). However, we have the freedom of choosing the potential vector, given by the gauge transformation, to add the gradient of a scalar field, for example,

$$\chi \equiv \tfrac{1}{2}\mathcal{B}xy \qquad \Longrightarrow \qquad \nabla\chi = \tfrac{1}{2}\begin{pmatrix} \mathcal{B}y \\ \mathcal{B}x \\ 0 \end{pmatrix} \qquad \Longrightarrow \qquad \mathbf{A}' \equiv \mathbf{A} + \nabla\chi = \mathcal{B}x\hat{\mathbf{e}}_y \ . \tag{33.51}$$

The potential vector $\mathbf{A}'$ gives the same magnetic field and only changes the general phase of the wavefunction, but the physical properties do not change. In this gauge, which is called *Landau gauge*, the Hamiltonian is,

$$\hat{H} = \frac{\hat{p}_x^2}{2m} + \frac{1}{2m}\left(\hat{p}_y - \frac{q\mathcal{B}}{c}\hat{x}\right)^2 \ . \tag{33.52}$$

The operator $\hat{p}_y$ commutes with this Hamiltonian, since the $\hat{y}$ operator is absent due to the choice of the gauge. Thus, the operator $\hat{p}_y$ can be replaced by its eigenvalue $\hbar k_y$. Hence, by introducing the *cyclotron frequency*,

$$\omega_c \equiv \frac{q\mathcal{B}}{mc} \ , \tag{33.53}$$

we obtain,

$$\boxed{\hat{H} = \frac{\hat{p}_x^2}{2m} + \frac{m\omega_c^2}{2}\left(\hat{x} - \frac{\hbar k_y}{m\omega_c}\right)^2} \ . \tag{33.54}$$

This is exactly the Hamiltonian of the quantum harmonic oscillator, except that the minimum of the potential is displaced in position space by the value,

$$x_0 \equiv \frac{\hbar k_y}{m\omega_c} \ . \tag{33.55}$$

To find the energies, we note that the translation of the potential of the harmonic oscillator does not affect the energies. The energies of this system are therefore identical to those of the standard quantum harmonic oscillator,

$$E_n = \hbar\omega_c \left(n + \tfrac{1}{2}\right) \ , \tag{33.56}$$

for $n \geq 0$. Since the energy does not depend on the quantum number k_y, we will have degeneracy. To derive the wavefunctions, we remember that $\hat{p}_y$ commutes with the Hamiltonian. Then the wavefunction splits into a product of eigenstates of the momentum in y-direction and eigenstates of the harmonic oscillator $|\phi_n\rangle$ shifted by a value x_0 in x-direction:

$$\Psi(x, y) = e^{\imath k_y y}\phi_n(x - x_0) \ . \tag{33.57}$$

That is, the state of the electron is characterized by two quantum numbers, n and k_y.

Each set of wavefunctions with the same n is called *Landau level*. Effects due to Landau levels are only observed, when the average thermal energy is lower than the separation of the energy levels, which means that low temperatures and strong magnetic fields are required. Each Landau level is degenerate, because of the second quantum number k_y which, for being confined in the xy plane, can adopt the values,

$$k_y = \frac{2\pi N}{L_y} \ , \tag{33.58}$$

with $N \in \mathbb{N}$. The allowed values of N are further restricted by the condition that the center of mass of the oscillator, x_0, must be physically inside the system, $0 \leq x_0 < L_x$. Using (33.55) this gives the following range for N,

$$0 \leq N < \frac{m\omega_c L_x L_y}{2\pi\hbar} \ . \tag{33.59}$$

For particles with charge $q = Ze$, the upper limit in N can simply be written as a ratio of fluxes,

$$Z\frac{\Phi}{\Phi_0} = \frac{Z\mathcal{B}L_x L_y}{(hc/e)} = N_{\max} \ , \tag{33.60}$$

where $\Phi_0 = h/2e$ is the fundamental *flux quantum* and $\Phi = \mathcal{B}A$ the flux through the system (with area $A = L_x L_y$). Thus, for particles with spin S, the maximum number of particles per Landau level is,

$$N_{\max} = Z(2S + 1)\frac{\Phi}{\Phi_0} \ . \tag{33.61}$$

33.2.6.1 Integer and fractional quantum Hall effect

In general, Landau levels are observed in electronic systems with $Z = 1$ and $S = 1/2$. As the magnetic field increases, more and more electrons can fit a certain Landau level. The occupation of the highest Landau level ranges from entirely full to entirely empty, leading to oscillations in various electronic properties (see *de Haas-van Alphen effect*, *Shubnikov-de Haas effect* and *quantum Hall effect*. The most direct observation of the

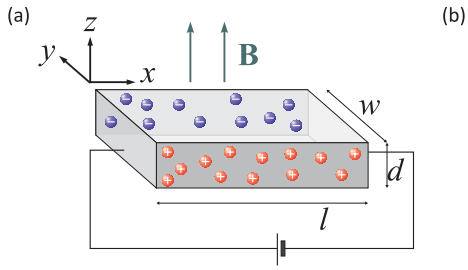

Figure 33.4: Scheme of the Quantum Hall effect.

Landau levels is done via the quantum Hall effect. To discuss this effect let us briefly recapitulate the Hall effectoriginally studied in Sec. 12.1.1. In the scheme of Fig. 33.4, charges are deviated by the Lorentz force exerted by an applied magnetic field $\vec{\mathcal{B}}$ from a driven current density j_x into a current density j_y until a sufficient amount of surface charge density has accumulated to generate an electric field exerting a Coulomb force on the charges which neutralizes the Lorentz force, $\mathbf{F} = q(\vec{\mathcal{E}} + \mathbf{v} \times \vec{\mathcal{B}}) = 0$. Resolving this condition by $\mathbf{v}$, we obtain for the current density,

$$\mathbf{j} = \varrho q \mathbf{v} = \varrho q \frac{\mathcal{E}}{\mathcal{B}} \hat{\mathbf{e}}_x = \varsigma \vec{\mathcal{E}} \ , \tag{33.62}$$

where the last equation is Ohm's law and

$$\varsigma = \begin{pmatrix} \varsigma_{xx} & \varsigma_{xy} \\ -\varsigma_{xy} & \varsigma_{yy} \end{pmatrix} \qquad \text{and} \qquad \varrho = \varsigma^{-1} = \frac{1}{\varsigma_{xx}^2 + \varsigma_{yy}^2} \begin{pmatrix} \varsigma_{xx} & -\varsigma_{xy} \\ \varsigma_{xy} & \varsigma_{yy} \end{pmatrix} \tag{33.63}$$

the conductivity and the resistivity, respectively. The Hall resistivity does therefore depend linearly on the magnetic field,

$$\varrho_{xy} = \frac{\mathcal{E}}{j} = \frac{\mathcal{B}}{\varrho q} \ . \tag{33.64}$$

In two-dimensional systems this is, however, not observed. Instead, plateaus emerge whenever the magnetic field is ramped across a value where a new Landau level is possible binding one more electron,

$$\varrho_{xy} = \frac{2\pi\hbar}{e^2} \frac{1}{\nu} \qquad \text{with} \qquad \nu \in \mathbb{Z} \ . \tag{33.65}$$

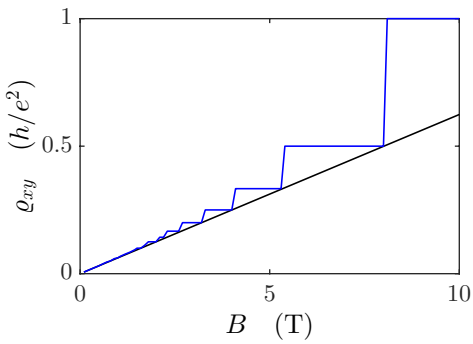

Figure 33.5: (code) Scheme of the quantum Hall effect.

33.2.7 Exercises

33.2.7.1 Ex: Zeeman effect with different quantization axes

The Zeeman effect can be described in several ways depending on the choice of the quantization axis. Consider a magnetic field $\vec{\mathcal{B}} = \mathcal{B}_x \hat{\mathbf{e}}_x$ and calculate the interaction Hamiltonian $V(\mathcal{B}) = -\vec{\mu}_J \cdot \vec{\mathcal{B}}$
a. choosing the quantization axis $\hat{\mathbf{e}}_x$ in the direction of the magnetic field,
b. choosing the quantization axis $\hat{\mathbf{e}}_z$ perpendicular to the direction of the magnetic field.

33.2.7.2 Ex: Zeeman shift and quantization axes

Choosing the fixed quantization axis $\hat{\mathbf{e}}_z$ and a magnetic field $\vec{\mathcal{B}}(\mathbf{r})$ in an arbitrary direction, calculate the Hamiltonian of the Zeeman interaction with an angular momentum $J = 1$ and show that the energy shift depends only on absolute value $|\vec{\mathcal{B}}(\mathbf{r})|$.

33.2.7.3 Ex: Coupling of two electrons

Consider a two-electron system.
a. Show that the operator $(\hbar A/\hbar^2)\hat{\mathbf{s}}_1 \cdot \hat{\mathbf{s}}_2$ distinguishes the triplet from the singlet states.
b. Consider now, that the electrons are exposed to a magnetic field $\mathcal{B}$ applied in the direction $\hat{\mathbf{e}}_z$, so that they acquire the interaction energy with the field $(\mu_{\mathrm{B}}\mathcal{B}/\hbar)(g_1\hat{s}_{1z} + g_2\hat{s}_{2z})$. Obtain the matrix associated with the total Hamiltonian and demonstrate that in the regime $\hbar A \gg \mu_{\mathrm{B}}\mathcal{B}$, the representation that favors the total momentum is more adequate.
c. Show that in the regime $\hbar A \ll \mu_{\mathrm{B}}\mathcal{B}$, it is convenient to use the representation that privileges the *individual* spins of the total momentum.
d. Analyze the intermediate regime $\hbar A \simeq \mu_{\mathrm{B}}\mathcal{B}$.

33.2.7.4 Ex: Breit-Rabi formula

Derive the analytical Breit-Rabi formula for the hyperfine structure (33.47) supposing $J = \frac{1}{2}$.

33.2.7.5 Ex: Reciprocal pollution of the Paschen-Back and Zeeman regimes

a. Determine the interaction matrix $\langle \tilde{m}_J \tilde{m}_I | \hat{V}_{\text{hfs}} + \hat{V}_{\text{Zeem}}(\mathcal{B}) | m_J m_I \rangle$ of an atom with electron spin **J** and nuclear spin **J** in the decoupled base without considering the quadrupolar terms.
b. Determine the interaction matrix explicitly for the case of ^{6}Li ($I = 1$) in its ground state $^2S_{1/2}$ ($A_J = h \cdot 152.137\,\text{MHz}$) for a magnetic field of $\mathcal{B} = 100$ G.
c. For the system defined in (b) determine the eigenvalues $E(\mathcal{B})$ of the interaction matrix and the eigenvectors $|\alpha(\mathcal{B})\rangle$ on the decoupled base $|m_J m_I\rangle$.
d. For the system defined in (c) determine the eigenvectors $|\alpha(\mathcal{B})\rangle$ in the coupled base $|F m_F\rangle$.
e. How good are the selection rules for transitions $S_{1/2} - P_{3/2}$ in the intermediate regime between Zeeman and Paschen-Back? We start by calculating the Zeeman shifts for both levels (s denotes the structure $S_{1/2}$, p the structure $P_{3/2}$)

$$
\begin{aligned}
{}_B\langle m_J^s m_I^s | H_{\text{hfs}} + H_B | m_J^s m_I^s \rangle_B &= E^s(\mathcal{B}) \\
{}_B\langle m_J^p m_I^p | H_{\text{hfs}} + H_B | m_J^p m_I^p \rangle_B &= E^p(\mathcal{B}) \ .
\end{aligned}
$$

For the level $P_{3/2}$ the interval factor is less. In particular for ^{6}Li it is so small that we are immediately in the Paschen-Back scheme. This means that the matrix $\overline{{}_\infty\langle \tilde{m}_J^p \tilde{m}_I^p | m_J^p m_I^p \rangle_B} = \delta_{m_J^p, \tilde{m}_J^p} \delta_{m_I^p, \tilde{m}_I^p}$ is diagonal. The element of the transition matrix is then,

$$
\begin{aligned}
&{}_B\langle m_J^p m_I^p | T_q^{(E\kappa)} | m_J^s m_I^s \rangle_B \\
&\quad = \sum_{\tilde{m}_J^s \tilde{m}_I^s} \sum_{\tilde{m}_J^p \tilde{m}_I^p} \overline{{}_\infty\langle \tilde{m}_J^p \tilde{m}_I^p | m_J^p m_I^p \rangle_B} \ {}_\infty\langle \tilde{m}_J^s \tilde{m}_I^s | m_J^s m_I^s \rangle_B \ {}_\infty\langle \tilde{m}_J^p \tilde{m}_I^p | T_q^{(E\kappa)} | \tilde{m}_J^s \tilde{m}_I^s \rangle_\infty \\
&\quad = \sum_{\tilde{m}_J^s \tilde{m}_I^s} {}_\infty\langle \tilde{m}_J^s \tilde{m}_I^s | m_J^s m_I^s \rangle_B \ {}_\infty\langle m_J^p m_I^p | T_q^{(E\kappa)} | \tilde{m}_J^s \tilde{m}_I^s \rangle_\infty \ .
\end{aligned}
$$

The matrix elements in the pure Zeeman regime can be expressed by [Deh07, unpublished],

$$
\begin{aligned}
&\langle F^p m_F^p | T_q^{(E\kappa)} | F^s m_F^s \rangle = {}_0\langle m_J^p m_I^p | \, T_q^{(E\kappa)} \, | m_J^s m_I^s \rangle_0 \\
&\quad = \begin{pmatrix} J^s & \kappa & J^p \\ m_J^s & \text{sign}(m^p - m^s) & -m_J^p \end{pmatrix}^2 \begin{Bmatrix} J^p & J^s & \kappa \\ F^s & F^p & I \end{Bmatrix}^2 \frac{(2F^s+1)(2J^p+1)(2\kappa+1)}{2I+1} \ .
\end{aligned}
$$

Discuss the pure Paschen-Back regime via ${}_\infty\langle m_J^p m_I^p | T_q^{(E\kappa)} | m_J^s m_I^s \rangle_\infty$.

33.2.7.6 Ex: Diamagnetism of the ground states of H atoms

Calculate the quadratic Zeeman effect for the ground state of the hydrogen atom caused by the (usually neglected) diamagnetic term of the Hamiltonian in first order TPIT. Write down the energy shift as $\Delta E = -\frac{\chi}{2}\mathcal{B}^2$ assuming a constant magnetic field in order to obtain the diamagnetic susceptibility χ.

33.3 Interaction with electric fields

33.3.1 Stark Effect

Electric fields interact with the electrons of the atom. Describing the atom by its dipole moment, according to (33.13), the interaction energy is,

$$\hat{V}_{\text{Stark}} = -\hat{\mathbf{d}} \cdot \vec{\mathcal{E}} \ . \tag{33.66}$$

This is the *Stark effect*. This effect is usually weak, and its observation requires strong fields or high spectral resolution. Stationary perturbation theory TIPT gives,

$$E_n^{(1)} = \langle \psi_n^{(0)} | - \hat{\mathbf{d}} \cdot \mathcal{E} | \psi_n^{(0)} \rangle = e\mathcal{E}_z \int_{\mathbb{R}^3} z |\psi_n^{(0)}|^2 d^3r = 0 \ , \tag{33.67}$$

with $\mathbf{d} = -e\mathbf{r}$ and $\vec{\mathcal{E}}_z = \mathcal{E}_z \hat{\mathbf{e}}_z$. This only applies when the states have well-defined parity and are NOT degenerate in ℓ. When they ARE degenerate in ℓ, which is the case of hydrogen, the states have no defined parity $(-1)^\ell$. For example, the states s and p contributing to the same state $|\psi_{n,j}\rangle$ have different parities. In this case, the condition (33.67) is not automatically satisfied, and the first perturbation order yields a value. This is the case of the *linear Stark effect*. In the Excs. 33.3.2.1 and 33.3.2.2 we explicitly calculate the Stark energy shift for a hydrogen atom subject to an electric field.

Other atoms do not have this degeneracy, and we must calculate the *quadratic Stark effect* in second order TIPT,

$$|\psi_n^{(1)}\rangle = e\mathcal{E}_z \sum_{n' \neq n} |\psi_{n'}^{(0)}\rangle \frac{\langle \psi_{n'}^{(0)} | \hat{z} | \psi_n^{(0)} \rangle}{E_n - E_{n'}} \ . \tag{33.68}$$

and

$$E_n^{(2)} = e^2 \mathcal{E}_z^2 \sum_{n' \neq n} \frac{|\langle \psi_{n'}^{(0)} | \hat{z} | \psi_n^{(0)} \rangle|^2}{E_n - E_{n'}} \ . \tag{33.69}$$

To simplify the matrix elements, we separate the radial part from the angular part,

$$\langle \psi_{n'}^{(0)} | \hat{z} | \psi_n^{(0)} \rangle = \langle n' J' m'_J | \hat{z} | n J m_J \rangle = \int_0^\infty r^3 R_{n'J'} R_{nJ} dr \int Y^*_{J'm'_J} \tfrac{z}{r} Y_{Jm_J} d\Omega \ . \tag{33.70}$$

The radial part, written as

$$\langle n'_J J' || \hat{z} || n_J J \rangle \equiv \int_0^\infty r^3 R_{n'_J J'} R_{n_J J} dr \ , \tag{33.71}$$

and called the *irreducible matrix element*, no longer depends on the magnetic quantum number. On the other hand, the angular part may be expressed by Clebsch-Gordan coefficients, as will be discussed more extensively in Sec. 39.2.3. The result is called *Wigner-Eckart theorem*,

$$\boxed{\frac{\langle n'_J J' m'_J | \hat{z} | n_J J m_J \rangle}{\langle n'_J J' || \hat{z} || n_J J \rangle} = \int Y^*_{J'm'_J} \tfrac{z}{r} Y_{Jm_J} d\Omega = \frac{1}{2J'+1} \begin{pmatrix} J & 1 & J' \\ m_J & 0 & -m'_J \end{pmatrix}} \ . \tag{33.72}$$

With $[\hat{z}, \hat{L}_z] = 0$, which was shown in Exc. 25.3.4.2, and obviously $[\hat{z}, \hat{S}_z] = 0$ we find,

$$0 = \langle J' m'_J | [\hat{z}, \hat{J}_z] | J m_J \rangle = (m_J - m'_J) \langle J' m'_J | \hat{z} | J m_J \rangle \ . \tag{33.73}$$

This means that for $m_J \neq m'_J$, the matrix elements $\langle J' m'_J | \hat{z} | J m_J \rangle$ should disappear. Therefore, the matrix is diagonal in m_J. We consider dipole transitions with $|J - J'| \leq 1$ [1],

$$\begin{pmatrix} J & 1 & J+1 \\ m_J & 0 & -m_J \end{pmatrix} = \frac{(J+1)^2 - m_J^2}{(2J+1)(J+1)}, \tag{33.74}$$

$$\begin{pmatrix} J & 1 & J \\ m_J & 0 & -m_J \end{pmatrix} = \frac{m_J^2}{J(J+1)} \ ,$$

$$\begin{pmatrix} J & 1 & J-1 \\ m_J & 0 & -m_J \end{pmatrix} = \frac{J^2 - m_J^2}{J(2J+1)} \ .$$

States with the same $|m_J|$ lead to the same quadratic Stark effect,

$$\Delta E \sim A + B |m_J|^2 \ . \tag{33.75}$$

The factors A and B depend on the main quantum number n and also on L, S, J. Moreover, they depend on the energy distance of all contributing levels, because of the denominator in the perturbation equation (33.68). Only levels with different parity $(-1)^L$ contribute. The formulae (33.74) will be derived explicitly in Exc. 33.3.2.3.

33.3.2 Exercises

33.3.2.1 Ex: Stark effect in hydrogen

Consider the hydrogen atom immersed in a uniform electric field $\vec{\mathcal{E}}$ applied along the $\hat{\mathbf{e}}_z$-direction. The term corresponding to this interaction in the total Hamiltonian is $\hat{H}^{(1)} = -e\vec{\mathcal{E}}\hat{z}$. For typical electric fields produced in laboratory, the condition $\hat{H}^{(1)} \ll \hat{H}_0$, which allows the use of TIPT, is satisfied. The effect of the perturbation $\hat{H}^{(1)}$, called Stark effect, is the removal of the degeneracy of some of the hydrogen atom states. Calculate the Stark effect for the state $n = 2$.

33.3.2.2 Ex: Stark effect in the $1s$ hydrogen level

Calculate the Stark shift of the hydrogen ground state by taking into account the contributions of the excited states $n = 2, 3, ...$

33.3.2.3 Ex: Stark effect

Derive the Eqs. (33.74) from the formula (28.7).

[1] For it is possible to show that $\langle n'_J J' || \hat{z} || n_J J \rangle = 0$ for $|J - J'| > 1$.

Chapter 34

Atoms with many electrons

The electronic shell of an atom consists of many electrons occupying different quantum states and interacting with each other. Being fermions forced into the lowest energy states of a tight potential imposed by their attraction to the Coulomb potential of a nucleus, the electronic wavefunction must obey quantum statistical symmetrization rules. The rules have been derived in Sec. 30.1, so that we can restrict here to a brief recapitulation focusing to the case of an electronic shell. This will be done in Sec. 34.1. In Sec. 34.2 we will discuss consequences of the symmetrization requirement at the simplest possible case, which is the helium atom. In Sec. 34.3 we extend the discussion to many-electron systems, which leads us finally to the explanation of the periodic system of elements presented in Sec. 34.4.

34.1 Symmetrization of bosons and fermions

Quantum mechanics must be formulated in a way to avoid any possibility of distinguishing identical particles. However, the language of mathematics (based on 'classical' letters and symbols) automatically assigns a particle to a wavefunction; for example, $\psi_a(x_1)$ is the wavefunction a of particle 1 and $\psi_b(x_2)$ the wavefunction b of particle 2. In the absence of interactions, the total wavefunction, $\Psi = \psi_a(x_1)\psi_b(x_2)$, solves the Schrödinger equation of two particles. Now, by changing the coordinates of the particles we get a different state $\Psi' = \psi_a(x_2)\psi_b(x_1)$ [1]. This erroneously suggests that the wavefunction of a particle plays the role of a *label* (or 'soul') characterizing the particle beyond its set of quantum numbers. Why this is a problem, we will see in the following example [2].

[1] We note that the states are orthogonal, because

$$\int \Psi^{*(1,2)}\Psi^{(2,1)}dx_1dx_2 = \int \psi_a^*(x_1)\psi_b^*(x_2)\psi_a(x_2)\psi_b(x_1)dx_1dx_2$$
$$= \int \psi_a^*(x_1)\psi_b(x_1)dx_1 \int \psi_b^*(x_2)\psi_a(x_2)dx_2 = \delta_{n_a,n_b} \ .$$

[2] Ultimately, all this is simply a consequence of the uncertainty principle, which forbids us to specify a wavefunction as a function of two non-commuting coordinates: We have to choose one coordinate on which the wavefunction depends and treat the other as a quantum number, for example, $\psi_{\mathbf{k}}(\mathbf{r}) = e^{\imath\mathbf{k}\cdot\mathbf{r}}$ or $\psi_n(x) = \cos\frac{n\pi x}{L}$. When we now exchange the coordinates of two particles without changing their quantum numbers, we get obviously different states. In classical physics, the wavefunction of a particle would be written $\psi(x,p)$. If two classical particles are not distinct by any other mean, an exchange of *all* their coordinates would reproduce exactly the same state.

Example 249 (*Indistinguishability of particles*): We consider a system of two non-interacting spinless particles in an infinite potential well. The total wavefunction is,

$$\Psi^{(1,2)} \equiv \psi_a(x_1)\psi_b(x_2) = C\cos\frac{n_a\pi x_1}{L}\cos\frac{n_b\pi x_2}{L} \tag{34.1}$$

with the energy,

$$E_{a,b} = \frac{\pi^2 n_a^2}{2mL^2} + \frac{\pi^2 n_b^2}{2mL^2} \ .$$

For observable quantities, such as $|\Psi^{(1,2)}|^2$, we must ensure, $|\Psi^{(1,2)}|^2 = |\Psi^{(2,1)}|^2$, that is,

$$C^2\cos^2\tfrac{n_a\pi x_1}{L}\cos^2\tfrac{n_b\pi x_2}{L} = C^2\cos^2\tfrac{n_a\pi x_2}{L}\cos^2\tfrac{n_b\pi x_1}{L} \ ,$$

but this is not valid for $n_a \neq n_b$. Only if $n_a = n_b$, we have $\psi_a = \psi_b$. In this case, the particles stay in the same state, and we do not need to worry about indistinguishability:

$$\Psi^{(2,1)} = \psi_a(x_2)\psi_b(x_1) = \Psi^{(1,2)} \qquad \text{and} \qquad E_{a,b} = E_{b,a} \ .$$

However, the fact that this state is never observed with two electrons shows, that theory must be corrected to allow for a true description of reality. Will deepen this argument in Exc. 34.1.3.1.

We need to construct the total wavefunction in another way. Let us consider linear combinations of $\Psi^{(1,2)}$,

$$\Psi^{\mathrm{S,A}} \equiv \tfrac{1}{\sqrt{2}}(\Psi^{(1,2)} \pm \Psi^{(2,1)}) = \tfrac{1}{\sqrt{2}}\left[\psi_a(x_1)\psi_b(x_2) \pm \psi_a(x_2)\psi_b(x_1)\right] \ . \tag{34.2}$$

This *(anti-)symmetrized* represents a trick to eradicate the *label* sticking to the particles. For, under position exchange described by the operator $\mathcal{P}_x\psi_a(x_1)\psi_b(x_2) \equiv \psi_a(x_2)\psi_b(x_1)$, the (anti-)symmetrized functions behave like [3],

$$\mathcal{P}_x\Psi^{\mathrm{S,A}} = \pm\Psi^{\mathrm{S,A}} \qquad \text{while} \qquad \mathcal{P}_x\Psi^{(1,2)} = \Psi^{(2,1)} \neq \mp\Psi^{(1,2)} \ . \tag{34.3}$$

The (anti-)symmetrized function solves the Schrödinger equation, as well. As $[\hat{H}, \mathcal{P}_x] = 0$, we can say that the system exhibits an *exchange symmetry* or *exchange degeneracy* upon particle exchange. Observables such as $\Psi^{*S,A}\Psi^{\mathrm{S,A}}$ stay conserved, for example, the probability

$$\begin{aligned}|\Psi^{\mathrm{S,A}}|^2 &= \tfrac{1}{2}\left[|\psi_a(x_1)\psi_b(x_2)|^2 + |\psi_a(x_2)\psi_b(x_1)|^2\right] \\ &\pm \tfrac{1}{2}\left[\psi_a^*(x_1)\psi_b^*(x_2)\psi_a(x_2)\psi_b(x_1) + \psi_a^*(x_2)\psi_b^*(x_1)\psi_a(x_1)\psi_b(x_2)\right] = \mathcal{P}_x|\Psi^{\mathrm{S,A}}|^2\end{aligned} \tag{34.4}$$

does not change, when we exchange x_1 for x_2. For $x_1 = x_2$, we observe,

$$|\Psi^{\mathrm{S,A}}|^2 = |\psi_a(x)\psi_b(x)|^2 \pm |\psi_a(x)\psi_b(x)|^2 \ . \tag{34.5}$$

That is, for a symmetric system, the probability of finding two particles at the same location is doubled, whereas for an antisymmetric system, this probability is zero.

[3] To guarantee $|\mathcal{P}_x\Psi^{\mathrm{S,A}}|^2 = |\Psi^{\mathrm{S,A}}|^2$, we have $\mathcal{P}_x\Psi^{\mathrm{S,A}} = e^{\imath\phi}\Psi^{\mathrm{S,A}}$. From this, $\mathcal{P}_x\mathcal{P}_x\Psi^{\mathrm{S,A}} = e^{2\imath\phi}\Psi^{\mathrm{S,A}} = \Psi^{\mathrm{S,A}}$. Hence, $\mathcal{P}_x\Psi^{\mathrm{S,A}} = \pm\Psi^{\mathrm{S,A}}$.

Wolfgang Pauli showed that the (anti-)symmetric character is related to the spin of the particles. Particles with *integer spin* called *bosons* must be symmetric. Particles with *semi-integer spin* called *fermions* must be antisymmetric. Electrons are fermions. Therefore, in an atom, they can not be in the same state (location), but must be distributed over a complicated shell of orbitals. We note, that this applies not only to elementary particles, but also to composed particles such as, for example, atoms. We will determine in Exc. 34.1.3.2 the bosonic or fermionic character of several atomic species.

34.1.1 Pauli's Principle

Two electrons with anti-parallel spins can be separated by inhomogeneous magnetic fields, even if they are initially in the same place. Therefore, they are distinguishable and the wavefunction need not be antisymmetric. But if we exchange the spin along with the position, the particles must be indistinguishable. This must be taken into account in the wavefunction by assigning a spin coordinate, $\psi_a(x_1, s_1)$. The exchange operator should now be generalized,

$$\mathcal{P}_{x,s}\Psi^{(1,2)} \equiv \mathcal{P}_{x,s}\psi_a(x_1, s_1)\psi_b(x_2, s_2) = \psi_a(x_2, s_2)\psi_b(x_1, s_1) = \Psi^{(2,1)} \ . \tag{34.6}$$

We now assume that the electrons not only do *not* interact with each other, but there is also *no interaction* between the position and the spin of each electron. That is, for a while we will discard $\mathbf{L}\cdot\mathbf{S}$-coupling [4]. We can then write the total wavefunction of an electron as the *product* of a spatial function, $\psi(x)$, and a spin function, $\chi(s) = \alpha\uparrow + \beta\downarrow$, where α and β are probability amplitudes of finding the electron in the respective spin state, such that,

$$\psi(x, s) = \psi(x)\chi(s) \ . \tag{34.7}$$

For two particles, the total spin function is,

$$X^{(1,2)} = \chi_a(s_1)\chi_b(s_2) \ . \tag{34.8}$$

The (anti-)symmetrized version is

$$X^{\mathrm{S,A}} = \tfrac{1}{\sqrt{2}}(X^{(1,2)} \pm X^{(2,1)}) = \tfrac{1}{\sqrt{2}}[\chi_a(s_1)\chi_b(s_2) \pm \chi_a(s_2)\chi_b(s_1)] \ , \tag{34.9}$$

as we have already seen in Sec. 25.4.1. Since there are only two spin directions, there are four possibilities to attribute the spins $\uparrow$ and $\downarrow$ to the functions $\chi_m(s_n)$,

$$X^{\mathrm{S}} = \begin{cases} \uparrow\uparrow & = \chi_{1,1} \\ \frac{1}{\sqrt{2}}(\uparrow\downarrow + \downarrow\uparrow) & = \chi_{1,0} \\ \downarrow\downarrow & = \chi_{1,-1} \end{cases} \qquad \text{and} \qquad X^{\mathrm{A}} = \tfrac{1}{\sqrt{2}}(\uparrow\downarrow - \downarrow\uparrow) = \chi_{0,0} \tag{34.10}$$

For the total wavefunction, which must be antisymmetric for electrons, there are two

[4] In the case of $\mathbf{L}\cdot\mathbf{S}$-coupling, the total wavefunction can not be written as a product of spatial and spin functions, but it must be antisymmetric anyway.

possibilities,

$$\Theta^{\mathrm{A}} = \begin{cases} \Psi^{\mathrm{S}} X^{\mathrm{A}} = \frac{1}{2}(\Psi^{(1,2)} + \Psi^{(2,1)})(X^{(1,2)} - X^{(2,1)}) = \frac{1}{\sqrt{2}}[\psi_a(x_1)\psi_b(x_2) + \psi_a(x_2)\psi_b(x_1)]\chi_{0,0} \\ \Psi^{\mathrm{A}} X^{\mathrm{S}} = \frac{1}{2}(\Psi^{(1,2)} - \Psi^{(2,1)})(X^{(1,2)} + X^{(2,1)}) = \frac{1}{\sqrt{2}}[\psi_a(x_1)\psi_b(x_2) - \psi_a(x_2)\psi_b(x_1)] \begin{cases} \chi_{1,1} \\ \chi_{1,0} \\ \chi_{1,-1} \end{cases} \end{cases} . \tag{34.11}$$

That is, the two electrons may be in a *triplet* state with the antisymmetric spatial wavefunction, or in a *singlet* state with the symmetric spatial wavefunction [5].

How to generalize these considerations to N particles? The symmetric wavefunctions contain all permutations of the label a_k, where we understand by a_k the set of quantum numbers unambiguously specifying the state of the particle k,

$$\Theta^{\mathrm{S}} = \mathcal{N} \sum_{\mathcal{P}_{x,s} a_k} \psi_{a_1}(x_1) ... \psi_{a_N}(x_N) \ , \tag{34.12}$$

with a normalization factor $\mathcal{N}$ [6]. The (anti-)symmetrized wavefunction is obtained from the *Slater determinant*,

$$\Theta^{\mathrm{A}} = \frac{1}{N!} \det \psi_{a_k}(x_n) = \frac{1}{N!} \begin{vmatrix} \psi_{a_1}(x_1) & \cdots & \psi_{a_1}(x_N) \\ \vdots & \ddots & \vdots \\ \psi_{a_N}(x_1) & \cdots & \psi_{a_N}(x_N) \end{vmatrix} . \tag{34.13}$$

This function satisfies

$$\mathcal{P}_{x,s} \Theta^{A,(1,..,i,j,..,N)} = \Theta^{A,(1,..,j,i,..,N)} = -\Theta^{A,(1,..,i,j,..,N)} \ . \tag{34.14}$$

The Slater determinant is zero, when two sets of quantum numbers are identical, $a_i = a_j$. For example, for two electrons in an electronic shell, $|n_i, l_i, m_i, s_i\rangle = |n_j, l_j, m_j, s_j\rangle$. This is *Pauli's strong exclusion principle*:

> *The total wavefunction must be antisymmetric with respect to the exchange of any pair of identical fermions and symmetrical with respect to exchange of any pair of identical bosons.*

Pauli's weak exclusion principle (usually sufficient for qualitative considerations) says that two fermions in identical states can not occupy the same region in space. That is, their Broglie waves interfere destructively, as if Pauli's principle exerted a repulsive interaction on the particles. This 'force' has a great impact on the phenomenology of the bonds between atoms, as we will discuss in the following sections.

34.1.2 Consequences for quantum statistics

The indistinguishability of quantum particles has interesting consequences on the statistical behavior of bosons and fermions. This becomes obvious when we consider

[5] In the coupled image, the total spin $\mathbf{S} = \mathbf{s}_1 + \mathbf{s}_2$ can have the following values $S = |s_1 - s_2|, .., s_1 + s_2 = 0, 1$. In the case $S = 0$ the magnetic quantum number can only have one value (singlet), $m_S = 0$. In the case $S = 1$ it can have three values $m_S = -1.0, +1$ (triplet) (see Exc. 33.2.7.3).

[6] It is possible to show $\mathcal{N} = \sqrt{\frac{\Pi_{k=1}^{m} n_k!}{N!}}$, where n_k is the population of state ψ_{a_k}, that is, the number of particles with the same set of quantum numbers a_k.

two particles 1 and 2 being able to adopt two different states a and b. Distinguishable particles can be in one of the following four states,

$$\Psi = \{\psi_a(x_1)\psi_a(x_2), \psi_a(x_1)\psi_b(x_2), \psi_b(x_1)\psi_a(x_2), \psi_b(x_1)\psi_b(x_2)\} \tag{34.15}$$

with the same probability of $p = 1/4$. When the quantum particles approach each other, $x_1 \simeq x_2$, they must become indistinguishable. Bosonic indistinguishable particles can stay in one of the following three states,

$$\Psi = \{\psi_a(x_1)\psi_a(x_2), \tfrac{1}{\sqrt{2}}[\psi_a(x_1)\psi_b(x_2) + \psi_b(x_1)\psi_a(x_2)], \psi_b(x_1)\psi_b(x_2)\} \tag{34.16}$$

with the same probability of $p = 1/3$. Finally, fermionic indistinguishable particles can only be in one state,

$$\Psi = \{\tfrac{1}{\sqrt{2}}[\psi_a(x_1)\psi_b(x_2) - \psi_b(x_1)\psi_a(x_2)]\} \tag{34.17}$$

with the probability of $p = 1$. We see that a simple two-particle system already exhibits qualitative modifications of its statistical behavior. These differences generate different physics as we deal with systems of large numbers of particles, as we can see in the cases of the free electron gas and the Bose-Einstein condensate. For a broader discussion, see Chap. 30.1.

We finally note a result of the standard model of particle physics assigning a fermionic character to all fundamental constituent particles of matter while the mediators of fundamental forces are always bosons.

34.1.3 Exercises

34.1.3.1 Ex: Indistinguishability of particles

Consider the observable quantity $\int_0^{L/2}\int_0^{L/4}|\Psi(x_1,x_2)|^2 dx_1 dx_2$ for the case of the wavefunction defined in (34.1) and show, that it *does* depend on particle exchange.

34.1.3.2 Ex: Bosonic and fermionic isotopes

Consulting an isotope table determine the bosonic or fermionic character of the following atomic species: ^{87}Sr, ^{86}Sr, ^{87}Rb, ^{39}K, and ^{40}K.

34.1.3.3 Ex: Interference of bosons and fermions

a. Consider two clouds of ultracold bosonic atoms (BECs at temperature $T = 0$) moving into opposite direction with velocities $v_\pm = \pm v$, respectively. Describe the matter wave interference pattern.
b. Repeat the consideration for the case of (i) fermionic clouds and (ii) only two counterpropagating atoms. Is matter wave interference possible at all for fermions?

34.2 Helium

The simplest atom to discuss Pauli's principle is helium. The helium atom has a charged nucleus $Z = +2e$ and mass $m_{\rm He} \approx 4m_{\rm H}$.

34.2.1 The ground state

The ground state of the *helium* atom brings together the two electrons, that is, $(1s)^2$. To treat the helium atom, we can, as a first trial, describe the atom by the Bohr model, assuming independent electrons. Neglecting the electronic repulsion term (which depends on $r_{12} = |\mathbf{r}_1 - \mathbf{r}_2|$), we can separate the total wavefunction:

$$\Psi(\mathbf{r}_1, \mathbf{r}_2) = \Psi_1(\mathbf{r}_1)\Psi_2(\mathbf{r}_2) \ , \tag{34.18}$$

and we get two Schrödinger equations, the Hamiltonian being equal to the one of hydrogen-like atoms:

$$\left[-\frac{\hbar^2}{2\mu}\nabla_i^2 - \frac{e^2}{4\pi\varepsilon_0}\frac{Z}{r_i}\right]\Psi_i(\mathbf{r}_i) = E_n^{(i)}\Psi_i(\mathbf{r}_i) \ , \tag{34.19}$$

with $i = 1, 2$. For hydrogen-like atoms we have,

$$E = E_n^{(1)} + E_n^{(2)} = E_\mathrm{B} Z^2 \left(\frac{1}{n_1^2} + \frac{1}{n_2^2}\right) \ , \tag{34.20}$$

with $E_\mathrm{B} = -13.6\,\mathrm{eV}$. With this, we get the energy for the ground state:

$$E_\mathrm{He}(1s) = -2Z^2 E_\mathrm{B} = -108.8\,\mathrm{eV} \ . \tag{34.21}$$

The value predicted by Bohr's model is far from experimental reality: The ionization energy measured for the first electron is 24.6 eV, for the second 54.4 eV, totalizing a binding energy for two electrons of $-78.983\,\mathrm{eV}$. This corresponds to an error of about 38%. The lower energy of the first electron is due to the shielding of the nucleus by the second.

34.2.1.1 First-order perturbation of the energy

Treating the repulsion term between the electrons as a perturbation [39] and using the eigenfunctions of hydrogen atoms $|n, \ell, m_\ell\rangle$, the total wavefunction is $|n_1, \ell_1, m_{\ell_1}; n_2, \ell_2, m_{\ell_2}\rangle$, we obtain as first order TIPT correction for the energy:

$$\Delta E = \langle n_1, \ell_1, m_{\ell_1}; n_2, \ell_2, m_{\ell_2}|\frac{e^2}{4\pi\varepsilon_0 r_{12}}|n_1, \ell_1, m_{\ell_1}; n_2, \ell_2, m_{\ell_2}\rangle \ . \tag{34.22}$$

This correction is called the *Coulomb integral* and has the value:

$$\Delta E = \frac{e^2}{4\pi\varepsilon_0}\int |\Psi_{n_1,\ell_1,m_{\ell_1}}(\mathbf{r}_1)|^2 \left(\frac{1}{r_{12}}\right)|\Psi_{n_2,\ell_2,m_{\ell_2}}(\mathbf{r}_2)|^2 dV_1 dV_2 \ . \tag{34.23}$$

This integral is always positive. The term $|\Psi_{n_1,\ell_1,m_{\ell_1}}(\mathbf{r}_1)|^2 dV_1$ is the probability of finding the electron inside the volume element dV_1 and, when multiplied by $-e$, gives the charge associated with that region. Thus, the integral represents the Coulombian interaction energy of the confined charges within the two volume elements dV_1 and dV_2. ΔE is the total contribution to the potential energy. Calculating the Coulomb integral for the ground state, which will be done in Exc. 34.2.3.1, we obtain,

$$\Delta E = \frac{5Z}{4}\left(\frac{e^2}{4\pi\varepsilon_0 2a_\mathrm{B}}\right) = \frac{5Z}{4}E_\mathrm{B} \ , \tag{34.24}$$

with $a_{\rm B}$ the Bohr radius. ΔE corresponds to 34 eV. Thus, the ground state energy is $E_{\rm He}(1s) = -108.8\,{\rm eV} + 34\,{\rm eV} = -74.8\,{\rm eV}$. Comparing with the experimental value of $-78.983\,{\rm eV}$ we still have an error around 5.3%.

34.2.1.2 Shielding of the nuclear charge

We can make the approximation in which we consider that each electron moves in a Coulombian potential, with respect to the nucleus, shielded by the charge distribution of the other electron [246]. The resulting potential will be generated by an effective charge $\zeta e \equiv (Z - B)e$. The quantity $B \in [0, 1]$ is called the shielding constant.

The first electron feels a total nuclear charge Ze, while the second feels an effective nuclear charge ζe. We exchange Z for ζ in the energy term for hydrogen-like atoms,

$$E_n = -\zeta \frac{E_{\rm B}}{n^2} \ , \tag{34.25}$$

and the energy for the ground state becomes, assuming total shielding, $B = 1$,

$$E = E_1 + E_2 = -Z^2 E_{\rm B} - \zeta^2 E_{\rm B} = -4E_{\rm B} - E_{\rm B} = -5E_{\rm B} = -67.5\,{\rm eV} \ . \tag{34.26}$$

Comparing with the experimental value of $-78.983\,{\rm eV}$ we have an error around 15%. For a shielding constant of around $B = 0.656$ the experimental value is reproduced. This means that the effective nuclear charge felt by the second electron is only *partly* shielded by the former. The TPIT method (34.22) and the shielding concept (34.25) can be combined in a variational calculation, where the effective charge ζ is the variational parameter. In Exc. 34.2.3.2 we study the reciprocal shielding of the electrons at the example of the helium-type ion H^-.

34.2.2 Excited states

Let us now investigate the excited states of helium, in particular those, where *only one electron* is excited, the other one being in the ground state, $(1s)^1(2s)^1$ and $(1s)^1(2p)^1$. All energies are considerably higher (weaker binding) than predicted by Bohr's model with $Z = 2$, because of the interaction with the other electron. Also, the $(2s)$ and $(2p)$ levels are no longer degenerate, because the electrostatic potential is no longer Coulombian (see Fig. 34.1).

As we have seen in the discussion of the fine structure of hydrogen, the energy of the $\mathbf{L} \cdot \mathbf{S}$-coupling given by (32.130) is $\propto E_n(Z\alpha)^2 \propto Z^4$. For helium which still has a small Z, the energy of the coupling is weak ($\sim 10^{-4}\,{\rm eV}$), so that we can count on a direct coupling of the spins of the two electrons. If in an excited state the orbits of the electrons are different, we can construct combinations of symmetric **or** antisymmetric spatial wavefunctions $\Psi^{\rm S,A}$, and therefore combinations $X^{A,S}$ of antiparallel or parallel spins. When the spins are parallel ($S = 1$), the spatial wavefunction is antisymmetric, when they are antiparallel ($S = 0$), it is symmetric. From the symmetry of the wavefunction depends the energy of the Coulombian interelectronic interaction, because in the symmetric state the average distance of the electrons is much smaller than in the antisymmetric state, where *the total spatial function disappears for zero distance*. Consequently, the configuration $(1s)^1(2s)^1$ has two states with $S = 0$ and $S = 1$, with energy $E_{S=0} > E_{S=1}$. Likewise, all configurations are

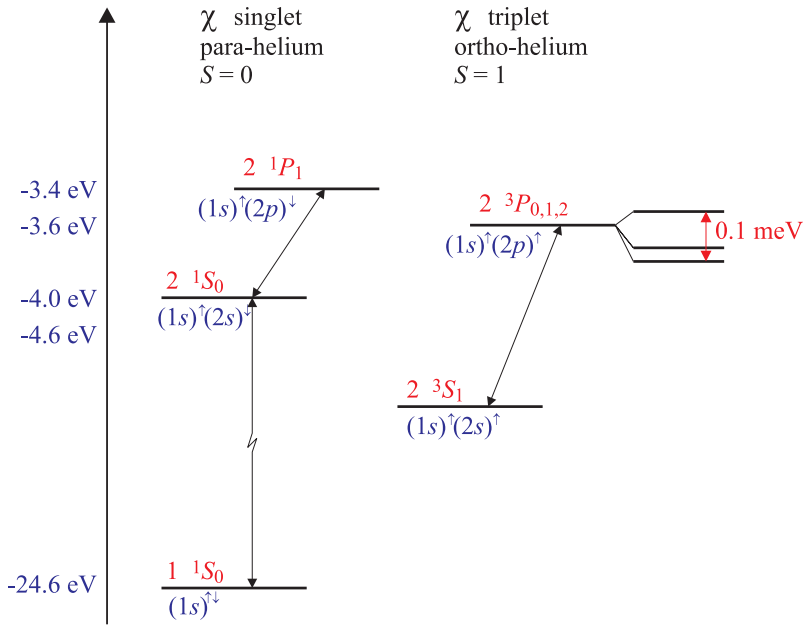

Figure 34.1: Helium levels for the excitation of the first electron and allowed singlet and triplet transitions. Note that the state $(1s)^{\uparrow\uparrow} \equiv (1s)^{\uparrow}(1s)^{\uparrow}$ does not exist, because it would be totally symmetric.

split, as shown in Fig. 34.1. The energy difference ($\sim$ 0.6 eV) is considerable and larger than the energy of fine structure interaction. This explains why the two spins first couple to a total spin, $\mathbf{s}_1 + \mathbf{s}_2 = \mathbf{S}$, before this spin couples to the total orbital angular momentum, $\mathbf{S} + \mathbf{L} = \mathbf{J}$. This is the $\mathbf{L} \cdot \mathbf{S}$-coupling.

34.2.2.1 Exchange energy

The energy difference between the two states $S = 0$ and $S = 1$ is called *exchange energy*. It comes out of a first-order perturbation calculation perfomed with symmetrized states. For example, for the two possible states $(1s)^1(2s)^1$, we write the total antisymmetric wavefunctions,

$$\Theta^{\mathrm{A}}_{\pm} = \tfrac{1}{\sqrt{2}} \left[\psi_{100}(\mathbf{r}_1)\psi_{200}(\mathbf{r}_2) \pm \psi_{100}(\mathbf{r}_2)\psi_{200}(\mathbf{r}_1)\right] \cdot \chi^{A,S} \ , \tag{34.27}$$

where the (+) sign holds for $\chi^{\rm A}$ ($S=0$) and the (−) sign for $\chi^{\rm S}$ ($S=1$). The energies are,

$$\begin{aligned}\Delta E^{\rm S,A} &= \tfrac{1}{2}\int dr_1^3 \int dr_2^3 \Theta_\pm^{*A} \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_1-\mathbf{r}_2|}\Theta_\pm^{\rm A} \\ &= \tfrac{1}{2}\int dr_1^3 \int dr_2^3 \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_1-\mathbf{r}_2|}[|\psi_{100}(\mathbf{r}_1)|^2|\psi_{200}(\mathbf{r}_2)|^2+|\psi_{100}(\mathbf{r}_2)|^2|\psi_{200}(\mathbf{r}_1)|^2] \\ &\quad \pm \tfrac{1}{2}\int dr_1^3 \int dr_2^3 \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_1-\mathbf{r}_2|} 2\psi_{100}^*(\mathbf{r}_1)\psi_{200}^*(\mathbf{r}_2)\psi_{100}(\mathbf{r}_2)\psi_{200}(\mathbf{r}_1) \\ &\equiv \Delta E_{\rm Coulomb} \pm \Delta E_{\rm exchange}\ .\end{aligned} \tag{34.28}$$

The first integral,

$$\Delta E_{\rm Coulomb} = \int dr_1^3 \int dr_2^3 \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_1-\mathbf{r}_2|}|\psi_{100}(\mathbf{r}_1)|^2|\psi_{200}(\mathbf{r}_2)|^2\ , \tag{34.29}$$

is the Coulomb energy (34.23) between the electronic orbitals. We note that this part can be calculated from the Hamiltonian using *non-symmetrized* orbitals. The second integral,

$$\Delta E_{\rm exchange} = \int dr_1^3 \int dr_2^3 \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_1-\mathbf{r}_2|}\psi_{100}^*(\mathbf{r}_1)\psi_{200}^*(\mathbf{r}_2)\psi_{100}(\mathbf{r}_2)\psi_{200}(\mathbf{r}_1)\ , \tag{34.30}$$

called *exchange energy* corresponds to the interference terms of the symmetrization and must be added or subtracted according to their symmetry character. It is interesting to note that up to this point the spin does not enter directly into the helium Hamiltonian,

$$\hat{H}^{\rm S,A} = \frac{p_1^2}{2m}+\frac{p_2^2}{2m}+V(r_1)+V(r_2)+V(|\mathbf{r}_1-\mathbf{r}_2|)\pm\Delta E_{\rm exchange}\ , \tag{34.31}$$

but only through the symmetry character of the spatial wavefunction. On the other hand, on a much smaller energy scale, the spin enters through the $\mathbf{L}\cdot\mathbf{S}$-interaction.

The potential is not spherically symmetric, the term r_{12} depends on the angle between $\mathbf{r}_1$ and $\mathbf{r}_2$. Thus, the total wavefunction $\Psi(\mathbf{r}_1,\mathbf{r}_2)$ is not separable into a radial and an angular part. By consequence, unlike for hydrogen, the Schrödinger equation with the Hamiltonian (34.21) has no analytical solution.

Example 250 (*TIPT for excited helium states*): We consider the two electrons of a helium atom occupying different orbits described by wavefunctions denoted by $\psi_a(1)\equiv\psi_{n_1,\ell_1,m_{\ell_1}}(\mathbf{r}_1)$ and $\psi_b(2)\equiv\psi_{n_2,\ell_2,m_{\ell_2}}(\mathbf{r}_2)$. Applying the Hamiltonian without the interelectronic interaction term, the total states $\Theta=\psi_a(1)\psi_b(2)$ and $\psi_a(2)\psi_b(1)$ have the same energy E_a+E_b. To calculate the energy correction, we use TIPT for degenerate states. We have to calculate the secular determinant $\det(\langle n,\nu|H^{(1)}|n,\mu\rangle - E^{(1)}_{n,\mu}\delta_{\mu,\nu})$. The terms of the perturbation matrix $H^{(1)}$ are:

$$\begin{aligned}H_{11}^{(1)} &= \langle\psi_a(1)\psi_b(2)|\frac{e^2}{4\pi\varepsilon_0 r_{12}}|\psi_a(1)\psi_b(2)\rangle \\ H_{22}^{(1)} &= \langle\psi_a(2)\psi_b(1)|\frac{e^2}{4\pi\varepsilon_0 r_{12}}|\psi_a(2)\psi_b(1)\rangle \\ H_{12}^{(1)} &= \langle\psi_a(1)\psi_b(2)|\frac{e^2}{4\pi\varepsilon_0 r_{12}}|\psi_a(2)\psi_b(1)\rangle = H_{21}^{(1)}\ .\end{aligned}$$

The terms $J \equiv H_{11}^{(1)} = H_{22}^{(1)}$ are Coulomb integrals. The term $K \equiv H_{12}^{(1)}$ is called *exchange integral*:

$$K = \frac{e^2}{4\pi\varepsilon_0}\langle\psi_a(1)\psi_b(2)|\frac{1}{r_{12}}|\psi_a(2)\psi_b(1)\rangle \ .$$

Hence, as J and K are positive, the determinant is:

$$\begin{vmatrix} J-E & K \\ K & J-E \end{vmatrix} = 0 \ ,$$

yielding,

$$E^{(1)} = J \pm K \ .$$

That is, the states that were previously degenerate with energy $E = E_a + E_b$ are now split into two states with energies $E = E_a + E_b + J \pm K$. And the corresponding eigenfunctions are:

$$\Psi^{\mathrm{S,A}}(1,2) = \frac{1}{\sqrt{2}}[\psi_a(1)\psi_b(2) \pm \psi_b(1)\psi_a(2)] \ .$$

This result shows that the repulsion between the two electrons breaks the degeneracy (of separable functions written in product form) into states with an energy difference $2K$. Note that the eigenfunctions are symmetric, which is discussed in the next section.

34.2.2.2 The spectrum of helium

So far we have seen that, if the electrons are in the same orbital, we have an energy term $E = 2E_a + J$ and, when they are in *different orbitals*, we have $E = E_a + E_b + J \pm K$, with a separation between levels of $2K$.

In practice, we consider only the excitation of *one* electron, because the energy to excite the two electrons exceeds the ionization energy of the helium atom. To find the selection rules for transitions between symmetric and antisymmetric states, we calculate the dipole moment of the transition. For a two-electron system the dipole moment is $\hat{\mathbf{d}} = -e\mathbf{r}_1 - e\mathbf{r}_2$, which is symmetric with respect to a permutation of the two electrons. The matrix element for the dipolar transition is:

$$\langle\Psi^{\mathrm{A}}|\hat{\mathbf{d}}|\Psi^{\mathrm{S}}\rangle = -e\int \Psi^{*A}(\mathbf{r}_1,\mathbf{r}_2)(\mathbf{r}_1+\mathbf{r}_2)\Psi^{\mathrm{S}}(\mathbf{r}_1,\mathbf{r}_2)dV_1dV_2 \ . \tag{34.32}$$

If we exchange the electrons, the above integral changes sign, because $\Psi^{\mathrm{A}}(\mathbf{r}_1,\mathbf{r}_2)$ changes sign. But the integral can not depend on the nomenclature of the integration variables, so *it must be zero*. The transition between a symmetric and an antisymmetric state can not occur. Looking at the spin wavefunction in $\Theta = \Psi^{\mathrm{S}}\chi^{\mathrm{A}}$ or $\Psi^{\mathrm{A}}\chi^{\mathrm{S}}$, we find that transitions are only allowed between singlet states or between triplet states. That is, there is a *selection rule* for the spin postulating $\Delta S = 0$ [7,8].

[7] Moreover, transitions between the states ${}^1S_0$ and ${}^3S_1$ are impossible, because they violate the selection rule for the angular momentum, $\Delta L = \pm 1$.

[8] We can understand the selection rules as follows: As long as the wavefunction can be written as a product, $\Theta = \Psi(x)\chi(s)$, the symmetry character is preserved for the two functions separately. The eigenvalues of the operators $\mathcal{P}_x$ and $\mathcal{P}_s$ are then good quantum numbers. But this only holds for

Because of the differences observed in the singlet and the triplet spectrum of helium, illustrated in Fig. 34.1, it was first believed that they belong to different atomic species, called *para-helium* and *ortho-helium*. A chemical analysis showed later that it was the same element.

34.2.3 Exercises

34.2.3.1 Ex: Helium atom

Compare the measured binding energy with the prediction of Bohr's model considering the inter-electronic interaction up to first order TIPT.

34.2.3.2 Ex: Shielding in helium

The helium atom (or helium-like atoms such as H^-) has two interacting electrons in its composition, which means that these systems have no exact solution. To circumvent this problem we have to come up with a series of approximate methods for calculating their eigenstates and their respective eigenenergies. Among these methods, a widely used one, due mainly to its ease and practicality, is the variational method, in which we calculate the fundamental state of a given problem through a test function that is not a solution of the original problem. This method, when applied to a helium atom, uses as test function the solution of the problem without coulombian interaction between the electrons, which only feel the interaction with the original charge of the nucleus. However, this method could be further improved if we considered an effective nuclear charge, due to its interaction with the electrons themselves, and then obtaining the test function. Apply this correction to the case of helium. Interpret the result. **Help:**

$$\int \frac{\sin\theta_2}{\sqrt{r_1^2+r_2^2-2r_1^2r_2^2\cos\theta_2}}d\theta_2 = \frac{\sqrt{r_1^2+r_2^2-2r_1^2r_2^2\cos\theta_2}}{r_1r_2} \qquad \text{and} \qquad \left\langle\frac{1}{r}\right\rangle = \frac{Z}{a_\mathrm{B}} \ .$$

34.3 Electronic shell structure

The interelectronic interaction and the need to antissimetrize the wavefunction of the electrons both contribute to excessively increase the complexity of multielectronic atoms. The Hamiltonian describing a multielectronic atom of atomic number Z,

$$\hat{H} = E_\mathrm{kin} + V_\mathrm{ncl:ele} + V_\mathrm{ele:ele} = \sum_{i=1}^{Z}\frac{p_i^2}{2m} - \sum_{i=1}^{Z}\frac{Ze^2}{4\pi\varepsilon_0|\mathbf{r}_i|} + \sum_{i<j=1}^{Z}\frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_i-\mathbf{r}_j|} \ , \quad (34.33)$$

is extremely complicated to solve, even for the simplest case ($Z = 2$) we must use approximation methods.

weak $\mathbf{L}\cdot\mathbf{S}$-coupling. The electric dipole operator for the transition does not act on the spin (which prevents the recoupling $S = 1 \leftrightarrow S = 0$ via $E1$-radiation) and also does not act on the symmetry character of the orbitals (which prevents transitions $\Psi^\mathrm{S} \leftrightarrow \Psi^\mathrm{A}$).
In principle, this holds for any species of atoms with two valence electrons. In reality however, the influence of the $\mathbf{L}\cdot\mathbf{S}$-coupling grows with Z, which weakens the interdiction of the intercombination transition. In this case, only the operator $\mathcal{P}_{x,s}$ yields good eigenvalues.

34.3.1 TIPT method

Note that, if we assume independent electrons ($V_{\text{ele:ele}} = 0$), that is, each electron moves independently of the others within the electrostatic potential generated by the nucleus and the other $Z-1$ electrons, the problem would be solvable: We could solve the Schrödinger equation for a product state of all the electronic wavefunctions, and we would know the eigenfunctions and individual eigenenergies of each electron (as for the hydrogen atom). In principle, we should use antisymmetric wavefunctions, but as a first approach we can choose to only respect Pauli's weak principle, that is, assign an *individual and unique* set of quantum numbers to each electron. The total energy would be the sum of the energy of every electron, and the associated physical eigenstates would be obtained by means of an antisymmetrization of the tensor product of the multielectronic state.

Thus, as a first approximation, we use the states of individual electrons (orbital approximation) and consider $V_{\text{ele:ele}}(|\mathbf{r}_i - \mathbf{r}_j|)$ as a perturbation making use of *time-independent perturbation theory*. However, this term is not small enough to justify this procedure, since approximating

$$V_{\text{ncl:ele}} \simeq \frac{Z^2 e^2}{a_{\text{B}}} \quad \text{and} \quad V_{\text{ele:ele}} \simeq \frac{Z(Z-1)e^2}{2a_{\text{B}}} \,, \tag{34.34}$$

we realize that $V_{\text{ele:ele}}/V_{\text{ncl:ele}}$ varies between $\frac{1}{4}$ for $Z = 2$ and $\frac{1}{2}$ for $Z \gg 1/2$. For this reason the use of alternative methods to describe multielectronic atoms is necessary. Nevertheless, the set of quantum numbers derived from Bohr's atomic model are still the same as those used for many-electron atoms, and the orbitals are used as starting points for more sophisticated methods.

To calculate most of the atomic properties we need reasonably realistic potentials. The most important terms of the Hamiltonian are the Coulombian potential between the nucleus and the electrons, V_{ne}, being naturally spherical, and the interaction potentials between the electrons, V_{ee}, which we will try to approximate by a spherical potential and treat the deviations caused by the approximation afterward. Knowing the effect of the shielding of the nucleus by electronic charges, we already know the asymptotes (see Fig. 34.2),

$$V_{\text{eff}} = -\frac{Ze^2}{4\pi\varepsilon_0 r} \quad \text{for} \quad r \to 0 \quad \text{and} \quad V_{\text{eff}} = -\frac{e^2}{4\pi\varepsilon_0 r} \quad \text{for} \quad r \to \infty. \tag{34.35}$$

34.3.2 Thomas-Fermi model for an electron gas

A first approach to getting a reasonable *effective potential* V_{eff} is provided by the *Thomas-Fermi model*. This is a semi-classical model that aims to roughly describe the total energy of the electrons as a *density functional* of atomic/molecular electrons. It serves as a basis for more sophisticated methods aiming at determining the electronic structure, such as *density functional theory* (DFT), and the wavefunctions determined by this method often serve as a starting point for the Hartree method discussed below. One of the important predictions of the *Thomas-Fermi model* is that the average radius of an atom depends on the nuclear charge as $\bar{R} \propto Z^{-1/3}$.

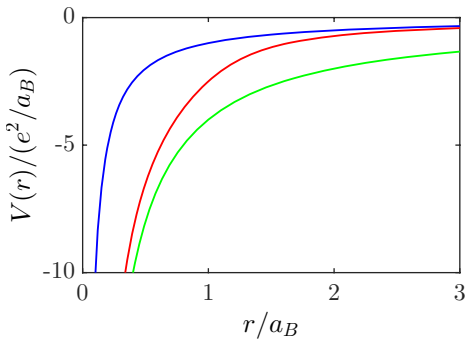

Figure 34.2: (code) External potential (shielded Coulombian) $V_{\mathrm{C}} \propto \frac{e^2}{r}$ (blue, upper curve), interior potential (non-shielded Coulombian for $Z = 4$) $V_{\mathrm{nsh}} \propto \frac{Ze^2}{r}$ (green, lower curve), and effective potential (red, middle curve).

The Thomas-Fermi model allows us to understand the electronic configuration of the fundamental states and provides the basis for the periodic system of elements. In this model, the electrons are treated as independent particles, on one side forming an effective radial electric potential, on the other side being subjected to this potential. Instead of requiring anti-symmetry of the wavefunction, it is only necessary to ensure that all electrons are distinguished by at least one quantum number. The orbitals of complex atoms are similar to the wavefunctions of hydrogen. So, we can use these quantum numbers n, ℓ, m_ℓ, and m_s for every electron.

However, the effective radial potential depends very much on the species and is quite different from the Coulomb potential. So, the degeneracy in ℓ is lifted. In general, electrons with small ℓ are more strongly bound, because they have a higher probability of being near the nucleus, where the potential is deeper (see Fig. 34.2). The same argument explains why electrons with small n are more strongly bound. We will discuss these effects in more depth in Sec. 34.4.1 by comparing the excitation levels of the valence electron in different alkalis.

34.3.2.1 Density of states in the Fermi gas model

Even though the real potential sensed by the electrons bound to a nucleus is very different from the three-dimensional well, we can roughly imagine that the atom is subdivided into small volumes, understood as box potentials, all filled with electrons. From this we can calculate the distribution of the electronic charge, such that the average local energy is homogeneous and the electronic cloud in equilibrium. The distribution, in turn, serves to determine the shape of the electrostatic potential which, when subdivided into small volumes filled with electrons, produces the same charge distribution. This principle is called *self-consistency*.

According to the Fermi gas model, we consider an infinite potential well, that we gradually fill up with electrons. The Pauli principle allows us to place at most two electrons in each orbital,

$$\Psi = \psi_{1,\uparrow}(x_1)\psi_{1,\downarrow}(x_2)\psi_{2,\uparrow}(x_3)\psi_{2,\downarrow}(x_4)\cdot\ldots\,. \tag{34.36}$$

This total wavefunction satisfies the weak Pauli principle, but is obviously not antisymmetric. The approximation is good, when the interaction between the electrons is negligible. Otherwise, we need to consider the exchange energy terms. This model, called *Fermi gas model*, is often used to describe the behavior of electrons that can freely move within the conductance band of a metal.

We divide the atom into small volumes (cells) containing uniformly distributed non-interacting electrons, whose total number is N, and we analyze each cell individually. The whole volume can be modeled by a box potential: $V(\mathbf{r}) = 0$ for $0 \leq x, y, x \leq L$ and $V(\mathbf{r}) = \infty$ in all other places. In this case we find the possible states $\{|n_x, n_y, n_z\rangle\}$ with $n_x, n_y, n_z = 1, 2, 3$ and the single electron energies,

$$E_{n_x,n_y,n_z} = \frac{\pi^2\hbar^2}{2m_eL^2}(n_x^2 + n_y^2 + n_z^2) = \frac{\hbar^2}{2m_e}\mathbf{k}^2_{n_x,n_y,n_z} \ , \tag{34.37}$$

where $\mathbf{k}^2_{n_x,n_y,n_z} = k_x^2 + k_y^2 + k_z^2 = (\frac{n_x\pi}{L})^2 + (\frac{n_y\pi}{L})^2 + (\frac{n_z\pi}{L})^2$. Each set of values $\mathbf{k} = (k_x, k_y, k_z)$ corresponds to an accessible state of the system, and each state is associated with a volume element $(\pi/L)^3$ in k-space. Defining the density of states $\eta(E)$, we can express the total number of states below a particular energy E by,

$$\begin{aligned} n(E) &= \int_0^E \eta(E')dE' \equiv \frac{1}{(2\pi)^3}\int d^3r d^3k = \frac{L^3}{(2\pi)^3}4\pi\int k^2 dk \\ &= \frac{L^3}{(2\pi)^3}4\pi\left(\frac{2m_e}{\hbar^3}\right)^{3/2}\int_0^E \sqrt{E'}dE' = \frac{L^3}{3\pi^2}\left(\frac{2m_eE}{\hbar^3}\right)^{3/2} \ . \end{aligned} \tag{34.38}$$

$\eta(E)dE$ is the number of states with energies between E and $E + dE$.

At temperature $T = 0$ K all N electrons are in their energetically lowest available state, obeying the Pauli exclusion principle and considering the spin. The energy of the N-th electron (the most energetic one) is then called the *Fermi energy* E_F. That is, below E_F all states are occupied, and all states above E_F are unoccupied. The total energy is given by the sum of the energies of the N less energetic states, and the final physical state is given by the antisymmetrization of the corresponding wavefunction. With the formula (34.38), we can express the Fermi energy via $n(E_\mathrm{F}) \equiv N$, such that,

$$E_\mathrm{F} = \frac{\hbar^2}{2m_eL^2}(3\pi^2N)^{2/3} \ , \tag{34.39}$$

so that the density of states can be expressed as,

$$\boxed{\eta(E) = \frac{dn(E)}{dE} = \frac{L^3}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}E^{1/2} = \frac{3N}{2}\frac{E^{1/2}}{E_\mathrm{F}^{3/2}}} \ . \tag{34.40}$$

34.3.2.2 Thomas-Fermi energy

Fermi's box potential trick allowed us to model the impact of Pauli's principle on the spatial distribution of fermions in a restricted volume, but we did not take into account yet the fact that electrons are charged and will interact. Hence, the energy calculated so far is purely kinetic and will have to be complemented by potential energy.

The total kinetic energy of the electrons with the system in its ground state is,

$$E_{\rm tot} = \int_0^{E_{\rm F}} E\eta(E)dE = \frac{L^3}{2\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2}\int_0^{E_{\rm F}} E^{3/2}dE \tag{34.41}$$
$$= \frac{L^3}{5\pi^2}\left(\frac{2m_e}{\hbar^2}\right)^{3/2} E_{\rm F}^{5/2} = \frac{\hbar^2 3^{5/3}\pi^{4/3}}{10m_e}L^3\left(\frac{N}{L^3}\right)^{5/3} = CL^3\rho^{5/3} \ ,$$

where $\rho \equiv N/L^3$ is the density of electrons per unit volume and C just a proportionality constant. Now understanding ρ as a quantity depending on position in space, we calculate the total number of electrons as,

$$N = \int_{\mathbb{R}^3} \rho(\mathbf{r})d^3r \ , \tag{34.42}$$

and the kinetic energy density by,

$$u_{\rm kin}(\mathbf{r}) = C\rho^{5/3}(\mathbf{r}) \ , \tag{34.43}$$

such that the total kinetic energy of the electrons in the electronic shell is,

$$T[\rho] = C\int \rho^{5/3}(\mathbf{r})d^3r \ . \tag{34.44}$$

The potential associated with the electron-nucleus interaction is,

$$V_{ep}[\rho] = -\frac{Ze^2}{4\pi\varepsilon_0}\int \frac{\rho(\mathbf{r}')}{r'}d^3r' = \int V_p(\mathbf{r}')\rho(\mathbf{r}')d^3r' \ , \tag{34.45}$$

with the electrical potential generated by the nucleus,

$$\Phi_p(\mathbf{r}) = \frac{V_p(\mathbf{r})}{-e} = \frac{Ze}{4\pi\varepsilon_0}\frac{1}{r} \tag{34.46}$$

The potential associated with the electron-electron interaction is,

$$V_{ee}[\rho] = \frac{1}{2}\frac{e^2}{4\pi\varepsilon_0}\int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}d^3rd^3r' = \int V_e(\mathbf{r}')\rho(\mathbf{r}')d^3r' \ , \tag{34.47}$$

with the electrical potential generated by the electron cloud,

$$\Phi_e(\mathbf{r}) = \frac{V_e(\mathbf{r})}{-e} = -\frac{1}{2}\frac{e}{4\pi\varepsilon_0}\int \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}d^3r' \tag{34.48}$$

Thus, the total energy (*Thomas-Fermi energy*) can be written as a functional of the electronic density of the atom,

$$\boxed{H_{\rm TF}[\rho] = T[\rho] + V_{ep}[\rho] + V_{ee}[\rho]} \ . \tag{34.49}$$

34.3.2.3 Electronic density and the Thomas-Fermi equation

Exploiting the variational principle, we are interested in the electronic density $\rho(\mathbf{r})$ which minimizes the Thomas-Fermi energy. We can perform this process via Lagrange multipliers under the constraint, that the number of electrons remains constant in the atom. Thus,

$$0 = \delta \left\{ H_{\mathrm{TF}}[\rho] - \mu \left(\int \rho(\mathbf{r}) d^3 r - N \right) \right\} \ . \tag{34.50}$$

Inserting the Thomas-Fermi energy (34.49) we calculate,

$$\mu = \frac{\delta}{\delta \rho(\mathbf{r})} \left\{ C\rho^{5/3}(\mathbf{r}) + V_p(\mathbf{r})\rho(\mathbf{r}) + V_e(\mathbf{r})\rho(\mathbf{r}) \right\} = \tfrac{5}{3} C\rho^{2/3}(\mathbf{r}) + V_p(\mathbf{r}) + V_e(\mathbf{r}) \ . \tag{34.51}$$

Resolving for the electronic density,

$$\rho(\mathbf{r}) = \left(\frac{3}{5C} \right)^{3/2} [\mu - V_p(\mathbf{r}) - V_e(\mathbf{r})]^{3/2} \ . \tag{34.52}$$

The above expression is called the *Thomas-Fermi equation* and describes the electron density of the atom in its ground state. The expression (34.48) can be rewritten as a Poisson equation,

$$\nabla^2 V_e(\mathbf{r}) = \frac{e^2}{2\varepsilon_0} \rho(\mathbf{r}) \ , \tag{34.53}$$

so that,

$$\nabla^2 V_e(\mathbf{r}) = \frac{e^2}{2\varepsilon_0} \left(\frac{3}{5C} \right)^{3/2} [\mu - V_p(\mathbf{r}) - V_e(\mathbf{r})]^{3/2} \ . \tag{34.54}$$

For the effective potential introduced via $V_{\mathrm{eff}} = V_p + V_e$, we find,

$$\begin{aligned} \nabla^2 V_{\mathrm{eff}}(\mathbf{r}) &= \nabla^2 \left(-\frac{Ze^2}{4\pi\varepsilon_0} \frac{1}{r} \right) + \nabla^2 V_e(\mathbf{r}) \\ &= -\frac{Ze^2}{\varepsilon_0} \delta^3(\mathbf{r}) + \frac{e^2}{2\varepsilon_0} \left(\frac{3}{5C} \right)^{3/2} [\mu - V_{\mathrm{eff}}(\mathbf{r})]^{3/2} \ . \end{aligned} \tag{34.55}$$

We note that, with (34.50), we can identify the Lagrange multiplier μ as a *chemical potential*. In particular, for non-interacting neutral atoms, we have $\mu = 0$. In addition, since for an atom both the potential and the electronic density must have spherical symmetry, we can write for $r \neq 0$,

$$\frac{1}{r} \frac{\partial^2}{\partial r^2} [r V_{\mathrm{eff}}(r)] = \frac{e^2}{2\varepsilon_0} \left(\frac{3}{5C} \right)^{3/2} [-V_{\mathrm{eff}}(\mathbf{r})]^{3/2} \ . \tag{34.56}$$

We now make the ansatz,

$$V_{\mathrm{eff}}(r) \equiv -\frac{Z}{r} \chi(\alpha r) \qquad \text{setting} \qquad \alpha \equiv \frac{3e^{4/3}}{5C\varepsilon_0^{2/3}} Z^{1/3} \ . \tag{34.57}$$

This transforms the expression (34.56) into,

$$\frac{\partial^2}{\partial r^2} \chi(\alpha r) = -\frac{e^2}{Z\varepsilon_0} \left(\frac{3Z}{5C} \right)^{3/2} \frac{\chi^{3/2}(\alpha r)}{r^{1/2}} \ , \tag{34.58}$$

or, substituting $x \equiv \alpha r$,

$$\frac{d^2\chi}{dx^2} = -\frac{\chi^{3/2}}{x^{1/2}} \ . \tag{34.59}$$

It is important to note the last equation does not depend on the parameter Z, thus being a general result for any neutral atom. The function $\chi(x)$ is determined numerically, but we can analyze its asymptotic values given the expected behavior of the effective potential $V_{\text{eff}}(r)$: for $r \to 0$ we expect that $V_{\text{eff}}(r) = V_p(r)$, hence $\chi(0) = 1$. On the other hand, for $r \to \infty$, we expect $V_{\text{eff}}(r) = 0$, hence $\chi(\infty) = 0$. Do the Exc. 34.3.5.1.

With $\chi(x)$ known, we obtain the charge density $\rho(x)$, and hence we are able to calculate the total energy of the atom under investigation. Thus, it is possible to show that [39],

$$H_{\text{TF}}[\rho] = -0.7687 \frac{e^2}{4\pi\varepsilon_0 a_{\text{B}}} Z^{7/3} \ . \tag{34.60}$$

It is important to highlight some points:

1. The result holds for neutral atoms.

2. There is no electronic shell structure assumed; apart from the fact that the kinetic energy was derived in a way as to respect Pauli's principle, the whole calculation was done within the laws of classical electromagnetism; no quantum mechanics was involved and, hence, no set of quantum numbers has been found.

3. Apart from the Pauli principle used to calculate the density of states (34.40), quantum statistical effects of identical particles (such as wavefunction anti-symmetrization) are not taken into account.

A more refined model which deals with third criticism and, in addition, is closer to density functional theory (DFT) is the Thomas-Fermi-Dirac model.

34.3.3 Hartree method

The effective potential obtained from the Thomas-Fermi model can serve as a starting point for quantum treatments. Assuming that all electrons are subject to the same effective potential V_{eff}, we numerically solve the Schrödinger equation for each electron independently,

$$\hat{H}_i = \left(-\frac{\hbar^2}{2m}\nabla_i^2 + V_{\text{eff}} \right) \psi_i(\mathbf{r}_i) = e_i \psi_i(\mathbf{r}_i) \ . \tag{34.61}$$

With this we calculate all energies and eigenfunctions (only the radial parts are of interest) minimizing the total energy and respecting the weak Pauli principle, that is, we classify the states in the order of increasing energies e_i and fill them successively with electrons. For the total wavefunction we obtain,

$$\left(\sum_{i=1}^{N} \hat{H}_i \right) \Psi_N = E_n \Psi_N \quad \text{with} \quad \Psi_N = \psi_1 \cdot .. \cdot \psi_N \quad \text{and} \quad E_n = \sum_{i=1}^{N} e_i \ . \tag{34.62}$$

With the eigenfunctions we calculate the charge densities $e|\psi_j(\mathbf{r}_j)|^2$. We integrate the interaction energy between these charge densities and the potentials exerted by the

nucleus and all other electrons $j \neq i$ to obtain an effective potential that represents an improved estimation for the electronic mean field,

$$V_{\text{eff}} \longleftarrow -\frac{Ze^2}{4\pi\varepsilon_0 r_i} + \sum_{j\neq i} \int d^3 r_j \frac{e^2}{4\pi\varepsilon_0 |\mathbf{r}_i - \mathbf{r}_j|} |\psi_j(\mathbf{r}_j)|^2 \ . \tag{34.63}$$

We replace that potential in the Schrödinger equation, and repeat the whole process from the beginning, until the total energy $\sum_i e_i$ does not get any lower. This self-consistent method is called *Hartree method*. Fock improved these calculations using antisymmetric wavefunctions for the valence electrons. This method is called *Hartree-Fock method*.

34.3.4 Hartree-Fock method

The Hartree-Fock method used to treat atomic or molecular many-body systems aims at obtaining the electronic wavefunction of the system. Dealing with anti-symmetrized wavefunctions, it represents a refinement of the Hartree method. The method is based on the variational principle and on the assumption that we can write the global wavefunction as a Slater determinant, with each electron occupying a specific orbital state (spin-orbital) and interacting with an effective potential stemming from the electrons which occupy other orbitals. Instead of solving the Schrödinger equation, we must now solve a set of equations called Hartree-Fock equations of the type $\hat{F}\psi_k(1) = \epsilon_k \psi_k(1)$. The method is performed iteratively until convergence of the atomic orbitals and their respective energies is reached. The procedure is then called *self-consistent*: Starting from an initial trial global wavefunction we calculate the effective potential in each orbital and a new set of wavefunctions which, in turn, generate a new effective potential. This new potential is then used in a new set of Hartree-Fock equations.

34.3.4.1 Hartree-Fock equations

To start with, we write the Hamiltonian (34.33) of a multi-electronic atom as [39],

$$\hat{H} = \sum_{i=1}^{Z} \hat{h}_i + \tfrac{1}{2} \sum_{i\neq j} \hat{V}_{ij} \ , \tag{34.64}$$

where $\hat{h}_i$ is the Hamiltonian only of the electron i, and $\hat{V}_{ij}$ is the interaction term between the electrons i and j. To implement the method we must suppose that the multi-electronic state can be written as the product of the individual states of each electron:

$$\Psi'(1, ..., Z) = \psi_1(1)\psi_2(2)...\psi_Z(Z) \ , \tag{34.65}$$

where $\psi_i(1) = \phi_i(r_1)\chi(\alpha) = \psi_i^{\alpha}(r_1)$ represents the spin-orbital state of electron 1, that is, the spatial wavefunction of the electron in the state i and with spin α. However, due to the symmetrization postulate, the physical state of the system must be expressed by a Slater determinant,

$$\Psi(1, ..., Z) = \frac{1}{\sqrt{Z!}} \det \ [\psi_1(1)\psi_2(2)...\psi_Z(Z)] \ . \tag{34.66}$$

Now, we use the variational principle to minimize the expectation value of the ground state energy by varying the functions $\psi_k(n)$. In this way, the correct orbitals are those that minimize the energy. The expectation value is written as,

$$E = \langle\Psi|\hat{H}|\Psi\rangle = \langle\Psi|\sum_{i=1}^{Z}\hat{h}_i|\Psi\rangle + \langle\Psi|\tfrac{1}{2}\sum_{i\neq j}\hat{V}_{ij}|\Psi\rangle \ . \tag{34.67}$$

It is possible to show that,

$$\langle\Psi|\sum_{i=1}^{Z}\hat{h}_i|\Psi\rangle = \sum_{i=1}^{Z}\langle\psi_i|\hat{h}_i|\psi_i\rangle \qquad \text{and} \tag{34.68}$$

$$\langle\Psi|\tfrac{1}{2}\sum_{i\neq j}\hat{V}_{ij}|\Psi\rangle = \tfrac{1}{2}\sum_{i,j}^{Z}[\langle\psi_i\psi_j|\hat{V}_{ij}|\psi_i\psi_j\rangle - \langle\psi_j\psi_i|\hat{V}_{ij}|\psi_j\psi_i\rangle] \ .$$

Hence,

$$E = \sum_{i=1}^{Z}\langle\psi_i|\hat{h}_i|\psi_i\rangle + \tfrac{1}{2}\sum_{i,j}^{Z}[\langle\psi_i\psi_j|\hat{V}_{ij}|\psi_i\psi_j\rangle - \langle\psi_j\psi_i|\hat{V}_{ij}|\psi_j\psi_i\rangle] \ . \tag{34.69}$$

The above expression can be minimized via Lagrange multipliers under the constraint that the states are orthogonal $\langle\psi_i|\psi_j\rangle = \delta_{ij}$,

$$\delta\left\{\langle\Psi|\hat{H}|\Psi\rangle - \sum_{i,j}\epsilon_{ij}[\langle\psi_i\psi_j|\hat{V}_{ij}|\psi_i\psi_j\rangle - \langle\psi_j\psi_i|\hat{V}_{ij}|\psi_j\psi_i\rangle]\right\} \tag{34.70}$$

Thus, we obtain the following set of *Hartree-Fock equations*:

$$\hat{F}\psi_k(1) = \epsilon_k\psi_k(1) \qquad \text{where} \qquad \hat{F} = \hat{h}_1 + \sum_i(2\hat{J}_i - \hat{K}_i) \tag{34.71}$$

is the Fock operator and ϵ_k is the energy associated with the spin-orbital ψ_k. The operator $\hat{J}_i$, called *Coulomb operator*, represents the mean potential sensed by electron 1 in the orbital k due to the presence of electron 2 in the orbital i:

$$\hat{J}_i\psi_k(1) = \left\{\int \psi_i^*(2)V_{12}\psi_i(2)dr_2\right\}\psi_k(1) \ . \tag{34.72}$$

The operator $\hat{K}_i$, denominated *exchange operator*, is a consequence of the symmetrization process and therefore a purely quantum effect, that is, without classical analogue:

$$\hat{K}_i\psi_k(1) = \left\{\int \psi_i^*(2)V_{12}\psi_k(2)dr_2\right\}\psi_k(1) \ . \tag{34.73}$$

Once we know all wavefunctions, the energies of the orbitals can be obtained in the following way:

$$\int dr_1\psi_k^*(1)\left\{\hat{h}_1 + \sum_i(2\hat{J}_i - \hat{K}_i)\right\}\psi_k^*(1) = \epsilon_k\int dr_1\psi_k^*(1)\psi_k(1) = \epsilon_k \ , \tag{34.74}$$

that is,

$$\epsilon_k = \int dr_1 \psi_k^*(1) \hat{h}_1 \psi_k^*(1) + \sum_i (2\hat{J}_{ki} - \hat{K}_{ki}) \ , \tag{34.75}$$

where,

$$\hat{J}_{ki} = \int dr_1 \psi_k^*(1) \hat{J}_i \psi_k(1) \qquad \text{is the Coulomb integral} \tag{34.76}$$

$$\hat{K}_{ki} = \int dr_1 \psi_k^*(1) \hat{K}_i \psi_k(1) \qquad \text{is the exchange integral} \ .$$

The total atomic energy can be calculated by,

$$E = 2\sum_k \epsilon_k - \sum_{k,i} (2\hat{J}_{ki} - \hat{K}_{ki}) \ . \tag{34.77}$$

Furthermore, if assuming that, taking an electron away from the orbital ψ_k the electronic distribution remains unchanged, it is possible to associate the energy ϵ_k with the ionization energy of the electron in this orbital, $I_k \simeq \epsilon_k$. This equality is known as *Koopman's theorem*.

34.3.5 Exercises

34.3.5.1 Ex: Effective potential in the Thomas-Fermi model

Calculate numerically and plot the effective potential in the Thomas-Fermi model from the differential equation (34.59) for $Z = 40$ [1006].

34.4 The periodic system of elements

Completely filled principal layers n, ℓ are isotropic, $\Psi_N(\mathbf{r}) = \Psi(r)$, as we will show in Exc. 34.4.4.1. It is important to distinguish three different energetic sequences: 1. Tab. 34.5 shows, for a given atom, the excited orbitals of the *last electron*. 2. The energy sequence shown in Tab. 34.6 tells us in which orbital the next electron will be placed, when we go to the *next atom* in the periodic table 34.8 which has one more proton in the nucleus. 3. The inner electrons are subject to different potentials and, hence, follow a different sequence energetic sequence: While for the inner electrons we find,

$$E_{n,\ell} < E_{n,\ell+1} \ll E_{n+1,\ell} \ , \tag{34.78}$$

the sequence is partially inverted for the outermost electron. Note that it is the outermost electrons that determine the chemical reactivity of the atom. The sequence is illustrated in Fig. 34.4.

Noble gases have small radii, high excitation energies and high ionization energies. The outermost electrons in a noble gas atom must overcome a large energy gap to any higher quantum numbers. Halogens have strong electro-affinities, since the outer electron layer (n_{max}) is incomplete and therefore malleable, such that an electron approaching the halogen perceives the nuclear charge through a partially transparent shield. Alkalis are similar to hydrogen and have excitation energies in the optical

regime. Their fundamental state $^2S_{1/2}$ is determined by a single valence electron in the $\ell = 0$ orbital. Unlike hydrogen, excitation energies are highly dependent on ℓ, since orbits with small ℓ correspond to eccentric ellipses and have higher probabilities to be in the unshielded region $-Z^2e^2/r$ than orbits with large ℓ, who spend more time in the shielded region $-e^2/r$. For the same reason, energies corresponding to larger n resemble more those of the hydrogen spectrum.

34.4.0.1 Inner shell electrons

The interior shell structure of the atoms can be analyzed by X-ray scattering. Electrons decelerated by atoms emit a continuous spectrum called *Bremsstrahlung*, but they can also expel electrons from the inner layers leaving a hole behind. When a hole is filled by cascades of electrons falling down from higher layers, the atom emits a specific X-ray spectrum ($\approx 10^4\,\mathrm{eV}$). The selection rules $\Delta\ell = \pm 1$ and $\Delta j = \pm 1$ split the lines in two components. X-ray spectra of neighboring elements in the periodic table are very similar, because the inner layers not being shielded, they see a potential close to $\propto Z^2/r$ dominating the interaction with electrons from the outer layers. Therefore, the Z-dependency of inner energy levels along a horizontal rows in the periodic table is more or less $\omega \propto Z^2$, as predicted by Bohr's atomic model.

34.4.1 Electronic shell model

In the Fermi gas model, each of the energy levels contains several states, and each of these states can be occupied by a single electron, according to the Pauli principle. In this way, we obtain the electronic configuration for the atoms of the periodic system. In this picture, the energies of the ground states of the elements, normalized by $1/Z^2$, can be arranged in the scheme of Fig. 34.3.

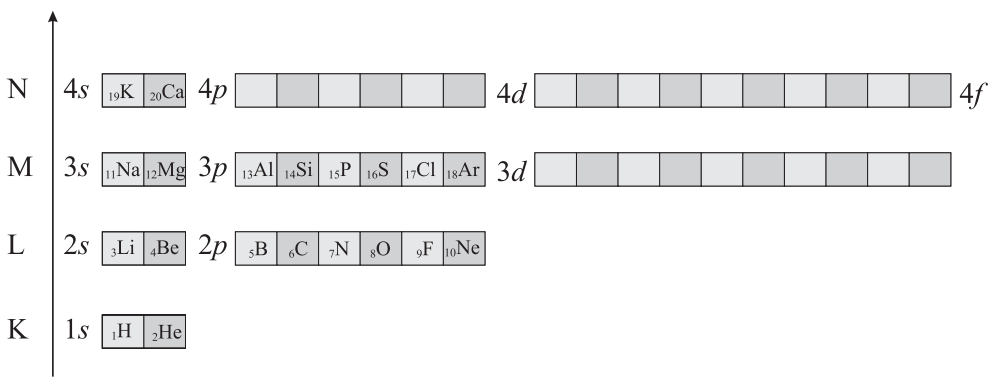

Figure 34.3: Periodic order.

This only works for atoms with up to 18 electrons. When the layer $3p$ is completely filled, the next to be occupied is not $3d$ but the $4s$. The new scheme is illustrated in Fig. 34.4. The anomalies beginning at $Z = 18$ arise due to electron-electron interaction. The real potential evolves from one to the other Coulombian potential, as distance from the nucleus is increased, as illustrated in Fig. 34.2. Near the nucleus,

the electrons shield the positive charge less than for large distances r. Thus, those states that have a high probability near the nucleus are energetically lowered. That is,

$$E_{2s} < E_{2p} \qquad \text{and} \qquad E_{6s} < E_{6p} < E_{6d} \ . \tag{34.79}$$

The degeneracy of the orbital angular momentum in the Schrödinger model is thus lifted. The shielding is, as can be seen in the example of the excited states of lithium, a large effect in the range of some eV.

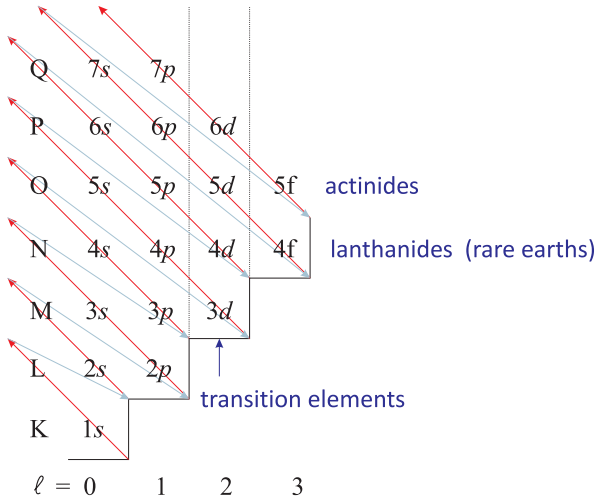

Figure 34.4: Illustration of the sequence of filling the orbitals with electrons.

The shielding also accounts for the anomalies in the periodic system, such as in K or Ca. Since $E_{4s} < E_{3d}$, the $4s$ state is filled before the $3d$. Similar anomalies also occur in Rb ($5s$), Cs ($6s$), and Fr ($7s$). In rare earths the shielding effect is even more pronounced. Here, the energy of the state $6s$ is even below the energy of the $4f$, which means that the shells $6s$, $5s$, $5p$, and $5d$ protect the $4f$ shell very well [9]. Resolve Exc. 34.4.4.2.

34.4.1.1 Alkalines

The electronic shell structure of alkalines consists of a completed noble gas shell and an additional valence electron. Their spectrum is therefore very similar to hydrogen. An empirical approach can be stressed to describe this feature,

$$E_{n,\ell} = -\frac{\mu_{\text{EG}} c^2}{2} \frac{Z^2 \alpha^2}{(n - \Delta_{n,\ell})^2} \ , \tag{34.80}$$

where μ_{EG} is the reduced mass relative to the noble gas shell and $\Delta_{n,\ell}$ is called *quantum defect*. The quantum defect is tabulated for most alkaline states and is

[9] An example of this is Nd:YAG (Neodymium in Yttrium Aluminum Garnet). In this crystal, optical transitions can be excited within the $4f$ shell of the Nd. However, these transitions are only allowed due to perturbations of the crystalline field. The very strong shielding ensures a long life of the excited state. For this reason this crystal is an excellent laser material.

particularly important for low energy states. For sodium, for example, the values are:

ℓ	$n = 3$	$n = 4$	$n = 5$	$n = 6$
s	1.37	1.36	1.35	1.34
p	0.88	0.87	0.86	0.86
d	0.10	0.11	0.13	0.11
f	-	0.00	-0.01	0.008

For states with a large angular momentum, the quantum defect disappears. In these states, the electron is far from the nucleus and the potential is similar to that of hydrogen. Alkalines are currently widely studied in quantum optics laboratories, for being comparatively simple, but having a sufficiently rich structure to be interesting. The fundamental electronic transitions typically lie in the visible and near-infrared spectral range and can be excited with comparatively simple laser sources. The lifetime of excited states is typically longer than 20 ns, which corresponds natural linewidths of approximately (2π) 10 MHz.

34.4.1.2 Excited states

The experimentally easiest and most precise approach to determining orbital energies consists in measuring excitation spectra of valence electrons. The diagram of Fig. 34.5 compares such excitation spectra for various alkaline atoms. Although this is not to be confused with the binding energies of valence electrons of different atoms, it gives us a qualitative idea of the impact of shielding and indicates, which orbital will be occupied by the additional valence electron of the next species in the periodic table.

34.4.2 LS and jj-coupling

Following Hund's rule, the $\mathbf{L} \cdot \mathbf{S}$-coupling is energetically favorable compared to the $\mathbf{j} \cdot \mathbf{j}$-coupling, which means that the spins of the outermost electrons, that is, the electrons outside of filled subshells (n, ℓ), prefer to orient their spins in parallel in order to anti-symmetrize the spatial wavefunctions and thus maximize the distance between the electrons. Every sub-layer of the series shown in Fig. 34.4 must be filled in the listed order before placing new electrons in the next layer.

In the case of helium, we have seen that the Pauli principle first determines the relative orientation of the electron spins. The spins $\mathbf{s}_i$ of the individual electrons therefore add up to a total angular momentum $\mathbf{S}$. The *orbital* angular momenta $\mathbf{l}_i$ also adopt a relative orientation. It is determined by a residual spherically non-symmetric Coulomb interaction: A certain combination $\mathbf{L}$ of orbital angular momenta leads to a certain spatial distribution of the electrons and thus to a certain electrostatic energy distribution.

The total spin $\mathbf{S}$ and the total orbital angular momentum $\mathbf{L}$ subsequently couple to a total angular momentum $\mathbf{J}$ very similar to the $\mathbf{l} \cdot \mathbf{s}$ spin-orbit coupling in single electron systems. States with different $\mathbf{J}$ then have the respective energies that the

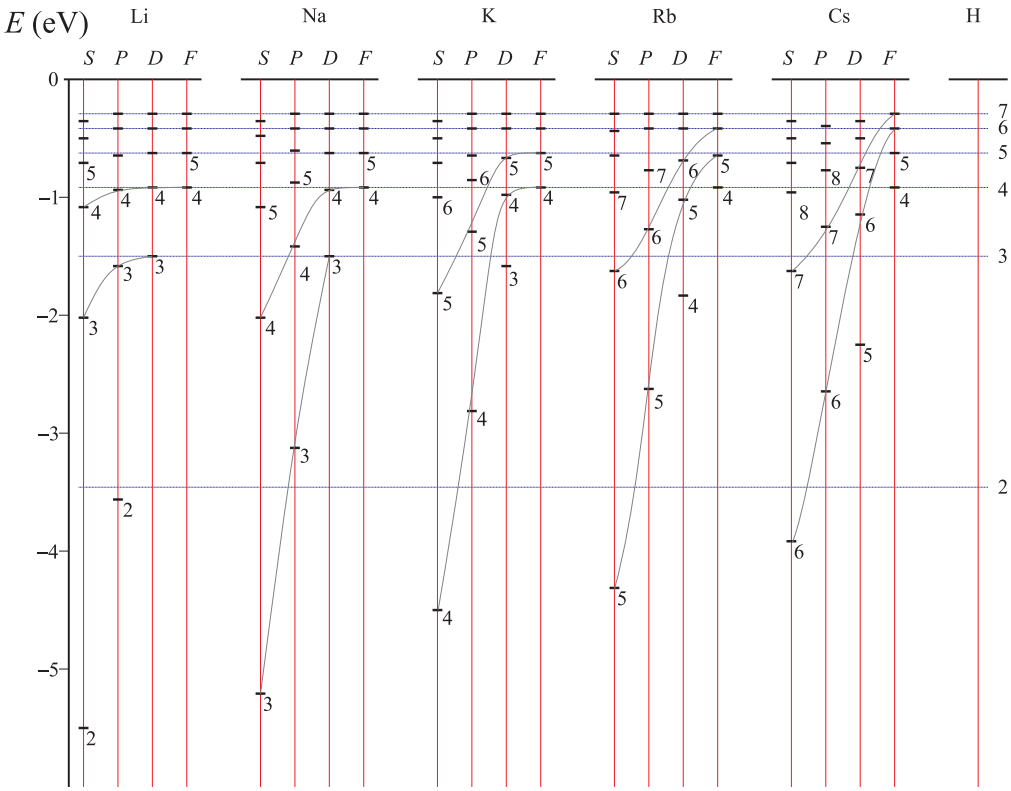

Figure 34.5: Comparison of the excitation energies of the *valence electron* for several alkaline atoms. Grey line are meant to guide the eye.

total spin $\mathbf{S}$ adopts in the field generated by the total orbital angular momentum $\mathbf{L}$ [10].

The above coupling scheme is called *Russel-Saunders coupling* or *LS-coupling*. It works well when the spin-orbit coupling of individual electrons is small. In this case, intercombination is forbidden, which means that there can be no electromagnetic transition between states with different spins (see the case of metastable helium in Sec. 34.2.2).

Since $E_{\ell s} \simeq (Z\alpha)^4 \simeq Z^4$, as shown in (32.130), for heavy atoms, the coupling of an electronic spin to its own orbital momentum grows strongly with Z, as well as the symmetrization and the exchange energy, which mutually orient the spins, and the residual Coulomb interaction, which mutually couples the angular orbital momenta. In this case, the orientation of $\mathbf{L}_i$ relative to $\mathbf{S}_i$ delivers more energy than the exchange energy and the residual energy cost. Hence, the spin and the orbital angular momentum of an individual electron couple first,

$$\mathbf{j}_i = \mathbf{l}_i + \mathbf{s}_i \ . \tag{34.81}$$

[10] In addition, there are the small contributions due to $\mathbf{l}_i \cdot \mathbf{l}_j$-coupling and to $\mathbf{s}_i \cdot \mathbf{s}_j$-coupling, where $i \neq j$.

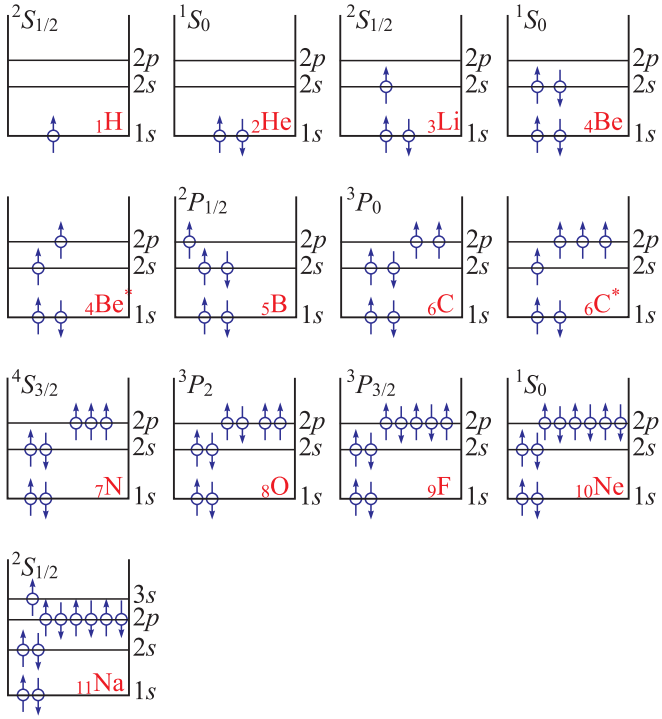

Figure 34.6: Illustration of Hund's rule.

We obtain a new Hamiltonian of fine structure of the form,

$$H_{\text{fs}} \propto \mathbf{j}_i \cdot \mathbf{j}_j \ . \tag{34.82}$$

Pure jj-coupling only exists for very heavy nuclei. Normally, we have a so-called *intermediate coupling*, which is a mixture of LS and jj-coupling. This can considerable relax the intercombination prohibition. When the coupling is pure, we have the following dipolar selection rules:

LS-coupling: $\Delta S = 0$, $\Delta L = \pm 1$, $\Delta \ell = \pm 1$

jj-coupling: $\Delta j = 0, \pm 1$ for one e^-, $\Delta j = 0$ for all others

In addition we have for the two couplings: $\Delta J = 0, \pm 1$, but $J, J' = 0$ is forbidden, $\Delta m_J = 0, \pm 1$ when $\Delta J = 0$ but $m_J, m_{J'} = 0$ is forbidden.

34.4.3 Summary of contributions to the atomic energy levels

The total Hamiltonian of a single atom is composed of the kinetic energy of the nucleus and the electrons, of various interaction potentials between the nucleus and the electrons, and of interactions with various types of external electromagnetic fields.

$$\hat{H} = -\frac{\hbar^2}{2m}\nabla_R^2 + \sum_{i=1}^{N}\left(-\frac{\hbar^2}{2m}\nabla_{r_i}^2\right) + V(\mathbf{r}_1, \mathbf{s}_1, .., \mathbf{r}_N, \mathbf{s}_N) + V_{\text{ext}} \ . \tag{34.83}$$

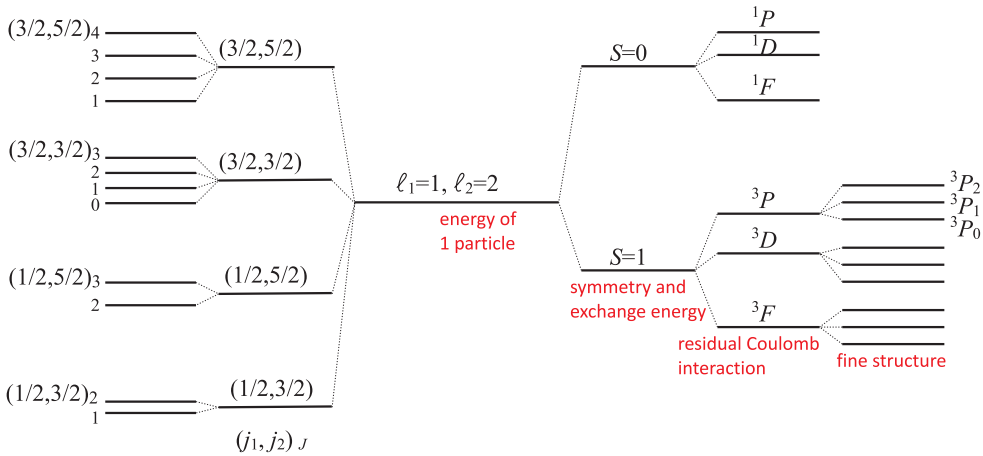

Figure 34.7: Hierarchy of coupling energies at the example of two electrons out of closed shells, $(2p)(3d)$, under the presumption of perfect jj-coupling (left) or LS-coupling (right).

Of course, with the presence of other atoms, other interactions may generate other relevant contributions to the Hamiltonian.

The following interactions contribute to the potential V: The Coulomb interactions,

$$V_{\text{ncl:ele}} = -\sum_{i=1}^{Z} \frac{Ze^2}{4\pi\varepsilon_0|\mathbf{r}-\mathbf{r}_i|} \quad \text{and} \quad V_{\text{ele:ele}} = \sum_{i<j=1}^{Z} \frac{e^2}{4\pi\varepsilon_0|\mathbf{r}_i-\mathbf{r}_j|} \ , \tag{34.84}$$

the antisymmetry of the wavefunction, that is, exchange integrals,

$$V_{\text{sym}} \ , \tag{34.85}$$

the energies of spin-orbit couplings,

$$V_{\ell s} = -\sum_{i=1}^{Z} \frac{1}{e2m^2c^2} \frac{1}{|\mathbf{r}-\mathbf{r}_i|} \frac{dV_{\text{C}}}{dr_i} (\mathbf{l}_i \cdot \mathbf{s}_i) \ , \tag{34.86}$$

the energies of spin-spin couplings,

$$V_{ss} = \sum_{i\neq j=1}^{Z} \frac{e^2}{m^2} \left[\frac{\sigma_{\mathbf{i}} \cdot \sigma_{\mathbf{j}}}{|r_i - r_j|^3} - 3\frac{[\sigma_{\mathbf{i}} \cdot (\mathbf{r}_i - \mathbf{r}_j)][\sigma_{\mathbf{j}} \cdot (\mathbf{r}_i - \mathbf{r}_j)]}{(\mathbf{r}_i - \mathbf{r}_j)^5} \right] \ , \tag{34.87}$$

the energies of orbit-orbit couplings,

$$V_{ll} = \sum_{i\neq j=1}^{Z} c_{ij} (\mathbf{l}_i \cdot \mathbf{l}_j) \ , \tag{34.88}$$

interactions between the spin of the electrons and the nuclear spin and between the orbital angular momentum of the electrons and the nuclear spin,

$$V_{\text{hfs}} = \frac{A}{\hbar^2} \mathbf{J} \cdot \mathbf{I} \ , \tag{34.89}$$

and relativistic corrections.

$$V_{\text{rel}} \ , \tag{34.90}$$

In addition, static external fields may displace energy levels and can influence the internal coupling of angular momenta and spins,

$$V_{\text{ext}} = -\mathbf{d} \cdot \vec{\mathcal{E}} \ , \ \ -\vec{\mu} \cdot \vec{\mathcal{B}} \ . \tag{34.91}$$

What quantum numbers are good depends on the relative amplitudes of intra-atomic interactions:
Case 1: fine structure with $\mathbf{L} \cdot \mathbf{S}$-coupling plus Zeeman splitting of hyperfine structure: $V_{\text{ncl:ele}}, V^r_{\text{ele:ele}} \gg V^a_{\text{ele:ele}}, V_{\text{sym}} \gg V_{\ell s} \gg V_{\text{hfs}} \gg V_B$ the quantum number are $|n_i, \ell_i, \mathbf{L}, \mathbf{S}, \mathbf{J}, \mathbf{F}, m_F\rangle$.
Case 2: fine structure with $\mathbf{j} \cdot \mathbf{j}$-coupling plus Zeeman splitting of hyperfine structure: $V_{\text{ncl:ele}}, V^r_{\text{ele:ele}} \gg V_{\ell s} \gg V^a_{\text{ele:ele}}, V_{\text{sym}} \gg V_{\text{hfs}} \gg V_B$ the quantum number are $|n_i, \ell_i, j_i, \mathbf{J}, \mathbf{F}, m_F\rangle$.
Case 3: fine structure with $\mathbf{L} \cdot \mathbf{S}$-coupling plus hyperfine structure of Zeeman splitting: $V_{\text{ncl:ele}}, V^r_{\text{ele:ele}} \gg V^a_{\text{ele:ele}}, V_{\text{sym}} \gg V_{\ell s} \gg V_B \gg V_{\text{hfs}}$ the quantum number are $|n_i, \ell_i, \mathbf{L}, \mathbf{S}, \mathbf{J}, m_J, m_I\rangle$.
Case 4: fine structure with $\mathbf{L} \cdot \mathbf{S}$-coupling plus Paschen-Back splitting of fine structure: $V_{\text{ncl:ele}}, V^r_{\text{ele:ele}} \gg V^a_{\text{ele:ele}}, V_{\text{sym}} \gg V_B \gg V_{\ell s} \gg V_{\text{hfs}}$ the quantum number are $|n_i, \ell_i, \mathbf{L}, \mathbf{S}, m_L, m_S, m_I\rangle$.

Chapter 35

Molecular dimers

In systems of many particles (gases, fluids, or solids) interatomic interactions must be considered. These interactions usually have electrostatic origins, but generally can not be given in the form of closed expressions. For example, the collision of two atoms i and j can occur in a multitude of channels, that is, interaction potentials $V(\mathbf{r}_i - \mathbf{r}_j)$. Interatomic forces do not only govern collisions, but can sustain molecular bound states. This introduces new degrees of freedom in the systems of many particles through possible excitations of vibration or rotation movements.

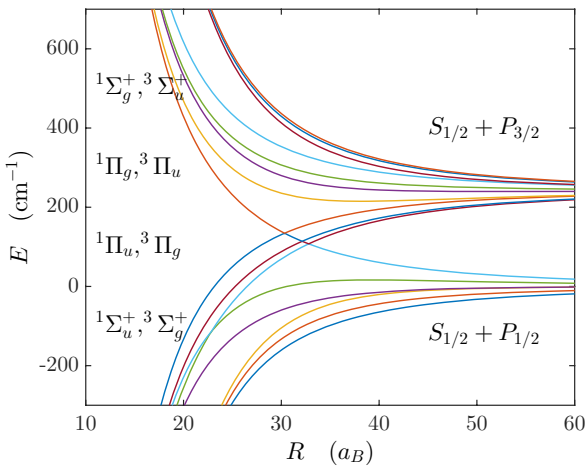

Figure 35.1: (code) Example of an interatomic potential spaghetti: The lowest states of the molecule $^{85}Rb_2$.

In this course, we will not go beyond homo- or heteronuclear dimers, that is, molecules consisting of two identical or different atoms.

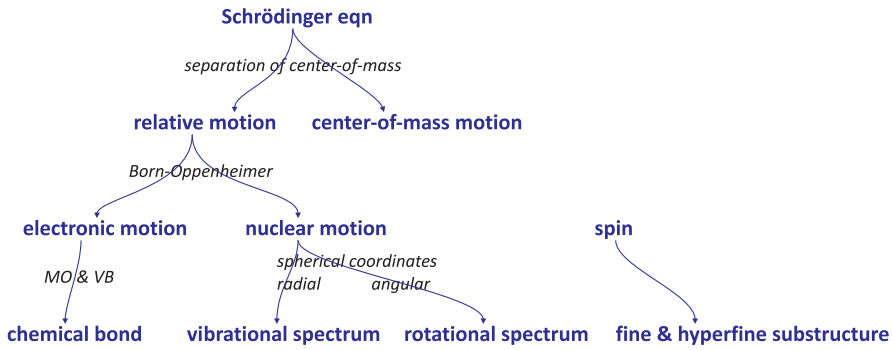

Figure 35.2: Approximations made in the molecular physics.

35.1 Molecular binding

35.1.1 Ionic and covalent binding

There are two fundamental ways of binding two atoms together, the ionic bond and the covalent bond [1]. The *ionic bond* is ruled by the quantities *electroaffinity* (EA), *electronegativity* (EN), and *ionization energy* (IE):

- **Ionization energy:** This energy is needed for the release of an electron by a neutral atom, e.g. $\mathrm{Na} + 5.1\,\mathrm{eV} \to \mathrm{Na}^+ + e^-$.
- **Electroaffinity**: This energy is released by the capture of an electron by a neutral atom, e.g. $\mathrm{Cl} + e^- \to \mathrm{Cl}^- + 3.8\,\mathrm{eV}$.
- **Electronegativity**: This quantity measures the stability of a valence orbital, e.g. that of fluorine (3.98) is more stable than that of cesium (0.79), such that fluorine holds its electrons tighter than cesium.

At short distances, the exchange of an electron between atoms can decrease energy. The so-called *ionic bond* is then sustained by the Coulombian attraction between two ions, and the binding energy can be estimated through electrostatic interaction.

Example 251 (*Ionic binding in NaCl*): For example, a sodium and a chlorine atom gain energy by forming a molecule,

$$\begin{aligned}
\mathrm{Na} + 5.1\,\mathrm{eV} &\to \mathrm{Na}^+ + e^- \\
\mathrm{Cl} + e^- &\to \mathrm{Cl}^- + 3.8\,\mathrm{eV} \\
\mathrm{Na}^+ + \mathrm{Cl}^- &\to \mathrm{NaCl} + 4.9\,\mathrm{eV} \\
\hline
\mathrm{Na} + \mathrm{Cl} &\to \mathrm{NaCl} + (-5.1 + 3.8 + 4.9)\,\mathrm{eV}\ .
\end{aligned} \tag{35.1}$$

[1] We are not considering metallic bonds nor hydrogen bridge bonds, here.

The molecules are polar and, therefore, have a permanent electric dipole moment. The bond has no preferential direction, since each atom is perfectly isotropic. Therefore, this type is well suited for the construction of crystalline lattices.

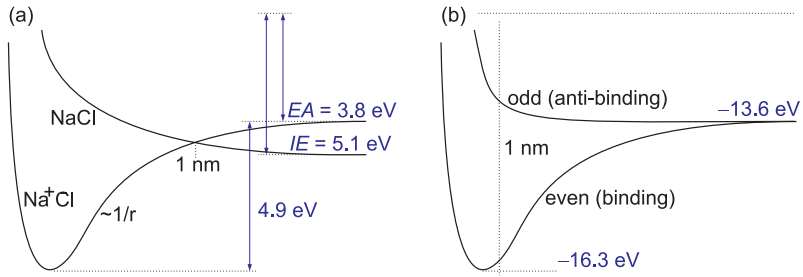

Figure 35.3: Scheme for (a) ionic binding of NaCl and (b) covalent binding of H_2.

To understand *covalent bond*, we consider the example $H_2{}^+$ and estimate the interaction energy for each distance R between the nuclei. In this case, in contrast to atoms, the spherical symmetry is broken, and therefore the energy degeneracy with respect to parity is abolished, that is, for wavefunctions $\psi(-x) = \pm\psi(x)$ the energies vary differently with R. The even wavefunction, which has an increased probability of the electron of being between the nuclei, is binding, which means that the interaction potential exhibits a minimum at a certain distance. The odd wavefunction, which disappears between the nuclei, is anti-binding, which means that the interaction potential is repulsive at all distances. In fact, an electron located at the center between two positive charges can overcome the Coulomb repulsion between the nuclei, whose mutual distance is twice. Obviously, the energy can not fall below that of the fundamental state of He^+, being approximately $-4 \times 13.6\,\text{eV}$. With two electrons, as in the case of the neutral molecule H_2, the anti-parallel orientation of the spins, $\uparrow\downarrow$, allows us to place the two electrons in the same orbital, while for parallel orientation, $\uparrow\uparrow$, we expect anti-binding. Each electron without a partner in an orbital can form a covalent bond, for example, phosphorus [P]=[Ne]$3s^2 3p^{\uparrow\uparrow\uparrow}$ has three available orbitals corresponding to different magnetic quantum numbers. The covalent bond is directional (sp^1, sp^2, or sp^3 hybridization), which is essential for the molecular structure such as in CH_4. Do the Exc. 35.1.6.1.

35.1.2 Born-Oppenheimer approximation and the $H_2{}^+$ molecule

The *Born-Oppenheimer approximation* in molecular physics consists in considering, at first, the positions of the nuclei as being fixed in space. This allows us to study the stationary states of the electrons subject to the potential created by the nuclei for a given internuclear distance R. Varying R, the electronic energies (computed for a fixed R) remain the same, because the electronic wavefunctions adjust instantaneously due to their mass being much lower than that of the nuclei. The non-varying electronic energies play the role of interaction potential energies between the nuclei [39].

35.1.2.1 Separation of the center-of-mass

Let us consider two heavy masses, $M_{a,b} = M$ separated by a distance R and interacting through a potential $V_{nn}(R)$. Furthermore, there is a light-weighted mass m_e interacting with the other masses through $V_{ne}(r)$. The Hamiltonian is,

$$\hat{H} = \frac{-\hbar^2}{2M}\nabla_a^2 + \frac{-\hbar^2}{2M}\nabla_b^2 + \frac{-\hbar^2}{2m_e}\nabla_e^2 + V_{nn}(|\mathbf{R}_a - \mathbf{R}_b|) + V_{ne}(|\mathbf{R}_a - \mathbf{R}_e|) + V_{ne}(|\mathbf{R}_b - \mathbf{R}_e|) \ . \tag{35.2}$$

We transform to the center-of-mass system of the two heavy masses anchored at

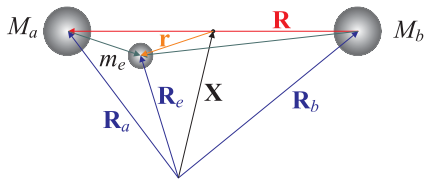

Figure 35.4: System with two heavy and one light mass.

$\mathbf{X} \equiv \frac{M_a\mathbf{R}_a + M_b\mathbf{R}_b}{M} = \frac{1}{2}(\mathbf{R}_a + \mathbf{R}_b)$. The distance of the *heavies* is $\mathbf{R} \equiv \mathbf{R}_a - \mathbf{R}_b$, and the coordinate of the light mass counting from the center-of-mass is $\mathbf{r} = \mathbf{R}_a - \frac{1}{2}\mathbf{R} - \mathbf{R}_e$. Introducing the reduced mass of the *heavies* $M_r = \frac{M}{2}$,

$$\left[\frac{-\hbar^2}{2M}\nabla_X^2 + \frac{-\hbar^2}{2M_r}\nabla_R^2 + V_{nn}(R) + \frac{-\hbar^2}{2m_e}\nabla_r^2 + V_{ne}(|\mathbf{r} + \tfrac{\mathbf{R}}{2}|) + V_{ne}(|\mathbf{r} - \tfrac{\mathbf{R}}{2}|)\right]\Theta(\mathbf{X})\Psi(\mathbf{R}, \mathbf{R}_e)$$
$$= E_{tot}\Theta(\mathbf{X})\Psi(\mathbf{R}, \mathbf{R}_e) \ , \tag{35.3}$$

Here, we made the ansatz for the total wavefunction $\Psi = \Theta(\mathbf{X})\Psi(\mathbf{R}, \mathbf{R}_e)$, assuming that the center-of-mass is only determined by the heavy masses,

$$\frac{-\hbar^2}{2M}\nabla_X^2\Theta(\mathbf{X}) = E_{cm}\Theta(\mathbf{X}) \tag{35.4}$$
$$\left[\frac{-\hbar^2}{2M_r}\nabla_R^2 + V_{nn}(R) + \frac{-\hbar^2}{2m_e}\nabla_r^2 + V_{ne}(|\mathbf{r} + \tfrac{1}{2}\mathbf{R}|) + V_{ne}(|\mathbf{r} - \tfrac{1}{2}\mathbf{R}|)\right]\Psi(\mathbf{R}, \mathbf{R}_e) = E\Psi(\mathbf{R}, \mathbf{R}_e) \ ,$$

where $E_{tot} = E_{cm} + E$.

35.1.2.2 Adiabatic approximation

The Born-Oppenheimer approximation now consists in assuming that the movement of the *heavies* is independent of the position of m_e, which allows us to separate the corresponding wavefunction ϕ via the ansatz $\Psi(\mathbf{R}, \mathbf{R}_e) = \psi(\mathbf{R}, \mathbf{r})\phi(\mathbf{R})$. On the other hand, the orbital ψ of the light mass m_e does not change much, when we vary the distance of the *heavies*, $\nabla_R\psi(\mathbf{R}, \mathbf{r}) \simeq 0$. This is only valid, as long as the *heavies* are inert on the time scale of the movement of m_e. Therefore, we can approximate the second derivative,

$$\nabla_R^2[\psi(\mathbf{R}, \mathbf{r})\phi(\mathbf{R})] = \phi(\mathbf{R})\nabla_R^2\psi(\mathbf{R}, \mathbf{r}) + 2[\nabla_R\phi(\mathbf{R})] \cdot [\nabla_R\psi(\mathbf{R}, \mathbf{r})] + \psi(\mathbf{R}, \mathbf{r})\nabla_R^2\phi(\mathbf{R})$$
$$\simeq \psi(\mathbf{R}, \mathbf{r})\nabla_R^2\phi(\mathbf{R}) \ , \tag{35.5}$$

postulating that the first two terms are negligible compared to the third. We can now separate the second equation (35.4) in two parts, the first being,

$$\boxed{\left[\frac{-\hbar^2}{2m_e}\nabla_r^2 + V_{ne}(|\mathbf{r}+\tfrac{1}{2}\mathbf{R}|) + V_{ne}(|\mathbf{r}-\tfrac{1}{2}\mathbf{R}|)\right]\psi(\mathbf{r},\mathbf{R}) = \varepsilon(R)\psi(\mathbf{r},\mathbf{R})}\,. \tag{35.6}$$

We solve this equation for the electronic degree of freedom $\mathbf{r}$ by choosing a fixed internuclear distance $\mathbf{R}$, and we substitute in the second expression (35.4), which gives,

$$\boxed{\left[\frac{-\hbar^2}{2M_r}\nabla_R^2 + V_{nn}(R) + \varepsilon(R)\right]\phi(\mathbf{R}) = E\phi(\mathbf{R})}\,. \tag{35.7}$$

Treating the interatomic distance R as a fixed parameter, the solution of Eq. (35.6) provides the electronic orbitals and their energies $\varepsilon(R)$. The *Born-Oppenheimer potential* is composed of the electrostatic repulsive potential of the nuclei and the kinetic energy of the electron, $V_{nn}(R) + \varepsilon(R)$. In other words, the presence of the electrons generates an additional interaction energy between the nuclei. By inserting this complete interatomic potential into Eq. (35.7), we can determine its vibrational structure $\phi_{\text{vib}}(\mathbf{R})$.

Fig. 35.5 shows an example of binary effective nuclear potentials, as a function of the distance R between the two nuclei. Each curve corresponds to a different solution of the electronic equation, that is, to a different electronic state. In many cases, such nuclear potentials have a stable equilibrium region. The bound states located in these regions are *molecular* bound states of two atoms.

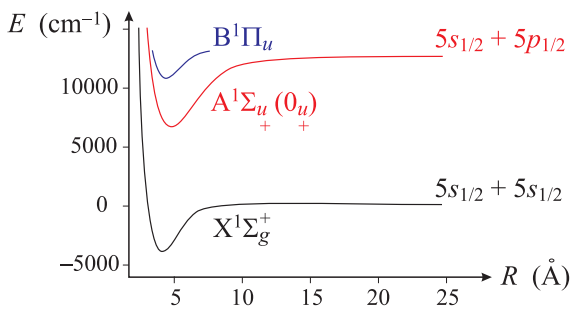

Figure 35.5: Effective nuclear potentials for the interaction between two rubidium atoms (Rb_2).

In practice, the calculation of adiabatic Born-Oppenheimer potentials is difficult and makes it the subject of sophisticated theories, such as the *molecular orbital model* or the *valence bond model* [2]. We study in Exc. 35.1.6.2 a generalization of the Born-Oppenheimer approximation.

[2]Note that the Born-Oppenheimer approximation is no longer good in the presence of relativistic or spin-orbit coupling effects.

35.1.3 Linear combination of orbitals and the H_2 molecule

In the following we will discuss the electronic structure of the simplest neutral molecule: H_2. For the low electron states of this molecule, the Born-Oppenheimer approximation is totally satisfactory, that is, we want to solve a Schrödinger type equation (35.6), but with two electrons. We are, therefore, interested in the electronic Hamiltonian,

$$\boxed{\hat{H} = -\frac{\hbar^2}{2m_e}(\nabla_1^2 + \nabla_2^2) + \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{R_{ab}} - \frac{1}{|\mathbf{r}_1-\mathbf{R}_a|} - \frac{1}{|\mathbf{r}_1-\mathbf{R}_b|} - \frac{1}{|\mathbf{r}_2-\mathbf{R}_a|} - \frac{1}{|\mathbf{r}_2-\mathbf{R}_b|} + \frac{1}{r_{12}}\right)}\,, \tag{35.8}$$

where '1' and '2' denote the two electrons and 'a' and 'b' the nuclei.

This problem can not be solved analytically. The standard procedure begins with choosing a suitable basis, i.e. a very compact basis which does not depend on the configuration of the molecule. That is, we want the basis to be composed of functions that do not depend on the distance between the two nuclei, R_{ab}, to avoid calculations for different bond lengths.

The most natural basis functions are the available atomic orbitals of the individual hydrogen atoms. When the bond length is too large, the system approaches the limit of two non-interacting hydrogen atoms. In this case, the electron wavefunction can be approximated by the product of *atomic orbitals* (AO) of atom 'a' and atom 'b'. Therefore, the smallest basis that gives us a realistic picture of the fundamental state of the H_2 molecule must comprise two functions: $|1s_a\rangle$ and $|1s_b\rangle$. For finite bond lengths, it is advisable to allow the AOs to polarize and deform in response to the presence of the other electron (and the other nucleus). However, the $|1s_a\rangle$ and $|1s_b\rangle$ functions do not have to be exactly the hydrogenic eigenfunctions. It is sufficient to require them to be similar to the $1s$ orbitals and be centered on them. Since the actual shape of the orbitals is not yet fixed, we will give all the expressions in abstract matrix form, leaving the spatial integration for once the shape of the orbitals has been specified. This is the method of *linear combination of atomic orbitals* (LCAO).

35.1.4 Molecular orbital theory

We are now in a position to discuss the basic principles of the *molecular orbital method* (MO), which is the basis of the theory of the electronic structure of real molecules. The first step in any MO approach is to separate the Hamiltonian into two parts, one part describing the electrons '1' and '2' separately and one part counting for the interaction between them:

$$\hat{H} = \hat{h}(1) + \hat{h}(2) + \hat{V}_{12} + \frac{e^2}{4\pi\varepsilon_0}\frac{1}{R_{ab}} \qquad \text{with} \tag{35.9}$$

$$\hat{h}(i) = -\frac{\hbar^2\nabla_i}{2m_e} - \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{|\mathbf{r}_i-\mathbf{R}_a|} + \frac{1}{|\mathbf{r}_i-\mathbf{R}_b|}\right) \qquad \text{and} \qquad \hat{V}_{12} = \frac{e^2}{4\pi\varepsilon_0}\frac{1}{r_{12}}\,,$$

where $i = 1, 2$. We must remember that, within the BO approximation, R_{ab} is just a number. We choose the Hamiltonian $h(i)$ as the one-electron part of the complete Hamiltonian in matrix representation on the minimum basis:

$$\begin{pmatrix} \langle 1s_a|\hat{h}|1s_a\rangle & \langle 1s_a|\hat{h}|1s_b\rangle \\ \langle 1s_b|\hat{h}|1s_a\rangle & \langle 1s_b|\hat{h}|1s_b\rangle \end{pmatrix} \equiv \begin{pmatrix} \epsilon & h_{ab} \\ h_{ab} & \epsilon \end{pmatrix}\,, \tag{35.10}$$

defining the average one-electron energy $\epsilon \equiv \langle 1s_a|\hat{h}|1s_a\rangle$ and the non-diagonal coupling (often called *resonance integral*) $h_{ab} \equiv \langle 1s_a|\hat{h}|1s_b\rangle = \langle 1s_a|\hat{h}|1s_b\rangle$. We can immediately diagonalize this matrix, the eigenvalues and the eigenvalues being:

$$\epsilon_\pm = \epsilon \pm h_{ab} \qquad \text{and} \qquad |\phi_\pm\rangle \propto \tfrac{1}{2}(|1s_a\rangle \pm |1s_b\rangle) \ . \tag{35.11}$$

The one-electron effective Hamiltonian eigenstates are called *molecular orbital* (MO). They are one-electron wavefunctions delocalized over the spatial regions of the molecule.

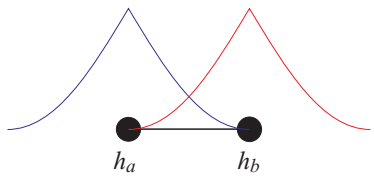

Figure 35.6: Illustration of the atomic orbitals.

We need to first normalize the MOs, which is more complicated than it might seem, because the AOs are not orthogonal. For example, when the atoms approach each other, their AOs may have the shape shown in Fig. 35.6. However, by defining the overlap integral by $S \equiv \langle 1s_a|1s_b\rangle$, we can normalize as follows:

$$|\phi_\pm\rangle = \tfrac{1}{\sqrt{2(1\pm S)}}(|1s_a\rangle \pm |1s_b\rangle) \ , \tag{35.12}$$

since,

$$\langle\phi_\pm|\phi_\pm\rangle = \tfrac{1}{2(1\pm S)}(\langle 1s_a|1s_a\rangle \pm \langle 1s_a|1s_b\rangle \pm \langle 1s_b|1s_a\rangle + \langle 1s_b|1s_b\rangle) = 1 \ . \tag{35.13}$$

These eigenfunctions merely show the symmetry of the molecule. The two hydrogen atoms are equivalent and, therefore, the eigenorbital must give equal weight to each $1s$ orbital. Thus, our choice of the one-electron Hamiltonian does not really matter that much, because every one-electron Hamiltonian exhibiting the symmetry of the molecule would give the same molecular orbitals. For historical reasons, $|\phi_+\rangle$ is denoted by $|\sigma\rangle$ and $|\phi_-\rangle$ by $|\sigma^*\rangle$.

The second step in MO theory consists of constructing the determinant from the MOs corresponding to the wanted states. For illustration we will look at the lowest singlet state constructed from molecular orbitals. We note that $h_{ab} < 0$, such that $|\sigma\rangle$ has an energy inferior to $|\sigma^*\rangle$. Neglecting the interaction, the lowest singlet state,

$$|\Phi_{\rm MO}\rangle = |\sigma\rangle|\sigma^*\rangle \ , \tag{35.14}$$

is the molecular ground state of H_2. To estimate the validity of the approximation, we calculate the expectation value of the energy, $\left|\langle\sigma|\langle\sigma^*|\hat{H}|\sigma\rangle|\sigma^*\rangle\right|$, decomposing the wavefunction into spin and spatial parts, noting that the spin part is normalized:

$$\begin{aligned}\left|\langle\sigma|\langle\sigma^*|\hat{H}|\sigma\rangle|\sigma^*\rangle\right| &= \langle\sigma(1)|\langle\sigma(2)|\hat{H}|\sigma(1)\rangle|\sigma(2)\rangle\langle\Phi_{\rm spin}|\Phi_{\rm spin}\rangle \\ &= \langle\sigma(1)|\langle\sigma(2)|\hat{H}|\sigma(1)\rangle|\sigma(2)\rangle \ .\end{aligned} \tag{35.15}$$

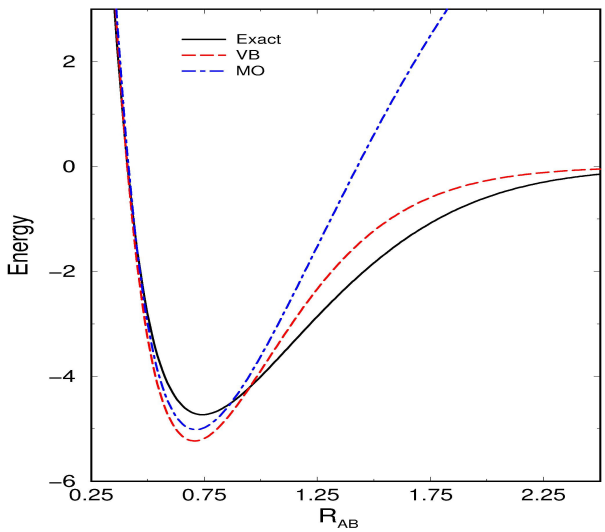

Figure 35.7: Total energy as a function of interatomic distance.

Hence, with (35.10) we get,

$$\begin{aligned}
\langle\sigma(1)|\langle\sigma(2)|\hat{h}(2)|\sigma(1)\rangle|\sigma(2)\rangle &= \langle\sigma(1)|\sigma(1)\rangle\langle\sigma(2)|h(2)|\sigma(2)\rangle = \langle\sigma(2)|h(2)|\sigma(2)\rangle \equiv \epsilon_\sigma \\
\langle\sigma(1)|\langle\sigma(2)|\hat{h}(1)|\sigma(1)\rangle|\sigma(2)\rangle &= \langle\sigma(1)|h(1)|\sigma(1)\rangle\langle\sigma(2)|\sigma(2)\rangle = \langle\sigma(1)|h(1)|\sigma(1)\rangle \equiv \epsilon_\sigma \\
\langle\sigma(1)|\langle\sigma(2)|\hat{V}_{12}|\sigma(1)\rangle|\sigma(2)\rangle &\equiv J_{\sigma\sigma} \ . \qquad (35.16)
\end{aligned}$$

Putting these facts together, we can write,

$$\begin{aligned}
\langle\Phi_{\rm MO}|\hat{H}|\Phi_{\rm MO}\rangle &= \langle\Phi_{\rm MO}|\hat{h}_1|\Phi_{\rm MO}\rangle + \langle\Phi_{\rm MO}|\hat{h}_2|\Phi_{\rm MO}\rangle + \langle\Phi_{\rm MO}|\hat{V}_{12}|\Phi_{\rm MO}\rangle + \frac{e^2}{4\pi\varepsilon_0 R_{ab}} \\
&= 2\epsilon_\sigma + J_{\sigma\sigma} + \frac{e^2}{4\pi\varepsilon_0 R_{ab}} \ . \qquad (35.17)
\end{aligned}$$

Each of the first two terms represents the energy of a single electron (either 1 or 2) in the field produced by both the nuclei ($\hat{h}$), while the third is the average repulsion between the two electrons. Note that the first and second term are both positive, such that the bond must come from the one-electron part. This is the MO energy for the ground state of the H_2. We can try a more reasonable ansatz for the $1s$-type basis functions [3] by determining the unknown quantities from above (ϵ_σ and $J_{\sigma\sigma}$) numerically and plot the total energy as a function of R_{ab} (blue dotted curve in Fig. 35.7). The exact adiabatic energy function determined from experimental data (solid black curve) agrees well at low energies. Summarizing the results with some key numbers, we note that MO theory predicts a bond distance of 0.072 nm in reasonable agreement with the exact value of 0.074 nm. We can also compare the

[3] It turns out that it is more convenient to adjust the exponential decomposition of the hydrogenic orbitals to a sum of Gaussians.

binding energies,

$$D_e = E_{\mathrm{H}_2}(R_{\mathrm{equil}}) - 2E_{\mathrm{H}} \ . \tag{35.18}$$

MOs theory predicts a binding energy of 5.0 eV compared to the experimental value of 4.75 eV. In view of the simplicity of the wavefunction and the absence of adjustable parameters the agreement is not so bad. Unfortunately, far away from the equilibrium distance, we have an unpleasant surprise: the molecule does not dissociate into two hydrogen atoms!

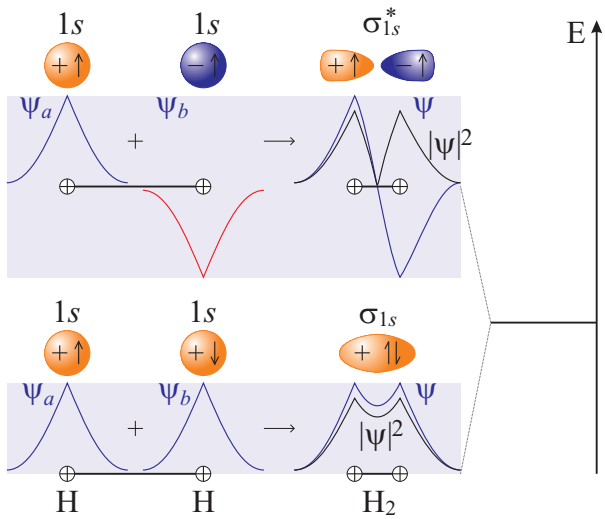

Figure 35.8: Illustration of MO theory for a dimer of two equal atoms, each one with a valence electron in the atomic 1s orbital: When the atoms approach, the atomic orbitals form new molecular binding and anti-biding orbitals.

To get an idea of what is happening near dissociation, we expand the fundamental MO state in terms of AO configurations:

$$\begin{aligned}|\Phi_{\mathrm{MO}}\rangle &\propto |\sigma(1)\rangle|\sigma(2)\rangle|\Phi_{\mathrm{spin}}\rangle \\ &= \tfrac{1}{2(1+S)}(|1s_a(1)\rangle + |1s_b(1)\rangle)(|1s_a(2)\rangle + |1s_b(2)\rangle)|\Phi_{\mathrm{spin}}\rangle \\ &= \tfrac{1}{2(1+S)}(|1s_a(1)\rangle|1s_a(2)\rangle + |1s_a(1)\rangle|1s_b(2)\rangle + |1s_b(1)\rangle|1s_a(2)\rangle + |1s_b(1)\rangle|1s_b(2)\rangle)|\Phi_{\mathrm{spin}}\rangle \ .\end{aligned} \tag{35.19}$$

The two terms in the middle of the last line, called *covalent configurations*, are exactly what we expect near dissociation: one electron in each hydrogen atom. However, the first and last term (which are called *ionic configurations*) correspond to having two electrons in one atom and none in the other, which gives us H^+ and H^- at dissociation! Since the weight of these terms is fixed, it is obvious that we got the wrong wavefunction (and therefore the wrong energy) when dissociating the molecule. Near the equilibrium point, the ionic terms contribute significantly to the true wavefunction, such that the MO theory is good at this point. But it is always terrible at dissociation.

35.1.5 Valence binding

An alternative to MO theory represents the *valence bond* theory (VB). Here, we use significantly more physical intuition and discard the ionic configurations from the MO wavefunction. Thus, the VB ground state wavefunction is:

$$\begin{aligned}|\Psi\rangle &\propto \frac{|1s_a(1)\rangle|1s_a(2)\rangle + |1s_b(1)\rangle|1s_a(2)\rangle}{\sqrt{2}} \frac{|\uparrow(1)\rangle|\downarrow(2)\rangle + |\downarrow(1)\rangle|\uparrow(2)\rangle}{\sqrt{2}} \\ &\equiv |\Psi_{\text{space}}\rangle|\Psi_{\text{spin}}\rangle \ . \end{aligned} \tag{35.20}$$

VB theory assumes that this wavefunction is a good approximation to the true wavefunction at *all* binding distances and not only at large distances R_{ab}. To verify this approximation, we can calculate the average energy for this VB state. First, we normalize the VB wavefunction,

$$\begin{aligned}\langle\Psi|\Psi\rangle &= \langle\Psi_{\text{space}}|\langle\Psi_{\text{spin}}|\Psi_{\text{space}}\rangle|\Psi_{\text{spin}}\rangle = \langle\Psi_{\text{space}}|\Psi_{\text{space}}\rangle \\ &= \tfrac{1}{2}\left(\langle 1s_a(1)|\langle 1s_b(2)| + \langle 1s_b(1)\langle 1s_a(2)|\right)\left(|1s_a(1)\rangle|1s_a(2)\rangle + |1s_b(1)\rangle|1s_a(2)\rangle\right) \\ &= \tfrac{1}{2}\left(\langle 1s_a(1)|1s_b(2)|1s_a(1)\rangle|1s_b(2)\rangle + \langle 1s_a(1)|1s_b(2)|1s_b(1)\rangle|1s_a(2)\rangle\right. \\ &\quad \left.+\langle 1s_b(1)|1s_a(2)|1s_a(1)\rangle|1s_b(2)\rangle + \langle 1s_b(1)|1s_a(2)|1s_b(1)\rangle|1s_a(2)\rangle\right) \\ &= \tfrac{1}{2}(1 + S^2 + S^2 + 1) = 1 + S^2 \ . \end{aligned} \tag{35.21}$$

Therefore, the correctly normalized VB wavefunction is:

$$|\Psi_{\text{VB}}\rangle = \frac{1}{2\sqrt{1+S^2}}\left(|1s_a(1)\rangle|1s_a(2)\rangle + |1s_b(1)\rangle|1s_a(2)\rangle\right)\left(|\uparrow(1)\rangle|\downarrow(2)\rangle - |\downarrow(1)\rangle|\uparrow(2)\rangle\right) \ . \tag{35.22}$$

Now we want to calculate $\langle\hat{H}_{el}\rangle$ for this state. We note that the spin part does not matter, since the Hamiltonian is independent of spin:

$$\begin{aligned}\langle\Psi_{\text{VB}}|\hat{H}|\Psi_{\text{VB}}\rangle &= \langle\Psi_{\text{spin}}|\langle\Psi_{\text{space}}|\hat{H}|\Psi_{\text{space}}\rangle|\Psi_{\text{spin}}\rangle \\ &= \langle\Psi_{\text{space}}|\hat{H}|\Psi_{\text{space}}\rangle\langle\Psi_{\text{spin}}|\Psi_{\text{spin}}\rangle = \langle\Psi_{\text{space}}|\hat{H}|\Psi_{\text{space}}\rangle \ . \end{aligned} \tag{35.23}$$

The only remnant of the spin state is the fact that the spatial wavefunction is symmetric, which is only possible when the spin part is antisymmetric. Treating each term in $\langle\hat{H}\rangle$ separately,

$$\begin{aligned}\langle\Psi|\hat{h}_1|\Psi\rangle &= \tfrac{1}{2}\left(\langle 1s_a(1)|\langle 1s_b(2)| + \langle 1s_b(1)|1s_a(2)|\right)\hat{h}_1\left(|1s_a(1)\rangle|1s_a(2)\rangle + |1s_b(1)\rangle|1s_a(2)\rangle\right) \\ &= \tfrac{1}{2}\Big(\langle 1s_a(1)|1s_b(2)|\hat{h}_1|1s_a(1)\rangle|1s_b(2)\rangle + \langle 1s_a(1)|1s_b(2)|\hat{h}_1|1s_b(1)\rangle|1s_a(2)\rangle \\ &\quad +\langle 1s_b(1)|1s_a(2)|\hat{h}_1|1s_a(1)\rangle|1s_b(2)\rangle + \langle 1s_b(1)|1s_a(2)|\hat{h}_1|1s_b(1)\rangle|1s_a(2)\rangle\Big) \\ &= \tfrac{1}{2}(\epsilon + Sh_{ab} + \epsilon + Sh_{ab}) \ , \end{aligned} \tag{35.24}$$

or,

$$\boxed{\langle\Psi_{\text{VB}}|\hat{h}_1|\Psi_{\text{VB}}\rangle = \frac{\epsilon + Sh_{ab}}{1+S^2}} \ . \tag{35.25}$$

Since the two electrons are identical, the elements of the $\hat{h}_2$ are the same as those of $\hat{h}_1$. The only remaining term is the average value of the interaction:

$$\langle\Psi|\hat{V}_{12}|\Psi\rangle = \tfrac{1}{2}\left(\langle 1s_a(1)|\langle 1s_b(2)| + \langle 1s_b(1)|1s_a(2)|\right)\hat{V}_{12}\left(|1s_a(1)\rangle|1s_a(2)\rangle + |1s_b(1)\rangle|1s_a(2)\rangle\right) \tag{35.26}$$

$$= \tfrac{1}{2}\Big(\langle 1s_a(1)|1s_b(2)|\hat{V}_{12}|1s_a(1)\rangle|1s_b(2)\rangle + \langle 1s_a(1)|1s_b(2)|\hat{V}_{12}|1s_b(1)\rangle|1s_a(2)\rangle$$
$$+ \langle 1s_b(1)|1s_a(2)|\hat{V}_{12}|1s_a(1)\rangle|1s_b(2)\rangle + \langle 1s_b(1)|1s_a(2)|\hat{V}_{12}|1s_b(1)\rangle|1s_a(2)\rangle\Big) \ .$$

The second and third terms are the same. They are called *exchange integrals*, because the 'bra' orbitals have switched order as compared to the 'kets':

$$K = \langle 1s_a(1)|1s_b(2)|\hat{V}_{12}|1s_b(1)\rangle|1s_a(2)\rangle = \langle 1s_b(1)|1s_a(2)|\hat{V}_{12}|1s_a(1)\rangle|1s_b(2)\rangle \ . \tag{35.27}$$

The first and forth terms are also the same. They are called *Coulomb integrals*, because they seem to be due to the Coulomb interaction between two charge densities:

$$J = \langle 1s_b(1)|1s_a(2)|\hat{V}_{12}|1s_a(1)\rangle|1s_b(2)\rangle = \langle 1s_a(1)|1s_b(2)|\hat{V}_{12}|1s_b(1)\rangle|1s_a(2)\rangle \ . \tag{35.28}$$

Therefore, we have the result,

$$\boxed{\langle\Psi_{\rm VB}|\hat{V}_{12}|\Psi_{\rm VB}\rangle = \frac{J+K}{1+S^2}} \ . \tag{35.29}$$

Adding all terms, we get:

$$\langle\Psi_{\rm VB}|\hat{H}|\Psi_{\rm VB}\rangle = \langle\Psi_{\rm VB}|\hat{h}_1|\Psi_{\rm VB}\rangle + \langle\Psi_{\rm VB}|\hat{h}_2|\Psi_{\rm VB}\rangle + \langle\Psi_{\rm VB}|\hat{V}_{12}|\Psi_{\rm VB}\rangle + \frac{1}{R_{ab}}$$
$$= 2\frac{\epsilon + Sh_{ab}}{1+S^2} + \frac{J+K}{1+S^2} + \frac{1}{R_{ab}} \ . \tag{35.30}$$

The Coulomb and exchange terms are positive. Nuclear repulsion is clearly positive. Thus, the only terms that lead to binding in this picture are the average energy of an electron ϵ and the resonance integral h_{ab}. If the first term is dominant, the bond is due to *electronic delocalization*, since an electron located near one of the atoms would only contribute the atomic value to ϵ, which does not imply a bound state. If h_{ab} is large, the bond involves some resonance character, which can be related to the familiar concept of resonance between different Lewis point structures.

A numerical evaluation of all integrals gives the potential curve presented in Fig. 35.7 for VB theory. As expected, this simple VB wavefunction gives the correct dissociation threshold, where MO theory fails. In addition, the accuracy of the simple VB result is surprisingly good even near the equilibrium distance: The VB predicts a bond distance of 0.071 nm (compared to the correct value of 0.074 nm) and $D_e = 5.2$ eV (compared to 4.75 eV). Thus, the VB wavefunction also gives a good agreement without adjustable parameters. But more importantly, it indicates a way of improving the wavefunction whenever we encounter an obvious error: in this case, we saw that the description of the dissociation was weak, and we constructed a VB ansatz curing the problem. This approach to VB is often generalized as follows

when dealing with polyatomic molecules. We write the wavefunction as a product of a spatial part and a spin:

$$|\Psi\rangle = |\Psi_{\text{space}}\rangle|\Psi_{\text{spin}}\rangle \ . \tag{35.31}$$

The main assumption in VB theory is that the spatial part can be well represented by a product of atomic-like functions. For example, for water, we would immediately write a spatial part as:

$$|\Psi_{\text{space}}\rangle \simeq |1s_{H_a}\rangle|1s_{H_b}\rangle|1s_O\rangle|1s_O\rangle|2s_O\rangle|2s_O\rangle|2p_{xO}\rangle|2p_{xO}\rangle|2p_{yO}\rangle|2p_{yO}\rangle \ . \tag{35.32}$$

However, there are two things wrong with this wavefunction. First, we know that atomic orbitals hybridize in a molecule. Therefore, we need to make appropriate linear combinations of AOs (in this case sp^3 hybrids) to obtain the hybridized AOs. In this case, the four sp^3 hybrids can be written symbolically as:

$$|sp^3\rangle = c_{s,i}|2s\rangle + c_{x,i}|2p_x\rangle + c_{y,i}|2p_y\rangle + c_{z,i}|2p_z\rangle \ . \tag{35.33}$$

and therefore, a more appropriate spatial configuration is:

$$|\Psi_{\text{space}}\rangle \simeq |1s_{H_a}\rangle|1s_{H_b}\rangle|1s_O\rangle|1s_O\rangle|sp^3_{1O}\rangle|sp^3_{1O}\rangle|sp^3_{2O}\rangle|sp^3_{2O}\rangle|sp^3_{3O}\rangle|sp^3_{4O}\rangle \ . \tag{35.34}$$

The other problem with this state is that it lacks the adequate symmetry to describe fermions; the general state must be antisymmetric. In the case of two electrons this concept is easy to apply - singlets have symmetric space parts and triplets antisymmetric ones. However, in the case of many electrons, the rules are not so simple; in fact, the time of numerical computation grows exponentially with the number of electrons.

Formally, we will leave the derivation at this point to defining an operator $\mathcal{A}$ which 'antisymmetrizes' the wavefunction. In this case,

$$|\Psi_{\text{space}}\rangle \simeq \mathcal{A}\left[|1s_{H_a}\rangle|1s_{H_b}\rangle|1s_O\rangle|1s_O\rangle|sp^3_{1O}\rangle|sp^3_{1O}\rangle|sp^3_{2O}\rangle|sp^3_{2O}\rangle|sp^3_{3O}\rangle|sp^3_{4O}\rangle\right] \ . \tag{35.35}$$

In general, the results of VB theory are very accurate for small systems, where it can be applied. The predicted bond lengths are rather short, and the binding energies tend to be too small, but the results are nevertheless qualitatively excellent. In addition, the correct hybridized atomic orbitals fall directly off the calculation, giving a good qualitative insight. Also, note that the atomic configurations should not change (or very little) when the geometry of the molecule changes (since the orbitals depend on the atom and not on the molecular structure). Therefore, these VB wavefunctions have a strong connection to the diabatic states discussed above. However, the exponential amount of time that one must invest to perform these calculations makes them impractical for most molecules of interest.

35.1.6 Exercises

35.1.6.1 Ex: Classical model of the covalent binding

Consider the molecule H_2^+ with the two nuclei separated by 1 nm and an electron located in the middle between the nuclei. Calculate the electrostatic force acting on the nuclei.

35.1.6.2 Ex: Beyond the Born-Oppenheimer approximation for molecules

For molecules, the Born-Oppenheimer approximation may fail in some situations. Therefore, it is common to use another approach known as Born-Huang. To illustrate this approach, we consider a diatomic molecule in the laboratory frame.
a. Write down the many-body Hamiltonian of the molecule in atomic units.
b. If we change the coordinate system to the position of the center-of-mass of the nuclei of the molecule, we eliminate the dependency on the global translation of the molecule. The Hamiltonian is now given by,

$$-\frac{\nabla_R^2}{2\mu_{AB}} - \sum_{i,j} \frac{1}{2M} \nabla_i \nabla_j - \sum_i \frac{\nabla_i^2}{2} + V$$

where that the Coulombian interactions are included in the fifth term. Write down the time-independent Schrödinger equation for this molecule.
c. The Born-Huang approximation consists in assuming that the total wavefunction can be expanded on a basis of wavefunctions of the nuclei and the electrons, that is,

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_k |\chi_k(\mathbf{R})\rangle |\phi_k(\mathbf{r}, \mathbf{R})\rangle \ ,$$

where χ and ϕ are the wavefunctions of the nuclei and the electrons, respectively. For the Schrödinger equation calculated in the previous item, use the Born-Huang approximation and obtain the set of coupled equations

$$\left\{ \sum_k \left[-\frac{1}{2\mu_{AB}} \left(\nabla_R^2 + \langle \phi_k | \nabla_R^2 | \phi_k \rangle + 2 \langle \phi_k | \nabla_R | \phi_k \rangle . \nabla_R | \right) \right] - \right.$$
$$\left. \sum_k \left[\frac{1}{2M} \left(\sum_{i,j} \langle \phi_i | \nabla_i . \nabla_j | \phi_k \rangle \right) + \frac{1}{2} \sum_i \langle \phi_i | \nabla_i^2 | \phi_k \rangle - \langle \phi_i | V | \phi_k \rangle | \right] \right\} |\chi_k\rangle = E \sum_k |\chi_k\rangle$$

which includes, although approximately, the kinetic energy of nuclei and electrons. **Help:** Use $\nabla^2(\alpha\beta) = \alpha\nabla^2\beta + \beta\nabla^2\alpha + 2\nabla\alpha \cdot \nabla\beta$.
d. Make a brief comparison between the Born-Huang approximation (and the coupled equations obtained in the previous equation) and the Born-Oppenheimer approximation.

35.1.6.3 Ex: Classical model of the covalent bond

Calculate the energies of the ground state and the last bound state of the potential $V_n = -\frac{C}{r^n}$ for any n.

35.1.6.4 Ex: Homonuclear collision

We consider the example of homonuclear collisions of ^{85}Rb atoms. For ground state collisions in the channel $^3\Sigma_+$, $|f = 2, m_f = -2\rangle$, the long-range part of the potential is fixed by $C_6 = 4550$, $C_8 = 550600$, and $C_{10} = 7.67 \times 10^7$ [200, 785], where $R_m = 9.8a_B$, $D_m = 0.13$, and $B_m = 1/2.5a_B$. The potentials can be merged at a given distance $R_t = 27.6a_B$. Prepare a plot of potential.

35.2 Rovibrational structure of molecular potentials

The separation of the motion of the nuclei from the electronic dynamics made in the Born-Oppenheimer approximation led to equations (35.6) and (35.7). In a preceding section we analyzed in detail the equation (35.6) with the objective of understanding the phenomenon of molecular binding.

In the following section we will analyze the equation (35.7), which determines the motion of the nuclei. By separating the radii and angular parts of the motion, we will discover vibrational and rotational states.

35.2.1 The radial and angular equations

The interaction between two identical atoms is described by the following Hamiltonian, where $M_r = (M_a^{-1} + M_b^{-1})^{-1} = M/2$ is the *reduced mass* of the nuclei,

$$\hat{H} = \frac{\mathbf{P}^2}{2M_r} + V_{\text{mol}}(R) \qquad \text{with} \qquad V_{\text{mol}}(R) = \frac{e^2}{4\pi\epsilon_0 R} + V_{BO}(R) \ . \tag{35.36}$$

The interaction potential V_{mol} is composed of a repulsive internuclear Coulomb force and a Born-Oppenheimer adiabatic potential due to the interaction of the electrons with each other and with the two nuclei [4]. The kinetic energy is that of the relative motion (the center-of-mass motion has already been separated in Sec. 35.1.2, such that this inertial system is free of translational kinetic energy). In spherical coordinates,

$$\frac{\mathbf{P}^2}{2M_r}\phi(\mathbf{R}) = -\frac{\hbar^2}{2M_r}\left[\frac{1}{R}\frac{\partial^2}{\partial R^2}[R\phi(\mathbf{R})] + \frac{1}{R^2}\frac{\hat{\mathbf{L}}^2}{\hbar^2}\phi(\mathbf{R})\right] \ . \tag{35.37}$$

The wavefunction can be separated into an angular part and a radial part, $\phi(\mathbf{R}) = \mathcal{R}_v(R)Y_{\ell m}(\theta,\phi)$. The angular part, which was discussed in Sec. 25.1.3, describes a *rigid rotation* of the homonuclear atoms around their center-of-mass with the rotation energy,

$$\boxed{V_\ell(R) = \frac{\mathbf{L}^2}{2M_r R^2} = \frac{\hbar^2\ell(\ell+1)}{2M_r R^2}} \ , \tag{35.38}$$

also called *centrifugal barrier*. The radial part is ruled by,

$$\boxed{\left[-\frac{\hbar^2}{2M_r}\frac{\partial^2}{\partial R^2} + V_\ell(R) + V_{BO}(R)\right]u_v(R) = Eu_v(R)} \ , \tag{35.39}$$

where $u_v(R) = r\mathcal{R}_v(R)$ is the radial wavefunction of nuclear motion. The interatomic potential causes a motion of *vibration*. The vibrational states of the adiabatic potential are quantized and characterized by a well-defined vibrational energy. We will discuss the ro-vibrational structure in the following sections.

[4] We note here that at great distances other forces called *van der Waals forces* dominate the interatomic interaction. These will be discussed in Sec. 35.3.

35.2.1.1 Rotational and vibrational bands

Molecules have much more degrees of freedom than atoms. For example, the atoms of a molecular dimer may vibrate inside the mutual interaction potential. In the center-of-mass system we can imagine these vibrations as oscillations of an atom with reduced mass and quantized energy. The molecule can rotate and have a momentum of inertia. These degrees of freedom contribute energies to the molecule's Hamiltonian, either directly or through interactions with other degrees of freedom. Therefore, molecular spectra are characterized by a much greater complexity.

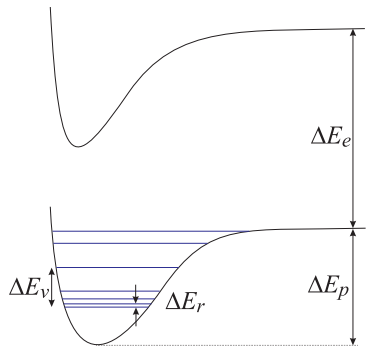

Figure 35.9: Molecular energy scales.

However, the energy regimes of the strongest excitations are quite different. A typical range for binding energies (depth of the interatomic potential) is $\Delta E_p \simeq$ 20..200 THz (0.1..1 eV) [5]. Electronic excitations occur in the regime $\Delta E_e \simeq$ 100..1000 THz (1..10 eV). The spacing between vibrational excitations typically is $E_{v+1} - E_v \simeq$ THz (0.01 eV). Finally, the rotational excitations are on the scale of $E_{\ell+1} - E_\ell \simeq 100$ MHz (10^{-6} eV). Since at room temperature (a gas of molecules in thermal equilibrium at $T = 300$ K) the energy is on a scale of 2.5×10^{-2} eV, the degree of freedom of the electronic excitation is frozen, while a wide distribution of vibrational and rotational states can be excited (e.g. by intermolecular collisions). The large difference of scales facilitates their separation and, therefore, the identification of the origin of the observed states in experimental measurements.

35.2.2 Vibrational molecular states

The potential energy of a molecule grows when the nuclei are displaced from their equilibrium positions. When the displacement, $x \equiv R - R_e$ is small, we can expand the potential energy,

$$V_{\rm mol}(x) = V_{\rm mol}(0) + \frac{dV_{\rm mol}(0)}{dx}x + \frac{1}{2}\frac{d^2V_{\rm mol}(0)}{dx^2}x^2 + \ldots \tag{35.40}$$

[5] Electronically excited states (that is, one of the valence electrons moves to an excited orbital) are more weakly bound, because the electrons are not in the most binding orbital.

The equilibrium energy is not of interest here, and the first derivative disappears in equilibrium. Therefore,

$$V_{\rm mol}(x) \simeq \tfrac{1}{2}k^2x^2 \qquad \text{with} \qquad k \equiv \frac{d^2V_{\rm mol}(0)}{dx^2} \ . \tag{35.41}$$

Using the effective mass we can write the Hamiltonian,

$$\hat{H}_{\rm mol} = -\frac{\hbar^2}{2m_1}\frac{d^2}{dx_1^2} - \frac{\hbar^2}{2m_2}\frac{d^2}{dx_2^2} + \frac{1}{2}kx^2 = -\frac{\hbar^2}{2M_r}\frac{d^2}{dx^2} + \frac{1}{2}kx^2 \ . \tag{35.42}$$

The energy spectrum of this degree of freedom, therefore, is

$$\boxed{E_v = \hbar\omega(v + \tfrac{1}{2})} \ . \tag{35.43}$$

with $\omega = \sqrt{k/M_r}$. That is, at the bottom of deep potentials, the energy levels are equidistant.

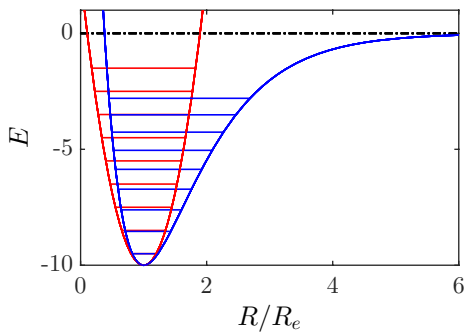

Figure 35.10: (code) Many potentials are approximately harmonic at the center such as, for instance, the Morse potential (blue). The red curve shows the approximate harmonic potential.

35.2.2.1 Anharmonic vibrations in the Morse potential

For larger displacements we can no longer despise the anharmonic terms in the Taylor expansion. A better approximation is the *Morse potential*. This potential (blue in Fig. 35.10), unlike the harmonic potential (red in Fig. 35.10), is characterized by an asymptote for large interatomic distances. Therefore, it is often used as an analytical approximation to molecular potentials,

$$\boxed{V_{\rm Morse} = D_e(1 - e^{-a(R-R_e)})^2} \ , \tag{35.44}$$

where r is the interatomic distance, r_e the equilibrium bond distance, D_e the depth of the potential measuring from the *dissociation limit*, and a a parameter controlling the range of the potential. At the bottom of the potential we can make the harmonic

approximation, $V_{\rm Morse}(R) \simeq \frac{k}{2}(R-R_e)^2$ with $k = 2a^2 D_e$. Rewriting the potential in the form,

$$\tilde{V}(R) \equiv V(R) - D_e = D_e(e^{-2a(R-R_e)} - 2e^{-a(R-R_e)}) \ , \tag{35.45}$$

we see, that it is a combination of a short-range repulsive potential and long-range attractive potential (similar to the Lennard-Jones's potential).

The calculation of the energy spectrum of this potential is more difficult [214],

$$E_v = \hbar\omega(v+1/2) - \hbar\omega\chi_e(v+1/2)^2 - D_e, \tag{35.46}$$

with $\omega\chi_e \equiv \frac{\hbar a^2}{2M_r}$ and $\omega \equiv \sqrt{k/M_r}$, but the availability of an analytical expression is interesting for the calibration of numerical methods. The second term of the expression (35.46), which is proportional to the anharmonicity constant χ_e, becomes dominant at high excitations. The potential is finite with a dissociation energy of,

$$D_0 = D_e - E_0 \ . \tag{35.47}$$

The number of vibrational states is limited $v = 0, 1, .., v_{\rm max}$. With $E < 0$, we find,

$$v_{\rm max} < \frac{1}{x_e} - \frac{1}{2} \ . \tag{35.48}$$

Example 252 (*Morse potential*): To solve the Schrödinger equation

$$\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial R^2} + V(R)\right)\Psi(v) = E_v\Psi(v) \ ,$$

it is convenient to introduce new variables,

$$x \equiv aR \quad , \quad \lambda \equiv \frac{\sqrt{2mD_e}}{a\hbar} \quad , \quad \varepsilon_v \equiv \frac{2m}{a^2\hbar^2}E_v \ ,$$

such that,

$$\left(-\frac{\partial^2}{\partial x^2} + V(x)\right)\Psi_n(x) = \varepsilon_n\Psi_n(x) \quad \text{with} \quad V(x) = \lambda^2\left(e^{-2(x-x_e)} - 2e^{-(x-x_e)}\right) \ .$$

The eigenvalues and eigenfunctions are [214]:

$$\varepsilon_n = 1 - \frac{1}{\lambda^2}\left(\lambda - n - \frac{1}{2}\right)^2 = \frac{2}{\lambda}(n+\frac{1}{2})^2 - \frac{1}{\lambda^2}(n+\frac{1}{2})^2 \quad \text{and} \quad \Psi_n(z) = N_n z^{\lambda-n-\frac{1}{2}}e^{-\frac{1}{2}z}L_n^{(2\lambda-2n-1)}(z) \ ,$$

where $z = 2\lambda e^{-(x-x_e)}$ and $N_n = \left[\frac{n!(2\lambda-2n-1)}{\Gamma(2\lambda-n)}\right]^{\frac{1}{2}}$ and,

$$L_n^{(\alpha)}(z) = \frac{z^{-\alpha}e^z}{n!}\frac{d^n}{dz^n}\left(z^{n+\alpha}e^{-z}\right) = \frac{\Gamma(\alpha+n+1)/\Gamma(\alpha+1)}{\Gamma(n+1)}\ {}_1F_1(-n, \alpha+1, z) \ ,$$

is the generalized Laguerre polynomial. The matrix elements of the spatial operator $\hat{x}$ are (assuming $m > n$ and $N = \lambda - \frac{1}{2}$),

$$\langle\Psi_m|x|\Psi_n\rangle = \frac{2(-1)^{m-n+1}}{(m-n)(2N-n-m)}\sqrt{\frac{(N-n)(N-m)\Gamma(2N-m+1)m!}{\Gamma(2N-n+1)n!}} \ .$$

In the original variables the eigenenergies are:

$$E_v = \hbar\omega(v+1/2) - \frac{[\hbar\omega(v+1/2)]^2}{4D_e} \ ,$$

where v is the vibrational quantum number and $\omega = a\sqrt{\frac{2D_e}{m}}$. The energy difference between adjacent levels decreases with v,

$$E_{v+1} - E_v = \hbar\omega - (\hbar\omega)^2 \frac{v+1}{2D_e} \ .$$

This fact describes well the vibrational structure of non-rotating molecules. However, the equation fails above some value of $v > v_{\max}$, where $E_{v_{\max}+1} - E_{v_{\max}}$ is zero or negative,

$$v_{\max} = \frac{2D_e - \hbar\omega}{\hbar\omega} \ .$$

This failure is due to the finite number $v_{\max}$ of bound states in the Morse potential. For energies above $v_{\max}$ all energies are possible, and the equation for E_v is no longer valid.

35.2.2.2 Vibrational selection rules

Electromagnetic fields of the type $E1$, e.g., black body radiation, can induce transitions between vibrational states and redistribute their populations such as to establish a thermal equilibrium. However, as the stronger transitions are induced by dipole migrations of charges, we need to analyze in more detail the selection rules imposed on the dipole moment $\langle f|\mathbf{d}|i\rangle$.

The states which are relevant for vibrational transitions are specified by $|\epsilon, v\rangle$, where ϵ denotes the electronic state of the molecule, since the vibrational spectrum depends on the electronic structure. The *Born-Oppenheimer approximation* allows us to consider the slow vibrations separately from the dynamics of the electrons. The time scale for electronic transitions is $1/\Delta E_e = 10^{-16}\,\mathrm{s}^{-1}$, and for a nuclear vibration it is $1/\Delta E_v = 10^{-13}\,\mathrm{s}^{-1}$. For each internuclear distance the electrons form an adapted stationary state, minimizing their energy for that distance. This is equivalent to the formation of an adiabatic interaction potential between the nuclei on which the nuclei can vibrate. To find out which vibrational transitions are possible, we need to calculate the matrix,

$$\langle \epsilon', v'|\hat{\mathbf{d}}|\epsilon, v\rangle = \langle v'|\hat{\mathbf{d}}_\epsilon|v\rangle \ . \tag{35.49}$$

The dipole moment, $\mathbf{d}_\epsilon = \langle\epsilon|\hat{\mathbf{d}}|\epsilon\rangle$, of the molecule depends on the distance of the nuclei, since the electronic orbitals $|\epsilon\rangle$ depend on distance. Therefore, we can expand,

$$\hat{\mathbf{d}} = \hat{\mathbf{d}}_0 + \frac{d\hat{\mathbf{d}}_0}{dx}\hat{x} + \frac{1}{2}\frac{d^2\hat{\mathbf{d}}_0}{dx^2}\hat{x}^2 + .. \ . \tag{35.50}$$

Therefore, the transition matrix is,

$$\langle \epsilon', v'|\hat{\mathbf{d}}|\epsilon, v\rangle = \hat{\mathbf{d}}_0\delta_{v,v'} + \frac{d\hat{\mathbf{d}}_0}{dx}\langle v'|\hat{x}|v\rangle + \frac{d^2\hat{\mathbf{d}}_0}{dx^2}\langle v'|\hat{x}^2|v\rangle + .. \ . \tag{35.51}$$

The first term disappears, that is, transitions can only occur, when the dipole moment varies with the distance. Therefore, *homonuclear dimers do not undergo vibrational transitions.*

For heteronuclear molecules with electronic charges that do not depend on the interatomic distance, the dipole moment varies linearly with small displacements. In this case, we only need the second term of the expansion. Within the harmonic

approximation, the position operator can be expressed by, $\hat{x} \propto \hat{a} + \hat{a}^\dagger$. Therefore, only transitions $\Delta v = \pm 1$ are possible. However, due to anharmonicities, higher order terms, $\hat{x}^n \propto (\hat{a} + \hat{a}^\dagger)^n$ become influential, and transitions with $\Delta v = \pm 2, \pm 3, ..$ become possible.

Thus, in anharmonic potentials, the vibrational selection rules are replaced by the concept the overlapping wavefunctions called *Franck-Condon factor*.

Raman spectroscopy is a very useful tool to analyze ro-vibrational spectra. In this method, inelastic Raman scattering gives rise to Stokes and anti-Stokes lines in the spectrum at frequencies corresponding to $\Delta v = \pm 1, \pm 2$. The ground state spectrum is asymmetric, because of the absence of the lower state. In homonuclear dimers, the nuclear spins have a major impact on the Raman spectra. Parity considerations show that there can only be odd or even lines.

35.2.3 The Franck-Condon principle

The intensity of molecular transitions are, qualitatively, described by the *Franck-Condon principle*, whose *classical* formulation goes as follows:

> *The jump of an electron in a molecular transition occurs during a very small time compared to the time scale of the nuclear motion, so that immediately after the jump, the nuclei remain practically at the same positions and at the same velocities as before the jump* [437].

For this reason, the transitions are drawn vertically in the scheme of potentials shown in Fig. 35.11(right). To yield considerable rates, transitions must occur when the nuclear velocities in the two coupled states are similar, which is the case at the classical turning points. At these points, the wavefunctions are maximal [6].

With this Franck-Condon principle, we can determine which are the strongest transitions between vibrational levels of a molecule, as represented in Fig. 35.11(left). In particular, we are interested in transitions between vibrational levels of different electronic states.

The exact transition probabilities are calculated via the square module of the *transition dipole moment* (TDM). The TDM is an out-of-diagonal matrix element of the electric dipole operator $\mathbf{M}$, given by:

$$\mathbf{M}_{AB} = \langle \Psi^{(A)} | \hat{\mathbf{M}} | \Psi^{(B)} \rangle \ , \tag{35.52}$$

being $|\Psi^{(A)}\rangle$ and $|\Psi^{(B)}\rangle$ two molecular states.

Still within the Born-Oppenheimer approximation, we can split the dipole moment operator into two terms, a nuclear and an electronic term, according to:

$$\hat{\mathbf{M}}(\mathbf{r}, \mathbf{R}) = \hat{\mathbf{M}}_e(\mathbf{r}, \mathbf{R}) + \hat{\mathbf{M}}_n(\mathbf{R}) \ . \tag{35.53}$$

Thus, the TDM is:

$$\begin{aligned} \mathbf{M}_{AB} &= \int \Psi^{(A)*} \hat{\mathbf{M}} \Psi^{(B)} dR dr \qquad (35.54) \\ &= \int \hat{\mathbf{M}}_e \psi_e^{(A)*} \ \psi_e^{(B)} \ \psi_n^{(A)*} \ \psi_n^{(B)} dR dr + \int \hat{\mathbf{M}}_n \psi_n^{(A)*} \ \psi_n^{(B)} \int \psi_e^{(A)*} \ \psi_e^{(B)} dr dR \ . \end{aligned}$$

[6] Note that the presence of a hyperfine structure can modify the selection rules.

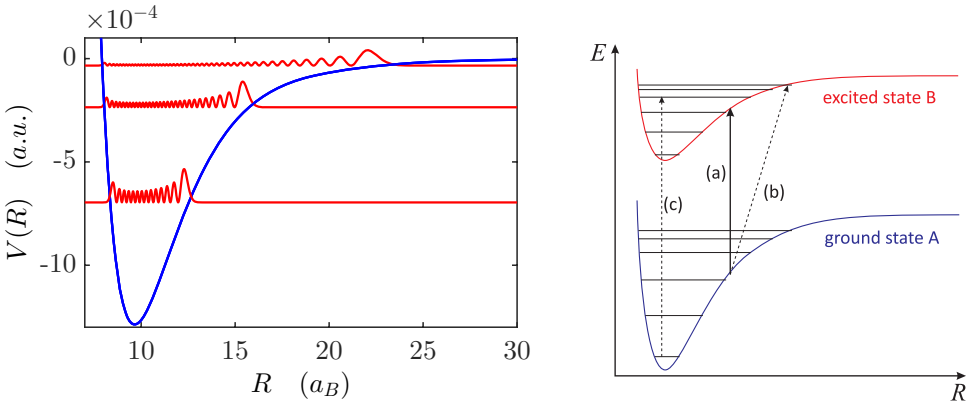

Figure 35.11: (Left, code) Molecular wavefunctions in a potential for three different vibrational states. (Right) Pictorial representation of the classical statement of the Franck-Condon principle. Transition (a) has high intensity (or probability), because here both, the position and the relative velocity of the nuclei do not change. Transitions (b) and (c) are unlikely, because they necessitate either a change in the position of the nuclei (case b) or in velocity (case c).

Since the electronic wavefunctions of different states are orthogonal, it follows that $\int \psi_e^{(A)*}\psi_e^{(B)}dr = 0$, canceling the second term.

Looking at the first term, we note that the electronic dipole moment $\hat{\mathbf{M}}_e(\mathbf{r},\mathbf{R})$ also depends on the nuclear coordinates as a parameter. The quantum formulation of the Franck-Condon principle consists in stating that, in a *molecular state, the electronic dipole moment varies little with the nuclear coordinates*. Thus, along with the condition of the Born-Oppenheimer approximation, we can split the first TDM term into electronic and nuclear integrals:

$$\mathbf{M}_{AB} = \int \hat{\mathbf{M}}_e \psi_e^{(A)*}\ \psi_e^{(B)}\ dr \int \psi_n^{(A)*}\ \psi_n^{(B)} dR\ . \tag{35.55}$$

Thus, we have a comparative expression for the transition probability given by:

$$P_{AB} \propto |\mathbf{M}_{AB}|^2 = \left|\int \hat{\mathbf{M}}_e \psi_e^{(A)*}\ \psi_e^{(B)}\ dr\right|^2 \left|\int \psi_n^{(A)*}\ \psi_n^{(B)} dR\right|^2\ . \tag{35.56}$$

The second factor in equation (35.56) is called *Franck-Condon factor*. When we study the transitions between two electronic states, this factor compares the intensities of the transitions between distinct pairs of vibrational levels.

Example 253 (*Ultracold molecules*): Ultracold molecules have been proposed for a variety of applications, such as ultra high resolution spectroscopy [631], test of fundamental laws of physics [244, 822], quantum computation [243] and others[158]. Most of these applications, however, require that the molecular sample be in a single quantum state. This is an experimental challenge, since molecules have more degrees of freedom than atoms, such as rotation and

vibration.

To create a sample of molecules trapped in the ground state of vibration, a possible method is to first produce the molecules from ultracold atoms using a process called *photoassociation*, and then pump these molecules to the vibrational ground state.

Photoassociation consists in the excitation of a pair of free atoms to the bound state of an excited electronic potential by the absorption of a photon. The pair then decays by spontaneous emission either back to the state of two free atoms (which is not desirable), or to a bound state of the fundamental electronic potential. For Rb_2 molecules, photoassociation is efficient at certain frequencies [636], with the $A^1\Sigma_u^+$ potential as the excited state (see Fig. 35.12).

Soon after being formed, the molecules are usually in levels of high vibrational energy (around $\nu \approx 80$), because these levels connect best (high Franck-Condon overlap) to the excited state. The transfer of population to the fundamental state of vibration is done by 'optical pumping'.

Vibrational cooling via optical pumping can be done by irradiating a broad frequency band of light that excites transitions to vibrational levels of the excited nuclear potential. These excited states are chosen such that their Franck-Condon overlap with the ground states of lower vibrational energy is larger. As a consequence, a molecule sent to an excited state returns with higher probability to a level of lower vibrational energy. The absorption and emission cycles are repeated, until the molecules reach the fundamental vibrational state.

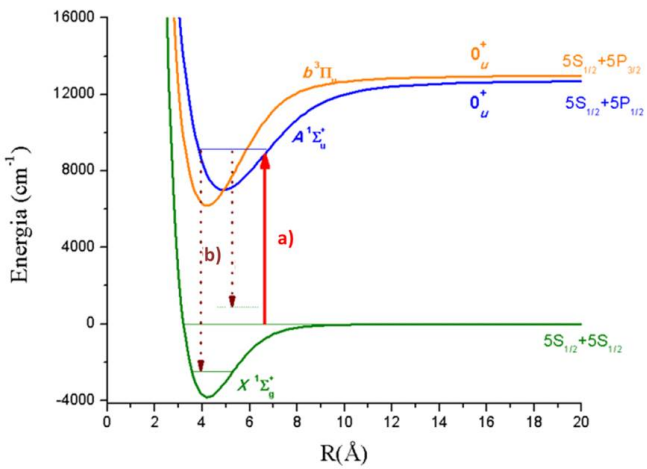

Figure 35.12: Photoassociation scheme to form Rb_2 molecules. In process (a), a pair of free atoms absorbs a photon of the incident radiation, forming a bound state in the excited potential. Then, in (b), the newly formed molecule decays by spontaneous emission to a bound state of the fundamental potential, or it can return to a state of two free atoms.

35.2.4 Rotational progression

Until now we neglected the centrifugal energy (35.38),

$$V_\ell(R) = \frac{\mathbf{L}^2}{2M_r R^2} = \frac{\hbar^2 \ell(\ell+1)}{2M_r R^2} \ . \tag{35.57}$$

As we shall now see, this energy creates a substructure of the vibrational levels.

The moments of inertia in the three axes of space are,

$$I_{qq} = \sum_i m_i r_i^2(q) \ . \tag{35.58}$$

The kinetic energy of the rotation is,

$$E_{\rm rot} = \tfrac{1}{2} \sum_{q=1,2,3} m_q \mathbf{v}_q^2 = \tfrac{1}{2} \sum_{q=1,2,3} I_{qq}\omega_q^2 = \frac{L_x^2}{2I_{xx}} + \frac{L_y^2}{2I_{yy}} + \frac{L_z^2}{2I_{zz}} \ , \tag{35.59}$$

with the angular momentum $L_q = I_{qq}\omega_q$.

Many molecules have a symmetry axis, such that there are two different moments of inertia, $I_\perp \equiv I_{xx} = I_{yy}$ and $I_\parallel \equiv I_{zz}$. Interpreting angular momenta as quantum operators,

$$\hat{H} = \frac{\hat{\mathbf{L}}^2}{2I_\perp} + \left(\frac{1}{2I_\parallel} - \frac{1}{2I_\perp}\right) \hat{L}_z^2 \ . \tag{35.60}$$

We must first consider the rotation of the molecule relative to the symmetry axis of the molecule. Forgetting external fields we calculate the energy of the molecule associated with the observables $\hat{\mathbf{L}}^2$ with the quantum number ℓ and $\hat{\mathbf{L}}_z$ with the quantum number K. We find the eigenvalues,

$$E(\ell, K, M_\ell) = \frac{\hbar^2 \ell(\ell+1)}{2I_\perp} + \left(\frac{1}{2I_\parallel} - \frac{1}{2I_\perp}\right) \hbar^2 K^2 = B\ell(\ell+1) + (A-B)K^2 \ , \tag{35.61}$$

with $\ell = 0, 1, .., \ K = -\ell, .., \ell$, and $M_\ell = -\ell, .., \ell$ and introducing the *rotational constants*, $A \equiv \hbar^2/2I_\parallel$ and $B \equiv \hbar^2/2I_\perp$. We then analyze this equation in the context of applying an external field that defines both, the direction $\hat{\mathbf{e}}_z'$ in the laboratory as well as the projection of the angular motion $\hat{\mathbf{L}}^2$ on this direction, m_ℓ. That is, we have two axes, the internuclear axis $\hat{\mathbf{e}}_z$ and the rotation axis of the molecule $\hat{\mathbf{e}}_z'$.

Each level $|\ell, m_\ell\rangle$ is $2(2\ell+1)$ times degenerate, because $K = -\ell, .., \ell$ and K can be positive or negative. Each level ℓ contains $2\ell+1$ states. Note that for spherical molecules, $A = B$, and the degree of freedom K disappears. In Exc. 35.2.6.2 we calculate the rotational spectrum of a homonuclear diatomic molecule.

The rotational constant can be approximated by,

$$E_{\rm rot} = \frac{\hbar^2 \ell(\ell+1)}{2M_r \langle R^2 \rangle} \ , \tag{35.62}$$

where $\sqrt{\langle R^2 \rangle}$ is the expectation value for the outer turning point of the vibrational level. As an example, the rotational constant for the vibrational state of $^{87}\mathrm{Rb}_2$ which is 5.9 cm^{-1} below the dissociation limit is $B_v = \nu_{\rm rot}^{\ell=1} - \nu_{\rm rot}^{\ell=0} = 81$ MHz. To be more precise, we would need to calculate $\langle R^2 \rangle_v = \langle \psi_v | R^2 | \psi_v \rangle$.

Transitions between vibrational levels occur together with rotational transitions $\Delta\ell = \pm 1$. Therefore, the frequencies of transitions depend on the rotational constant B_v, which depends on the vibrational state. The energies of the molecule are,

$$E_{v,\ell} = \hbar\omega(v+1/2) - \hbar\omega x_e(v+1/2)^2 + .. + hcB_v\ell(\ell+1) - hcD_v\ell^2(\ell+1)^2 + .. \ . \quad (35.63)$$

Under the influence of a rapid rotation, the atoms of the molecule are subjected to centrifugal force and, hence, are further away from each other [7].

Since at ambient temperatures many rotational levels are populated, we experimentally observe many lines known as P-branch, when $\Delta\ell = -1$, as Q-branch, when $\Delta\ell = 0$, and as R-branch, when $\Delta\ell = 1$. See Exc. 35.2.6.3.

35.2.4.1 Rotational selection rules

For transitions between electronic states, the selection rules are $\Delta r = 0, \pm 1$. Rotational transitions can occur between levels $\Delta r = \pm 1$. $\Delta r = 0$ is not allowed, because it violates the conservation of parity. Note also that the nuclear isotope influences the ro-vibrational levels via the reduced mass.

We consider a linear molecule in the state $|\epsilon, \ell, M_\ell\rangle$, where ϵ denotes the electronic and vibrational state of the molecule. To find out which transitions are possible, we need to calculate the matrix,

$$\langle \epsilon', \ell', M'_\ell | \mathbf{d} | \epsilon, \ell, M_\ell \rangle = \langle \ell', M'_\ell | \mathbf{d}_\epsilon | \ell, M_\ell \rangle \ , \quad (35.64)$$

with $\mathbf{d}_\epsilon = \langle \epsilon | \mathbf{d} | \epsilon \rangle$. Here, we apply the *Born-Oppenheimer approximation*, which allows us to separate the dynamics of the electrons and also the vibrations of the molecule, because these movements are so fast, that they are always in a steady state, adiabatically following the slow movement of the rotation.

The selection rules can now be derived from the *Wigner-Eckart theorem*,

$$\frac{\langle \ell', M'_\ell | \mathbf{d}_\epsilon | \ell, M_\ell \rangle|^2}{|\langle \ell' \parallel \mathbf{d}_\epsilon \parallel \ell, M_\ell \rangle|^2} = \frac{1}{2\ell'+1} \begin{pmatrix} \ell & 1 & \ell' \\ m_\ell & \kappa & -m'_\ell \end{pmatrix} \ . \quad (35.65)$$

We find $\Delta\ell = 1$ e $\Delta M_\ell = 0, \pm 1$. See Exc. 35.2.6.4.

35.2.5 Computation of vibrational states

35.2.5.1 Estimation of the localization energy

One consequence of Heisenberg's uncertainty relation is that a certain *localization energy* is always required to localize a particle. The zero-point energy of the harmonic oscillator is an example: If the potential is shallower than this energy, it will not be capable of localizing a particle.

As another example, let us consider the attractive potential,

$$V = -\frac{C_n}{R^n} \ . \quad (35.66)$$

[7] See [39], p.326

The space available for the particle is limited between the classical turning point, which for a given energy is $R_t = (C_n/|E|)^{1/n}$. The momentum corresponding to this energy is $k_t = (2m_{\rm red}|E|/\hbar^2)^{1/2}$. Heisenberg's uncertainty relation requires,

$$k_t R_t > \pi \ , \tag{35.67}$$

that is, at least half of the wavelength must fit within the potential (between 0 and R_t) at the height of the bound state. Therefore,

$$\boxed{|E| > E_{\rm loc} \equiv \left(\frac{\pi\hbar^2}{2m_{\rm red}}\right)^{1/(1-2/n)} C_n^{1/(1-n/2)}} \ . \tag{35.68}$$

For a Coulomb potential, with $n = 1$ and $C_1 = e^2/4\pi\varepsilon_0$, we obtain the energy of the ground state of the hydrogen atom,

$$E > E_1 = -\frac{e^2}{4\pi\varepsilon_0 2a_B}\frac{4}{\pi^2} \ , \tag{35.69}$$

apart from a numerical factor. Note that the condition $k_t R_t > 2n$ yields the correct Bohr energies, $E = E_1/m^2$.

For $n = 2$, we do not get a condition for the energy. For the Casimir-Polder potential, $n = 3$ and $C_3 = 3\hbar\Gamma/2k^3$, we obtain,

$$E < -\frac{\pi^6\hbar^6}{8m_{\rm red}^3 C_3^2} = \frac{(\pi\hbar k)^6}{2m_{\rm red}^3(3\hbar\Gamma)^2} \ . \tag{35.70}$$

This means that for $n \geq 3$, in contrast to the Coulomb potential, to minimize the momentum-position uncertainty, the *binding energy* must be *lower* than a certain limit.

We find that for a Coulomb potential the state with the smallest momentum-position uncertainty is the ground state. No other state can have a lower energy, but there is an infinite number of states just below the threshold. In contrast, for a $1/R^3$ potential the state with the smallest momentum-position uncertainty is the least bound state. No other state can have a higher energy, but there is an infinite number of states at the bottom of the potential. In other words, *$1/R$ potentials do not have a lid and $1/R^3$ potentials do not have a bottom.*

35.2.5.2 The LeRoy-Bernstein method

The *LeRoy-Bernstein method* allows us to estimate the highest bound levels. It only applies near the dissociation limit, where the semi-classical formula of quantization is valid,

$$v + \tfrac{1}{2} = \sqrt{\frac{8m_{\rm red}}{\hbar^2}}\int_0^{R_t} dR\sqrt{E(v) - V(R)} \ . \tag{35.71}$$

Inserting the potential

$$V(R) = D_e - \frac{C_n}{R^n} \ , \tag{35.72}$$

we get

$$\boxed{E(v^*) = D_e - E_{\rm loc}\left(\frac{(n-2)\Gamma\left(1+\frac{1}{n}\right)}{\sqrt{\pi}\Gamma\left(\frac{1}{2}+\frac{1}{n}\right)}\ v^*\right)^{2n/(n-2)}}\ , \tag{35.73}$$

where $v^* = v_D - v$ is a number counting the vibrational levels from the top to the bottom starting at the dissociation limit and $E_{\rm loc}$ is the localization energy calculated in (35.68).

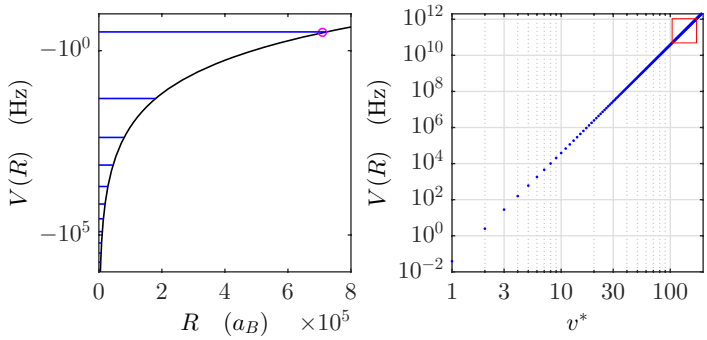

Figure 35.13: (code) (a) Highest vibrational states of the $(2)\Sigma_u^+$ potential of Yb_2 dimers obtained by the LeRoy-Bernstein method. The magenta circle corresponds to the localization energy calculated in (35.74). (b) Energies of the highest vibrational states as a function of the vibrational quantum number v^*. The states inside the red box have been measured [905].

Again, for the Casimir-Polder potential we get [905],

$$E(v^*) = D_e - X_0(v_D - v)^6 \qquad \text{with} \qquad X_0 = \frac{h^6}{m_{\rm red}^3 C_3^2}\left(\frac{\Gamma(4/3)}{2\sqrt{2\pi}\Gamma(5/6)}\right)^6 . \tag{35.74}$$

Do the Exc. 35.2.6.5.

35.2.5.3 Open channels

For a given interatomic potential $V(R)$, neglecting the spin structure [496], the relative wavefunction of a two-atom system satisfies the Schrödinger equation,

$$\left[-\tfrac{1}{2\mu}\Delta + V(R)\right]\psi(\mathbf{R}) = E\psi(\mathbf{R})\ . \tag{35.75}$$

Separating the radial and angular contributions, $\psi(\mathbf{R}) \equiv Y(\vartheta,\varphi)f(R)/R$, we obtain,

$$\left[-\frac{1}{2\mu}\frac{\partial^2}{\partial R^2} + V(R) + \frac{l(l+1)}{2\mu R^2}\right] f(R) = Ef(R)\ . \tag{35.76}$$

Now, we introduce the local wavevector, $k(R) = \sqrt{2\mu[E - V(R)] - l(l+1)/R^2}$ and write,

$$f'' = -k^2 f\ . \tag{35.77}$$

This differential equation can be solved numerically [see Fig. 35.14(a)].

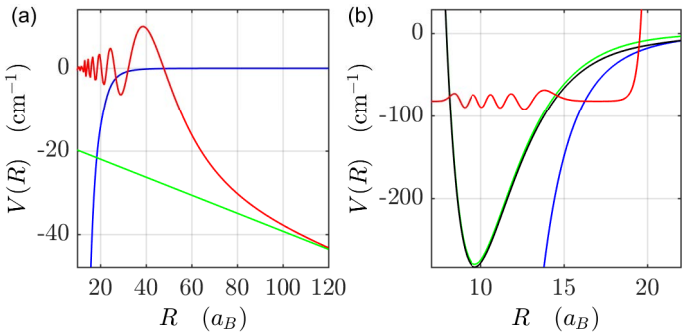

Figure 35.14: (code) (a) Numerical computation of the relative wavefunction for a low energy collision, $E \gtrsim 0$ and $\ell = 0$. The blue curve shows the interatomic Li-Rb potential (a)$^3\Sigma$, the red curve illustrates the relative Broglie wavefunction of the molecule. The asymptote of this extrapolated wavefunction (green curve) cuts the abscissa at $a_s = -120a_B$, which is just the scattering length for collisions in this channel. (b) Numerical computation of the wavefunction for a vibrational state. The potential is an interpolation (black) between a short-range Morse potential (green), and a long range potential (blue). The red curve illustrates the relative wavefunction for the ninth vibrational state (counting from ground state).

35.2.5.4 Milne equation

The Schrödinger equation,

$$\left[\frac{d^2}{dR^2} + k(R)^2\right]\Psi(R) = 0 \qquad \text{with} \qquad k(R) = \sqrt{\tfrac{2m_{\rm red}}{\hbar^2}(E - V)} \tag{35.78}$$

can be transformed using the following ansatz,

$$\Psi(R) \equiv \sqrt{\frac{2m_{\rm red}}{\pi\hbar^2}}\alpha(R)\sin\beta(R) \ . \tag{35.79}$$

Insertion yields,

$$\left(\alpha'' + k^2\alpha - \alpha\beta'^2\right)\sin\beta + \left(2\alpha'\beta' + \alpha\beta''\right)\cos\beta = 0 \ . \tag{35.80}$$

Setting the oscillatory terms separately to zero, we obtain,

$$\frac{\beta''}{\beta'} = -\frac{2\alpha'}{\alpha} \qquad \text{and} \qquad \alpha'' + k^2\alpha - \alpha\beta'^2 = 0 \ . \tag{35.81}$$

The first differential equation is solved by,

$$\beta' = \frac{1}{\alpha^2} \qquad \text{that is} \qquad \beta(R) = \int \frac{dR}{\alpha(R)^2} \ . \tag{35.82}$$

Insertion into the second one yields the so-called *Milne equation* ,

$$\alpha'' + k^2\alpha - \frac{1}{\alpha^3} = 0 \ . \tag{35.83}$$

Example 254 (*Milne equation for van der Waals potentials*): Here, we analyze the solution of the Milne equation for a C_6-potential at very long range, $R \to \infty$, and vanishing temperature, $E \to 0$. Semi-classically, the amplitude $\alpha_{WKB}(R) \simeq 1/\sqrt{k(R)}$ diverges asymptotically, so that,

$$\left(\frac{d^2}{dR^2} - \frac{2m_{\rm red}C_6}{\hbar^2 R^6}\right)\alpha \simeq 0$$

with the solution for $R \gg R_B$,

$$\alpha(R) = \alpha_\infty\left(1 - (R/R_B)^4\right) \qquad \text{with} \qquad R_B \equiv \left(\frac{2m_{\rm red}C_6}{20\hbar^2}\right)^{1/4} .$$

Substituting this into the phase equation,

$$\begin{aligned}\beta(R) &= k_\infty(R_\infty - a_s) + \int_{R_\infty}^{R} \frac{dR}{\alpha(R)^2} \\ &\simeq k_\infty(R_\infty - a_s) - \tfrac{1}{\alpha_\infty^2}\int_R^{R_\infty}\left(1 + 2\left(\tfrac{R}{R_B}\right)^4\right)^2 dR = k_\infty\left(R - a_s - \frac{2}{3}\left(\tfrac{R_B}{R}\right)^4 R\right)\end{aligned}$$

with $\beta_\infty = k_\infty(R_\infty - a_s)$ and a_s is the s-wave scattering length.

35.2.5.5 Bound states

For bound states, we must simultaneously satisfy the eigenvalue problem. We can, for example, guess an eigenvalue E, calculate the associated wavefunction $f(R)$, check whether it diverges for $R \to \infty$, and vary E until $f(R)$ no longer diverges. Fig. 35.14(b) shows the wavefunction of a vibrational state obtained by solving the Schrödinger equation and adjusting the energy until the function stops diverging in the classically forbidden range.

35.2.5.6 The Fourier grid method

Another, extremely rapid, numerical method for determining the spectrum of vibrational states of a potential, is the *Fourier grid method*. It is based on the discretization of the Hamiltonian along the interatomic potential. We write the Hamiltonian as,

$$H\psi(R) = [T(R) + V(R)]\psi(R) = E\psi(R) \ , \tag{35.84}$$

and put it in a matrix form using the set of functions of the basis $\phi_i(R_j) = \delta(R_i - R_j)$ with $i = 1, .., N$, where $R_i = R_0 + i(R_N - R_0)/N$. This problem has N eigenvalues E_i. The Fourier grid method now evaluates the kinetic energy at each point in the grid. We insert the local terms $H_{ii} = H(R_i)$ and the non-local terms $H_{ij} = H(R_i, R_j)$ into the Hamiltonian, as well as the potential energies $V_{ij} = V(R_i)\delta_{ij}$. The kinetic energy is the inverse Fourier transform from momentum space of $T_{rs} = T(k_r)\delta_{rs} = (k_r^2/2\mu)\delta_{rs}$ and becomes [642, 616, 279],

$$H_{ij} = \frac{\pi^2}{4\mu(R_N - R_1)^2}(-1)^{i-j}\left(\frac{1}{\sin^2\frac{\pi(i-j)}{2N}} - \frac{1}{\sin^2\frac{\pi(i+j)}{2N}}\right) \qquad \text{for} \qquad i \neq j \tag{35.85}$$

$$H_{ij} = \frac{\pi^2}{4\mu(R_N - R_1)^2}\left(\frac{2N^2+1}{3} - \frac{1}{\sin^2\frac{\pi i}{2N}}\right) + V(R_i) \qquad \text{for} \qquad i = j \ .$$

To improve the wavefunction, we can interpolate,

$$\psi(q) = \sum\nolimits_{j=1}^{n} \psi(q_j)\ \mathrm{sinc}\frac{\pi(q-q_j)}{\Delta q}\ . \tag{35.86}$$

The method can be extended to coupled channels $\sigma = A, B$ via,

$$H_{\{i\sigma\}\{j\tau\}} = T_{ij}\delta_{\sigma\tau} + V_{\sigma\tau}(R_i)\delta_{ij}\ . \tag{35.87}$$

The Hamiltonian has the general form,

$$H = \begin{pmatrix} T & 0 \\ 0 & T \end{pmatrix} + \begin{pmatrix} V_A & 0 \\ 0 & V_B \end{pmatrix} + \begin{pmatrix} W_{AA} & W_{AB} \\ W_{AB} & W_{BB} \end{pmatrix}\ , \tag{35.88}$$

where all matrices V_k and W_k are diagonal [8].

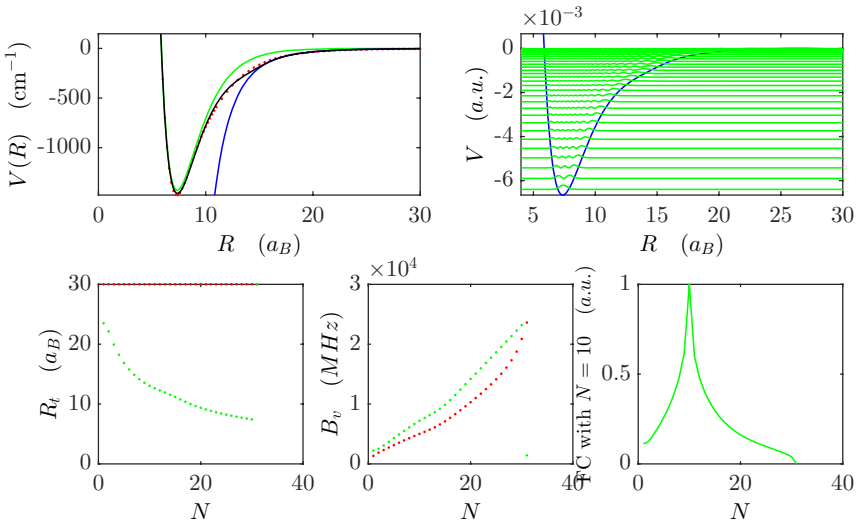

Figure 35.15: (code) Numerical computation of the wavefunction using the Fourier grid method at example of the interatomic potential Li-Rb $(1)^1\Pi$. (a) Short range Morse potential (green), long range (blue), interpolation (black) and [532]. (b) Vibrational wavefunctions, (c) external turning point (red) and center of mass (green), (d) rotational progression, and (e) Franck-Condon overlap with the tenth vibrational state.

35.2.6 Exercises

35.2.6.1 Ex: Transitions between vibrational states

Calculate the dipole moment between two arbitrary vibrational states of (a) a harmonic potential and (b) a Morse potential.

[8] Note that the Fourier grid method can be improved by using a grid with spacings adjusted to the potential gradient [529, 917, 580].

35.2.6.2 Ex: Rotational spectrum of diatomic molecules

Calculate the rotational spectrum for a diatomic molecule from the result (35.59).

35.2.6.3 Ex: Ro-vibrational spectrum

Determine the frequency spectra of ro-vibrational transitions for the branches P, Q, and R.

35.2.6.4 Ex: Rotational spectrum

Determine the rules and the spectrum of rotational transitions for a spherical molecule.

35.2.6.5 Ex: Momentum-position uncertainty for various potentials

a. Calculate the momentum-position uncertainty in Fock states of a 1D harmonic oscillator.
b. Calculate the radial momentum-position uncertainty of the Bohr levels ($\ell = 0$) in a hydrogen atom.
c. Calculate the radial momentum-position uncertainty of the vibrational states of two bound atoms numerically.
d. Interpret the results.

35.3 Van der Waals forces and spin coupling

The individual atoms have a complex substructure due to the angular momenta of the electronic motion, its spins and the nuclear spin. All of these angular momenta can interact, couple and generate new energy terms, which need to be taken into account when calculating the various potentials of interatomic interaction,

$$\hat{H} = \frac{\mathbf{P}^2}{2M_r} + V_{\text{Coulomb}}(R) + \sum_{k=1,2} \left(V_{\text{hfs}}^{(k)} + V_{\text{Zeem}}^{(k)} \right) + V_{\text{dipole,spin:spin}}(R) + V_{\text{dipole,spin:orbit}}(R) \ , \tag{35.89}$$

where k labels the two atoms. The Coulomb interaction for interacting alkaline gases can be expressed as:

$$V_{\text{Coulomb}}(R) = V_{\text{Coulomb}}^{S=0} \mathcal{P}_{S=0} + V_{\text{Coulomb}}^{S=1} \mathcal{P}_{S=1} \ . \tag{35.90}$$

The projectors $\mathcal{P}_{S=0,1}$ will be required to expand the Hilbert space for the degrees of freedom of the spins.

The *van der Waals forces* include all intermolecular forces. These are long-range forces that occur between mutually induced atomic dipoles [9].

[9] They also occur, in a pure form, in optical resonators such as in the *Casimir effect*. Since the lowest frequency in a cavity is $\omega = \sqrt{2}\pi c/L$, the zero point energies inside and outside the cavity are different. This causes an attractive force between the cavity mirrors $\sim 1/r^3, 1/r^4$.

35.3.1 Analytical models for short and long-range potentials

In general, the potentials are estimated by ab initio Hartree-Fock calculations. A short-range potential, or *Morse potential*, can be approximated by,

$$\boxed{V_{\text{Morse}} = D_m \left(\left[1 - e^{-B_m (R - R_m)} \right]^2 - 1 \right)} \ . \tag{35.91}$$

Here, B_m is the width of the minimum, R_m the position of the minimum, D_m the length. A long-range potential can be written,

$$\boxed{V_{\text{vdW}}(R) = D_e - \frac{C_6}{R^6} - \frac{C_8}{R^8} - \frac{C_{10}}{R^{10}}} \ . \tag{35.92}$$

D_e is the energy of dissociation. The *van der Waals coefficients* C_k, which determine the potential shape at large distances, can be calculated using other methods with higher precision. To obtain a closed formula, the short and long range parts can be joined by,

$$V = V_{\text{Morse}} F + V_{\text{vdW}} (1 - F) \ , \tag{35.93}$$

where $F \equiv e^{-(R/R_t)^{10}}$.

The situation is different for collisions of identical atoms, one in the ground and the other in an excited state. In this case, an additional *Movre-Pichler potential* dominated by a coefficient C_3 arises,

$$\boxed{V^e_{\text{vdW}} = -\frac{C_3}{R^3}} \ . \tag{35.94}$$

The interaction is interpreted as an exchange of excitation between resonances of two neighboring atoms and can be derive from the vectorial Green tensor for the interaction between two classical dipoles [10]. In the limit of small distances as compare to an optical wavelength, $kR \ll 1$, we find,

$$V^e_{\text{vdW}}(R) = -\frac{3}{2} \lambda \Gamma^{(0)} \hat{\mathbf{e}}^*_d \mathfrak{Re}\, \mathcal{G}_b(\mathbf{r}, \mathbf{r}', \omega) \hat{\mathbf{e}}_d = -\frac{3}{2} \lambda \Gamma^{(0)} \frac{2}{k^3 R^3} \frac{k}{4\pi} \equiv \frac{C_3}{R^3} \ . \tag{35.95}$$

Hence, the potential depends mainly on the decay rate Γ,

$$C_3 = \frac{3\hbar\Gamma}{2k^3} \ , \tag{35.96}$$

and as it comes into play at larger distances, orbital characteristics will only cause minor deviations of the C_3 coefficient from the value (35.96).

In contrast, excited state collisions of different species are non-resonant, and hence $C_3 = 0$.

[10] See script on *Electrodynamics* (2023), Sec. 7.3.1.3.

35.3.2 Spin coupling in dimers, molecular quantum numbers

We consider two interacting alkaline atoms, each being described by a set of quantum numbers of internal angular momenta, they couple their spins:

$$\begin{aligned}
\mathbf{l}_i &\quad \text{angular momentum of the individual atom} \\
\mathbf{s}_i &\quad \text{electronic spin} \\
\mathbf{i}_i &\quad \text{nuclear spin} \\
\mathbf{l}_i + \mathbf{s}_i = \mathbf{j}_i &\quad \text{total electronic angular momentum} \\
\mathbf{j}_i + \mathbf{i}_i = \mathbf{f}_i &\quad \text{total angular momentum .}
\end{aligned} \tag{35.97}$$

When the atoms approach each other, at intermediate distances, they couple their spins:

$$\begin{aligned}
\ell \perp \hat{\mathbf{e}}_z &\quad \text{molecular rotation} \\
\mathbf{\Lambda} \equiv |M_L|\hat{\mathbf{e}}_z &\quad \text{projection of } \mathbf{L} \text{ onto the interatomic } \hat{\mathbf{e}}_z \\
\mathbf{\Sigma} \equiv M_S\hat{\mathbf{e}}_z &\quad \text{projection of } \mathbf{S} \text{ onto the interatomic } \hat{\mathbf{e}}_z \\
\mathbf{\Omega} \equiv \mathbf{\Lambda} + \mathbf{\Sigma} &\quad \text{projection of } \mathbf{L} + \mathbf{S} \text{ onto the interatomic } \hat{\mathbf{e}}_z \text{ .}
\end{aligned} \tag{35.98}$$

At short distances, they form a molecular dimer described by the quantum numbers:

$$\begin{aligned}
\mathbf{L} = \mathbf{l}_1 + \mathbf{l}_2 &\quad \text{total electronic angular momentum} \\
\mathbf{S} = \mathbf{s}_1 + \mathbf{s}_2 &\quad \text{electronic spin} \\
\mathbf{I} = \mathbf{i}_1 + \mathbf{i}_2 &\quad \text{nuclear spin} \\
\mathbf{f} = \mathbf{f}_1 + \mathbf{f}_2 &\quad \text{total angular momentum or } (\mathbf{L}, \mathbf{S})\mathbf{k} + \mathbf{I} \\
\mathbf{J} = \mathbf{\Omega} + \ell & \\
\mathbf{F} = \mathbf{f} + \ell & \quad .
\end{aligned} \tag{35.99}$$

The quantum numbers couple like,

$$\begin{array}{ccccccccccc}
\mathbf{l}_1 & + & \mathbf{l}_2 & = & \mathbf{L} & \xrightarrow{\hat{\mathbf{e}}_z} & \mathbf{\Lambda} & & & & \\
+ & & + & & + & & + & & & & \\
\mathbf{s}_1 & + & \mathbf{s}_2 & = & \mathbf{S} & \xrightarrow{\hat{\mathbf{e}}_z} & \mathbf{\Sigma} & & & & \\
= & & = & & = & & = & & & & \\
\mathbf{j}_1 & + & \mathbf{j}_2 & = & \mathbf{j} & \xrightarrow{\hat{\mathbf{e}}_z} & \mathbf{\Omega} & + & \ell & = & \mathbf{J} \\
+ & & + & & + & & & & & & + \\
\mathbf{i}_1 & + & \mathbf{i}_2 & = & \mathbf{I} & & & & & & \mathbf{I} \\
= & & = & & = & & & & & & = \\
\mathbf{f}_1 & + & \mathbf{f}_2 & = & \mathbf{f} & & & + & \ell & = & \mathbf{F}
\end{array} \tag{35.100}$$

Obviously, the atomic angular momentum is no longer a conserved quantity, but its projection onto the interatomic molecular axis is. The various possibilities how $\mathbf{L}$, $\mathbf{S}$, and $\mathbf{j}$ are projected onto the internuclear axis or directly couple to the rotational angular momentum ℓ are handled by Hund's cases (a) to (e). The spin coupling is described by $\{9j\}$-symbols, as discussed below.

35.3.3 Hund's coupling cases

The coupling force between atomic spins depends on the distance between the atoms. Due to the variety of spins appearing in atoms, there are many possibilities how they can couple. These were classified by Hund into five cases.

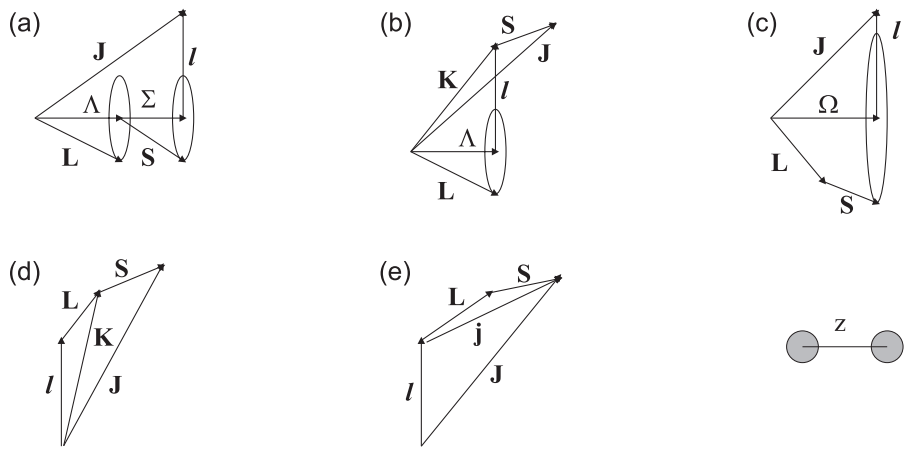

Figure 35.16: Hund's coupling cases.

35.3.3.1 Hund's case (a)

The molecular interaction is so strong that $\mathbf{L}$ and $\mathbf{S}$ couple to the z-axis instead of coupling to each other. This case is analogous to the Paschen-Back effect,

$$\begin{aligned} &\mathbf{L} \to \mathbf{\Lambda} \qquad \text{and} \qquad \mathbf{S} \to \mathbf{\Sigma} \\ &((\mathbf{\Lambda}, \mathbf{\Sigma})\mathbf{\Omega}, \ell)\mathbf{J} \ . \end{aligned} \tag{35.101}$$

A common notation is to label the states $\mathbf{\Lambda} = \mathbf{\Sigma}, \mathbf{\Pi}, \mathbf{\Delta}, ...$ That is, in the symbol $X(^{2S+1}\Lambda_\Omega)^{\pm}_{\sigma}$, where $\sigma = g, u$ is the inversion symmetry, $X, A, B, ..$ and $a, b, ..$ are the singlet and triplet series starting from the lowest energy levels. An alternative notation is to assign labels ordered by energy $X = (1), (2), ...$ Finally, $\pm$ is the symmetry upon reflection. For example, $X^1\Sigma^+_g$.

35.3.3.2 Hund's case (b)

$\mathbf{L}$ is projected onto the z-axis before coupling to ℓ. The resulting angular momentum afterward directly couples to $\mathbf{S}$.

$$\begin{aligned} &\mathbf{L} \to \mathbf{\Lambda} \\ &((\mathbf{L}, \ell)\mathbf{k}, \mathbf{S})\mathbf{J} \ . \end{aligned} \tag{35.102}$$

35.3.3.3 Hund's case (c)

L and **S** couple together instead of projecting themselves onto the z-axis. This case is analogous to the Zeeman effect,

$$(\mathbf{L},\mathbf{S})\mathbf{j} \to \mathbf{\Omega} \qquad (35.103)$$
$$(\mathbf{\Omega},\ell)\mathbf{J}\ .$$

A common notation is to label the states by $\mathbf{\Omega} = 0, 1, 2, ...$ That is, in the symbol $X(\Omega)_s^{\pm}$, the letter $X = 1, 2, ..$ is a label ordered by energy. For example $2(0_g^-)$.

35.3.3.4 Hund's case (d)

L is not projected on the z- axis, but directly couples to the rotational angular momentum. The resulting angular momentum afterward only couples to the **S**

$$((\mathbf{L},\ell)\mathbf{k},)\mathbf{J}\ . \qquad (35.104)$$

35.3.3.5 Hund's case (e)

L and **S** mutually couple as in the case (c), but are not projected on the z-axis, but couple directly with ℓ, which is quantized,

$$((\mathbf{L},\mathbf{S})\mathbf{j},\ell)\mathbf{J}\ . \qquad (35.105)$$

35.3.4 Molecular hyperfine structure

The scattering length in specific channels can be expressed via singlet and triplet scattering lengths,

$$a_{|f_1,m_{f1}\rangle+|f_2,m_{f2}\rangle} = P_{S=0}a_s + P_{S=1}a_t\ . \qquad (35.106)$$

The projectors are $P_S = |\langle S|(f_1f_2)f\rangle|$. According to [138, 644] the recoupling from the uncoupled hyperfine representation into the short range representation is given by,

$$\langle Sm_S\ Im_I\ \ell' m_{\ell'}|f_1m_{f1}\ f_2m_{f2}\ \ell m_\ell\rangle = \delta_{\ell\ell'}\delta_{m_\ell m'_\ell}\sum_{f,m_f}\langle Sm_S\ Im_I|fm_f\rangle\langle f_1m_{f1}\ f_2m_{f2}|fm_f\rangle\times$$
$$\times\begin{Bmatrix} s_1 & s_2 & S \\ i_1 & i_2 & I \\ f_1 & f_2 & f \end{Bmatrix}\sqrt{\hat{S}\hat{I}\hat{f}_1\hat{f}_2}\left(\frac{1-(1-\delta_{f_1f_2})(-1)^{S+I+\ell}}{\sqrt{2-\delta_{f_1f_2}}}\right)\ . \qquad (35.107)$$

The last bracket is dropped for unsymmetrized recoupling. We will study examples of spin recoupling in the ground state channels in Exc. 35.3.5.1, 35.3.5.2, and 35.3.5.3.

35.3.5 Exercises

35.3.5.1 Ex: Spin recoupling of identical ^{87}Rb ground state channels

a. Unravel the molecular hyperfine structure of identical ^{87}Rb ground state channels.
b. Project the collisional channels $|f_1m_{f1}\ f_2m_{f2}\rangle = |1-1\ 1-1\rangle$ and $|22\ 22\rangle$ on the singlet and triplet potentials, $S = 0, 1$.

35.3.5.2 Ex: Spin recoupling of ^{6}Li^{87}Rb ground state channels

a. Unravel the molecular hyperfine structure of ^{6}Li^{87}Rb ground state channels.
b. Project the collisional channels on short range potentials.

35.3.5.3 Ex: Hyperfine structure of ^{6}Li^{23}Na and ^{6}Li^{87}Rb

a. Unravel the molecular hyperfine structure of ^{6}Li^{23}Na and ^{6}Li^{87}Rb bound state.
b. How about the open channels?

Chapter 36

Collisions

Until now, we mostly restricted our studies to individual atoms or molecules. In practice, however, we investigate atomic or molecular gases by spectroscopic methods. The constituents of thermal gases are constantly in motion. They are subject to Doppler-shifts of their spectral lines and they collide with each other. Colliding atoms often get so close, that the electronic orbitals affect each other, which leads to distortions of the interaction potentials, spectral lineshifts and modifications of the interatomic forces. These are the topics to be addressed in the present chapter.

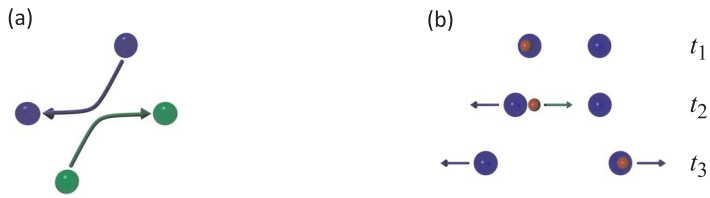

Figure 36.1: Atoms may interact via exchange of (a) virtual photons or (b) real photons.

36.1 Motion of interacting neutral atoms

The following sections, devoted to the relative motion of two neutral atoms, are adapted from J. Walraven's excellent lectures on *Quantum Gases* available at [953]. The atoms are presumed to move slowly, typically at large separation, and to interact pair wise through a potential of the Van der Waals type. The term slowly refers to,

$$k_{\text{therm}} r_0 \ll 1 \qquad \text{where} \qquad \lambda_{\text{therm}} = \frac{2\pi}{k_{\text{therm}}} = \sqrt{\frac{2\pi\hbar^2}{m k_{\text{B}} T}} \tag{36.1}$$

is the *thermal de Broglie wavelength* and r_0 the range of the interaction potential. As the Van der Waals interaction gives rise to elastic collisions, the total energy of the relative motion is conserved in time. As the potential energy vanishes at large interatomic separation the total energy is usually expressed in the form $E = \hbar^2 k^2 / 2m_r$. This implies that also the wavenumbers for the relative motion before and after the collision must be the same and shows that, far from the potential center, the collision can only affect the phase of the wavefunction - not its wavelength. Apparently, the appearance of a shift in phase relative to the free atomic motion

provides the key to the quantum mechanical description of elastic collisions. This being said, we postpone the discussion of the actual collisional behavior to Sec. 36.2. First we prepare ourselves for this discussion by analyzing the stationary states for the motion in the presence of an interaction potential.

An important simplifying factor in the description of ultracold collisions is the emergence of universal behavior in the relative motion of the atoms. The latter applies to low-energy collisional states as well as to weakly bound states. Universal means in this context that, asymptotically (for $r \gg r_0$), the wavefunctions become independent of the details of the interaction potential but can be characterized in terms of a few parameters, each representing some characteristic length scale of the collisional system. In other words, very different short-range physics can give rise to the same scattering behavior. From a theory point of view this universality has the enormous advantage that the essential features of ultracold collisions can be described with the aid of simple model potentials for which analytical solutions can be obtained.

In our analysis of the collisional motion three characteristic length scales will appear, the interaction range r_0 the scattering length a and the effective range r_e, each expressing a different aspect of the interaction. The range r_0 is the distance beyond which the interaction may be neglected even for $k \to 0$. The second characteristic length, the s-wave scattering length a, acts as an effective hard-sphere diameter. It is a measure for the interaction strength and determines the collision cross section in the limit $k \to 0$ as will be elaborated on in Sec. 36.2. The third characteristic length, the effective range re expresses how the potential affects the energy dependence of the cross section and determines when the $k \to 0$ limit is reached.

The s-wave scattering length is the central parameter for the theoretical description of bosonic quantum gases. It determines both the thermodynamic and the collisional properties of these gases. In single-component fermionic gases the s-wave scattering length plays no role because the wavefunction for the relative motion of the atoms has to be antisymmetric. In two-component fermionic gases this restriction is absent for collisions between atoms of different components. As a consequence, in these systems the inter-component s-wave scattering length determines the collision related properties - for instance the thermalization rate.

In Sec. 36.1.1 we show how the phase shift appears as a result of interatomic interaction in the wavefunction for the relative motion of two atoms. For free particles the phase shift is zero. An integral expression for the phase shift is derived. In Sec. 36.1.2 and beyond we specialize to the case of low-energy collisions ($kr_0 \ll 1$). The basic phenomenology is introduced and analyzed for simple model potentials like the hard-sphere (Sec. 36.1.2) and the spherical well (Sec. 36.1.3), where the existence of a short range is manifest. For the discussion of arbitrarily shaped potentials, we refer to the script [953].

36.1.1 The collisional phase shift

36.1.1.1 Schrödinger equation

The starting point for the description of the relative motion of two atoms at energy E is the Schrödinger equation (25.33),

$$\left[\frac{1}{2m_r}\left(p_r^2+\frac{\mathbf{L}^2}{r^2}\right)+V(r)\right]\psi(r,\vartheta,\varphi)=E\psi(r,\vartheta,\varphi)\ . \tag{36.2}$$

Here m_r is the reduced mass of the atom pair and $V(r)$ the interaction potential. As discussed in Sec. 25.1.3 the eigenfunctions $\psi(r,\vartheta,\varphi)$ can be separated in a radial and a angular part, $\psi = R_\ell(r)Y_{\ell m}(\vartheta,\varphi)$, where the functions $Y_{\ell m}$ are spherical harmonics and the functions $R_\ell(r)$ satisfy the radial wave equation,

$$\left[\frac{\hbar^2}{2m_r}\left(-\frac{d^2}{dr^2}-\frac{2}{r}\frac{d}{dr}+\frac{\ell(\ell+1)}{r^2}\right)+V(r)\right]R_\ell(r)=ER_\ell(r)\ . \tag{36.3}$$

By the separation procedure the angular momentum term is replaced by a repulsive effective potential,

$$V_{\rm rot}(r)=\frac{\hbar^2\ell(\ell+1)}{2m_r r^2}\ , \tag{36.4}$$

representing the rotational energy of the atom pair at a given distance and for a given rotational quantum number ℓ. In combination with an attractive interaction it gives rise to a centrifugal barrier for the radial motion of the atoms. This is illustrated in Fig. 36.2 for the example of hydrogen.

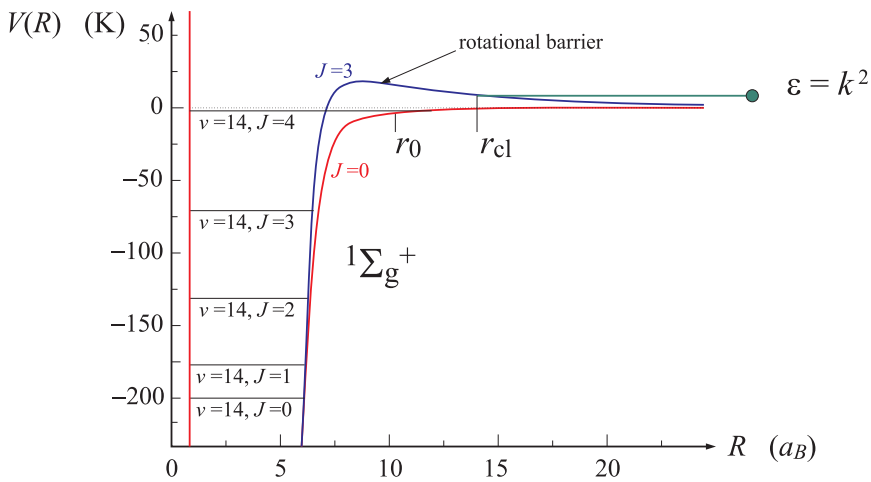

Figure 36.2: Example showing the high-lying bound states near the continuum of the singlet potential ${}^1\Sigma_g^+$ (the bonding potential) of the hydrogen molecule; v and J are the vibrational and rotational quantum numbers, respectively. The dashed line shows the effect of the $J=3$ centrifugal barrier. The presence of a rotational barrier gives rise to an exponential suppression of the radial wavefunction for $r<r_{tp}$ and is negligible at distances where the interaction becomes noticeable $r \ll r_0$.

To analyze the radial wave equation we introduce reduced energies,

$$\varepsilon = \frac{2m_r E}{\hbar^2} = \begin{cases} k^2 & \text{for } k > 0 \\ -\kappa^2 & \text{for } k < 0 \end{cases} \qquad \text{and} \qquad \tilde{V}(r) = \frac{2m_r V(r)}{\hbar^2} \ , \tag{36.5}$$

choosing k and κ as real positive number. This puts Eq. (36.3) in the form,

$$\boxed{R_\ell'' + \frac{2}{r} R_\ell' + \left[\varepsilon - \tilde{V}(r) - \frac{\ell(\ell+1)}{r^2}\right] R_\ell = 0} \ . \tag{36.6}$$

With the substitution $u_\ell(r) = rR_\ell(r)$ it reduces to a 1D Schrödinger equation,

$$\boxed{u_\ell'' + \left[\varepsilon - \tilde{V}(r) - \frac{\ell(\ell+1)}{r^2}\right] u_\ell = 0} \ . \tag{36.7}$$

36.1.1.2 Low-energy limit: the s-wave regime

For two atoms with relative angular momentum $\ell > 0$ there exists a distance r_{tp}, called the classical turning point, below which the rotational energy exceeds the total energy E,

$$k^2 = \frac{\ell(\ell+1)}{r_{tp}^2} \ . \tag{36.8}$$

This is illustrated in Fig. 36.2. In the classically inaccessible region of space ($r < r_{tp}$) the radial wavefunction is exponentially suppressed [1]. Combining Eq. (36.8) with the condition (36.1) we obtain the inequality,

$$kr_0 = \sqrt{\ell(\ell+1)}\frac{r_0}{r_{tp}} \ll 1 \ , \tag{36.9}$$

which implies that, for $\ell \neq 0$, the classical turning point is found at a distance much larger than the range r_0 of the interaction. As the range r_0 defines the distance beyond which the potential can be neglected, this inequality shows that the radial motion is not affected by the presence of the potential $V(r)$ in the radial wave equation. The notable exception is the case $\ell = 0$, where the barrier is absent and the potential gives rise to a substantial distortion of the radial waves. In other words, for $kr_0 \ll 1$ phase shifts (i.e. scattering) can *only arise from collisions with zero angular momentum.* The range of collision energies where the inequalities (36.9) are valid is called the s-wave regime.

36.1.1.3 Free particle motion

We first have a look at the case of free particles or particles in a homogeneous potential, $V(r) = V_0$. By introducing the dimensionless variable $\varrho = kr$, where $k \equiv \sqrt{2m(E - V_0)/\hbar^2}$, the radial wave equation (36.6) can be rewritten in the form of the spherical Bessel differential equation,

$$R_\ell'' + \frac{2}{\varrho} R_\ell' + \left[1 - \frac{\ell(\ell+1)}{\varrho^2}\right] R_\ell = 0 \ . \tag{36.10}$$

[1] At this point we exclude tunneling through the barrier and the occurrence of shape resonances.

Here, the derivatives are with respect to the new variable.

The general solution of Eq. (36.10) for angular momentum ℓ is a linear combination of two particular solutions, one regular with amplitude A_ℓ, the spherical Bessel function $j_\ell(\varrho)$, and one irregular with amplitude B_ℓ, the spherical Neumann function $n_\ell(\varrho)$:

$$\boxed{R_\ell(\varrho) = A_\ell j_\ell(\varrho) + B_\ell n_\ell(\varrho) = c_\ell[\cos\eta_\ell\ j_\ell(\varrho) + \sin\eta_\ell\ n_\ell(\varrho)]}\ , \tag{36.11}$$

where the new parameters c_ℓ and η_ℓ, defined by

$$A_\ell \equiv c_\ell \cos\eta_\ell \qquad \text{and} \qquad B_\ell \equiv c_\ell \sin\eta_\ell\ , \tag{36.12}$$

represent the amplitude c_ℓ and the asymptotic phase η_ℓ of the wavefunction. Note that this equation is singular in the origin except for the case of vanishing phase shifts. Therefore, in the case of free particles we require $\eta_\ell = 0$ for all angular momentum values ℓ. This implies that the general solution reduces to the regular one,

$$R_\ell(\varrho) = c_\ell \cos\eta_\ell\ j_\ell(\varrho)\ . \tag{36.13}$$

36.1.1.4 Significance of the phase shifts

To investigate the effect of a short-range interaction potential $V(r)$ we return to the radial wave equation (36.6). As the potential is of short range it may be neglected for $r \gg r_0$ and the general solutions coincide with those of the spherical Bessel equation,

$$R_\ell(k,r) \underset{r\gg r_0}{\longrightarrow} c_\ell[\cos\eta_\ell\ j_\ell(kr) + \sin\eta_\ell\ n_\ell(kr)]\ . \tag{36.14}$$

For $r \gg 1/k$ the spherical Bessel and Neumann functions assume their asymptotic form and we find,

$$\begin{aligned} R_\ell(k,r) &\underset{kr\to\infty}{\longrightarrow} \frac{c_\ell}{kr}[\cos\eta_\ell \sin(kr - \tfrac{1}{2}\ell\pi) + \sin\eta_\ell \cos(kr - \tfrac{1}{2}\ell\pi)] \\ &= \frac{c_\ell}{kr}\sin(kr + \eta_\ell - \tfrac{1}{2}\ell\pi)\ . \end{aligned} \tag{36.15}$$

where we introduced a the constant η_ℓ representing the asymptotic phase shift. For a given value of k this phase shift fixes the general solution of the radial wavefunction $R_\ell(k,r)$ up to an ℓ dependent normalization constant c_ℓ. Note that in view of the k dependence of the phase shift, R_ℓ is a function of k and r rather than a function of the product kr. Whereas in the case of free particles the phase shifts must all vanish, in the presence of the interaction they provide the proper asymptotic form of the distorted waves. The non-zero asymptotic phase shift is the signature of the interaction at short distance; the motion becomes free-particle like (undistorted) only at large distance from the scattering center. In elastic scattering the relative energy $\hbar^2k^2/2m$ is conserved; hence, asymptotically also k and the de Broglie wavelength. This leaves only the asymptotic phase of the wave to be affected.

Example 255 (*Scattering matrix*): Rewriting Eq. (36.15) in complex notation,

$$R_\ell(k,r) \underset{r\to\infty}{\simeq} \frac{c_\ell}{2k}\imath\left[e^{-\imath\eta_\ell}\frac{e^{-\imath(kr-\frac{1}{2}\ell\pi)}}{r} - e^{i\eta_\ell}\frac{e^{\imath(kr-\frac{1}{2}\ell\pi)}}{r}\right]\ , \tag{36.16}$$

we see that for $r \to \infty$ the stationary solution $R_\ell(k,r)$ can be regarded as an 'incoming' spherical wave interfering with an 'outgoing' spherical wave. It is convention to choose the phase of the normalization constant such that the phase of the incoming wave is zero,

$$R_\ell(k,r) \underset{r\to\infty}{\simeq} \frac{c'_\ell}{2k}\imath \left[\frac{e^{-\imath kr}}{r} - e^{-\imath\ell\pi}e^{2\imath\eta_\ell}\frac{e^{\imath kr}}{r}\right] , \tag{36.17}$$

Apart from the sign, the ratio of the phase factors of the outgoing over the incoming wave is,

$$\mathcal{S}_\ell = e^{2\imath\eta_\ell} . \tag{36.18}$$

This quantity is called the scattering matrix ($\mathcal{S}$ matrix) or, better, the l-wave contribution to the $\mathcal{S}$ matrix. Being unitary it does not suffer from the divergences of the ratio $B_\ell/A_\ell = \tan\eta_\ell$. In the present context the name scattering matrix is a bit heavy because we only have a single matrix element (1×1 matrix). The term matrix finds its origin in the description of scattering of particles with an internal degree of freedom (like spin), for which the phase factor is replaced by a unitary matrix.

36.1.2 Hard-sphere potentials

We now turn to analytical solutions for model potentials in the limit of low energy. We first consider the case of two hard spheres of equal size. These can approach each other to a minimum distance equal to their diameter a. For $r \le a$ the radial wave function vanishes, $R_\ell(r) = 0$: Outside the hard sphere we have free atoms, $V(r) = 0$, with relative wave number $k = [2m_rE/\hbar^2]^{1/2}$. Thus, for $r \le a$ the general solution for the radial wave functions of angular momentum ℓ is given by the free atom expression (36.11), which asymptotically this takes the form (36.15) of a phase-shifted spherical Bessel function,

$$R_\ell(k,r) = c_\ell[\cos\eta_\ell\ j_\ell(kr) + \sin\eta_\ell\ n_\ell(kr)] \underset{r\to 0}{\simeq} \frac{c_\ell}{kr}\sin(kr + \eta_\ell - \tfrac{1}{2}\ell\pi) . \tag{36.19}$$

To determine the phase shift we require as a boundary condition that $R_\ell(k,r)$ vanishes at the surface of the hard sphere (see Fig. 36.3),

$$\cos\eta_\ell\ j_\ell(ka) + \sin\eta_\ell\ n_\ell(ka) = 0 . \tag{36.20}$$

Hence, the phase shift follows from the expression,

$$\tan\eta_\ell = \frac{j_\ell(ka)}{n_\ell(ka)} . \tag{36.21}$$

This expression allows to derive asymptotic expressions (for $ka \ll 1$ and for $ka \gg 1$) for the radial wave function (36.19), as will be shown in Exc. 36.1.5.1.

36.1.2.1 s-wave phase shifts for hard spheres

For the case $\ell = 0$, inserting the analytical expressions for the Bessel and von Neumann function, (36.19) becomes without approximation,

$$R_0(k,r) = \frac{c_0}{kr}(\cos\eta_0\sin kr + \sin\eta_0\cos kr) = \frac{c_0}{kr}\sin(kr+\eta_0) . \tag{36.22}$$

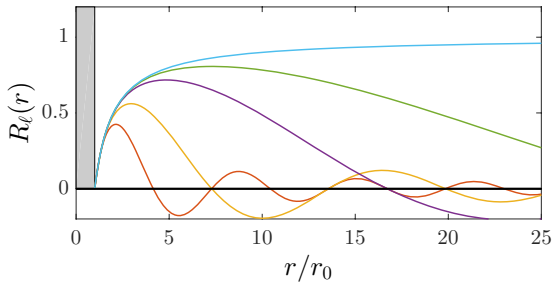

Figure 36.3: (code) Radial wavefunctions ($\ell = 0$) for various values of k (down to the $k \to 0$ limit) in the case of a hard sphere potential. The boundary condition is fixed by the requirement that the wavefunction vanishes at the edge of the hard sphere, $R_0(ka) = 0$.

The phase shift follows from the boundary condition $R_0(k, a) = 0$, which can be written in the form,

$$\cos\eta_0 \sin ka + \sin\eta_0 \cos ka = 0 \ . \tag{36.23}$$

Hence, the phase shift is

$$\eta_0 = -ka \ . \tag{36.24}$$

With this expression Eq. (36.22) reduces to

$$R_0(k, r) = \frac{c_0}{kr} \sin[k(r - a)] \ . \tag{36.25}$$

This expression is exact for any value of k, as announced above. The linear k dependence of η_0 simply expresses its definition in which the shift of the wave (by a) is compared to the de Broglie wavelength λ_{dB}, $\eta_0 = -2\pi a/\lambda_{dB}$. As a consequence the phase shift vanishes for $k \to 0$,

$$\lim_{k\to 0} \eta_0(k) = 0 \ . \tag{36.26}$$

This result is obvious when comparing the finite shift a to the diverging wavelength λ_{therm}. Interestingly, in the limit $k \to 0$ the expression (36.25) becomes k independent,

$$R_0(r) \underset{k\to 0}{\sim} 1 - \frac{a}{r} \qquad \text{for} \qquad a \le r \ll 1/k \ . \tag{36.27}$$

This important result is illustrated in Fig. 36.3. In the limit $k \to 0$ the wavefunction is essentially constant throughout space (up to a distance $1/k \to \infty$ at which it starts to oscillate), except for a small region of radius a around the potential center.

36.1.3 Spherical wells with a flat bottom

The second model potential to consider is the spherical well of range r_0 sketched in Fig. 36.4,

$$\tilde{V}(r) = \begin{cases} 2m_r V_0/\hbar^2 = \tilde{V}_0 = -\kappa_0^2 & \text{for } r \le r_0 \\ 0 & \text{for } r > r_0 \end{cases} \ . \tag{36.28}$$

Here $|U_0| = \kappa_0^2$ is called the well depth (κ_0 is chosen to be real and positive, $\kappa_0 > 0$). The energy of the continuum states is given by $\varepsilon = k^2$. In analogy, the energy of the bound states is written as,

$$\varepsilon_b = -\kappa^2 \ . \tag{36.29}$$

We now have to solve the radial wave equation (36.6) with the spherical well potential (36.28). Since the potential is constant inside the well ($r \leq r_0$) the wavefunction has to be free-particle like with the wave number given by,

$$K_+ = \sqrt{2m_r(E - V_0)/\hbar^2} = \sqrt{\kappa_0^2 + k^2} \ . \tag{36.30}$$

As the wavefunction has to be regular in the origin, inside the well it is given by,

$$R_\ell(r) = C_\ell j_\ell(K_+ r) \quad \text{for } r \leq r_0 \ , \tag{36.31}$$

where C_ℓ is a normalization constant. This expression holds for $E > V_0$ (both $E > 0$ and $E \leq 0$).

Outside the well ($r > r_0$) we have for $E > 0$ free atoms, $\tilde{V}(r) = 0$, with relative wavevector $k = [2m_r E/\hbar^2]^{1/2}$. Thus, for $r > r_0$ the general solution for the radial wave functions of angular momentum ℓ is given by the free atom expression (36.11),

$$R_\ell(k, r) = c_\ell[\cos\eta_\ell \ j_\ell(kr) + \sin\eta_\ell \ n_\ell(kr)] \quad \text{for } r > r_0 \ . \tag{36.32}$$

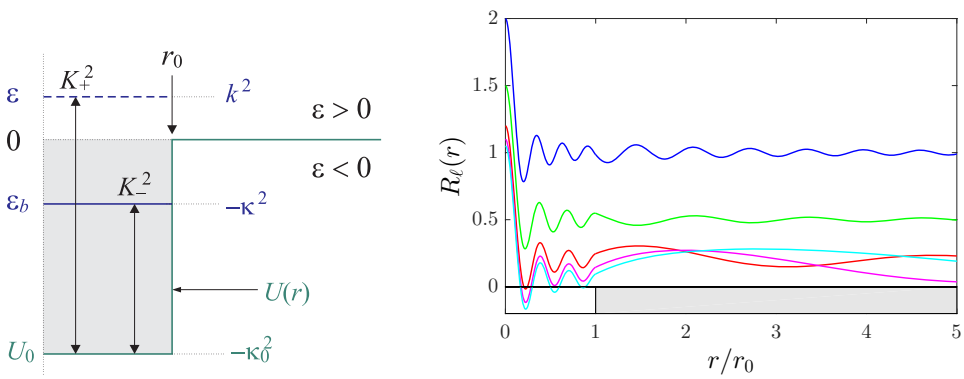

Figure 36.4: (code) (Left) Scheme of the flat bottom potential. (Right) (a) Radial wavefunctions for square wells: (a) continuum state ($\varepsilon = k^2 > 0$); (b) Zero energy state ($\varepsilon = k^2 = 0$) in the presence of an asymptotically bound level ($\varepsilon = -\kappa^2 = 0$); (c) bound state ($\varepsilon = -\kappa^2 < 0$). Note the continuity of $R_0(r)$ and $R_0'(r)$ at $r = r_0$. The wavefunctions are not normalized and are shifted relative to each other only for reasons of visibility.

The full solution [see Fig. 36.4(a)] is obtained by the continuity conditions for $R_\ell(r)$ and $R_\ell'(r)$ at the boundary $r = r_0$. These imply continuity of the logarithmic derivative with respect to r,

$$K_+ \frac{j_\ell'(\varrho_i)}{j_\ell(\varrho_i)} = \left.\frac{R_\ell'(r)}{R_\ell(r)}\right|_{r=r_0} = k \frac{\cos\eta_\ell \ j_\ell'(\varrho_e) + \sin\eta_\ell \ n_\ell'(\varrho_e)}{\cos\eta_\ell \ j_\ell(\varrho_e) + \sin\eta_\ell \ n_\ell(\varrho_e)} \ , \tag{36.33}$$

where we defined the abbreviations $\varrho_i \equiv K_+ r_0$ and $\varrho_e \equiv k r_0$. This ratio suffices to determine η_ℓ independently of the normalization constants C_ℓ and c_ℓ. Once the phase shift is known, the relation between C_ℓ and c_ℓ follows from the continuity condition for $R_\ell(r)$. Furthermore, it shows that the asymptotic phase shift η_ℓ can take any (real) value depending on the depth of the well. In view of the importance of the $\mathcal{S}$ matrix in scattering theory Sec. 36.2, it is advantageous to determine $e^{2\imath\eta_\ell}$ rather than η_ℓ itself. Expressing $\sin\eta_\ell$ and $\cos\eta_\ell$ in terms of $e^{\imath\eta_\ell}$ and $e^{-\imath\eta_\ell}$ Eq. (36.33) becomes,

$$K_+ \partial_\varrho \ln j_\ell(\varrho_i) = k \frac{e^{2\imath\eta_\ell} h_\ell^{(2)\prime}(\varrho_e) + h_\ell^{(1)\prime}(\varrho_e)}{e^{2\imath\eta_\ell} h_\ell^{(2)}(\varrho_e) + h_\ell^{(1)}(\varrho_e)} \ , \tag{36.34}$$

with the definition of the Hankel functions of the first and second kind: $h_\ell^{(1,2)} \equiv j_\ell \pm i n_\ell$. Solving for $e^{2i\eta_\ell}$ this leads to the following expression for the ℓ-wave contribution to the $\mathcal{S}$ matrix,

$$\boxed{e^{2i\eta_\ell} = -\frac{h_\ell^{(1)}(\varrho_e)}{h_\ell^{(2)}(\varrho_e)} \frac{K_+ \partial_\varrho \ln j_\ell(\varrho_i) - k \partial_\varrho \ln h_\ell^{(1)}(\varrho_e)}{K_+ \partial_\varrho \ln j_\ell(\varrho_i) - k \partial_\varrho \ln h_\ell^{(2)}(\varrho_e)}} \ , \tag{36.35}$$

where the expression $\partial_\varrho \ln$ stands for the logarithmic derivative. This expression may look a bit heavy, but is valuable as it represents the exact result for arbitrary ℓ. In Exc. 36.1.5.2 we simplify this formula for $\ell = 0$. As the formula (36.35) lacks transparency from the physical point of view, we analyze in the coming sections the case $\ell = 0$ directly discussing the radial wavefunctions u_ℓ.

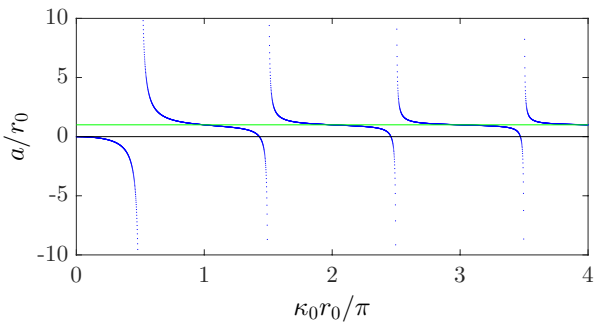

Figure 36.5: (code) The s-wave scattering length a normalized on r_0 as a function of the depth of a spherical square potential well (blue curve). Note that, typically, $a \simeq r_0$ (green line), except near the resonances at $\kappa_0 r_0 = (n + \frac{1}{2})\pi$ being an integer.

36.1.3.1 s-wave scattering ($E > 0$)

The analysis of spherical well potentials becomes particularly simple for the case $\ell = 0$. Let us first consider the case $E > 0$, for which the radial wave equation can be written as a 1D-Schrödinger equation (36.7) of the form,

$$u_0'' + [k^2 - \tilde{V}(r)] u_0 = 0 \ . \tag{36.36}$$

The solution is,

$$u_0(kr) = \begin{cases} C_0 \sin(K_+ r) & \text{for } r \leq r_0 \\ c_0 \sin(kr + \eta_0) & \text{for } r > r_0 \end{cases} . \tag{36.37}$$

To determine $\eta_0(k)$ it is sufficient to apply the boundary condition for continuity of the logarithmic derivative at the edge of the well,

$$\left.\frac{u_0'}{u_0}\right|_{r=r_0} = K_+ \cot K_+ r_0 = k \cot(kr_0 + \eta_0) \ . \tag{36.38}$$

Note that this expression coincides with the general result given by Eq. (36.33) for the case $\ell = 0$; i.e. the boundary condition of continuity for u_0'/u_0 coincides with that for R_0'/R_0, as we know from a calculation left to Exc. 36.1.5.3. Furthermore, for a vanishing potential ($\kappa_0 \to 0$) we have $K_+ \to k$ and the boundary condition properly yields a zero phase shift ($\eta_0 = 0$).

At this point we introduce the effective hard-sphere diameter $a(k)$ to describe, in analogy with Eq. (36.24), the behavior of the phase shift,

$$\eta_0(k) \equiv -ka(k) \ . \tag{36.39}$$

By this procedure we extract the linear k dependence as well as the negative sign from the phase shift. This is a good idea because the linear k-dependence does not arise from the potential but simply from the definition of the phase in which, as discussed earlier, the shift of the wave is compared to the de Broglie wavelength. In the limit $k \to 0$, we have $K_+ r_0 \to \kappa_0 r_0$ and with the definition,

$$a \equiv \lim_{k\to 0} a(k) = -\lim_{k\to 0} \eta(k)/k \tag{36.40}$$

the boundary condition (36.38) becomes,

$$\left.\frac{u_0'}{u_0}\right|_{r=r_0} = \kappa_0 \cot \kappa r_0 = \frac{1}{r_0 - a} \ . \tag{36.41}$$

Solving for a we find,

$$a = r_0 \left(1 - \frac{\tan\gamma}{\gamma}\right) \ , \tag{36.42}$$

where the dimensionless positive quantity,

$$\gamma \equiv \kappa_0 r_0 \tag{36.43}$$

is called the well parameter. As shown in Fig. 36.5, the value of a can be positive, negative or zero depending on the value of γ. Therefore, rather than using the pictorial term effective hard-sphere diameter the name scattering length is used for a. Next to the range, the scattering length represents the second characteristic length that can be associated with the interaction potential. As the name suggest, it is a measure for the scattering behavior of atoms, and we elaborate on this in Sec. 36.2. Also, in Sec. ?? we will show that a is also a measure for the effective strength of the interaction.

Fig. 36.5 and Eq. (36.42) show that a is typically a quantity of the size of r_0, although for $\gamma = \tan\gamma$ it is zero and for $\gamma = (\nu + \frac{1}{2})\pi$, with ν being an integer,

it diverges. The latter condition points to a resonance phenomenon occurring when (with increasing γ) a new bound level enters the potential well. For the square well potential the scattering length is mostly positive; it is negative in the regions with $\gamma < \tan\gamma$, which become narrower for increasing γ. This unlikely occurrence of negative a is atypical for the general case; e.g. for Van der Waals potentials the probability to find a negative scattering length is 25% .

For $r \geq r_0$ the radial wavefunction corresponding to Eq. (36.37) is of the form,

$$R_0(k,r) = \frac{c_0}{kr}\sin[kr - ka(k)] \ . \tag{36.44}$$

Recalling the definitions (36.39) and (36.40) we find that for $k \to 0$ this radial wavefunction becomes k-independent,

$$R_0(r) \underset{k\to 0}{\sim} 1 - \frac{a}{r} \qquad \text{for} \qquad r_0 < r \ll \frac{1}{k} \ . \tag{36.45}$$

The latter two expressions for the radial wavefunction have the same formal appearance as the hard sphere results (36.25) and (36.27). However, whereas the diameter of the hard-sphere has a fixed value, the scattering length for the well depends on γ. As shown in Fig. 36.6, for positive scattering length the s-wave has a characteristic node at $r = a$; for negative scattering length this becomes a virtual node.

Importantly, because Eq. (36.45) reaches the asymptotic value 1 only for distances $r \gg a$, the use of this equation in the modeling of dilute gases is only justified if a is much smaller than the interparticle spacing,

$$na^3 \ll 1 \ . \tag{36.46}$$

Otherwise, the interaction with neighboring atoms will distort the relative motion of the colliding pair. This violates the binary scattering approximation on which Eq. (36.45) is based. The dimensionless quantity na^3 is called the gas parameter. When its value is small, the gas is called nearly ideal or weakly interacting [2].

36.1.3.2 Bound s-levels ($E \leq 0$)

Let us turn to the case $E \leq 0$. We shall show that the divergences of the scattering length obtained by analyzing the continuum states ($E > 0$) result from the appearance of the next bound s-level when increasing the well parameter. The 1D Schrödinger equation takes the form,

$$u_0'' + [-\kappa^2 - \tilde{V}(r)]u_0(r) = 0 \ . \tag{36.47}$$

where $\varepsilon = -\kappa^2$ is the discrete energy eigenvalue of a bound state with $\ell = 0$. The solutions are of the type (see Fig. 36.29),

$$u_0(k,r) = \begin{cases} C_0 \sin K_- r & \text{for } r \leq r_0 \\ c_0 e^{-\kappa r} & \text{for } r \leq r_0 \end{cases} \tag{36.48}$$

[2] Note that weakly interacting does not mean that that the potential is 'shallow'. Any gas can be made weakly interacting by making the density sufficiently small.

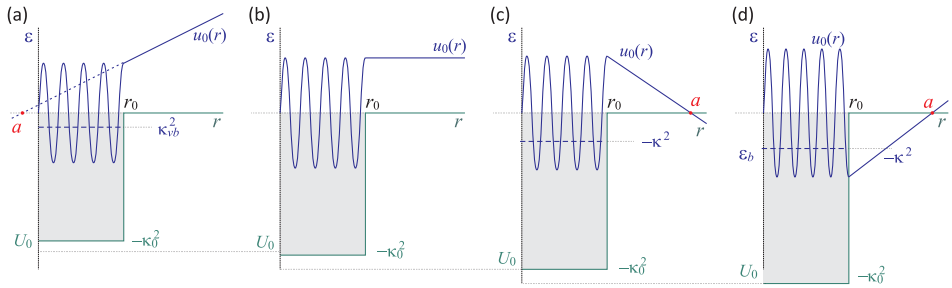

Figure 36.6: Reduced radial wavefunctions $u_0(r)$ for continuum states ($\varepsilon > 0$) in the $k \to 0$ limit for increasing well depth near the threshold value $\kappa_0 r_0 = (n + \frac{1}{2})\pi$: (a) presence of an almost bound state ($a < 0$); (b) presence of zero-energy resonance ($\kappa_{vb} = 0$, $a \to \pm\infty$); (c) presence of a weakly bound state ($a > 0$); (d) deeper binding of the least bound state. For $r > r_0$ the wavefunction is given by $u_0(r) = c_0(r - a)$; hence, the value of a is given by the intercept with the horizontal axis. This gives rise to a characteristic node at $r = a$, which is *real* for $a > 0$ (just as for hard spheres of diameter a), but *virtual* for $a < 0$. The wavefunctions are not normalized.

where $\kappa > 0$ because the bound state wavefunction has to be normalized. The bound state energy is obtained by requiring the continuity of the logarithmic derivative when connecting the inner part of the wavefunction to the outer part,

$$\left.\frac{u_0'(r)}{u_0(r)}\right|_{r=r_0} = K_- \cot K_- r_0 = -\kappa \ , \tag{36.49}$$

where $\kappa > 0$ and

$$K_- = [2m_r(E - V_0)/\hbar^2]^{1/2} = (\kappa_0^2 - \kappa^2)^{1/2} \ . \tag{36.50}$$

With decreasing γ, the least bound level disappears in the limit $\kappa \to 0$, $K_- \to \kappa_0$. In this limit Eq. (36.49) reduces to,

$$\left.\frac{u_0'(r)}{u_0(r)}\right|_{r=r_0} = \kappa_0 \cot \kappa_0 r_0 \underset{\kappa\to 0}{=} 0 \ , \tag{36.51}$$

Increasing from zero the vibrational levels appear sequentially for

$$\gamma = (v + \tfrac{1}{2})\pi \ , \tag{36.52}$$

where $v = 0, 1, .., r_{max}$ is the vibrational quantum number. This shows that a minimum well parameter ($\gamma = \pi/2$) is required to bind the first state [3]. For the least-bound level, v_{max}, we have,

$$(v_{max} + \tfrac{1}{2})\pi = \text{Int}\ (\tfrac{\gamma}{\pi} - \tfrac{1}{2}) \tag{36.53}$$

and the total number of bound s levels follows with,

$$N_b = v_{max} + 1 = \text{Int}\ (\tfrac{\gamma}{\pi} + \tfrac{1}{2}) \ . \tag{36.54}$$

[3]This conclusion cannot be extended to lower dimensions; in two dimensions bound states appear for arbitrarily shallow potentials.

The relation between κ and v for a given vibrational level depends on the ratio κ/K_- and is given by

$$\cot K_- r_0 = -\frac{\kappa}{K_-} \ . \tag{36.55}$$

Note that this relation corresponds to $K_- r_0 \simeq (v_{max} + \frac{1}{2})\pi$ for the least-bound state

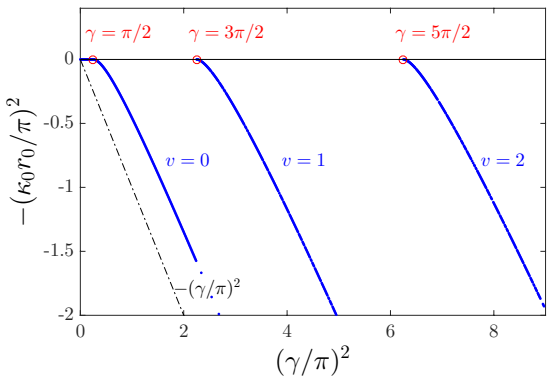

Figure 36.7: (code) Appearance and increase of binding of the first three bound levels for increasing well depth. The quadratic dependence near threshold is universal (i.e. independent of the well shape). The full crossover curve is obtained by numerical solution of Eq. (36.49) and corresponds to a $\pi/2$ phase shift of $K_+ r_0$ near threshold. The dashed line shows the increase in well depth.

$(\kappa/K- \ll 1)$ and to $K_- r_0 \simeq (v_{max} + 1)\pi$ for deeply bound levels $(K_-/\kappa \ll 1)$, as is illustrated in Fig. 36.8(a).

36.1.3.3 Weakly bound s-level: halo states

For weakly bound s levels $(0 < \kappa r_0 \ll 1)$ we have $K_- \to \kappa_0$ and Eq. (36.49) may be approximated by

$$\left.\frac{u_0'(r)}{u_0(r)}\right|_{r=r_0} = \kappa_0 \cot \kappa_0 r_0 = -\kappa \ , \tag{36.56}$$

Furthermore, we recall that in the presence of a weakly bound s-level the scattering length is large and positive, $a \gg r_0$. From Eq. (36.41) we recall that for $k \to 0$ the logarithmic derivative also satisfies the relation

$$\left.\frac{u_0'(r)}{u_0(r)}\right|_{r=r_0} = \kappa_0 \cot \kappa_0 r_0 = \frac{1}{r_0 - a} \simeq -\frac{1}{a} \ , \tag{36.57}$$

Interestingly, for $a \gg r_0$ the logarithmic derivative of the continuum states becomes independent of r_0 and κ_0; i.e. it becomes independent of the shape of the potential well. As we shall see it only depends on the well parameter γ and not on the well shape. This points to a universal limiting shape of the wavefunction for large scattering length. As is sketched in Fig. 36.8(b), for decreasing κ the least-bound state turns into a halo state; i.e. for $\kappa r_0 \ll 1$ most of the probability of the bound state is found in the classically inaccessible region outside the potential well, thus surrounding the

potential center like a halo. This behavior holds for arbitrary short-range potentials.

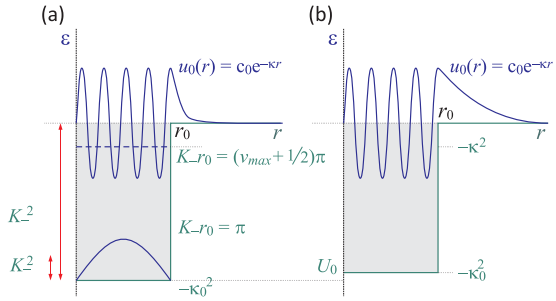

Figure 36.8: Bound states oscillate inside the well and decay exponentially outside the well: (a) the boundary condition depends on the ratio κ/K_-; (b) a slight reduction of the well depth can turn the least bound state into a halo state.

With Eqs. (36.56) and (36.57) we have obtained two expressions for $\kappa_0 \cot \kappa_0 r_0$ and arrive at the conclusion that in the presence of a weakly bound state the scattering length is given by,

$$a \underset{\kappa \to 0}{\simeq} 1/\kappa \ . \tag{36.58}$$

This expression reveals the tight relation between the binding energy of the least-bound state, given by Eq. (36.29), and the scattering length,

$$\boxed{E_b = -\frac{\hbar^2 \kappa^2}{2m_r} \underset{\kappa \to 0}{\longrightarrow} -\frac{\hbar^2}{2m_r a^2}} \ . \tag{36.59}$$

36.1.3.4 s-wave resonances in the continuum: The Breit-Wigner formula

To obtain the k-dependence of the phase shift for large but otherwise arbitrary well parameter ($\gamma \gg 1$) we rewrite the boundary condition (36.38) in the form,

$$\eta_0(k) = -kr_0 + \arctan \frac{kr_0}{K_+ r_0 \cot K_+ r_0} \equiv \eta_{bg} + \eta_{\text{res}} \ . \tag{36.60}$$

The first term of (36.60) is called the *background contribution* to the phase shift and the second term the s-wave *resonance contribution*. Note that the background contribution shows the same phase development as we found in Sec. 36.1.2 for hard spheres. The phase development of the resonance contribution is shown in Fig. 36.9(a) for the case of a large well parameter slightly detuned from the threshold value (at $\gamma = 31.5\pi \approx 98.960169$) such that the scattering length is negative ($\Delta_\gamma = -0.5$). For potentials with $\gamma \gg 1$ the argument of the arctangent is predominantly small, $kr_0/|K_+ r_0 \cot K_+ r_0| \ll 1$, because

$$K_+ r_0 = \kappa_0 r_0 (1 + k^2/\kappa_0^2)^{1/2} > \gamma \gg 1 \ . \tag{36.61}$$

However, the argument of the arctangent diverges when $\cot K_+ r_0$ passes through zero; i.e. for

$$K_+ r_0 = (\tilde{v} + \tfrac{1}{2})\pi \ , \tag{36.62}$$

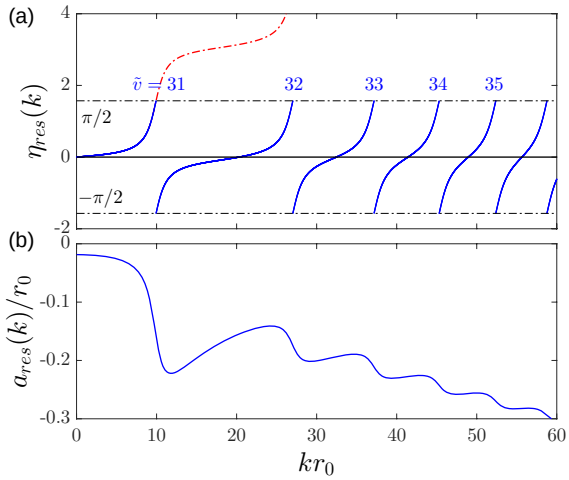

Figure 36.9: (code) (a) Resonance contribution to the s-wave phase shift $\eta_0(k)$ for a large well parameter slightly detuned from the threshold value (at $\gamma = 31.5\pi$), such that the scattering length is negative ($\Delta\gamma = -0.5$): The linear shift of the background contribution is not included in the plot. Note that the π phase jumps arise from the modulo-π representation of the arctangent and do not represent an observable phenomenon; the physical phase increases monotonically and equals $\eta_{\rm res} = \frac{1}{2}$ (modulo π) at the center of the resonances; (b) contribution of the resonances to the effective hard sphere diameter $a(k) = -\eta_0(k)/k$. As (in this example) the lowest resonance is not close to threshold the resonant enhancement is small, $|a_{\rm res}(k)| = r_0 \ll 1$.

where $\tilde{v}$ is an integer called the resonance index. This divergence is observed as a small resonant enhancement of $a(k)$, as shown in Fig. 36.9(b). The physical phase is a continuous function of k, which changes by π when sweeping across the resonance. Because the arctangent remains finite for $\cot K_+ r_0 = 0$ also the resonant phase shift remains finite, having the value $\eta_{\rm res}(k) = \frac{1}{2}\pi$ (modulo π) at the center of each resonance.

In the remainder of this section we shall analyze the width and separation of the s-wave resonances for the case $\gamma \gg 1$. Since $K_+ \geq \kappa_0 \geq K_-$, we have,

$$\tilde{v} \geq \frac{\gamma}{\pi} - \frac{1}{2} \geq v_{max} \ , \tag{36.63}$$

which shows that for $\gamma \gg 1$ the value of $\tilde{v}$ is large ($\tilde{v}_{min} \geq \tilde{v}_{max} \gg 1$). Hence, the resonance numbering starts where the numbering of bound states ends. To discuss the resonances we denote the wavevectors k and K_+ at resonance by $k_{\rm res}$ and $K_{\rm res} \equiv \sqrt{\kappa_0^2 + k_{\rm res}^2}$, respectively. The resonance energies $\varepsilon_{\rm res} = k_{\rm res}^2$ satisfy the condition,

$$\varepsilon_{\rm res} = K_{\rm res}^2 - \kappa_0^2 = (\tilde{v} + \tfrac{1}{2})\pi(\tfrac{\pi}{r_0})^2 - \kappa_0^2 \geq 0 \ . \tag{36.64}$$

The exceptional case for which the equal sign applies ($\tilde{v} = v_{max}$) corresponds to a resonant bound state ($\kappa = 0$) and the resonance is called a resonance at threshold or zero-energy resonance ($k_{\rm res} = 0$).

Let us first analyze s-wave resonances for large well parameters ($\tilde{v} = v_{max}$) and far from threshold, ($\kappa = 0$). The energy spacing between two subsequent resonances

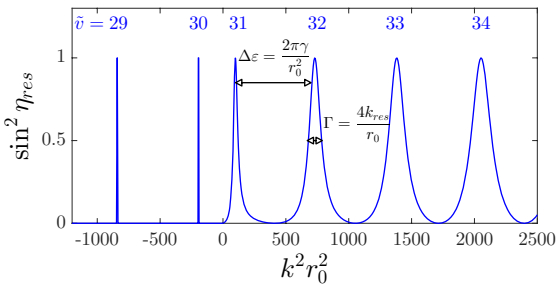

Figure 36.10: (code) (a) Transition from bound states to Breit-Wigner s-wave resonances plotted for $\Delta\gamma = -0.5$ with respect to the threshold at $\gamma = 31.5\pi$ (same conditions as Fig. 36.9). The bound states are indicated as zero-width spikes at energies $\varepsilon = -\kappa^2$, with κ following from Eq. (36.49). For $\varepsilon > 0$ the plot is based on Eqs. (36.60). The width of the resonances increases with the square root of the energy. Note that the band of energies typical for the quantum gases ($kr_0 \ll 1$) corresponds to a narrow zone, unresolved on the energy scale of the plot.

is,

$$\Delta\varepsilon_{\rm res} = \varepsilon_{\rm res}^{(\tilde{v}+1)} - \varepsilon_{\rm res}^{(\tilde{v})} = 2(\tilde{v}+1)\tfrac{\pi^2}{r_0^2} \simeq \tfrac{2\pi\gamma}{r_0^2} \ . \tag{36.65}$$

To analyze a given resonance we expand $K_+ \cot K_+ r_0$ about the point of zero crossing. For this purpose we introduce the notation,

$$K_+ = \sqrt{\kappa_0^2 + (k_{\rm res} + \delta k)^2} = K_{\rm res} + \frac{\delta k \ k_{\rm res}}{K_{\rm res}} \ , \tag{36.66}$$

where $\delta k = k - k_{\rm res}$ is called the detuning from resonance. Thus, restricting ourselves to the low-energy (but not zero energy) s-wave resonances ($1 < k_{\rm res} r_0 \ll K_{\rm res} r_0 \simeq \gamma$), we may approximate $K_+ \cot K_+ r_0 \simeq K_{\rm res} \cot K_+ r_0$. Expanding $\cot K_+ r_0$ about the zero crossing at $K_+ r_0 = (\tilde{v} + 1/2)\pi$ and retaining only the linear term we obtain (see Problem 3.4),

$$K_{\rm res} \cot K_+ r_0 = -\delta k \ k_{\rm res} r_0 \ . \tag{36.67}$$

Hence, the diverging argument of the arctangent becomes,

$$\tan\eta_{\rm res} = \frac{k}{K_+ \cot K_+ r_0} \simeq -\frac{1}{\delta k \ r_0} = \frac{-(k + k_{\rm res})}{(k^2 - k_{\rm res}^2) r_0} \simeq \frac{-2k_{\rm res}/r_0}{\varepsilon - \varepsilon_0} \ . \tag{36.68}$$

The expansion (36.66) is valid over the full range of the resonant change in phase provided the following condition holds,

$$\delta k \ r_0 \ll \frac{K_{\rm res}}{k_{\rm res}} \simeq \tfrac{\gamma}{k_{\rm res} r_0} \ , \tag{36.69}$$

which is satisfied for the lowest resonances as long as the well parameter is sufficiently large ($\gamma \gg k_{\rm res} r_0$). As long as $\delta k \ll k_{\rm res}$ we may further approximate $k \simeq k_{\rm res}$. With these approximations and after restoring the dimensions, Eq. (36.68) can be written as a function of the energy $E = \hbar^2 2k^2/2m_r$,

$$\tan\eta_{\rm res} = \frac{k}{K_+ \cot K_+ r_0} \simeq \frac{-\Gamma^2}{\varepsilon - \varepsilon_{\rm res}} \ , \tag{36.70}$$

where

$$\Gamma/2 = 2k_{\rm res}/r_0 \tag{36.71}$$

is called the spectral width of the resonance. Comparing the expressions for Γ and $\Delta E_{\rm res}$ we find that for given r_0 the width Γ is independent of γ, whereas the resonance spacing is proportional to γ . Thus, only for sufficiently large well parameters ($\gamma \gg 1$) the spectral width becomes smaller than the resonance spacing,

$$\Gamma \ll \Delta\varepsilon_{\rm res} \Longleftrightarrow k_{\rm res} r_0 \ll \pi\gamma \ . \tag{36.72}$$

Knowing the tangent of $\eta_{\rm res}$, we readily obtain the sine and Eq. (36.70) is replaced by the *Breit-Wigner formula*,

$$\sin^2 \eta_{\rm res} = \frac{(\Gamma/2)^2}{(\varepsilon - \varepsilon_0)^2 + (\Gamma/2)^2} \ . \tag{36.73}$$

For optical resonances this energy dependence is known as the Lorentz lineshape. Note that Γ corresponds to the full-width-at-half-maximum (FWHM) of this line shape. The lowest energy resonances are plotted in Fig. 36.10 along with the highest-energy bound states.

The resonance near threshold (almost bound level) deserves special attention, as this type of resonance is the only one that can play an important role within the band of energies relevant for the quantum gases ($kr_0 \ll 1$). Fig. 36.10 shows that near the threshold (at $\gamma = 31.5\pi$) the resonance narrows down and becomes asymmetric, which means that the Breit-Wigner lineshape is lost. Using Eq. (36.54) we calculate $\tilde{v} = 31$. The narrow line is reminiscent of a bound level but the scattering length is negative (see Fig. 36.10). Under these conditions the wavefunction has a virtual node at $r = -|a|$ (see Fig. 36.29). Accordingly, the level is called a virtual level and the wavefunction is said to represent a virtual bound state. In analogy with the bound states its energy is written as $\varepsilon = \kappa_{\rm res}^2$, where κ is to be defined later.

36.1.4 Other types of potentials

36.1.4.1 Zero-range potentials

An important model potential is obtained by considering a spherical well in the zero-range limit $r_0 \to 0$. As illustrated in Fig.36.11, it is possible to construct a zero-range well in such a way that the long-range properties of the wavefunction are unaffected; i.e. the scattering length a and the binding energy $\varepsilon = -\kappa^2$ of the least-bound state remain unchanged.

For $E < 0$ this can be demonstrated with the aid of the boundary condition (36.49),

$$-\kappa = K_- \cot K_- r_0 \ . \tag{36.74}$$

Reducing the radius r_0 the value of the binding energy $\varepsilon = -\kappa^2$, can be conserved by increasing κ_0. In the limit $r_0 \to 0$ the well depth should diverge in accordance with,

$$-\frac{\kappa}{K_-} = \cot K_- r_0 \to 0 \ . \tag{36.75}$$

This condition is satisfied for $K_- r_0 \simeq \pi/2$. To elucidate this point we consider the least-bound level with vibrational quantum number $v = v_{max}$, for which $K_- r_0 =$

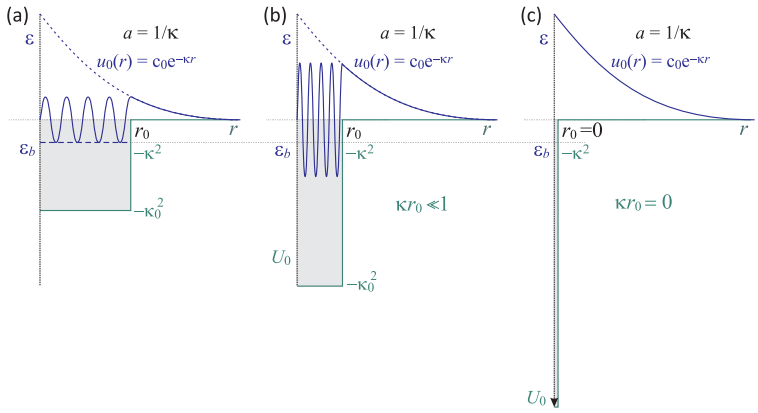

Figure 36.11: Wavefunctions corresponding to the same binding energy ($\varepsilon = -\kappa^2$) plotted for three different values of r_0. Outside r_0 the wavefunctions fall off exponentially, always with the same decay exponent κ; this is the essence of the Bethe-Peierls boundary condition. The dashed lines show the extrapolation for $r \to 0$. (a) reference case; (b) for $\kappa r_0 \ll 1$ most of the probability density of a bound state is found outside the well (halo state); (c) for zero-range potentials ($\kappa r_0 = 0$) the oscillating part of the wavefunction is compressed into a delta function and only the decaying exponent remains (universal limit). Note that these wavefunctions do not share the same normalization.

$(v_{max} + 1/2)\pi$. Reducing r_0 by a factor of 2 the wavenumber K_- has to be doubled to conserve the number of nodes in the wavefunction (i.e. to conserve v_{max}). This means that the kinetic energy inside the well has to increases by a factor 4. Since for the least-bound level we have $K_- r_0 \simeq \gamma$, it means that in this case the binding energy can be conserved at effectively constant well parameter. Obviously, the freedom to conserve (for decreasing r_0) the binding energy of one of the levels can only be used once. It does not hold for the other levels because the level separation diverges with κ_0. In the zero range limit the potential only supports a single bound state and the wavefunction of that state is given by,

$$R_0(r) = c_0 \frac{e^{-\kappa r}}{r} \qquad \text{for} \qquad r > 0 \ , \tag{36.76}$$

and with $\kappa > 0$. Unit normalization, $\int r^2 R_0^2(r) dr = 1$, is obtained for $c_0 = \sqrt{2\kappa}$. For $E > 0$ we can arrive at the same conclusion. The boundary condition for $k \to 0$ and given value of r_0 is given by Eq. (36.41), which we write in the form,

$$\frac{1}{r_0 - a} = \kappa_0 \cot \kappa_0 r_0 \ . \tag{36.77}$$

Reducing the radius r_0, the scattering length a can be conserved by increasing κ_0. In the limit $r_0 \to 0$ the well depth should diverge in accordance with,

$$-\frac{1}{\kappa_0 a} = \cot \kappa_0 r_0 \to 0 \ . \tag{36.78}$$

This is again satisfied for $\kappa_0 r_0 \simeq \pi/2$. In the zero-range limit the radial wavefunction

for $k \to 0$ is given by,

$$R_0(k,r) = \frac{1}{kr}\sin[k(r-a)] \qquad \text{for} \qquad r > 0 \ , \tag{36.79}$$

which implies $R_0(k,r) \simeq 1 - a/r$ for $0 < r \ll 1/k$.

36.1.4.2 Bethe-Peierls boundary condition

Note that Eq. (36.76) is the solution for $E < 0$ of the 1D-Schrödinger equation in the zero-range approximation,

$$u_0'' - \kappa^2 u_0 \qquad \text{for} \qquad r > 0 \ , \tag{36.80}$$

under the boundary condition,

$$\left.\frac{u_0'}{u_0}\right|_{r\to 0} = -\kappa \ . \tag{36.81}$$

The latter relation is called the *Bethe-Peierls boundary condition* and was first used to describe the deuteron, the weakly bound state of a proton with a neutron [**?**]. It shows that for weakly bound states the wavefunction has the universal form of a halo state, which only depends on the binding energy, $\varepsilon_0 = -\kappa^2$ (see Fig. 36.11).

For $E > 0$ the 1D-Schrödinger equation in the zero-range approximation is given by,

$$u_0' + k^2 u_0 = 0 \qquad \text{for} \qquad r > 0 \ . \tag{36.82}$$

The general solution is $u_0(k,r) = c_0 \sin[kr + \eta_0]$. Using the Bethe-Peierls boundary condition we obtain,

$$k \cot \eta_0(k) = -\kappa \ , \tag{36.83}$$

which yields after substituting $\eta_0(k \to 0) \simeq -ka$ the universal relation between the scattering length and the binding energy in the presence of a weakly bound s-level, $\varepsilon_0 = -\kappa^2 = -1/a^2$.

36.1.4.3 Power-law potentials

The general results obtained in the previous sections presumed the existence of a finite range of interaction, r_0. Thus far this presumption was based only on the heuristic argument presented in Sec. **??**. To derive a proper criterion for the existence of a finite range and to determine its value r_0 we have to analyze the asymptotic behavior of the interatomic interaction [672]. For this purpose we consider potentials of the power-law type,

$$V(r) = -\frac{C_s}{r^s} \ , \tag{36.84}$$

where $C_s = V_0 r_c^s$ is the power-law coefficient, with $V_0 \equiv |V(r_c)| \equiv \hbar^2\kappa_c^2/2m_r$ the well depth. These power-law potentials are important from the general physics point of view, because they capture major features of interparticle interactions.

For power-law potentials, the radial wave equation (36.6) takes the form,

$$R_\ell'' + \frac{2}{r}R_\ell' + \left[k^2 + \frac{\kappa_c^2 r_c^s}{r^s} - \frac{\ell(\ell+1)}{r^2}\right] = 0 \ . \tag{36.85}$$

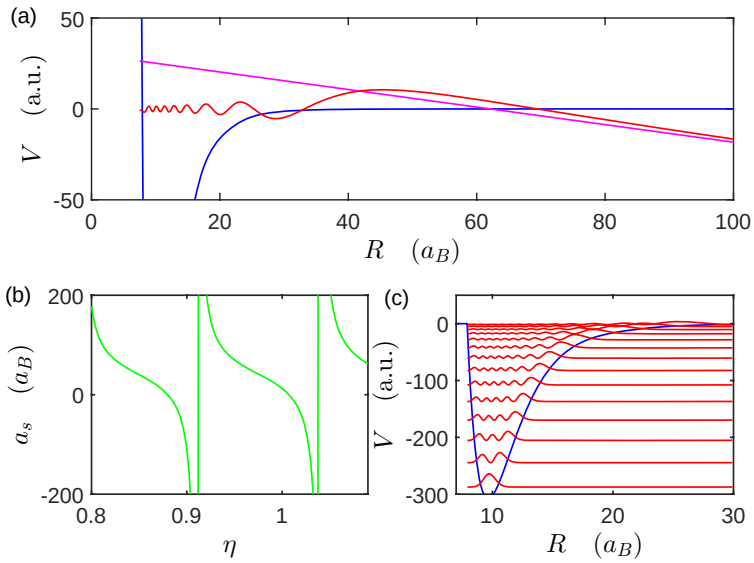

Figure 36.12: (code) Dependence of the scattering length on the potential depth.

Because this equation can be solved analytically in the limit $k \to 0$ it is ideally suited to analyze the conditions under which the potential $V(r)$ may be neglected and thus to determine r_0. To solve Eq. (36.85) we look for a clever substitution of the variable r and the function $R_\ell(r)$ to optimally exploit the known r dependence of the potential in order to bring the differential equation in a well-known form. To leave exibility in the transformation we search for functions of the type,

$$G_\ell(x) = r^{-\nu} R_\ell(r) \ , \tag{36.86}$$

where the power ν is to be selected in a later stage.

36.1.4.4 Computation of the scattering length

The scattering length depends on the *binding energy* E_v of weakly bound states. If a is positive and much greater than the range of the potential, then [384, 325] (36.59),

$$E_v = -\frac{\hbar^2}{2m_r a^2} \ . \tag{36.87}$$

More precisely, for a potential behaving at long range as,

$$V = -\frac{C_6}{R^6} \ , \tag{36.88}$$

we get,

$$E_v = -[(v_D - v)H(m_r, C_6)]^{-1/3} \ , \tag{36.89}$$

where v_D is the vibrational quantum number at the dissociation limit and H a constant. Also,

$$a = \frac{\Gamma(3/4)}{2\sqrt{2}\Gamma(5/4)} \left(\frac{2\mu C_6}{\hbar^2}\right)^{1/4} \left[1 - \tan\pi(v_D + \tfrac{1}{2})\right] \ . \tag{36.90}$$

36.1.4.5 Second method

It yields for $\gamma = \alpha, \beta$,

$$\tfrac{d^2}{dR^2}\varepsilon_\gamma(R) = 2m_r V(R)\varepsilon_\gamma(R) \ . \tag{36.91}$$

Successive approaches start with $\varepsilon_\alpha^{(0)} = R$ and $\varepsilon_\beta^{(0)} = 1$ and get superior orders via,

$$\tfrac{d^2}{dR^2}\varepsilon_\gamma^{(k+1)}(R) = 2m_r V(R)\varepsilon_\gamma^{(k)}(R) \ . \tag{36.92}$$

We define $\delta_\gamma^{(k)} \equiv \varepsilon_\gamma^{(k)} - \varepsilon_\gamma^{(k-1)}$ starting with $\delta_\gamma^{(0)} = \varepsilon_\gamma^{(0)}$, such that,

$$\tfrac{d^2}{dR^2}\delta_\gamma^{(k+1)}(R) = 2m_r V(R)\delta_\gamma^{(k)}(R) \ . \tag{36.93}$$

$\delta_\alpha(R \to \infty) = \delta_\beta(R \to \infty) = 0$. Since $\varepsilon_\alpha = \lim_{k\to\infty} \varepsilon_\alpha^{(k)}$, the wavefunction is thus obtained from,

$$U(R) = \alpha(1 + \delta_\alpha^{(1)} + \delta_\alpha^{(2)} + ..) + \beta(R + \delta_\beta^{(1)} + \delta_\beta^{(2)} + ..) \ . \tag{36.94}$$

This long-range expression must match the short-range value at a certain point R_0:

$$\begin{aligned} U(R_0) &= \alpha\varepsilon_\alpha(R_0) + \beta\varepsilon_\beta(R_0) \ . \\ U'(R_0) &= \alpha\tfrac{d}{dR}\varepsilon_\alpha(R_0) + \beta\tfrac{d}{dR}\varepsilon_\beta(R_0) \end{aligned} \tag{36.95}$$

and

$$a = -\frac{\beta}{\alpha} = \frac{U(R_0)\frac{d}{dR}\varepsilon_\alpha(R_0) - U'(R)\varepsilon_\alpha(R_0)}{U(R_0)\frac{d}{dR}\varepsilon_\beta(R_0) - U'(R)\varepsilon_\beta(R_0)} = \frac{\frac{d}{dR}\frac{\varepsilon_\alpha(R_0)}{U(R_0)}}{\frac{d}{dR}\frac{\varepsilon_\beta(R_0)}{U(R_0)}} \ . \tag{36.96}$$

Let us consider a specific potential,

$$\begin{aligned} V(R) &= \frac{1}{2}BR^{m_r}e^{-\eta R} - \left(\frac{C_6}{R^6} + \frac{C_8}{R^8} + \frac{C_{10}}{R^{10}}\right) f_c(R) \\ f_c(R) &= \theta(R_c - R)e^{-(R_c/R-1)^2} + \theta(R - R_c) \ . \end{aligned} \tag{36.97}$$

At very long range we have $V(R) \simeq -\frac{C_6}{R^6}$, such that,

$$\begin{aligned} \delta_\gamma^{(k+1)} &= \int_0^R 2m_r V\delta_\gamma^{(k+1)}dR = \delta_\gamma^{(k)}(\infty) - \int_R^\infty -\frac{2m_r C_6}{R^6}\delta_\gamma^{(k)}dR \\ &= 2m_r C_6 \int_R^\infty \frac{\delta_\gamma^{(k)}}{R^6}dR \ . \end{aligned} \tag{36.98}$$

In particular,

$$\begin{aligned} \delta_\alpha^{(1)} &= 2m_r C_6 \frac{-1}{4R^4} \quad , \quad \delta_\alpha^{(2)} = (2m_r C_6)^2 \frac{-1}{4\cdot 9R^9} \\ \delta_\beta^{(1)} &= 2m_r C_6 \frac{1}{5R^5} \quad , \quad \delta_\beta^{(2)} = (2m_r C_6)^2 \frac{1}{5\cdot 10R^{10}} \ . \end{aligned} \tag{36.99}$$

36.1.4.6 Third method

To estimate the scattering length for a particular interaction consult [615, ?, 712]. Following [615] we write the Schrödinger equation in atomic units as,

$$\frac{d^2U}{dR^2} = 2m_r V(R)U(R) \ . \tag{36.100}$$

The ansatz $U(R) = \alpha\varepsilon_\alpha(R) + \beta\varepsilon_\beta(R)$ with $\varepsilon_\alpha(R \to \infty) = R$ and $\varepsilon_\beta(R \to \infty) = 1$ shows that $a = -\beta/\alpha$ is the desired scattering length.

36.1.4.7 Fourth method

The equation for the accumulated phase follows from the Schrödinger equation,

$$\phi(r_0) \equiv \int_\infty^{r_0} k(r)dr \tag{36.101}$$

$$k^2(r) = \frac{2m_r}{\hbar^2}\sqrt{E - V(r) - \frac{\hbar^2 l(l+1)}{2m_r r^2}} \ .$$

According to [712] we start resolving,

$$\frac{d}{dR}\delta_{k,0}(R) = -k^{-1}V(R)\sin^2[kR + \delta_{k,0}(R)] \ . \tag{36.102}$$

36.1.4.8 Pseudo potentials

As in the low-energy limit ($k \to 0$) the scattering properties only depend on the asymptotic phase shift it is a good idea to search for the simplest mathematical form that generates this asymptotic behavior. The situation is similar to the case of electrostatics, where a spherically symmetric charge distribution generates the same far field as a properly chosen point charge in its center. Not surprisingly, the suitable mathematical form is a point interaction. It is known as the pseudo potential and serves as an important theoretical Ansatz at the two-body level for the description of interacting many-body systems [309, 458]. The existence of such pseudo potentials is not surprising in view of the zero-range square well solutions discussed in Sec. 36.6.2.

As the pseudo potential cannot be obtained at the level of the radial wave equation, we return to the full 3D Schrödinger equation for a pair of free atoms,

$$(\nabla^2 + k^2)\psi_k(r) = 0 \ , \tag{36.103}$$

where $k = \sqrt{2m_r E/\hbar^2}$ is the wavenumber for the relative motion. Restricting ourselves to s-wave collisions we derived earlier the solution of this equation as being given by $\psi_k(r) = \frac{c_0}{kr}\sin kr$. However, we are now looking a solution of the type (36.37), which includes a phase shift η_0,

$$\psi_k(r) = \frac{c_0}{kr}\sin(kr + \eta_0) \ . \tag{36.104}$$

Inserting this expression into the wave equation (36.103) we encounter the problem that the solution is irregular in the origin when $\eta_0 \neq 0$. Apparently, we need to complement the wave equation by a (pseudo-)potential to remove this problem.

Our claim is now that the operator,

$$-\frac{4\pi}{k\cot\eta_0}\delta^3(\mathbf{r})\frac{\partial}{\partial r}r \tag{36.105}$$

is the wanted s-wave *pseudo potential* $\tilde{V}(r)$. That is, the wave equation,

$$\boxed{\left(\nabla^2+k^2+\frac{4\pi}{k\cot\eta_0}\delta^3(\mathbf{r})\frac{\partial}{\partial r}r\right)\psi_k(r)=0} \tag{36.106}$$

lets the phase-shifted wavefunction (36.104) be regular at the origin.

The presence of the delta function makes the pseudo-potential act as a boundary condition at $r=0$,

$$\begin{aligned}\frac{4\pi\delta^3(\mathbf{r})}{k\cot\eta_0}\left[\frac{\partial}{\partial r}r\psi_k(r)\right]_{r=r_0} &= 4\pi\delta^3(\mathbf{r})\frac{c_0}{k}\sin\eta_0 \\ &= -4\pi\delta^3(\mathbf{r})\frac{c_0}{k}\sin(ka)\underset{k\to 0}{\simeq}-4\pi a c_0\delta^3(\mathbf{r})\ ,\end{aligned} \tag{36.107}$$

where we used the expression for the s-wave phase shift, $\eta_0=-ka$. This is the alternative boundary condition we were looking for. Substituting this into Eq. (36.106) we obtain the inhomogeneous equation

$$(\nabla^2+k^2)\psi_k(r)\underset{k\to 0}{\simeq}-4\pi a c_0\delta^3(\mathbf{r})\ . \tag{36.108}$$

This inhomogeneous equation has the solution (36.104), as demonstrated in Exc. 36.1.5.4.

For functions $f(\mathbf{r})$ with regular behavior in the origin we have [4],

$$\left[\frac{\partial}{\partial r}rf(\mathbf{r})\right]_{r=0}=f(\mathbf{0})+r\left[\frac{\partial}{\partial r}f(\mathbf{r})\right]_{r=0}=f(\mathbf{0})\ , \tag{36.109}$$

and the pseudo potential takes the form of a delta function potential [5],

$$\tilde{V}(r)=-\frac{4\pi}{k\cot\eta_0}\delta^3(\mathbf{r})\underset{k\to 0}{\simeq}4\pi a\delta^3(\mathbf{r})\ , \tag{36.110}$$

or, equivalently, restoring the dimensions,

$$\boxed{V(r)=\frac{g}{2}\delta^3(\mathbf{r})\qquad\text{with}\qquad g=\frac{4\pi\hbar^2}{m_r}}\ . \tag{36.111}$$

[4]Note that the wavefunction ψ_k is irregular,

$$\delta^3(\mathbf{r})\frac{\partial}{\partial r}[r\psi_k(r)]=\delta^3(\mathbf{r})\frac{\partial}{\partial r}\left(r\frac{c_0\sin(kr+\eta_0)}{kr}\right)=\delta^3(\mathbf{r})c_0\cos[k(r-a)]\underset{k\to 0}{=}c_0\delta^3(\mathbf{r})\ .$$

On the other hand,

$$\delta^3(\mathbf{r})\frac{\partial}{\partial r}[r\psi_k(r)]=\delta^3(\mathbf{r})\frac{c_0\sin(kr+\eta_0)}{kr}=\delta^3(\mathbf{r})\frac{c_0\sin[k(r-a)]}{kr}\underset{k\to 0}{=}c_0\delta^{(3)}(\mathbf{r})[1-\tfrac{a}{r}]\ .$$

[5]Note that the dependence on the relative position vector $\mathbf{r}$ rather than its modulus r is purely formal as the delta function restricts the integration to only zero-length vectors. This notation is used to indicate that normalization involves a 3-dimensional integration, $\int\delta^3(\mathbf{r})d^3r$. Pseudo potentials do not carry physical significance but are mathematical constructions that can chosen such that they provide wavefunctions with the proper phase shift.

This expression, for $na^3 \ll 1$ valid in the zero energy limit, is convenient for calculating the interaction energy, as will be shown in Sec. ??.

36.1.4.9 Coupling of potentials

When molecular potentials cross and couple via collisions, via radiative coupling, or via a Feshbach resonance (cf. Sec. 36.4.2), new adiabatic potentials are formed. These are obtained as the r-dependent eigenvalues of the coupling Hamiltonian,

$$\hat{H}_{cpl} = \begin{pmatrix} V_1(R) & \Omega \\ \Omega & V_2(R) \end{pmatrix} . \tag{36.112}$$

Such calculations are known as *coupled channels* calculations.

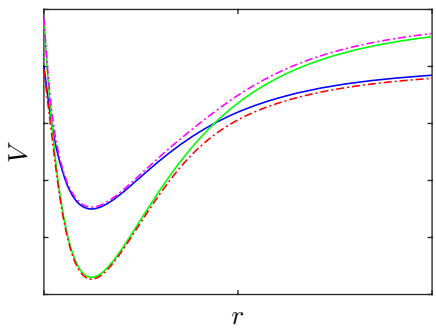

Figure 36.13: (code) The coupling of molecular potentials (solid lines) generates new adiabatic potentials (dash-dotted lines).

36.1.5 Exercises

36.1.5.1 Ex: Asymptotic radial function for hard-sphere potentials

Using asymptotic expressions for the Bessel and von Neumann functions derive the radial function $R_\ell(k, r)$ for the two limiting cases $ka \ll 1$ and $ka \gg 1$.

36.1.5.2 Ex: s-wave collision on flat bottom potentials

Simplify the scattering matrix (36.35) for the collisional flat bottom potential for the case of s-wave collisions.

36.1.5.3 Ex: Equivalence of boundary conditions

Show that the radial wavefunction R_ℓ and u_ℓ satisfy equivalent boundary conditions at the surface of the spherical box potential.

36.1.5.4 Ex: Derivation of a linear expansion

Derive the linear expansion (36.67).

36.1.5.5 Ex: Pseudo-potential for s-wave scattering

Verify the equation $(\nabla^2 + k^2)\psi_k(r) = 4\pi\delta^3(\mathbf{r})\frac{1}{k}\sin\eta_0$ by direct substitution of the solution (36.104) setting $c_0 = 1$.

36.2 Scattering theory

In this chapter we discuss scattering by time independent potentials satisfying $rV(r \to \infty) \to 0$, that is short-range potentials. Such a potential may have attractive regions supporting bound states with energy $E < 0$. Here, however, we only consider states $E > 0$. Since the potential is supposed independent of time, $\partial_t \hat{H} = 0$, we will focus on time-independent problems,

$$\hat{H}\psi_{\mathbf{k}}(\mathbf{r}) = E_k \psi_{\mathbf{k}}(\mathbf{r}) \ , \tag{36.113}$$

with $\hat{H} = p^2/2m + V(\mathbf{r})$ and $E_{\mathbf{k}} = \hbar^2 k^2/2m$. The boundary conditions are given by the scattering geometry in such a way that at long distances the wavefunction behaves as (see Fig. 36.14),

$$\psi_{\mathbf{k}}(\mathbf{r}) \sim e^{\imath \mathbf{k}\cdot\mathbf{r}} + f_k(\Omega)\frac{e^{\imath k_s r}}{r} \ . \tag{36.114}$$

For elastic scattering processes we have $k_s = k$. The *scattering amplitude* $f_k(\Omega)$ depends on the energy E_k and on the scattering solid angle. Experimentally, we scatter individual particles described by wave packets. Since the scattering theory is linear, we can describe the packets by superpositions of stationary solutions $\psi_{\mathbf{k}}$ [6].

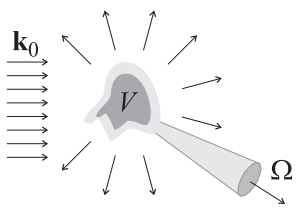

Figure 36.14: Scattering of incident light (wavevector $\mathbf{k}_0$) by a potential V.

36.2.1 Lippmann-Schwinger equation

In order to consider the example of two particles involved in a collision we may go into the center-of-mass system (using reduced masses), fix the origin of the coordinate system on one of the particles, and analyze the trajectory of the second particle inside the interaction potential.

The scattering theory is based on *Green's method*, which we already know from electrostatics. So, let us start of a brief reminder of the use of the *Green's function* as a method to solve electrostatic problems.

[6] Note that $\mathbf{k}$ is not a quantum number, since $\psi_{\mathbf{k}}$ contains momentum components $\neq \mathbf{k}$.

Example 256 (*Green's method in electrostatics*): From Maxwell's third equation we obtain,

$$\nabla^2\phi(\mathbf{r}) = -\varepsilon_0^{-1}\rho(\mathbf{r}) \ .$$

Being defined by,

$$\nabla^2 G(\mathbf{r}) = \delta^3(\mathbf{r}) \ ,$$

the Green function is,

$$G(\mathbf{r}) = \frac{-1}{4\pi}\frac{1}{|\mathbf{r}|} \ .$$

With this, we find the solution of the Maxwell equation,

$$\phi(\mathbf{r}) = \left(-G\star\varepsilon_0^{-1}\rho(\mathbf{r})\right)(\mathbf{r}) = -\frac{1}{\varepsilon_0}\int_V \rho(\mathbf{r}_0)G(\mathbf{r}-\mathbf{r}_0)d^3\mathbf{r}_0 = \frac{1}{4\pi\varepsilon_0}\int_V \frac{\rho(\mathbf{x})}{|\mathbf{r}-\mathbf{x}|}d^3\mathbf{x} \ ,$$

known as *Poisson's law*.

36.2.1.1 Green's method in quantum mechanics

Green's method can be used to solve Schrödinger's equation with the boundary condition (36.114). We start from the reduced stationary Schrödinger equation (36.113) [910],

$$(\Delta + k^2)\psi_{\mathbf{k}}(\mathbf{r}) = \tfrac{2m}{\hbar^2}V(\mathbf{r})\psi_{\mathbf{k}}(\mathbf{r}) \ . \tag{36.115}$$

This equation is not a common eigenvalue problem, since any energy E_k generates a solution. The equation (36.115) is a partial inhomogeneous differential equation with the left side describing free propagation and the right side describing a source that depends on the solution. Such differential equations are usually solved using Green's functions. We choose a point source and we solve,

$$(\Delta + k^2)G(\mathbf{r},k) = \delta^3(\mathbf{r}) \ , \tag{36.116}$$

along with the boundary conditions. The solution takes the form [98],

$$G(\mathbf{r},k) = -\frac{1}{4\pi}\frac{e^{\imath k|\mathbf{r}|}}{|\mathbf{r}|} \ , \tag{36.117}$$

such that,

$$\boxed{\psi_{\mathbf{k}}(\mathbf{r}) = e^{\imath\mathbf{k}\cdot\mathbf{r}} + \left(G\star\tfrac{2m}{\hbar^2}V\psi_{\mathbf{k}}\right)(\mathbf{r}) = e^{\imath\mathbf{k}\cdot\mathbf{r}} + \tfrac{2m}{\hbar^2}\int_V d^3r' G(\mathbf{r}-\mathbf{r}',k)V(\mathbf{r}')\psi_{\mathbf{k}}(\mathbf{r}')} \ . \tag{36.118}$$

The equation (36.118) is called *Lippmann-Schwinger equation*. Of course, this equation does not solve, but only reformulate the problem taking into account the boundary conditions. It is more appropriate for an implementation of approximations. See Exc. 36.2.7.1 and 36.2.7.2.

Now let us consider the far field, $r\to\infty$, to verify the asymptotic behavior and find an expression for $f_k(\Omega)$ as a function of $V(\mathbf{r})$. For $r\to\infty$ we can approximate

$$k|\mathbf{r}-\mathbf{r}'| = kr\sqrt{(\hat{\mathbf{e}}_r - \mathbf{r}'/r)^2} = kr\sqrt{1 - 2\hat{\mathbf{e}}_r\cdot\mathbf{r}'/r + (r'/r)^2} \simeq kr - \mathbf{k}'\cdot\mathbf{r}' \simeq kr \ , \tag{36.119}$$

with $\mathbf{k}' \equiv k\hat{\mathbf{e}}_r$. With this the Lippmann-Schwinger equation (36.118) becomes,

$$\begin{aligned}\psi(\mathbf{r}) &\to e^{\imath\mathbf{k}\cdot\mathbf{r}} - \frac{2m}{\hbar^2}\int_V \frac{1}{4\pi}\frac{e^{\imath k|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|}V(\mathbf{r}')\psi(\mathbf{r}')d^3r' \\ &= e^{\imath\mathbf{k}\cdot\mathbf{r}} - \frac{2m}{4\pi\hbar^2}\frac{e^{\imath kr}}{kr}\int_V e^{-\imath\mathbf{k}'\cdot\mathbf{r}'}V(\mathbf{r}')\psi(\mathbf{r}')d^3r' \equiv \psi_{\text{in}} + f_k(\Omega)\frac{e^{\imath kr}}{r} \ ,\end{aligned} \tag{36.120}$$

giving, in comparison with the expression (36.114), the *scattering amplitude*,

$$f_k(\Omega) = \frac{2m}{4\pi\hbar^2}\int_V e^{-\imath\mathbf{k}'\cdot\mathbf{r}'}V(\mathbf{r}')\psi(\mathbf{r}')d^3r' \ . \tag{36.121}$$

Starting from the wavefunctions $\psi_{\text{in}} \equiv e^{\imath\mathbf{k}\cdot\mathbf{r}}$ and $\psi_s \equiv f_k(\Omega)e^{\imath kr}/r$ we can calculate the current densities,

$$\begin{aligned}\mathbf{J}_{\text{in}} &= \frac{\hbar}{2m\imath}(\psi_{\text{in}}^\dagger\nabla\psi_{\text{in}} - c.c.) = \frac{\hbar\mathbf{k}}{m} \\ \mathbf{J}_s &= \frac{\hbar}{2m\imath}(\psi_s^\dagger\partial_r\psi_s - c.c.)\hat{\mathbf{e}}_r = \frac{\hbar\mathbf{k}'}{m}\frac{1}{r^2}|f_k(\Omega)|^2 + \mathcal{O}(r^{-3}) \ .\end{aligned} \tag{36.122}$$

The number $dI(\Omega)$ of particles scattered per second into the solid angle $d\Omega$ is simply $dI(\Omega) = |\mathbf{J}_s|r^2 d\Omega$. With this we can calculate the *differential effective cross section* defined by the ratio between $dI(\Omega)$ and the number $|\mathbf{J}_{\text{in}}|$ of incident particles per second,

$$\boxed{\frac{d\sigma}{d\Omega} \equiv \frac{dI(\Omega)}{|\mathbf{J}_{\text{in}}|d\Omega} = |f_k(\Omega)|^2} \ . \tag{36.123}$$

Finally we define the *total effective cross section*,

$$\sigma = \int d\Omega|f_k(\Omega)|^2 \ . \tag{36.124}$$

36.2.2 Wave packets

We now let a *wave packet* defined at a time $t = t_0$,

$$\psi(\mathbf{r}, t_0) = \int \frac{d^3k}{(2\pi)^3}a_{\mathbf{k}}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{36.125}$$

impinge on a scattering potential. The amplitude $a_{\mathbf{k}}$ be concentrated around $\mathbf{k}_0$, such that the wave packet approaches the scatterer with the velocity $\mathbf{v}_0 = \hbar\mathbf{k}_0/m$. The time evolution of the wavefunction $\psi(\mathbf{r}, t)$ determines the signal measured by a detector at a later time $t = t_0$. Our task is to determine $\psi(\mathbf{r}, t > t_0)$. The scattered states $\psi_{\mathbf{k}}$ solving the Schrödinger equation (36.113) are complete in the space of the extended wavefunctions, and we can write the temporal evolution as,

$$\psi(\mathbf{r}, t) = \int \frac{d^3k}{(2\pi)^3}A_{\mathbf{k}}\psi_{\mathbf{k}}(\mathbf{r})e^{-\imath E_k(t-t_0)/\hbar} \ . \tag{36.126}$$

At time t_0 the results (36.125) and (36.126) must match. To verify this, we write (36.125) replacing the plane wave $e^{\imath \mathbf{k}\cdot\mathbf{r}}$ using the Lippmann-Schwinger equation (36.118) with Green's function (36.117), and then we compare the coefficients,

$$\psi(\mathbf{r}, t_0) = \int \frac{d^3k}{(2\pi)^3} a_{\mathbf{k}} \left[\psi_{\mathbf{k}}(\mathbf{r}) + \frac{m}{2\pi\hbar^2} \int d^3r' \frac{e^{\imath k|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|} V(\mathbf{r}')\psi_{\mathbf{k}}(\mathbf{r}') \right] . \tag{36.127}$$

The scattering process is illustrated in Fig. 36.15. To simplify the calculation of the

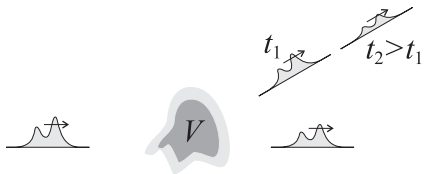

Figure 36.15: Scattering of wave packet at a potential.

second term in this equation, we assume that $\psi_{\mathbf{k}}$ is smooth, that is, there are no resonances, such that we can approximate, $\psi_{\mathbf{k}} \simeq \psi_{\mathbf{k}_0}$. With $k \simeq \mathbf{k}\cdot\hat{\mathbf{e}}_{k_0}$ we obtain,

$$\begin{aligned} \int \frac{d^3k}{(2\pi)^3} a_{\mathbf{k}} e^{\imath k|\mathbf{r}-\mathbf{r}'|} \psi_{\mathbf{k}}(\mathbf{r}') &= \int \frac{d^3k}{(2\pi)^3} a_{\mathbf{k}} e^{\imath \mathbf{k}\cdot(\hat{\mathbf{e}}_{k_0}|\mathbf{r}-\mathbf{r}'|)} \psi_{\mathbf{k}_0}(\mathbf{r}') \\ &\overset{(36.125)}{=} \psi(\hat{\mathbf{e}}_{k_0}|\mathbf{r}-\mathbf{r}'|, t_0)\psi_{\mathbf{k}_0}(\mathbf{r}') . \end{aligned} \tag{36.128}$$

Here, $\psi(\hat{\mathbf{e}}_{k_0}|\mathbf{r}-\mathbf{r}'|, t_0)$ is the incident wave package evaluated to the right, where by definition it is $\simeq 0$. The expression (36.127) therefore has the form,

$$\psi(\mathbf{r}, t_0) = \int \frac{d^3k}{(2\pi)^3} a_{\mathbf{k}} \psi_{\mathbf{k}}(\mathbf{r}) , \tag{36.129}$$

and a comparison of the coefficients with (36.126) gives, $A_{\mathbf{k}} = a_{\mathbf{k}}$. Finally, we evaluate $\psi(\mathbf{r}, t)$ at the time of detection $t > t_0$ to understand, that the above stationary analysis is actually physically correct. According to (36.126) we have,

$$\begin{aligned} \psi(\mathbf{r}, t) &= \int \frac{d^3k}{(2\pi)^3} A_{\mathbf{k}} \psi_{\mathbf{k}}(\mathbf{r}) e^{-\imath E_k(t-t_0)/\hbar} \\ &\overset{(36.120)(36.125)}{\simeq} \psi_0(\mathbf{r}, t) + \int \frac{d^3k}{(2\pi)^3} a_{\mathbf{k}} \frac{e^{\imath kr}}{r} f_k(\Omega) e^{-\imath E_k(t-t_0)/\hbar} . \end{aligned} \tag{36.130}$$

Hence, $\psi_0(\mathbf{r}, t)$ describes the evolution of the wave packet without scatterer,

$$\psi_0(\mathbf{r}, t) = \underbrace{\int \frac{d^3k}{(2\pi)^3} a_{\mathbf{k}} e^{\imath \mathbf{k}\cdot\mathbf{r}}}_{\psi(\mathbf{r}, t_0)} e^{-\imath E_k(t-t_0)/\hbar} . \tag{36.131}$$

If f_k it's smooth around $\mathbf{k} = \mathbf{k}_0$, which allows us to place this amplitude ($f_k \simeq f_{k_0}$) in front of the integral, and with $k \simeq \mathbf{k}\cdot\hat{\mathbf{k}}_0$ we obtain,

$$\psi(\mathbf{r}, t) \overset{t \text{ large}}{\Longrightarrow} \underbrace{\psi_0(\mathbf{r}, t)}_{\text{packet not scattered}} + \underbrace{\frac{f_{k_0}(\Omega)}{r} \psi_0(\hat{k}_0 r, t)}_{\text{packet scattered}} . \tag{36.132}$$

The scattering process is illustrated in Fig. 36.15: According to the last equation the scattering process involves the superposition of the non-scattered packet and a packet scattered in the direction Ω. The latter involves the amplitude $\Psi_0(\hat{k}_0 r, t)$ of a packet propagating in forward direction, which only needs to be evaluated at the right time and distance. This packet will then be multiplied with the amplitude describing the angular dependency f_{k_0}; the angle, therefore, only appears through this amplitude and not in the wavefunction ψ_0. In two situations the above analysis can not be applied :

- when V is long-ranged, f.ex., $V = 1/r$,
- when the incident energy E_k is resonant.

36.2.3 Born approximation

The Lippmann-Schwinger equation suggests the following perturbative iteration called *Born series* [98],

$$\begin{aligned}\psi(\mathbf{r}) &= \psi_{\text{in}}(\mathbf{r}) + \left(G \star \tfrac{2m}{\hbar^2} V\psi\right)(\mathbf{r}) \\ &= \psi_{\text{in}}(\mathbf{r}) + \tfrac{2m}{\hbar^2}(G \star V\psi_{\text{in}})(\mathbf{r}) + \left(\tfrac{2m}{\hbar^2}\right)^2 [G \star V(G \star V\psi_{\text{in}})](\mathbf{r}) \\ &= \psi_{\text{in}}(\mathbf{r}) + \tfrac{2m}{\hbar^2}\int_V G(\mathbf{r}-\mathbf{r}')V(\mathbf{r}')\psi_{\text{in}}(\mathbf{r}')d^3\mathbf{r}' \\ &\qquad + \left(\tfrac{2m}{\hbar^2}\right)^2 \int_V G(\mathbf{r}-\mathbf{r}')V(\mathbf{r}')G(\mathbf{r}-\mathbf{r}'')V(\mathbf{r}'')\psi_{\text{in}}(\mathbf{r}'')d^3r'd^3r'' \ .\end{aligned} \tag{36.133}$$

In the so-called *Born approximation* we consider only the first perturbation order, and inserting a plane wave, $\psi_{\text{in}}(\mathbf{r}) = e^{\imath kz}/(2\pi)^{3/2}$, we obtain,

$$\psi(\mathbf{r}) = \frac{e^{\imath kz}}{(2\pi)^{3/2}} - \frac{m}{(2\pi)^{3/2}2\pi\hbar^2}\int_V \frac{e^{\imath k|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|}V(\mathbf{r}')e^{\imath kz'}d^3r' \ . \tag{36.134}$$

The asymptotic behavior $r \gg r'$, it follows with (36.119) using $z' = \mathbf{r}'\cdot\hat{\mathbf{e}}_z$ and defining $\mathbf{k}_s = k\hat{\mathbf{e}}_r$ and $\mathbf{k}_i = k\hat{\mathbf{e}}_z$,

$$\begin{aligned}\psi(\mathbf{r}) &\simeq \frac{e^{\imath kz}}{(2\pi)^{3/2}} - \frac{m}{(2\pi)^{3/2}2\pi\hbar^2}\int_V \frac{e^{\imath k(r-\mathbf{r}\cdot\mathbf{r}'/r)}}{r}V(\mathbf{r}')e^{\imath\mathbf{k}\cdot\mathbf{r}'}d^3r' \\ &= \frac{e^{\imath kz}}{(2\pi)^{3/2}} + \frac{m}{(2\pi)^{3/2}2\pi\hbar^2}\frac{e^{\imath kr}}{r}\int_V V(\mathbf{r}')e^{\imath(\mathbf{k}_i-\mathbf{k}_s)\cdot\mathbf{r}'}d^3r' \\ &\equiv \frac{1}{(2\pi)^{3/2}}\left(e^{\imath kz} + \frac{e^{\imath kr}}{r}f(k_i,k_s)\right) \ ,\end{aligned} \tag{36.135}$$

with

$$\boxed{f(k_i,k_s) \equiv \frac{m}{2\pi\hbar^2}\int_V V(\mathbf{r}')e^{\imath(\mathbf{k}_i-\mathbf{k}_s)\cdot\mathbf{r}'}d^3r' = -\frac{m}{2\pi\hbar^2}\langle k_s|\tilde{V}|k_i\rangle} \ .$$

36.2.4 Spherical potentials

For spherically symmetric scattering potentials, $V(\mathbf{r}) = V(r)$, the Hamiltonian $\hat{H} = p^2/2m + V(r)$ commutes with the rotation operators $U_{\vec{\omega}} = e^{-\imath\vec{\omega}\cdot\mathbf{L}/\hbar}$ around any axis $\hat{\mathbf{e}}_{\vec{\omega}}$. Therefore, we can separate the angular problem and decompose the scattering problem following the irreducible representations of the rotation group. This *partial wave* decomposition can be written,

$$\psi_{\mathbf{k}}(\mathbf{r}) = \sum_{\ell=0}^{\infty}(2\ell+1)\imath^{\ell}P_{\ell}(\cos\theta)R_l(r) \ , \tag{36.136}$$

where the factor $(2\ell+1)i^{\ell}$ is a convention facilitating the calculation later on. By inserting this separation ansatz for the radial and angular variables into the stationary Schrödinger equation (36.113), we obtain the radial Schrödinger equation,

$$\left[\frac{\partial^2}{\partial r^2} - \frac{\ell(\ell+1)}{r^2} + k^2\right] rR_{\ell}(r) = \frac{2m}{\hbar^2}V(r)rR_{\ell}(r) \ , \tag{36.137}$$

where $\psi_{\mathbf{k}}$ must satisfy the boundary conditions (36.114). Fortunately, we can also expand the incident wave by partial waves [7],

$$e^{\imath kz} = e^{\imath r\cos\theta} = \sum_{\ell=0}^{\infty}(2\ell+1)\imath^{\ell}j_{\ell}(kr)P_{\ell}(\cos\theta) \ . \tag{36.138}$$

We now use the result (36.138) to find the boundary conditions for the radial waves R_{ℓ}. In the infinity we have $rV(r) \overset{r\to\infty}{\longrightarrow} 0$. For this reason,

$$R_{\ell}(r) \overset{r\to\infty}{\longrightarrow} \alpha_{\ell}[h_{\ell}^{(2)}(kr) + s_{\ell}h_{\ell}^{(1)}(kr)] \ , \tag{36.139}$$

where the Hankel functions $h_{\ell}^{(1,2)}(kr) \sim e^{\pm\imath(\rho-(\ell+1)\pi/2)}$ describe, respectively, incident $(h_{\ell}^{(2)})$ and outgoing $(h_{\ell}^{(1)})$ spherical waves.

To determine the coefficients α_{ℓ} and s_{ℓ} we note first that, without potential, $V(r) = 0$, the solution of the radial equation (36.137) is known,

$$R_{\ell}(r) = j_{\ell}(kr) = \tfrac{1}{2}[h_{\ell}^{(2)}(kr) + h_{\ell}^{(1)}(kr)] \ , \tag{36.140}$$

such that $\alpha_{\ell} = \frac{1}{2}$ and $s_{\ell} = 1$. For $V(r) \neq 0$ the incident wave $h_{\ell}^{(2)}$ is the same, but not the incident $h_{\ell}^{(1)}$, which results in $s_{\ell} \neq 1$. However, particle number conservation requires that the number of particles entering the potential is equal to the number of particles coming out. That is, the total radial flow must be,

$$0 = j_r^{\ell}(r) = \frac{\hbar}{2\imath m}[R_{\ell}^*\partial_r R_{\ell} - R_{\ell}\partial_r R_{\ell}^*] = \frac{\hbar}{4mkr^2}[|s_{\ell}|^2 - 1] \ , \tag{36.141}$$

[7] For the more general case of arbitrary vectors $\mathbf{k}$ e $\mathbf{r}$, we use the addition theorem for $Y_{\ell m}$ and express $P_{\ell}(\cos\theta)$ by spherical functions,

$$e^{\imath\mathbf{k}\cdot\mathbf{r}} = 4\pi\sum_{\ell=0}^{\infty}\sum_{m=-\ell}^{\ell}\imath^{\ell}j_{\ell}(kr)Y_{\ell m}^*(\Omega_{\mathbf{k}})Y_{\ell m}(\Omega_{\mathbf{r}}) \ .$$

approximating $2R_\ell \simeq \frac{e^{-\imath(kr+w_\ell)}}{kr} + s_\ell \frac{e^{\imath(kr+w_\ell)}}{kr}$. Hence, $|s_\ell| = 1$, that is,

$$s_\ell = e^{2\imath\delta_\ell(k)} \ , \tag{36.142}$$

where $\delta_\ell(k)$ is the *scattering phase*. The scattering phase determines the solution of the scattering problem, because it fixes the scattering amplitude: Evaluating the solution (36.136) in the asymptotic limit by the formula (36.138),

$$\begin{aligned}\psi_{\mathbf{k}}(\mathbf{r}) &\sim \tfrac{1}{2}\sum_{\ell=0}^{\infty}(2\ell+1)\imath^\ell P_\ell(\cos\theta)[h_\ell^{(2)}(kr) + e^{2i\delta_\ell}h_\ell^{(1)}(kr)] \qquad (36.143)\\ &= e^{\imath\mathbf{k}\cdot\mathbf{r}} + \tfrac{1}{2}\sum_{\ell=0}^{\infty}(2\ell+1)\imath^\ell P_\ell(\cos\theta)[e^{2\imath\delta_\ell}-1]h_\ell^{(1)}(kr) = e^{\imath\mathbf{k}\cdot\mathbf{r}} + f_k(\theta)\frac{e^{\imath kr}}{r} \ ,\end{aligned}$$

we obtain the scattering amplitude in the form [8]

$$\boxed{f_k(\theta) = \tfrac{1}{k}\sum_\ell (2\ell+1)P_\ell(\cos\theta)e^{\imath\delta_\ell}\sin\delta_\ell} \ . \tag{36.144}$$

We call

$$\frac{e^{2\imath\delta_\ell}-1}{2ik} = \frac{e^{\imath\delta_\ell}\sin\delta_\ell}{k} \equiv f_\ell \tag{36.145}$$

the *amplitude of the partial wave* [962, 121].

36.2.5 Scattering phase and length

In summary, we can, within the Born approximation, express the collisional state of any type of particles by isotropic potentials,

$$\psi(\mathbf{r}) \sim e^{\imath\mathbf{k}\cdot\mathbf{r}} + \frac{e^{\imath kr}}{r} f_k(\Omega) \ . \tag{36.146}$$

The scattering cross section can be written,

$$\begin{aligned}\sigma &= \int d\Omega |f_{\mathbf{k}}(\Omega)|^2 = \tfrac{1}{k^2}\int d\Omega |\sum_\ell (2\ell+1)P_\ell(\cos\theta)\sin\delta_\ell|^2 \qquad (36.147)\\ &= \frac{4\pi}{k^2}\sum_\ell (2\ell+1)\sin^2\delta_\ell = 4\pi\sum_\ell (2\ell+1)|f_\ell|^2 \ .\end{aligned}$$

The quantity

$$\boxed{\sigma_\ell = \frac{4\pi}{k^2}(2\ell+1)\sin^2\delta_\ell = \frac{4\pi}{k^2}(2\ell+1)|f_\ell|^2} \tag{36.148}$$

is called *effective partial cross section*. Obviously, $\sigma_\ell \le \frac{4\pi}{k^2}(2\ell+1)$ holds. The phase shift $e^{2i\delta_\ell}$ has a simple physical interpretation: We consider the function,

$$\begin{aligned}e^{\imath\delta_\ell} j_\ell(kr+\delta_\ell) &= \tfrac{e^{\imath\delta_\ell}}{2}[h_\ell^{(2)}(kr+\delta_\ell) + h_\ell^{(1)}(kr+\delta_\ell)] \qquad (36.149)\\ &\sim \frac{e^{\imath\delta_\ell}}{2}\left[\frac{(-\imath)^\ell e^{i(kr+\delta_\ell)}}{kr+\delta_\ell} + \frac{(+\imath)^\ell e^{-\imath(kr+\delta_\ell)}}{kr+\delta_\ell}\right] \overset{kr\gg\delta_\ell}{\longrightarrow} \tfrac{1}{2}[h_\ell^{(2)} + e^{2\imath\delta_\ell}h_\ell^{(1)}] \sim R_\ell \ .\end{aligned}$$

[8] With $h_\ell^{(1)} \sim (-\imath)^{\ell+1}\frac{e^{\imath kr}}{kr}$.

Now comparing the case $V = 0$ giving $R_\ell(r) = j_\ell(kr)$ with the case $V \neq 0$ giving $R_\ell(r) \sim e^{\imath\delta_\ell} j_\ell(kr + \delta_\ell)$, we notice that a positive displacement, $\delta_\ell > 0$, pulls the wavefunction into the potential, while a negative displacement, $\delta_\ell < 0$, pushes the wavefunction out, as illustrated in Fig. 36.16.

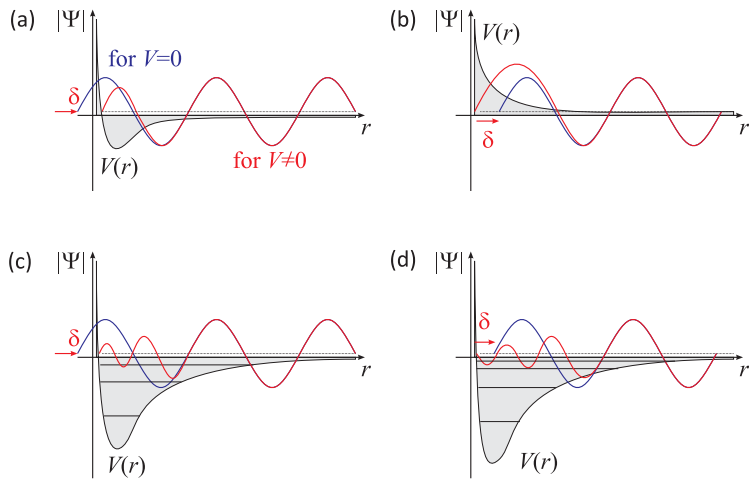

Figure 36.16: Phase shift $\delta_\ell(k)$ of the scattered wavefunction. (a) An attractive potential increases the kinetic energy and the wavefunction oscillates faster, which causes a positive phase shift and a negative scattering length. (b) A repulsive potential slows down the wavefunction oscillation and produces a positive scattering length. (c,d) In an attractive potential deep enough to support vibrational states, the wavefunction performs several oscillations. The sign of the scattering length then depends on the distance of the last bound state to the continuum.

36.2.6 Optical theorem

Consider the amplitude for forward scattering $f(0)$ by writing its imaginary part as,

$$\mathrm{Im}\, f(0) = \tfrac{1}{k} \sum_k (2\ell + 1) P_\ell(\cos\theta) \sin^2 \delta_\ell \big|_{\theta=0} = \tfrac{1}{k} \sum_k (2\ell+1) \sin^2 \delta_\ell \equiv \frac{k}{4\pi}\sigma \,. \quad (36.150)$$

With this we obtain the *optical theorem*,

$$\boxed{\sigma = \tfrac{4\pi}{k} \mathrm{Im}\ f(0)} \,. \quad (36.151)$$

The deeper meaning of the optical theorem is the conservation of particle number: The flux of scattered particles, $(\hbar k/m)\sigma = I_{sct}$, must be extracted from the incident flux I_0 by scattering, and therefore, is missing in the forward direction. It is the interference of the scattered wave with the incident wave, which diminishes the non-scattered wave and therefore creates a shadow of the scatterer in the forward direction. The particles missing in the shadow of the scatterer are precisely those that have been scattered. This is the message of the optical theorem, which is always valid in the absence of possible (inelastic) processes leading to trapping or a transformation of the particles.

Table 36.1: List of scattering length for various alkaline species.

36.2.6.1 Born approximation for the scattering phase

The scattering problem can be considered as solved when we know the scattering amplitude $f_k(\theta)$, since this quantity gives us the flux measured by the detector. Now, $f_k(\theta)$ is known, when we know the scattering phases $\delta_{\ell,k}$. These are, in general, determined by integrating the radial equation (36.137). Here, we expect that only angular momenta $\ell < kR_0$ (R_0 is the range of potential) produce significant phase shifts. Particles with larger angular momenta have collision parameters $b \sim \ell/k$ out of the potential reach. We notice that partial s-waves are always scattered, whereas partial p-waves (or higher) are only weakly scattered when the energy is weak, $E < \hbar^2/2mR_0^2$. In these cases an approximate calculation of δ_ℓ is sufficient: We insert (36.136) and $e^{\imath kz} = \sum_\ell \frac{1}{2}\sqrt{4\pi(2\ell+1)}\int_{-1}^{1} dz P_\ell(z) e^{ikz}$ into (36.121) and integration over Ω' yields,

$$\begin{aligned} f_k(\theta) &= \frac{2m}{4\pi\hbar^2}\int_V e^{-\imath \mathbf{k}'\cdot\mathbf{r}'} V(\mathbf{r}')\psi(\mathbf{r}')d^3\mathbf{r}' \\ &= -\tfrac{2m}{\hbar^2}\sum_{\ell=0}^{\infty}(2\ell+1)P_\ell(\cos\theta)\int_0^\infty dr\ r^2 V(r) j_\ell(kr) R_\ell(r)\ . \end{aligned} \tag{36.152}$$

Comparing this formula with (36.144) we find,

$$e^{\imath\delta_\ell}\sin\delta_\ell = -\tfrac{2mk}{\hbar^2}\int_0^\infty dr\ r^2 V(r) j_\ell(kr) R_\ell(r) \overset{R_\ell \simeq j_\ell}{\simeq} -\tfrac{2mk}{\hbar^2}\int_0^\infty dr\ r^2 V(r) j_\ell^2(kr)\ . \tag{36.153}$$

The result (36.153) is the Born approximation for the scattering phase $\delta_\ell(k)$. Note that $R_\ell \simeq j_\ell$ is not a good approximation, in ranges where V is large and R_ℓ strongly suppressed (f.ex., inside hard cores). For ℓ large we have $j_\ell \sim r^\ell$, and $\delta\ell$ is small for a limited potential $V(r)$.

36.2.6.2 Analyticity of $s_\ell(E)$

We consider a short-range potential that disappears at $r > R_0$. The radial solution out of the reach of the potential will then be given by,

$$R_\ell(r) = \tfrac{1}{2}[h_\ell^{(2)}(kr) + s_\ell h_\ell^{(1)}(kr)] \ , \tag{36.154}$$

while for $r < R_0$ the solution R_ℓ must be found by integrating the radial equation (36.137). The scattering phase s_ℓ must be chosen in a way that R_ℓ and $\partial_r R_\ell$ be continuous at R_0. The normalization factor vanishes in the logarithmic derivative, such that,

$$\gamma_\ell \equiv \partial_r \ln R_\ell|_{R_0^-} = \frac{1}{R_\ell}\frac{\partial R_\ell}{\partial r}\bigg|_{R_0^-} = \frac{\partial_r h_\ell^{(2)} + s_\ell \partial_r h_\ell^{(1)}}{h_\ell^{(2)} + s_\ell h_\ell^{(1)}}\bigg|_{R_0^+} \ . \tag{36.155}$$

Now [9]

$$s_\ell - 1 = \frac{2(\partial_r - \gamma_\ell) j_\ell}{(\gamma_\ell - \partial_r) h_\ell^{(1)}}\bigg|_{R_0} \tag{36.156}$$

or with $s_\ell - 1 = \frac{2\imath}{\cot\delta_\ell - \imath}$ expressing δ_ℓ by γ_ℓ,

$$\cot\delta_\ell = \frac{(\partial_r - \gamma_\ell) n_\ell}{(\partial_r - \gamma_\ell) j_\ell}\bigg|_{R_0} \ . \tag{36.157}$$

The partial effective cross section is,

$$\sigma_\ell = \frac{4\pi}{k^2}(2\ell+1)\sin^2\delta_\ell = \frac{4\pi}{k^2}\frac{2\ell+1}{1+\cot^2\delta_\ell} \ . \tag{36.158}$$

Analyzing the expressions for $s_\ell(\cot\delta_\ell)$ and $\sigma_\ell(\cot\delta_\ell)$ we find that

- for $\cos\delta_\ell = \imath$ the scattering phase s_ℓ has a pole and $\sigma_\ell \to \infty$;
- for $\cos\delta_\ell = 0$ the scattering phase is $s_\ell - 1$ and $\sigma_\ell = 4\pi(2\ell+1)/k^2$ is maximal.

The poles of s_ℓ are just the bound states: A bound state asymptotically satisfies $R_\ell(r) \sim h_\ell^{(1)}(\imath\kappa r) \propto e^{-\kappa r}$ with the binding energy $E_B = -\hbar^2\kappa^2/2m$. The condition of continuity is given by,

$$\gamma_\ell = \frac{\partial_r h_\ell^{(1)}}{h_\ell^{(1)}}\bigg|_{R_0} \ , \tag{36.159}$$

and the insertion into the general continuity condition (36.157) gives,

$$\cot\delta_\ell = \frac{h_\ell^{(1)}\partial_r n_\ell - n_\ell \partial_r h_\ell^{(1)}}{h_\ell^{(1)}\partial_r j_\ell - j_\ell \partial_r h_\ell^{(1)}} = \imath \ . \tag{36.160}$$

[9] We have for the spherical Hankel functions: $h_\ell^{(1,2)}(x) = j_\ell(x) \pm \imath y_\ell(x)$.

In the same way the zero crossings of $\cot\delta_\ell$ correspond precisely to the scattering resonances. To see this, we expand around a resonance,

$$\cot\delta_\ell(E) \simeq \cot\delta_\ell(E_r) - \frac{1}{\sin^2\delta_\ell}\left.\frac{d\delta_\ell}{dE}\right|_{E_r}(E-E_r) = -\left.\frac{d\delta_\ell}{dE}\right|_{E_r}(E-E_r) \equiv -\frac{2}{\Gamma_r}(E-E_r)\ , \tag{36.161}$$

defining the width $\Gamma_r = \left.\frac{2}{\partial_E\delta_\ell}\right|_{E_r}$ of the resonance peak in the effective section σ_ℓ in the form,

$$\sigma_\ell = \frac{4\pi}{k^2}(2\ell+1)\frac{(\Gamma_r/2)^2}{(E-E_r)^2+(\Gamma_r/2)^2}\ . \tag{36.162}$$

See Fig. 36.17,

$$s_\ell - 1 = \frac{-\imath\Gamma_r}{E-(E_r-\imath\gamma_r/2)}\ . \tag{36.163}$$

The scattering phase δ_ℓ increases by π. The value $\delta_\ell(E=0)$ gives the number of bound states, $\delta_\ell(0) = n^\ell_{\text{bound}}\pi$.

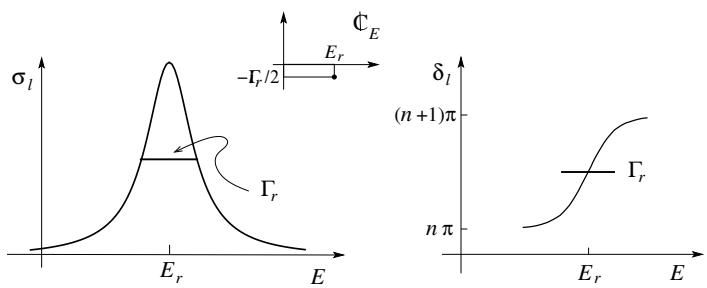

Figure 36.17: Peak of the resonance of width Γ_r: (Left) effective cross section $\sigma_\ell(E)$, (right) scattering phase $\delta_\ell(E)$, and (center) scheme of the position of the pole in the complex energy plane E.

36.2.7 Exercises

36.2.7.1 Ex: Green's method

Show that, knowing the solution of (36.116), that is, knowing the Green function, we can write the solution of the scattering problem (36.115) as,

$$\psi_{\mathbf{k}}(\mathbf{r}) = e^{\imath\mathbf{k}\cdot\mathbf{r}} + \tfrac{2m}{\hbar^2}\int d^3\mathbf{r}'\mathcal{G}(\mathbf{r}-\mathbf{r}',k)V(\mathbf{r}')\psi_{\mathbf{k}}(\mathbf{r})\ .$$

36.2.7.2 Ex: Green's function

Calculate the Green function of the equation (36.116).

36.2.7.3 Ex: Rutherford scattering

Consider the scattering of a particle of charge Q by a static charge distribution $\rho(\mathbf{r}) = \rho_0 e^{-\alpha r}$ totaling the charge Q'. Derive from (36.136) the formula (23.10) describing the Rutherford scattering.

36.2.7.4 Ex: Scattering length for hard-core potentials

Calculate the scattering length for a spherical box barrier and a spherical box potential as a function of potential depth (see also Excs. 25.1.5.4 and 25.1.5.5 and [952]).

36.3 Cold atomic collisions

Modern techniques developed in the area of atomic optics allow to cool atomic gases to temperatures well below 1 μK. We use the expansions $j_\ell \sim x^\ell/(2\ell+1)!!$ and $n_\ell \sim (2\ell-1)!!/x^{\ell+1}$ in the equation (36.157), and obtain for $kR_0 \ll 1$,

$$\cos\delta_\ell \simeq \frac{2\ell+1)!!(2\ell-1)!!}{(kR_0)^{2\ell+1}} \frac{\ell+1+R_0\alpha_\ell(E)}{\ell-R_0\alpha_\ell(E)} \ . \tag{36.164}$$

A coarse approximation leads to

$$\cos\delta_\ell = \frac{\cos\delta_\ell}{\sin\delta_\ell} \overset{\delta_\ell \ll 1}{\simeq} \frac{1}{\sin\delta_\ell} \simeq \frac{1}{(R_0k)^{2\ell+1}} \ , \tag{36.165}$$

that is,

$$\sin\delta_\ell \simeq (R_0k)^{2\ell+1} \ . \tag{36.166}$$

In other words, the scattering phases decrease rapidly, in the regime of cold collisions, with increasing ℓ, and $\ell = 0$ type collisions dominate,

$$k\cot\delta_0 \overset{\alpha_\ell(E)\simeq\alpha_\ell(0)}{\simeq} -\frac{1+R_0\alpha_0(0)}{R_0^2\alpha_\ell(E)} \ . \tag{36.167}$$

The s-wave *scattering length* defined by,

$$a_s \equiv \frac{R_0^2\alpha_\ell(E)}{1+R_0\alpha_0(0)} = \frac{\sin\delta_0}{k} \tag{36.168}$$

then it is the only relevant parameter of the collision. For $R_0\alpha_0 \gg 1$ we find $a \simeq R_0$. For example, for a hard sphere we have $R_\ell(R_0) = 0$, $\alpha_\ell = \infty$, $a = R_0 > 0$ and $\cot\delta_0 = -1/kR_0$. For small kR_0 we obtain $\delta_0 \simeq -kR_0 < 0$, which corresponds to a negative phase shift for the repulsive potential, as expected. The effective cross section is,

$$\boxed{\sigma_0 = \frac{4\pi}{k^2}\frac{1}{1+\cot^2\delta_0} \simeq \frac{4\pi}{k^2+1/a_s^2}} \ . \tag{36.169}$$

In comparison to the effective cross section for higher angular momenta, $\sigma_\ell \propto \frac{\sin^2\delta_\ell}{k^2}$ behaves like,

$$\sigma_\ell \propto R_0^2(R_0k)^{4\ell} \to 0 \ . \tag{36.170}$$

In contrast, we find that the scattering at low energies has an s-wave character, σ being dominated by σ_0,

$$\sigma(E=0) = 4\pi a_s^2 \ . \tag{36.171}$$

For a hard sphere ($a = R_0$) we find an effective cross section *four times larger* than classically expected ($\sigma_{cl} = \pi R_0^2$).

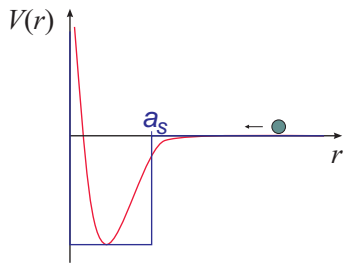

Figure 36.18: The cold collision can be described by a hard core potential.

In summary, for kinetic energies below the centrifugal barrier, only s-wave collisions are significant. The higher-order partial waves are *frozen* behind the centrifugal barrier. That is, the energy of cold collisions is not enough to excite a rotational motion, not even the one with the lowest rotational energy allowed by quantum mechanics. Such a collision is called *cold collision* or *s-wave collision*.

The relative wavefunction tends asymptotically to $\psi(R) \overset{R\to\infty}{\longrightarrow} k_{dB}^{-1} \sin\left[k_{dB}(R-a)\right] \overset{T\to 0}{\longrightarrow} R - a$. This means that for temperatures so low that the length of the Broglie wave of the relative motion is much longer than the potential range $k_{dB}^{-1} \gg R_{turning}$, the scattering becomes independent of temperature, and the scattering length a becomes well defined [10]

Generally, a repulsive interaction potential corresponds to a positive scattering length and an attractive potential to a negative one. However, if the attractive potential supports bound states, the value of the scattering length depends on the energy of the last bound state with respect to the dissociation threshold [952, 953].

36.3.1 Collision cross section, unitarity regime

Note that the scattering length a may have a value quite different from r_e, especially in the presence of a Feshbach resonance. The meaning of *universality*, $|a| \gg r_e$, is that short-range properties play no role in the dynamics.

At low temperatures, $kr_e \to 0$, we have the equation (36.169). In contrast, in the *unitarity limit*, $k \to \infty$, but $r_e \to 0$, we have,

$$\sigma = \frac{8\pi}{k^2} \ , \tag{36.172}$$

and the cross section becomes independent of atomic particularities. What the equation (36.169) says is, that the maximum attainable cross-section is limited to the

[10] At temperatures at which the trajectory of atoms is described by de Broglie waves the only difference between an atom before and after an elastic collision is the phase shift δ_0 of this wave.

smallest of the values $8\pi a$ and $8\pi/k$. Even though $a(B)$ can be increased to divergent values near a Feshbach resonance, for finite collision energies it will never exceed an effective value $a_{eff} = 1/\sqrt{a^2 + 1/k^2}$. For a thermal gas, $k = \hbar^{-1}\sqrt{2\pi m k_{\rm B} T}$, while for a pure condensate $k = 2\pi/L$, where L is the size of the condensate. Therefore, the effective scattering length can not exceed the size of the condensate. Unitarity also means that the kinetic energy exceeds the binding energy, $k_{\rm B}T \equiv \frac{\hbar^2 k^2}{2m} \leq \frac{\hbar^2}{2ma^2}$.

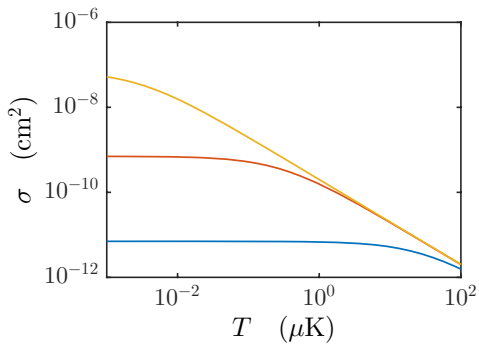

Figure 36.19: (code) Temperature dependence of the collision cross section for various scattering lengths. For higher scattering lengths, the unitarity limit is reached at lower temperatures.

The collision rate depends on the density, temperature and collisional cross section [509],

$$\gamma_{coll.peak} = \sqrt{2}\sigma_{elast}\bar{v}n_0 \ , \qquad (36.173)$$
$$\gamma_{coll.aver} = \gamma_{coll.peak}/2\sqrt{2} \ .$$

Note that at the unitary limit, as $\bar{v} \propto \sqrt{T}$, we have that $\sigma_{elas} \propto T$ and $n_0 \propto \bar{r}^{-3} \propto T^{-3/2}$, such that the collision rate is independent of temperature.

At low temperatures, $k \to 0$, the delocalization of the colliding particles is greater than its short-range structure. This is the *Wigner threshold law* [970, 962]. For elastic collisions of neutral ground state atoms, the cross section (36.169) becomes temperature-independent. Thus, the rate coefficient decreases as $\langle\sigma\bar{v}\rangle \propto \sqrt{T}$, while the collision rate increases as $\langle\sigma\bar{v}n_0\rangle \propto T^{-1}$.

For inelastic collisions, $\sigma \propto T^{-1}$. For three-body collisions see [301].

36.3.2 Collisions between identical particles

We consider collisions of two identical particles. Separating the center-of-mass coordinates, $\mathbf{R} = \mathbf{r}_1 + \mathbf{r}_2$, from the relative ones, $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$, we see that $\mathbf{R}$ is symmetric and $\mathbf{r}$ antisymmetric in $\mathbf{r}_1$ and $\mathbf{r}_2$. We separate the wavefunction into orbital and spin parts,

$$\Psi(x_1, x_2) = e^{\imath \mathbf{P}\cdot\mathbf{R}}\psi(\mathbf{r})\chi(s_1, s_2) \ . \qquad (36.174)$$

For indistinguishable particles the result of the scattering has the asymptotic form,

$$\psi(\mathbf{r}) \sim e^{\imath \mathbf{k}\cdot\mathbf{r}} + f(\theta)\frac{e^{\imath kr}}{r} \ . \qquad (36.175)$$

36.3.2.1 Spin 0 bosons

For bosons with spin 0 we have $\chi = 1$ and, because of the symmetry of Ψ, holds $\psi(\mathbf{r}) = \psi(-\mathbf{r})$. Consequently, we must symmetrize the result of the scattering. We make use of the fact that the exchange of particles via $\mathbf{r} \to -\mathbf{r}$ in polar coordinates corresponds to the transformation $\theta \to \pi - \theta$, $r \to r$,

$$\psi \sim (e^{\imath \mathbf{k}\cdot\mathbf{r}} + e^{-\imath \mathbf{k}\cdot\mathbf{r}}) + [f(\theta) + f(\pi - \theta)]\frac{e^{\imath kr}}{r} \ . \tag{36.176}$$

For the effective differential cross section we obtain,

$$\frac{d\sigma}{d\Omega} = |f(\theta) + f(\pi - \theta)|^2 = |f(\theta)|^2 + |f(\pi - \theta)|^2 + 2\mathfrak{Re}\,[f^*(\theta) f(\pi - \theta)] \ . \tag{36.177}$$

The first two terms are classical. The third (interference) term appears because of quantum statistics. The angles showing up in (36.177) are illustrated in Fig. 36.20. For bosons, the interference terms double the cross section as compared to the classical case, when $\theta = \pi/2$,

$$\boxed{\frac{d\sigma}{d\Omega} = 4|f(\tfrac{\pi}{2})|^2} \ . \tag{36.178}$$

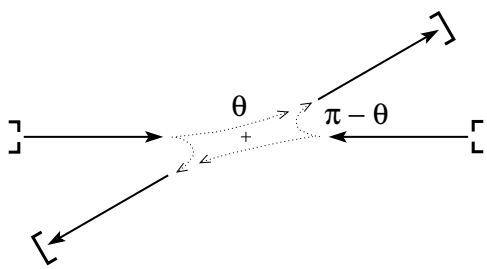

Figure 36.20: The symmetrization of the collision wavefunction produces two paths with angles θ and $\pi - \theta$, which must be added coherently.

For the isotropic potential $V(r)$ we use the partial wave representation,

$$f(\theta) = \sum_\ell \imath^\ell f_\ell P_\ell(\cos\theta) \ . \tag{36.179}$$

With $P_\ell(\cos\theta) = (-1)^\ell P_\ell(\pi - \cos\theta)$ we get,

$$f(\theta) - f(\pi - \cos\theta) = 2\sum_{\ell\mathrm{par}} \imath^\ell f_\ell P_\ell(\cos\theta) \ , \tag{36.180}$$

and we find that only *even angular momenta* appear [11]

[11] For ℓ odd the Legendre polynomial changes sign, and the contributions vanish.

36.3.2.2 Spin 1/2 fermions

In the case of fermions with spin $\frac{1}{2}$ two situations are possible [12]:

1. The singlet spin state $\chi_s = \frac{1}{\sqrt{2}}[(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle]$ is antisymmetric and, consequently, the orbital part,
$$\psi(\mathbf{r}) = \psi(-\mathbf{r}) \tag{36.181}$$
must be symmetric. The cross section is the same as for spin 0 bosons,
$$\left.\frac{d\sigma}{d\Omega}\right|_s = |f(\theta) + f(\pi - \theta)|^2 \ . \tag{36.182}$$

2. The triplet spin states,
$$\chi_s = \begin{cases} |\uparrow\uparrow\rangle \\ \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle) \\ |\downarrow\downarrow\rangle \end{cases} \tag{36.183}$$
require an antisymmetric orbital wavefunction, $\psi(\mathbf{r}) = -\psi(-\mathbf{r})$, and we obtain a scattering amplitude, $f(\theta) \to f(\theta) - f(\pi - \theta)$, which only contains *odd angular momenta* ℓ. With this, the cross section becomes,
$$\left.\frac{d\sigma}{\Omega}\right|_t = |f(\theta) - f(\pi - \theta)|^2 \overset{\theta=\pi/2}{=} 0 \ , \tag{36.184}$$
Note that polarized fermions only scatter in channels of odd angular momenta: cold bosonic atoms show a *contact potential* due to s-wave collisions (36.180)), polarized fermionic atoms only interact weakly in the p-channel. In the case of a statistically mixed ensemble of non-polarized fermions we have a the weighted average,
$$\frac{d\sigma}{d\Omega} = \frac{3}{4}\left.\frac{d\sigma}{\Omega}\right|_t + \frac{1}{4}\left.\frac{d\sigma}{\Omega}\right|_s = |f(\theta)|^2 + |f(\pi - \theta)|^2 - \mathfrak{Re}\left[f^*(\theta) f(\pi - \theta)\right] \ . \tag{36.185}$$

36.3.2.3 Molecular spectra

Here we consider rotational spectra of low energies $E_{\rm rot} = \hbar^2 \ell(\ell+1)/2\Theta \ll E_{eletronico} \sim eV$. In slow time scales we can consider the electronic shell to be rigid. We look at two examples of molecules with bosonic and fermionic nuclei:

- Molecules $(C^{12})_2$: the nuclei are 0-spin bosons, so only collisions with even ℓ are allowed.
- Molecules H_2: the nuclei are spin-$\frac{1}{2}$ fermions, so we have for a spin wavefunction,
$$\chi = \chi_s : \ell = \text{even, para-hydrogen}, \chi = \chi_t : \ell = \text{odd, ortho-hydrogen}. \tag{36.186}$$
The transformation of ortho-hydrogen into para-hydrogen is difficult (the nuclei being well shielded), such that we observe two types of gases with,
$$E_{rot,para} = 0, \frac{3}{\Theta}, \frac{10}{\Theta}, \frac{21}{\Theta}, ...E_{rot,orto} = \frac{1}{\Theta}, \frac{6}{\Theta}, \frac{15}{\Theta}, ... \ . \tag{36.187}$$

[12] This is analogous to the case of helium, where the spatial function of the state $2s^2 \uparrow\uparrow$ is always antisymmetric, but for the $2s\uparrow 2p\uparrow$ exist symmetric spatial orbitals.

36.3.3 Collisions between hot atoms

Angular moments with $\ell \leq kR_0$ should contribute a lot to σ, since the collision parameter is inside R_0. For a hard sphere we have $\alpha_\ell = \infty$ and $\cot\delta_\ell = n_\ell(kR_0)/j_\ell(kR_0)$. With the asymptotic expressions of j_ℓ and n_ℓ we obtain $\cot\delta_\ell \sim -\cot(kR_0 - \ell\pi/2)$, that is, $\delta_\sim - kR_0 + \ell\pi/2$ $(+\pi)$. With these scattering phases we can calculate the scattering cross section,

$$\sigma \simeq \tfrac{4\pi}{k^2}\sum_{\ell=0}^{kR_0}(2\ell+1)\sin^2\delta_\ell \tag{36.188}$$

$$\simeq \tfrac{4\pi}{k^2}\sum_{\ell=0}^{kR_0}(\ell+1)\cos^2[kR_0-(\ell+1)\pi/2] + \ell\sin^2(kR_0-\ell\pi/2)$$

$$= \tfrac{4\pi}{k^2}\sum_{\ell=0}^{kR_0}\ell(\cos^2+\sin^2) = \tfrac{4\pi}{k^2}\frac{kR_0(kR_0+1)}{2} = 2\pi R_0^2\ , \tag{36.189}$$

which is the double of the classical value.

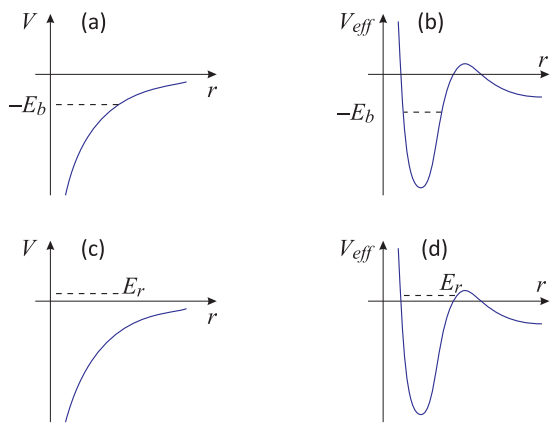

Figure 36.21: (a) Bound state for $\ell = 0$. (b) Bound state for $\ell > 0$ in a potential including the centrifugal barrier $\hbar^2\ell(\ell+1)/2mr^2$. (c) Resonances for $\ell = 0$ are broad and possibly not defined with $\Gamma_r > E_r$. A defined resonance with $\Gamma_r < E_r$ requires that $|\partial_E\alpha_0|$ be large. (d) For $\ell > 0$ we obtain narrow resonances called *shape resonances*, because the decay of the state is suppressed by the centrifugal barrier.

36.3.4 Ground state collisions

36.3.5 Hyperfine structure

We consider the scheme (35.100), we set $\mathbf{l}_j = 0$, and concentrate on s-waves, $\ell = 0$,

$$\begin{array}{ccccccc} \mathbf{s}_1 & + & \mathbf{s}_2 & = & \mathbf{S} & \xrightarrow{\hat{z}} & \mathbf{\Omega} \\ + & & + & & + & & \\ \mathbf{i}_1 & + & \mathbf{i}_2 & = & \mathbf{I} & & \\ = & & = & & = & & \\ \mathbf{f}_1 & + & \mathbf{f}_2 & = & \mathbf{f} & & \end{array} \tag{36.190}$$

At short distances the coupling $((S,I)f_1,f_2)f$ breaks up and a $((s_1,s_2)S,I)f$ coupling emerges. This does not hold for fully stretched spin states $f_1 + f_2 = f$, because f is a good quantum number at all distances (and small enough magnetic fields). In contrast m_f is a good quantum number at all distances and at all fields.

In order to obtain the potentials coupled by hyperfine interaction, we first calculate for a *single vibrational level* the relative wavefunctions $|\psi_{(f_1,f_2)f}(R)\rangle$ from the known perturbed but uncoupled potentials $V(R) + V_{hf}$, where,

$$V_{hf} = ha_{hf,1}\mathbf{s}_1\cdot\mathbf{i}_1 + ha_{hf,2}\mathbf{s}_2\cdot\mathbf{i}_2 \ . \tag{36.191}$$

The antisymmetric part is negligible [940], so that $V_{hf} \simeq \frac{1}{2}ha_{hf,1}\mathbf{S}\cdot\mathbf{i}_1 + \frac{1}{2}ha_{hf,2}\mathbf{S}\cdot\mathbf{i}_2$. Then couple the channels via,

$$|\psi_{(S,I)f}(R)\rangle = A\sum_{f_1,f_2}\sqrt{\hat{S}\hat{I}\hat{f}_1\hat{f}_2}\begin{Bmatrix} s_1 & s_2 & S \\ i_1 & i_2 & I \\ f_1 & f_2 & f \end{Bmatrix}|\psi_{(f_1,f_2)f}(R)\rangle \tag{36.192}$$

$$|\psi_{(f_1,f_2)f}(R)\rangle = A^{-1}\sum_{S,I}\sqrt{\hat{S}\hat{I}\hat{f}_1\hat{f}_2}\begin{Bmatrix} s_1 & s_2 & S \\ i_1 & i_2 & I \\ f_1 & f_2 & f \end{Bmatrix}|\psi_{(S,I)f}(R)\rangle \ .$$

which satisfies the orthogonality relation (see Tables in 28.2).

36.3.6 Scattering length in specific channels

The scattering length in specific channels can be expressed via singlet and triplet scattering length,

$$a_{|f_1,m_{f1}\rangle+|f_2,m_{f2}\rangle} = P_{S=0}a_s + P_{S=1}a_t \ . \tag{36.193}$$

The projectors are $P_S = |\langle S|(f_1f_2)f\rangle|$. According to [138] or [644] the recoupling from the uncoupled hyperfine representation into the short range representation is given by,

$$\langle Sm_S\ Im_I\ \ell'm_{\ell'}|f_1m_{f1}\ f_2m_{f2}\ \ell m_\ell\rangle = \delta_{\ell\ell'}\delta_{m_\ell m'_\ell}\sum_{f,m_f}\langle Sm_S\ Im_I|fm_f\rangle\langle f_1m_{f1}\ f_2m_{f2}|fm_f\rangle\times \tag{36.194}$$

$$\times\begin{Bmatrix} s_1 & s_2 & S \\ i_1 & i_2 & I \\ f_1 & f_2 & f \end{Bmatrix}\sqrt{\hat{S}\hat{I}\hat{f}_1\hat{f}_2}\left(\frac{1-(1-\delta_{f_1f_2})(-1)^{S+I+\ell}}{\sqrt{2-\delta_{f_1f_2}}}\right) \ .$$

The last bracket is dropped for unsymmetrized recoupling. Calculations have been done for ^{87}Rb collisions and for ^{6}Li^{87}Rb collisions. It turns out that the fully stretched states have pure triplet character.

Note that in strong magnetic fields the coupling $(i_1, i_2)I$ easily breaks up, and the recoupling to be considered is rather $\langle S m_S \; m_{i1} \; m_{i2} \; \ell' m_{\ell'} | f_1 m_{f1} \; f_2 m_{f2} \; \ell m_\ell \rangle$.

36.3.7 Hyperfine coupling in magnetic fields

36.3.7.1 Zeeman splitting of bound states

The splitting of the bound state is described by [940],

$$\begin{aligned} H_{int}^{+} &= V_{hf}^{+} + V_{Zeeman} \\ &= E_B + \frac{1}{2} h a_{hf,1} \mathbf{S} \cdot \mathbf{i}_1 + \frac{1}{2} h a_{hf,2} \mathbf{S} \cdot \mathbf{i}_2 + \mu_B \mathbf{B} (g_S \mathbf{S} + g_1 \mathbf{i}_1 + g_2 \mathbf{i}_2) \; , \end{aligned} \tag{36.195}$$

such that,

$$\begin{aligned} &\langle m'_{i1} m'_{i2} m'_S | H_{hfs} + H_B | m_S m_{i2} m_{i1} \rangle \\ &= E_B + (g_S m_S + g_{i1} m_{i1} + g_{i2} m_{i2}) \mu_B B \delta_{m'_{i1} \; m_{i1}} \delta_{m'_{i2} \; m_{i2}} \delta_{m'_S \; m_S} \\ &+ \tfrac{1}{2} h (a_{hf,1} m_{i1} m_S + a_{hf,2} m_{i2} m_S) \delta_{m'_{i1} \; m_{i1}} \delta_{m'_{i2} \; m_{i2}} \delta_{m'_S \; m_S} \\ &+ \tfrac{1}{4} h a_{hf,1} (i_{1,+} S_- \delta_{m'_S \; m_S+1} \delta_{m'_{i1} \; m_{i1}-1} + i_{1,-} S_+ \delta_{m'_{i1} \; m_{i1}-1} \delta_{m'_S \; m_S+1}) \delta_{m'_{i2} \; m_{i2}} \\ &+ \tfrac{1}{4} h a_{hf,2} (i_{2,+} S_- \delta_{m'_S \; m_S+1} \delta_{m2 \; m_{i2}-1} + i_{2,-} S_+ \delta_{m'_{i2} \; m_{i2}-1} \delta_{m'_S \; m_S+1}) \delta_{m'_{i1} \; m_{i1}} \; . \end{aligned} \tag{36.196}$$

For an example on how to evaluate the matrix at various magnetic fields and obtain the hyperfine structure of a bound state in the Zeeman and the Paschen-Back regime, we propose the systems ^{6}Li^{23}Na and ^{6}Li^{87}Rb.

36.3.7.2 Magnetic dipole interaction

Reads,

$$V_{dd} = \frac{\mu_0}{4\pi R^3} \left[\mu_1 \cdot \mu_1 - 3 (\mu_2 \cdot \mathbf{R})(\mu_2 \cdot \mathbf{R}) \right] \tag{36.197}$$

neglecting nuclear spin.

36.3.7.3 Second-order spin-orbit interaction

First-order spin-orbit interaction disappears for ground state collisions. But second-order spin-orbit interaction may occur. These lead to inelastic losses (see next section).

36.3.7.4 Selection rules

The selection rules for bosonic homonuclear collisions are,

$$\begin{aligned} S &= 0, .., s_1 + s_2 \\ I &= 0, .., i_1 + i_2 \\ f_j &= |i_j - s_j|, .., i_j + s_j \\ |I - S| \leq F &\leq I + S \\ |f_1 - f_2| \leq F &\leq f_1 + f_2 \\ (-1)^I &= (-1)^S \quad \text{for all } F \\ (-1)^{f_1} &= -(-1)^{f_2} \quad \text{for all odd } F \ . \end{aligned} \tag{36.198}$$

What does they look like for fermions? What does they look like for heteronuclear collisions?

36.3.8 Inelastic collisions

36.3.8.1 Spin changing collisions

These have their origin in *spin exchange* and spin dipole-dipole processes. Spin exchange occurs when the colliding electronic clouds overlap. At short distances the $((S, I)f_1, f_2)f$ breaks up and a $((s_1, s_2)S, I)f$ coupling remixes, as shown in Exc. 35.3.5.1. Hence, collisions between atoms $|f_1, m_{f1}\rangle|f_2, m_{f2}\rangle$ are subject to spin exchange induced by coupling of the spin states via the exchange interaction, e.g. $|2, 1\rangle|2, 1\rangle \rightarrow |2, 2\rangle|2, 0\rangle$. Typical exchange rates are on the order of $10^{-10}\,\text{cm}^3/\text{s}$.

Since f is a good quantum number at all distances (for $B = 0$), spin exchange processes conserve ℓ and f. Hence, the fully stretched spin states $f_1 + f_2 = f$ cannot decay into other states, except by higher-order processes, such as dipolar relaxation. Consequently, the relaxation rates for $|2, 2\rangle + |2, 2\rangle$ or $|1, -1\rangle + |1, -1\rangle$ states are only on the order of $10^{-15}\,\text{cm}^3/\text{s}$.

The cross section for inelastic spin exchange collisions is [965, 196],

$$\sigma = M_{if}\pi(a_t - a_s)^2 \ , \tag{36.199}$$

where,

$$\begin{aligned} M_{if} &= \left[\sum_{m_S, I, m_I} (C_{S=0}C'_{S=0} - C_{S=1}C'_{S=1}) \right]^2 \\ C &= \langle S, m_S; I, m_I | F_1 m_1; F_2 m_2 \rangle \ . \end{aligned} \tag{36.200}$$

See also [849]. The reason for the above dependence can be understood as follows. a_s and a_t determine the energy of the last bounds states of the singlet and triplet potentials. The more those energies are different, the stronger the coupling $\propto |E_t - E_s|^{-1}$. An alternative, physical picture is given in [139].

36.3.8.2 Dipolar relaxation

The fully stretched spin states, such as ^{87}Rb $|f = 2, m_f = 2\rangle$ are expected to be quite stable. However, relativistic effects (retardation?) (and 2nd order spin-orbit coupling) break the degeneracy of the molecule-fixed projection $|\Omega| = 0, 1$ of the $^3\Sigma$ potential [644]. When the atoms approach their spins recouple, i.e. from $[(s_1, i_1)f_1\ ,\ (s_2, i_2)f_2]f$ towards $[(s_1, s_2)s\ ,\ (i_1, i_2)i]f$ as described by the $9j$ coefficients Eq. (36.190). Due to the symmetry of the problem, f and its projection m_f are good quantum numbers at all distances. However, if there is a higher-order admixture of the orbit l_j, the symmetry is broken, and the quantum number depends on the coupling schemes. Consequently, transitions between different m_f become possible, i.e. dipolar relaxation may change f, m_f or $\ell = 0$, e.g. a collision can be s-wave in the entrance and d-wave in the exit channel.

36.3.8.3 Three-body collisions

The trapped low-field seeking alkali gases are metastable versus 3-body recombination. 3-body recombination is the combination of two colliding atoms to a dimer in presence of a third atom receiving the excess energy as kinetic energy and results in trap loss of the molecule and of the atom. They are suppressed as the gas gets more and more dilute since the rate goes like n^3. There might be interesting 3-body resonance phenomena like the *Efimov state* predicted for Helium droplets [287], [578] and recently seen in experiment [539, 890, 121, 604].

3-body recombination is in contrast to the more controlled way of creating molecules via photoassociation or coherent free-bound coupling.

Ultracold collisions are crucial for BEC. They provide the thermalizing elastic collisions necessary for evaporative cooling, they are the cause for the condensate self-energy and give rise to nonlinearities in the condensate dynamics. But they are also interesting by themselves. The spectrum of two-body collisions exhibits interesting features like shape- and Feshbach resonances [200, 463]. Their analysis facilitates detailed conclusions on the nature of the interaction potentials. Three body collisions are important to investigate, because they constitute a decay mechanism of the intrinsically metastable system that represents a trapped Bose-gas.

Three body collisions are not a quantum statistical effect and don't require the presence of a BEC, but they occur only at very high densities comparable to those necessary for BEC. It should be possible to detect them in *photoassociation* (PA) spectra. Photoassociation provides a tool to explore the level structure of excited states by shining in a laser with frequency ν tuned between the colliding channel and a vibrational bound level of the excited state potential. Since the excited state preferentially decays into the continuum, where the atoms have high kinetic energy, the transition rate may be monitored via trap losses. Or we can shine in an additional laser that further excites the excited atoms into the ionized continuum where they can be registered by an ion detector.

Three-body photoassociation processes should reveal themselves by additional lines in the two-body photoassociation spectra. Those lines should only appear at very high densities and their strength should scale as the density cubed,

$$Rb + Rb + Rb + h\nu \rightarrow Rb_3^* \ . \tag{36.201}$$

36.3.8.4 Other processes

Majorana spin flips and collisions involving higher partial waves ℓ can eventually lead to spin relaxation. In Eq. (35.100) we see that f is not necessarily a good quantum number in contrast to F, $|2,2\rangle|2,2\rangle \to |2,1\rangle|2,0\rangle + E_{\rm rot}$. However, the particles must tunnel across the centrifugal barrier, which sets temperature constraints.

36.3.8.5 Collisions between fermions

Very cold three-body collisions are suppressed for fermions, because two of them necessarily must have the same quantum state, which violates the Pauli exclusion principle. This is useful for employing Feshbach resonances to form molecular BECs made of fermions.

36.3.9 Excited states collisions

36.3.9.1 Adiabatic potentials

We consider the scheme (35.100), we set $\mathbf{I} = 0$, and we concentrate on s-waves, $\ell = 0$,

$$\begin{array}{ccccccc} \mathbf{l}_1 & + & \mathbf{l}_2 & = & \mathbf{L} & \xrightarrow{\hat{z}} & \mathbf{\Lambda} \\ + & & + & & + & & + \\ \mathbf{s}_1 & + & \mathbf{s}_2 & = & \mathbf{S} & \xrightarrow{\hat{z}} & \mathbf{\Sigma} \\ = & & = & & = & & = \\ \mathbf{j}_1 & + & \mathbf{j}_2 & = & \mathbf{j} & \xrightarrow{\hat{z}} & \mathbf{\Omega} \end{array} \tag{36.202}$$

The *spin-orbit interaction* splits the potential curves. The recoupling is described by,

$$|\psi_{(L,S)j}(R)\rangle \sim \sum_{j_1,j_2} \sqrt{\hat{L}\hat{S}j_1j_2} \begin{Bmatrix} l_1 & l_2 & L \\ s_1 & s_2 & S \\ j_1 & j_2 & j \end{Bmatrix} |\psi_{(j_1,j_2)j}(R)\rangle \ . \tag{36.203}$$

36.3.9.2 Homonuclear collisions

Let us consider the example of the fine structure in homonuclear ^{87}Rb collisions. Without hyperfine, rotational and Zeeman splitting the recoupling goes like illustrated in Fig. 36.22.

From Fig. 36.22 we see that the molecular states are remixed at long range: Every state $0_g^-, 0_u^-, 0_g^+, 0_u^+, 1_g, 1_u, 2_g, 2_u$ has several molecular states to which it connects, e.g. 0_g^- connects within the fine structure to $(2)^3\Sigma_g^+$ and $(2)^3\Pi_g$. Those multiplets form a closed interacting subspace. According to Movre and Pichler [673, 918] we get

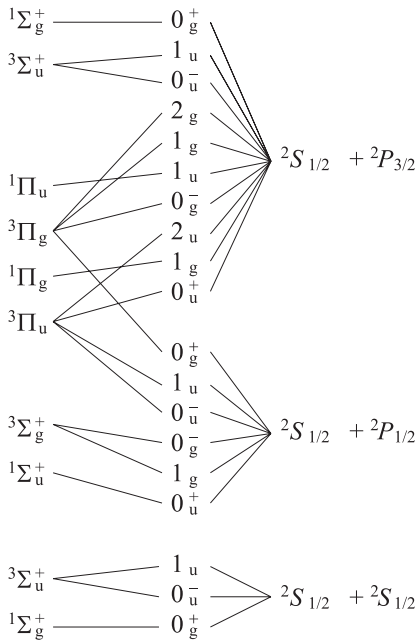

Figure 36.22: Movre coupling scheme.

with $\Delta = E(^2P_{3/2}) - E(^2P_{1/2}) = \frac{3}{2}A_{so}$,

$$0_\sigma^- = \begin{pmatrix} E(^3\Pi_\sigma) - \frac{1}{3}\Delta & \frac{\sqrt{2}}{3}\Delta \\ -\frac{\sqrt{2}}{3}\Delta & E(^3\Sigma_\sigma^+) \end{pmatrix} \quad , \quad 0_\sigma^+ = \begin{pmatrix} E(^3\Pi_\sigma) - \frac{1}{3}\Delta & -\frac{\sqrt{2}}{3}\Delta \\ -\frac{\sqrt{2}}{3}\Delta & E(^1\Sigma_\sigma^+) \end{pmatrix} \tag{36.204}$$

$$1_\sigma = \begin{pmatrix} E(^3\Pi_\sigma) & \frac{1}{3}\Delta & -\frac{1}{3}\Delta \\ \frac{1}{3}\Delta & E(^1\Pi_\sigma) & -\frac{1}{3}\Delta \\ -\frac{1}{3}\Delta & -\frac{1}{3}\Delta & E(^3\Sigma_\sigma^+) \end{pmatrix} \quad , \quad 2_\sigma = \left(^3\Pi_\sigma\right) \ .$$

At short range the potentials approximately go like,

$$\begin{aligned} E(^1\Sigma_g^+), E(^3\Sigma_u^+) &\propto 2C_3/R^3 \\ E(^1\Pi_u), E(^3\Pi_g) &\propto C_3/R^3 \\ E(^1\Pi_g), E(^3\Pi_u) &\propto -C_3/R^3 \\ E(^1\Sigma_u^+), E(^3\Sigma_g^+) &\propto -2C_3/R^3 \ . \end{aligned} \tag{36.205}$$

Inserting the short range potentials and defining $X = \sigma C_3/3\Delta R^3$, $Y = E/\Delta$ and

$\sigma = +$ for g and $-$ for u,

$$0^-_\sigma = \begin{pmatrix} 3X + \frac{1}{3} & \frac{\sqrt{2}}{3} \\ \frac{\sqrt{2}}{3} & -6X + \frac{2}{3} \end{pmatrix} \quad , \quad 0^+_\sigma = \begin{pmatrix} 3X + \frac{1}{3} & \frac{\sqrt{2}}{3} \\ \frac{\sqrt{2}}{3} & 6X + \frac{2}{3} \end{pmatrix} \tag{36.206}$$

$$1_\sigma = \begin{pmatrix} 3X + \frac{1}{3} & \frac{1}{3} & -\frac{1}{3} \\ \frac{1}{3} & -3X + \frac{1}{3} & -\frac{1}{3} \\ -\frac{1}{3} & -\frac{1}{3} & -6X + \frac{2}{3} \end{pmatrix} \quad , \quad 2_\sigma = (3X + 1) \ .$$

Note that the structure looks very much like the transition from the Zeeman to the Paschen-Back regime, where X plays the role of the magnetic field and Y the level shift. The characteristic equations are,

$$\begin{aligned} Y^2 - (1 - 3X)Y - 18X^2 = 0 \quad &\text{for} \quad 0^-_\sigma \\ Y^2 - (1 + 9X)Y + (4X + 18X^2) = 0 \quad &\text{for} \quad 0^+_\sigma \\ Y^3 + (-2 + 6X)Y^2 + (1 - 8X - 9X^2)Y + (2X + 6X^2 - 54X^3) = 0 \quad &\text{for} \quad 1_\sigma \\ Y - (1 + 3X) = 0 \quad &\text{for} \quad 2_\sigma \end{aligned} \tag{36.207}$$

36.3.10 Heteronuclear collisions

For a collision in the channel ^{6}Li P ^{87}Rb S we get the $\{9j\}$-symbol,

$$\begin{Bmatrix} l_6 & l_{87} & L \\ s_6 & s_{87} & S \\ j_6 & j_{87} & j \end{Bmatrix} = \begin{Bmatrix} 0 & 1 & 1 \\ \frac{1}{2} & \frac{1}{2} & S \\ \frac{1}{2} & j_{87} & j \to \Omega \end{Bmatrix} \ . \tag{36.208}$$

We thus expect a fine structure $j_{87} = \frac{1}{2}, \frac{3}{2}$ at long range and exchange interactions $S = 0, 1$ at short range. For the projection onto the internuclear axis $|L - S| \leq \Omega \leq L + S$.

Let $V_k(R)$ be the uncoupled potentials and,

$$\Delta_{kl}(R) = D_{kl} + A_{kl} \left([1 - e^{-B_{kl}(R - R_{kl})}]^2 - 1 \right) \tag{36.209}$$

the spin-orbit functions modeled as Morse potentials, where D_{kl} is related to the fine-structure splitting, $D_{kl} = \frac{1}{3}(E_k - E_l)$, for diagonal and, $D_{kl} = \frac{\sqrt{2}}{3}(E_k - E_l)$, for off-diagonal elements. For heteronuclear molecules like ^{6}Li^{87}Rb we have matrices like [84, 83],

$$\begin{array}{ccccccccc} H & |^3\Sigma^+\rangle & |^3\Pi\rangle & |^1\Sigma^+\rangle & |^3\Pi\rangle & |^3\Sigma^+\rangle & |^1\Pi\rangle & |^3\Pi\rangle & |^3\Pi\rangle \\ \langle {}^3\Sigma^+_{\Omega=0^-}| & V(^3\Sigma) & \Delta_{cb}\sqrt{2} & & & & & & \\ \langle {}^3\Pi_{\Omega=0^-}| & \Delta_{cb}\sqrt{2} & V(^3\Pi) - \Delta_{bb} & & & & & & \\ \langle {}^1\Sigma^+_{\Omega=0^+}| & & & V(^1\Sigma)(-2\Delta_{bb}) & -\Delta_{bb} & & & & \\ \langle {}^3\Pi_{\Omega=0^+}| & & & -\Delta_{bb} & V(^3\Pi)\,(+\Delta_{bb}) & & & & \\ \langle {}^3\Sigma^+_{\Omega=1}| & & & & & V(^3\Sigma) & \Delta_{cB} & \Delta_{cb} & \\ \langle {}^1\Pi_{\Omega=1}| & & & & & \Delta_{cB} & V(^1\Pi) & -\Delta_{bB} & \\ \langle {}^3\Pi_{\Omega=1}| & & & & & \Delta_{cb} & -\Delta_{bB} & V(^3\Pi) & \\ \langle {}^3\Pi_{\Omega=2}| & & & & & & & & V(^3\Pi) + \Delta_{bb} \end{array} \tag{36.210}$$

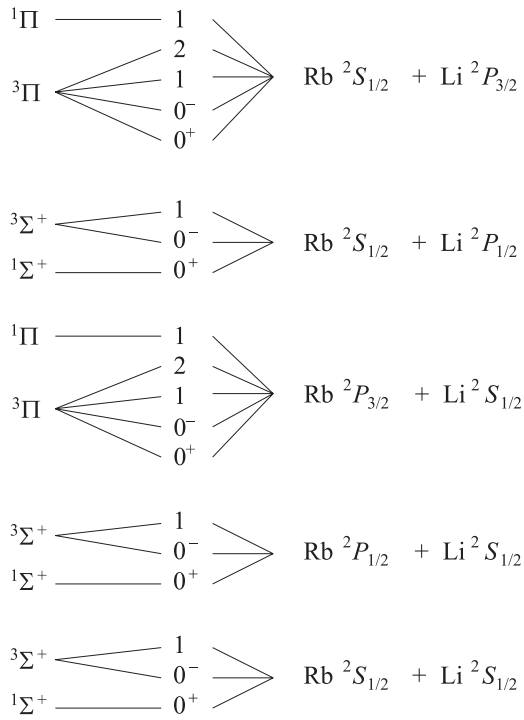

Figure 36.23: Movre type spin-orbit recoupling scheme for heteronuclear molecules.

for every fine structure. For example, there is a matrix for the two ^{6}Li $S_{1/2}$ ^{87}Rb$P_{1,3/2}$ asymptotes and another one for the ^{6}Li $P_{1/2,3/2}$ ^{87}Rb S_1 asymptotes. Additional terms enter via rotational effects [84].

Concretely,

$$\begin{aligned}
\Delta_{bb}(R \to \infty) &= \frac{1}{3}(E_{3/2} - E_{1/2}) \\
\Delta_{cB}(R \to \infty) &= \frac{1}{3}(E_{3/2} - E_{1/2}) \\
\Delta_{bB}(R \to \infty) &= \frac{1}{3}(E_{3/2} - E_{1/2}) \\
\Delta_{cb}(R \to \infty) &= \frac{1}{3}(E_{3/2} - E_{1/2}) \ .
\end{aligned} \tag{36.211}$$

36.3.10.1 Inelastic trap losses

Between ground and excited states *fine changing collisions* and *radiative escape* are possible. Between two ground states only *hyperfine changing collisions* may occur.

The nature of the collision process, whether it is a one- [13], two-, or three-body collision, reveals itself via the temporal behavior of trap losses. Using the abbrevia-

[13] By one-body collision we mean collisions with atoms of the background gas.

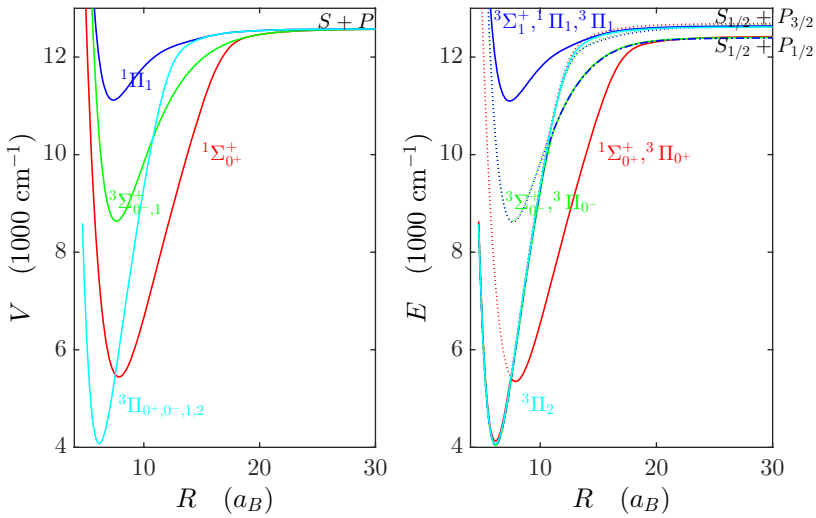

Figure 36.24: (code) Adiabatic potentials.

tion,

$$\langle \eta \rangle \equiv \frac{1}{N} \int \eta(\mathbf{r}) n(\mathbf{r}) d^3 r \ , \tag{36.212}$$

we can write the loss rates due to inelastic one-, two-, and three-body collisions,

$$B\langle 1 \rangle N \quad , \quad K\langle n \rangle N \quad , \quad L\langle n^2 \rangle N \ . \tag{36.213}$$

the prefactors depend on the collision velocity (that is, the temperature of the sample) and atomic parameters (for example, the collision cross section for two-body collisions, which may itself depend on temperature). Hence, the total number of trapped atoms evolves according to,

$$\boxed{\dot{N} = -B\langle 1 \rangle N - K\langle n \rangle N - L\langle n^2 \rangle N} \ . \tag{36.214}$$

Assuming a gaussian density distribution,

$$n(\mathbf{r}) = \frac{N}{(2\pi)^{3/2}\bar{r}^3} e^{-r^2/2\bar{r}^2} \ , \tag{36.215}$$

we calculate,

$$\dot{N} = -BN - \frac{K}{(4\pi)^{3/2}\bar{r}^3} N^2 - \frac{L}{3^{3/2}(2\pi)^3\bar{r}^6} N^3 \ . \tag{36.216}$$

Fig. 36.25 shows a simulation of Eq. (36.216).

For condensates in the Thomas-Fermi limit [864] found the following differential equations for two- and three-body collisions,

$$\frac{\dot{N}}{N} = -Gc_2 N^{2/5} - \frac{1}{\tau} \quad \text{and} \quad \frac{\dot{N}}{N} = -Lc_3 N^{4/5} - \frac{1}{\tau} \ . \tag{36.217}$$

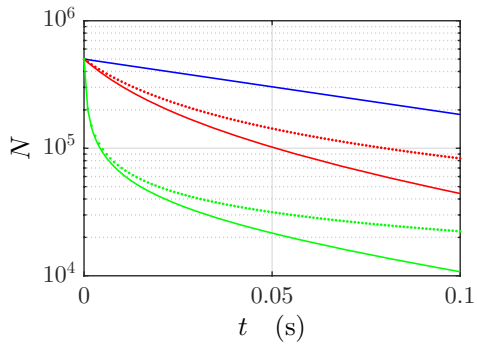

Figure 36.25: (code) One-, two-, and three-body losses.

36.3.11 Heteronuclear electric dipole moment

The *electric dipole moment* of a dimer is highest for big mass difference, as in the case of LiRb and for low vibrational quantum number [533, 42]. The electric dipole moment determines the rate for spontaneous and *black-body radiation*, $\bar{n} = (e^{-\beta\hbar\omega} - 1)^{-1}$, induced transitions between rovibrational states [534], $\Gamma^{tot}_{vlm} = \Gamma^{spnt}_{vlm} + \Gamma^{bb}_{vlm}$. With the transition rate between individual levels,

$$\Gamma^{\alpha}_{vlm\to v'l'm'} = \frac{8\pi}{3}\frac{\omega^3}{hc^3}|\langle|d|\rangle|^2 \ , \tag{36.218}$$

we can estimate the rates for spontaneous emission,

$$\Gamma^{spnt}_{vlm} = \sum\nolimits_{v'l'm'} \Gamma^{em}_{vlm\to v'l'm'} \ , \tag{36.219}$$

and for black-body radiation,

$$\Gamma^{bb}_{vlm} = \sum_{v'l'm'} \bar{n}\Gamma^{em}_{vlm\to v'l'm'} + \sum_{v''l''m''} \bar{n}\Gamma^{abs}_{vlm\to v''l''m''} \ . \tag{36.220}$$

Note that selection rules require $|l - l'| \leq 1$ and $|m - m'| \leq 1$, rotational transitions are inhibited by small ω^3, spontaneous emission is high for intermediate levels for which on one hand ω^3 is large enough and enough final states are available.

From calculations of the R-dependence of the electric dipole moments [42] the dipole moment of a specific vibrational state is easily estimated from,

$$d = \frac{\int \psi(R)R\psi(R)dR}{\int \psi(R)\psi(R)dR} \ . \tag{36.221}$$

In electric fields the dipole moments will lead to Stark shifts. For $|d| = 1$ Debye in a field of 1 V/m we expect a Stark shift of $H_{Stark} \approx 500$ kHz. It may be possible to measure this by photoassociation spectroscopy. Note also that since homonuclear dimers do not have a permanent electric dipole moment, transitions between vibrational ground states are forbidden.

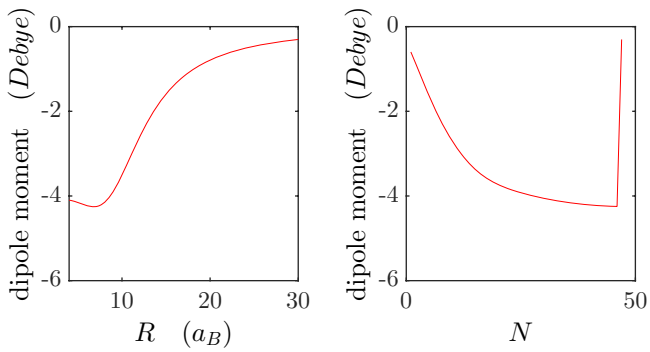

Figure 36.26: (code) (a) Dipole moment at the example of LiRb as a function of interatomic distance. (b) Dipole moment at the example of LiRb as a function of vibrational quantum number.

36.3.12.1 Ex: Vibrational structure of LiRb

Calculations of the vibrational structures of several ground states of the heteronuclear molecule LiRb.

36.4 Resonances in cold collisions

36.4.1 Shape resonances

The 'centrifugal' term can give rise to repulsive walls for attractive potentials. Behind these walls, quasi-bound states can develop and give rise to collision resonances. That is, resonances emerge in the collision cross section as a function of the collision temperature called *shape resonance*s.

36.4.2 Feshbach resonances

The so-called *Feshbach resonance* is due to an energetic match between a collision channel and a bound molecular state [310, 913, 915, 656, 307, 657, 941]. They allow to vary the scattering length a_s almost arbitrarily from zero, where the atomic cloud turns into an ideal gas, up to values exceeding the total size of the cloud.

The impact of a Feshbach resonance can be understood as a perturbation of the collisional channel leading to a modification of the depth of the scattering potential. When this leads to the promotion of one more vibrational state into (or from) the continuum, this obviously leads to a dramatic modification of the scattering length a_s [14]

Let us consider two very cold atoms colliding on an attractive interatomic potential $V(R)$ (see Fig. 36.28,right). At long distances the relative wavefunction is a sine

[14] Note that the divergence of the scattering length is an artifact of the hard core approximation, that is, the regularization of the interaction potential, since the matrix $\mathcal{T}$ by itself does not diverge.

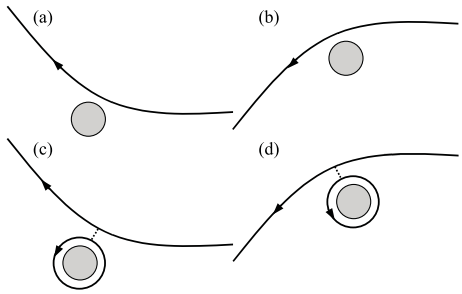

Figure 36.27: Classical illustration of a scattering resonance.

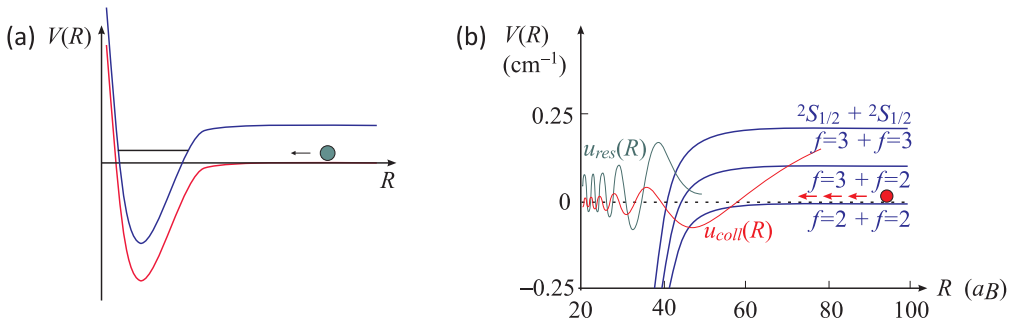

Figure 36.28: (a) The Feshbach resonance is due to a coincidence of collisional and bound channels. (b) Feshbach resonance in ^{85}Rb. The atoms collide in the hyperfine state $F = 2$, and the resonant bound state is in the $F = 3$ multiplet (courtesy [200]).

characterized by the Broglie wave vector k_{dB}. As the atoms approach each other, they mutually accelerate, and the Broglie wave performs some small and rapid oscillations within the potential. The number of nodes of the wavefunction within the potential corresponds to the number of bound vibrational levels that the potential with a given depth can support. The scattering length a_s is defined as the phase slip, which the Broglie wave would acquire during the collision at the boundary $k_{dB} \to \infty$.

With the possibility of gradually decreasing the depth of the molecular potential, at some point the last state below the ionization threshold goes to the continuum of unbound states, the wavefunction decreases the number of nodes by one unit, while the scattering cross section crosses a singularity. In fact, the potential $V(R)$ *can be manipulated* with the help of radiation fields [307, 104, 657] or, near a collisional *Feshbach resonance*, by magnetic fields [915, 916]. Feshbach resonances were predicted in nuclear systems [310]. Its recent revival in the context of cold atomic collisions is due to the prospect of its use for manipulating the scattering length and thus controlling the mean-field energy of a Bose-Einstein condensate [15]

[15] It is even possible to invert the sign of the scattering length. This was a prerequisite for condensation of the atomic species of ^{85}Rb [786]. In addition, Feshbach resonances are interesting because they can install a coherent free-bound coupling between an *open-channel* of colliding atoms and a bound molecular state of the same atoms, as shown in Fig. 36.28. This coupling can lead to the creation of molecular condensates.

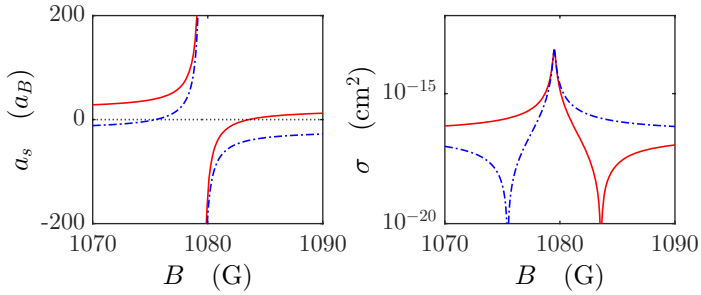

Figure 36.29: (code) (a) Scattering length and (b) collision cross section upon crossing a Feshbach resonance. The scattering length can be positive (solid red line) or negative (dashed blue line). A movie on a simulation of a Feshbach resonance can be watched here (watch movie).

The collisional *Feshbach resonance* arises when the energy of the state of two colliding atoms coincides with the energy of a vibrational molecular level belonging to a higher energy asymptote (see Fig. 36.28,right). This coincidence can strongly perturb the collisional channel, because the resonance shifts the phase of the relative de Broglie wavefunction and allows the atoms to tunnel into the molecular state for a short period of time, the duration of which is determined by the Heisenberg uncertainty relation. If the sum of the magnetic dipole moments of the atoms is different from the dipole moment of the molecule, the resonance can be tuned via external magnetic fields exploring the Zeeman effect. When a Feshbach resonance is crossed, the scattering length crosses a singularity, as shown in Fig. 36.29(left) [16].

36.4.3 Exercises

36.5 Light-assisted collisions

36.5.1 Optical shielding

The adiabatic potential for ground state collisions can be manipulated using light to admix an another potential. The laser light can either be blue-detuned to the continuum of states of a repulsive excited state potential or red-detuned to vibrational resonances of an attractive excited state potential [495, 307, 947, 962]. We can also admix another ground state potential with two-photon Raman transitions.

At cold collisions, the atom undergoes *Landau-Zener transitions* between the mixed states with the probability

$$P_{\mathrm{LZ}} = 1 - \exp\left(-\frac{2\pi\hbar\Omega^2}{D_C v}\right) \ , \tag{36.222}$$

where

$$D_C = \left|\frac{d}{dR}[V_e(R) - V_g(R)]\right|_{R=R_C} \tag{36.223}$$

16

is the slope of the difference potential evaluated at the Condon point. In the dressed states picture the dressed potentials display an avoided crossing. This modification of the collisional potential modifies the dynamics of the collision and the scattering length.

An example is the phenomenon of *optical suppression* or *shielding*. Here, two colliding atoms are inhibited to approach farther than a certain distance defined by the resonance condition set by a laser which is blue-detuned to a repulsive excited potential. The inhibition is probed by a photoassociation laser tuned to a resonance condition at smaller interatomic distances. The optical shielding scheme can be extended in the following way. Two lasers, one tuned to a repulsive another to an attractive excited state potential resonant at different interatomic distances.

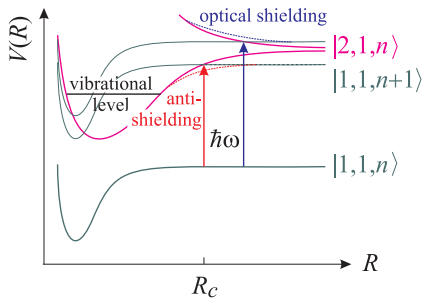

Figure 36.30: Molecular states (green and pink) resonantly coupled by a light field at the Condon point form an avoided intersection in the dressed states basis. For red detuning vibrational states can be populated, for blue detuning we get optical shielding.

36.5.2 Photoassociation during cold collisions

Ultra-cold collisions provide an interesting playground for studies on how light can be used to control the result of inelastic or reactive collisions. Here we discuss as a specific example *photoassociation*. The upper panel of Fig. 36.30 shows schematic curves of (bare) potentials relevant to our discussion. Two atoms in the ground state form a relatively shallow vibrational molecular ground state characterized by electrostatic dispersion

$$V_g(r) = -\frac{C_6}{R^6} \ . \tag{36.224}$$

or long-range *van der Waals potential*. Two other vibrational states arise from the interaction of an excited atom with the ground state atom. The predominant term of the interaction is the potential of resonant dipole-dipole interactions,

$$V_e(r) = D \pm \frac{C_3}{R^3} \ . \tag{36.225}$$

which gives rise to an attractive and a repulsive potential. The R^{-3} dependence of the resonant dipole interaction means that the associated potentials greatly modify the asymptotic level even at internuclear distances, where the ground state van der Waals potential is still relatively shallow. The photoassociation process involves a

slow approach of two identical ground state atoms. A mono-modal optical field, tuned to the red of the atomic resonance, is applied. When the two atoms reach an internuclear distance R such that the energy of the applied field $\hbar\omega$ exactly coincides with the potential difference $V_e(R) - V_g(R)$, the probability of transferring population from a fundamental molecular state to an excited molecular state is maximal. If now the potential $V_g(R)$ supports a vibrational state at the energy $E_C = V_g(R_\mathrm{C})$, the resonance condition is fulfilled,

$$V_e(R_\mathrm{C}) - V_g(R_\mathrm{C}) = \hbar\omega_\mathrm{C} \ , \tag{36.226}$$

and a transition can occur. The distance R_C is called *Condon point*, and it corresponds to the classical outer turning point of the molecular potential [962]. In a quantum picture the turning point corresponds to a maximum of the delocalized wavefunction describing the vibration of the bound atoms.

Within quantum mechanics, the proper conventional way of calculating this probability follows the procedure elaborated in Sec. 39.1.1 for a two-level atom:

1. solve the time-independent molecular Schrödinger equation to obtain the vibrational wavefunctions;

2. write down the coupled differential equations by describing the time dependence of the expansion coefficients of the relevant vibrational wavefunctions;

3. solve for the coefficients and calculate the square of their absolute values;

4. integrate the transition probability inside a region ΔR around the Condon point, where the transition probability is not negligible.

The dressed states picture illustrated in Fig. 36.30 allows to reduce this rather laborious program, essentially, to a problem of a curve crossing of two levels. The basis states are now product states made up of the field and the molecular levels. Furthermore, we approximate the molecular states themselves as products of atomic states. This approximation is justified by the long range, weakly perturbative influence of the van der Waals and resonant dipoles interactions. Calling the ground and excited states $|1\rangle$ and $|2\rangle$, respectively, the dressed state molecular curves $|2, 1, n\rangle$ and $|1, 1, n+1\rangle$ intersect at the Condon point and optically couple to the applied field. This optical coupling produces an *avoided crossing* near R_C and mixes the states of the molecule-field basis. The probability of traversing from one adiabatic molecular state to another is expressed by the Landau-Zener formula as a function of the interaction strength, the relative velocity of the collision partners, and the relative slopes of the two curves. Resolve Exc. 36.5.4.1.

36.5.2.1 Blue detuning

The S-matrix element describing the coupling of a ground state wavefunction by $\Psi_g(R, E) = \langle R|\Psi_g(E)\rangle$ via a light field of frequency ω_a to an excited state wavefunction $\langle R|\Psi_e(E + \omega_a)\rangle$ is,

$$S_{eg}(E, \Delta_a) = -2\pi\imath\hbar\langle\Psi_e(E + \hbar\omega_a)|\Omega_{eg}(R)|\Psi_g(E)\rangle \ , \tag{36.227}$$

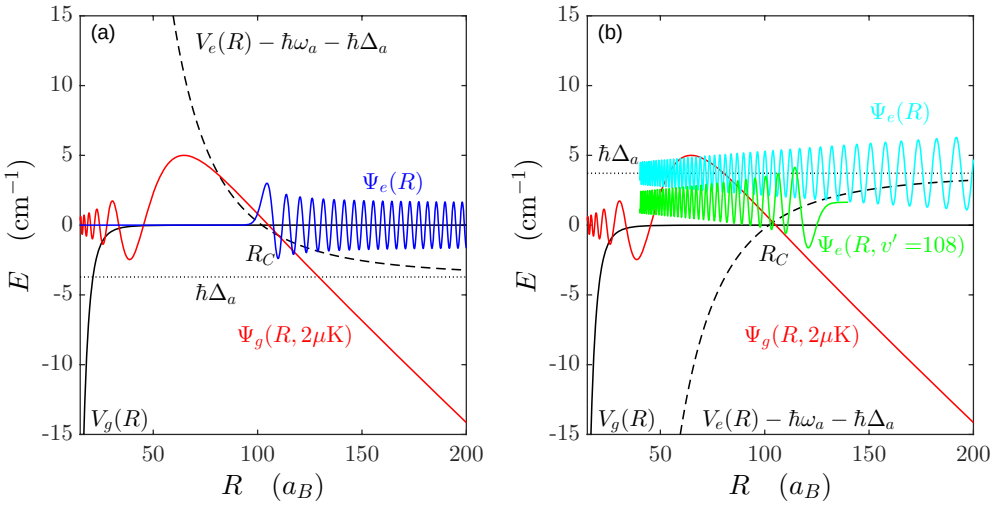

Figure 36.31: (code) Collisional and vibrational wavefunctions in C_6 ground state and C_3 excited state potentials [495] in the presence of (a) blue and (b) red-detuned light ($C_6 = 1500\,\mathrm{a.u.}$, $C_3 = 18\,\mathrm{a.u.}$, $\Delta_a = (2\pi)\ 700\,\mathrm{GHz}$). The colored curves denote (red) the wavefunction of two atoms colliding on their ground state with a velocity corresponding to $2\,\mu\mathrm{K}$, (blue) a wavefunction repelled from the excited state potential, (cyan) an unbound wavefunction of the excited state potential, and (green) a vibrational wavefunction of the excited state potential.

where the molecular Rabi frequency $\Omega_{eg}(R)$ may differ from the atomic Rabi frequency Ω_a. Now, with the probability

$$P_e(E, \Delta_a) = |S_{eg}(E, \Delta_a)|^2 \tag{36.228}$$

for the event by which two ground state atoms collide in a light field and produce one excited and one ground state atom, both of which have enough kinetic energy to escape any weak trapping potential, the event rate coefficient, averaged over ground state velocities $v_g = \hbar k_g/m_{\mathrm{red}}$, is

$$K_e(\Delta_a) = \left\langle \frac{\pi v_g}{k_g^2} P_e(E, \Delta_a) \right\rangle \ . \tag{36.229}$$

Assuming that the Rabi frequency does not depart much from its value near the Condon point, $\Omega_{eg}(R) \simeq \Omega_{eg}(R_{\mathrm{C}}) \equiv \Omega_C$. Then,

$$P_e(E, \Delta_a) = 4\pi^2 \Omega_C^2 F_{eg}(E, \Delta_a) \ . \tag{36.230}$$

where we defined the Franck-Condon overlap,

$$\boxed{F_{eg}(E, \Delta_a) = |\langle \Psi_e(R, E + \hbar\omega_a) | \Psi_g(R, E) \rangle|^2} \ . \tag{36.231}$$

It is now possible to show [495], that within the reflection approximation,

$$F_{eg}(E, \Delta_a) \simeq \frac{|\Psi_g(R_{\mathrm{C}}, E)|^2}{D_C} \ . \tag{36.232}$$

I.e. the Franck-Condon factor is directly proportional to the square of the ground state wavefunction. It only depends on the excited state through the slope term DC.

36.5.2.2 Red detuning

Bound states,

$$|S_{eg}(E,\Delta_a)|^2 = \frac{\gamma_p\gamma_s(E,v,\Delta_a)}{(E-\Delta_a)^2/\hbar^2 + (\gamma_p+\gamma_s(E,v,\Delta_a)+\gamma_0)^2/4} \ . \tag{36.233}$$

with

$$\gamma_s(E,v,\Delta_a) = \tfrac{2\pi}{\hbar}|\langle\Psi_e(v)|\Omega_C|\Psi_g(E)\rangle|^2 \simeq \tfrac{2\pi}{\hbar}\Omega_C^2 F_{eg}(E,v,\Delta_a) \tag{36.234}$$

vibrational spacing,

$$\frac{\partial E_v}{\partial v} = \hbar\omega_{vib} \simeq \frac{E_{v+1}-E_v}{2} \ . \tag{36.235}$$

In analogy to (36.232) we now get the Franck-Condon factor,

$$F_{eg}(E,v,\Delta_a) = \frac{\partial E_v}{\partial v}\frac{|\psi_g(R_\mathrm{C},E)|^2}{D_C} \ . \tag{36.236}$$

Example 257 (*Dimers*): For a C_6 ground state potential and a C_3 excited state potential at a given detuning Δ_a the Condon point R_C is given by,

$$\Delta_a = V_e(R_\mathrm{C}) - V_g(R_\mathrm{C}) = -\frac{C_3}{R_\mathrm{C}^3} + \frac{C_6}{R_\mathrm{C}^6} = -\frac{C_3}{R_\mathrm{C}^3} \tag{36.237}$$

and the differential slope is,

$$\begin{aligned} D_C = \left|\frac{d}{dR}(V_e(R)-V_g(R))\right|_{R=R_\mathrm{C}} &= \frac{d}{dR}\left(-\frac{C_3}{R^3}+\frac{C_6}{R^6}\right)\Bigg|_{R=R_\mathrm{C}} \\ &= \frac{3C_3}{R_\mathrm{C}^4} - \frac{6C_6}{R_\mathrm{C}^7} \simeq \frac{3C_3}{R_\mathrm{C}^4} = \frac{3|\Delta_a|}{R_\mathrm{C}} \ . \end{aligned} \tag{36.238}$$

Hence, for red-detuning,

$$F_{eg}(E,\Delta_a) \simeq R_\mathrm{C}^4\frac{|\Psi_g(R_\mathrm{C},E)|^2}{3C_3} = (C_3/\Delta_a)^{1/3}\frac{|\Psi_g((C_3/\Delta_a)^{1/3},E)|^2}{3|\Delta_a|} \ . \tag{36.239}$$

36.5.2.3 Photoassociation spectroscopy

Photoassociation is based on binary collisions. Transitions to excited states are followed by spontaneous decay and can be monitored in trap loss experiments. An alternative way, which suits especially well for sodium is photoassociative ionization. The trap loss rate can be expressed as,

$$\dot{n} = -2K_\mathrm{pa}n^2 \ . \tag{36.240}$$

The event rate for photoassociation in a thermal cloud with Boltzmann velocity distribution is:

$$K_{\rm pa}(T,\Delta_1,I_1) = \left\langle \frac{\pi v}{k^2}\sum_\ell (2\ell+1)|S(E,\ell,\Delta_1,I_1)|^2 \right\rangle \ , \tag{36.241}$$
$$= \frac{2\pi\hbar}{m_{\rm red}k}\sum_\ell (2\ell+1)\int_0^\infty |S(E,\ell,\Delta_1,I_1)|^2 e^{-\beta E} d(\beta E) \ ,$$

where the *S-matrix* is given by (36.233), γ_1 is the spontaneous linewidth and $\gamma_s(E,\ell,I_1)/2\pi \approx \Omega_1^2|\langle b_1|E,\ell\rangle|^2$ is the Franck-Condon overlap between the colliding channel and the excited state bound level. For cold ultra-cold collisions, we may only consider s-wave collisions, $\ell = 0$. In the regime of Bose-Einstein condensation $T \lesssim 1\,\mu$K and $n \gtrsim 10^{14}\,$cm^{-3}, we can replace $e^{-\beta E} \to \delta(E)$ and $E \to 0$. The photoassociation rate then simplifies to [140],

$$K_{\rm pa}(\Delta_1,I_1) \approx \frac{2\pi\hbar}{m_{\rm red}k}\frac{\gamma_1\gamma_s}{\Delta^2 + \frac{1}{4}(\gamma_1+\gamma_s)^2} \ . \tag{36.242}$$

Thus the S-matrix is maximized in resonance and saturation, i.e. $\Delta_1 = E$ and $\gamma_s = \gamma_1$ so that $|S|^2 = 1$, which case is called the *unitarity limit*. Note that increasing the laser power beyond saturation, $\gamma_s > \gamma_1$, decreases the photoassociation efficiency again because of *Autler-Townes splitting* [824].

36.5.3 Two-color photoassociation

We can also shine in a second laser frequency tuned between the excited potential bound state and a ground potential bound state. This second laser power broadens the resonance and spoils the transition rate for the first laser. Following [104]:

$$K_{\rm pa}(T,\Delta_1,\Delta_2,I_1,I_2) = \left\langle \frac{\pi v}{k^2}\sum_\ell (2\ell+1)|S(E,\ell,\Delta_1,\Delta_2,I_1,I_2)|^2 \right\rangle \ , \tag{36.243}$$

where,

$$|S|^2 = \frac{(E-\Delta_2)^2\gamma_1\gamma_s}{(E-\Delta_+)^2(E-\Delta_-)^2 + \frac{1}{4}(\gamma_1+\gamma_s)^2(E-\Delta_2)^2} \ , \tag{36.244}$$

where,

$$\Delta_\pm = \tfrac{1}{2}(\Delta_1+\Delta_2) \pm \tfrac{1}{2}\sqrt{(\Delta_1-\Delta_2)^2 + 4\Omega_{12}^2} \ . \tag{36.245}$$

Note that $\gamma_s(E,\ell,I_1)/2\pi \approx \Omega_1^2\,|\langle b_1|E,\ell\rangle|^2$ and $\Omega_{12} = \Omega_2\langle b_1|b_2\rangle$. The one-color signal follows with $\Omega_{12} \to 0$. Assuming the unitarity limit for the free-bound transition, $\Delta_1 = E$ and $\gamma_s = \gamma_1$ the two-color signal reads:

$$|S|^2 = \frac{1}{1+\Omega_{12}^4/(\Delta_1-\Delta_2)^2\gamma_1^2} \ . \tag{36.246}$$

The width of the two-color spectral lines is mainly limited by the Boltzmann distribution of kinetic energies in the atomic cloud. At very low temperatures, we may .... and the two-color resonance dip may be interpreted as a true dark resonance.

Two-color PA lines have been observed for ^{85}Rb in a FORT [341]. In order to measure this for very low temperatures and even for condensates, one has to switch to ^{87}Rb in a dark MOT. A technical requirement is, of course, that the two lasers involved in the Raman process be very stable, at least with respect to each other. This is easiest achieved by using AOMs, which limits the range of levels to be studied to a few GHz binding energy.

Another important aspect is the requirement of a reasonable Raman transition probability, i.e. large Franck-Condon overlap between the collisional and the bound excited state and between the two bound states. Note also that selection rules hold.

36.5.4 Exercises

36.5.4.1 Ex: Photoassociation

Consider a laser focused into a cold, confined cloud of Na atoms at a temperature of 450 µK. For a detuning of 600 MHz, calculate the laser intensity (in W/cm^2) required to produce a 25% probability of photoassociation. The transition moment (a.u.) of Na is 2.55.

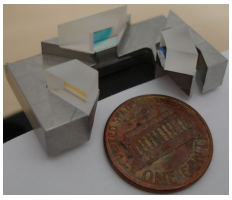
Part VII

Quantum Optics

Preface to the part *Quantum Optics*



Quantum optics is the field of physics which studies quantum characteristics of light fields. We have seen in Sec. 24.6 how to describe light in quantum mechanics as a quantum harmonic oscillator and introduced photon number states and coherent superposition states. In Chp. 37 the lecture these concepts will be deepened and extended to arbitrary photonic superposition states and to the coupling of different light modes. In Chp. 38 we will discuss the dynamics of light fields in optical cavities, their characterization, and their impact on the density-of-modes,

Chapter 37

Quantized radiation fields

We begin this chapter with the quantization of the light field in Sec. 37.1 and then present various ways of characterizing classical and quantum light fields in Secs. 37.2 and 37.3. In Sec. 37.4 we deepen the discussion for a particular type of quantum correlations known as *squeezed states of light* and in Sec. 37.5 we turn our attention to the coupling of different light modes via beam splitters.

37.1 Quantization of the electromagnetic field

We have already seen that the energy of a monochromatic light field with frequency ω is quantized in small equal portions, such that the total energy is $N\hbar\omega$, where N is an integer number. The energy spectrum is the same as the one of the harmonic oscillator. Therefore, we can identify a light mode with an oscillator and adopt the entire formalism developed for the harmonic oscillator. The formalism will be assumed as known in the following. We will, for simplicity use the term *photon* (respectively *phonon*) for excitations of a harmonic oscillator mode. It is however important to be aware that a photon is not a particle, as it simply *disappears when performing the transition from quantum to classical mechanics* [551].

37.1.1 Field operators

The basic idea behind field quantization is the replacement of the classical harmonic oscillators discussed in Sec. 24.5 by quantum oscillators. The simplest approach to perform this quantization is to introduce the scalar potential Φ and the potential vector $\mathbf{A}$ as done in electrodynamic theory [1]. In free space, without charges nor currents, and within the *Coulomb gauge* we have the solution of the wave equation (39.5) generalized to a distribution of wavevectors $\mathbf{k}$ [2],

$$\mathbf{A}(\mathbf{r},t) = \sum_{\mathbf{k}} \vec{\epsilon}_{\mathbf{k}} [A^{+}_{0\mathbf{k}} e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t)} + A^{-}_{0\mathbf{k}} e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t)}] \ , \tag{37.1}$$

where we already isolated the vectorial character due to the polarization $\vec{\epsilon}_{\mathbf{k}}$ of the light mode $\mathbf{k}$. Obviously, $A^{-}_{0\mathbf{k}} = (A^{+}_{0\mathbf{k}})^{*}$. As each amplitude and polarization of the wave

[1] See Sec. 14.3.

[2] The atom-light interaction may depend on the polarization of the light with respect to the quantization axis of the atom, as defined e.g. by a magnetic field. In these cases we need to extend the index $\mathbf{k}$ to include the polarization state $(\mathbf{k}, \lambda)$.

given by the vector potential $\mathbf{A}_\mathbf{k}$ and $\mathbf{A}^*_\mathbf{k}$ must satisfy the wave equation separately, we arrive at the dispersion relation,

$$\omega_\mathbf{k} = ck \ . \tag{37.2}$$

With the results (39.7) and (39.8) we know that the energy in each radiative mode containing $n_\mathbf{k}$ photons is,

$$E_\mathbf{k} = \hbar\omega_\mathbf{k} n_\mathbf{k} = u_\mathbf{k} V = 2\varepsilon_0 V \omega_\mathbf{k}^2 \overline{\mathbf{A}_{0\mathbf{k}}^2} = 2\varepsilon_0 V \omega_\mathbf{k}^2 (A_{0\mathbf{k}}^- A_{0\mathbf{k}}^+ + A_{0\mathbf{k}}^+ A_{0\mathbf{k}}^-) \ , \tag{37.3}$$

where the bar denotes cycle-averaging. The second quantization now consists in interpreting the mode as a *quantum harmonic oscillator*, that is, we understand the observables as *operators* satisfying commutation rules, such as $[\hat{A}_{0\mathbf{k}}^-, \hat{A}_{0\mathbf{k}'}^+] \propto \delta_{\mathbf{k},\mathbf{k}'}$, and hence being affected by quantum fluctuations:

$$\hat{H}_\mathbf{k} = \hbar\omega_\mathbf{k}(\hat{n}_\mathbf{k} + \tfrac{1}{2}) = 2\varepsilon_0 V \omega_\mathbf{k}^2 (\hat{A}_{0\mathbf{k}}^- \hat{A}_{0\mathbf{k}}^+ + \hat{A}_{0\mathbf{k}}^+ \hat{A}_{0\mathbf{k}}^-) \ . \tag{37.4}$$

We introduce normalized field operators following the commutation rule (24.85) via,

$$\hat{a}_\mathbf{k} \sqrt{\tfrac{\hbar}{4\varepsilon_0 V \omega_\mathbf{k}}} \equiv \hat{A}_{0\mathbf{k}}^+ \qquad \text{and} \qquad \hat{a}_\mathbf{k}^\dagger \sqrt{\tfrac{\hbar}{4\varepsilon_0 V \omega_\mathbf{k}}} \equiv \hat{A}_{0\mathbf{k}}^- \ , \tag{37.5}$$

such that,

$$\hat{H}_\mathbf{k} = \hbar\omega_\mathbf{k}(\hat{a}_\mathbf{k}^\dagger \hat{a}_\mathbf{k} + \tfrac{1}{2}) \ . \tag{37.6}$$

The analogy allows us to interpret them as *creation operator* and *annihilation operator* of photons. Finally, we can rewrite (37.1) as,

$$\boxed{\hat{\mathbf{A}}_\mathbf{k}(\mathbf{r}, t) = \sqrt{\tfrac{\hbar}{4\varepsilon_0 V \omega_\mathbf{k}}} \vec{\epsilon}_\mathbf{k} \left[\hat{a}_\mathbf{k} e^{-\imath(\mathbf{k}\cdot\mathbf{r} - \omega_\mathbf{k} t)} + \hat{a}_\mathbf{k}^\dagger e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega_\mathbf{k} t)} \right]} \ . \tag{37.7}$$

We already know such combinations of operators and their complex conjugates from the quantum harmonic oscillator (24.95).

In the Coulomb gauge, the electric and magnetic field operators for the cavity modes can be constructed from,

$$\boxed{\begin{aligned} \hat{\vec{\mathcal{E}}}_\mathbf{k} &= -\frac{\partial \hat{\mathbf{A}}_\mathbf{k}}{\partial t} = \imath \sqrt{\tfrac{\hbar\omega_\mathbf{k}}{2\varepsilon_0 V}} \left(\hat{a}_\mathbf{k} e^{-\imath(\mathbf{k}\cdot\mathbf{r} - \omega_\mathbf{k} t)} - \hat{a}_\mathbf{k}^\dagger e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega_\mathbf{k} t)} \right) \vec{\epsilon}_k \\ \hat{\vec{\mathcal{B}}}_\mathbf{k} &= \nabla \times \mathbf{A}_\mathbf{k} = \imath \sqrt{\tfrac{\hbar\omega_\mathbf{k}}{2\varepsilon_0 V}} \left(\hat{a}_\mathbf{k} e^{-\imath(\mathbf{k}\cdot\mathbf{r} - \omega_\mathbf{k} t)} - \hat{a}_\mathbf{k}^\dagger e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega_\mathbf{k} t)} \right) \mathbf{k} \times \vec{\epsilon}_k \end{aligned}} \ . \tag{37.8}$$

We can calculate the cycle-averaged energy of the $\mathbf{k}$-th cavity mode from a quantum version of Eq. (37.3),

$$\bar{E}_\mathbf{k} = \tfrac{\varepsilon_0}{2} \int \langle n_\mathbf{k} | \hat{\vec{\mathcal{E}}}_\mathbf{k} \cdot \hat{\vec{\mathcal{E}}}_\mathbf{k} | n_\mathbf{k} \rangle dV \ . \tag{37.9}$$

The result (37.6) is exactly Planck's quantum hypothesis (although strictly speaking, he rather suggested a quantization of oscillators in the conducting walls of the cavity, not of the field) on the distribution of the spectral intensity radiated by a black body. We now can see that it follows naturally from the quantization of the cavity field modes. With the results of the previous section the complete field Hamiltonian reads,

$$\hat{H}_{\text{field}} = \sum_\mathbf{k} \hbar\omega_\mathbf{k}(\hat{a}_\mathbf{k}^\dagger \hat{a}_\mathbf{k} + \tfrac{1}{2}) \ . \tag{37.10}$$

Solve Excs. 37.1.2.1 and 37.1.2.2.

37.1.2 Exercises

37.1.2.1 Ex: Photon statistics

An optical resonator contains on average 10 photons in the mode TEM_{00q}. What is the probability of finding, at any time, 1 photon resp. 10 photons, when the light is (a) thermal, (b) coherent? For case (a), what is the temperature of the light for $\lambda = 633\,\mathrm{nm}$?

37.1.2.2 Ex: Photon wavefunction

a. Show that for the *photonic wavefunction* $\mathbf{\Psi}$ and the current density $\mathbf{J}$ [803],

$$\mathbf{\Psi} = \mathbf{\Psi}^+ + \mathbf{\Psi}^- \qquad \text{with} \qquad \mathbf{\Psi}^\pm = \sqrt{\tfrac{\varepsilon_0}{2}}\vec{\mathcal{E}}_\pm \pm \imath\sqrt{\tfrac{1}{2\mu_0}}\vec{\mathcal{B}}_\pm \qquad \text{and} \qquad \hat{\sigma}\mathbf{\Psi}^\pm = \pm\mathbf{\Psi}^\pm$$

$$\mathbf{J} = \mathbf{J}_f + \nabla\times\vec{\mathcal{M}} + \frac{\partial\vec{\mathcal{P}}}{\partial t}\ ,$$

where $\vec{\mathcal{E}} \equiv \vec{\mathcal{E}}_+ + \vec{\mathcal{E}}_-$ and $\vec{\mathcal{B}} \equiv \vec{\mathcal{B}}_+ + \vec{\mathcal{B}}_-$ are the real electric and magnetic fields of the photon and $\hat{\sigma}$ is the helicity, the Bialynicki-Birula-Sipe wave equation

$$\boxed{\imath\hbar\frac{\partial\mathbf{\Psi}}{\partial t} = \hbar c\hat{\sigma}\nabla\times\mathbf{\Psi} - \tfrac{\imath\hbar}{\sqrt{2\varepsilon_0}}\mathbf{J} \qquad \text{and} \qquad \nabla\cdot\mathbf{\Psi} = 0}$$

is equivalent to the Maxwell equations.
b. Use the plane wavefunction

$$\mathbf{\Psi} \equiv \sum_s \int d^3k \sqrt{\tfrac{\hbar\omega}{(2\pi)^3}}\, e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)}\hat{a}_{\mathbf{k}s}\hat{\mathbf{e}}_{\mathbf{k}s}$$

to calculate the total energy $\hat{H} = \frac{1}{2}\int d^3r[\mathbf{\Psi}^\dagger(\mathbf{r},t), \mathbf{\Psi}(\mathbf{r},t)]_+$.

37.2 Density matrix

As long as we are only interested in coherent reversible processes the Schrödinger equation suffices to describe the evolution of a system. A problem arises when we want to describe dissipative processes, such as spontaneous emission or transmission of photons through a cavity mirror. Dissipation is due to coupling of the degree of freedom under investigation to other degrees of freedom imposed by the environment. While the impact of dissipation on the state of the system can be important, the impact of the system on the environment is generally negligible or not interesting. Therefore, we would like to remove it from the equations of motion, while maintaining its influence on the system. The disregarding of the environment represents a loss of information on the state of the whole system plus reservoir, which transform an initially pure state into a statistical distribution. This situation can not be described by a single wavefunction, but only by a distribution of wavefunctions, and we can only expect to calculate the probability of finding the system within this distribution. The Schrödinger equation, therefore, no longer applies, and we need to trace the time evolution of a system characterized by a density operator describing a statistical

mixture of quantum states. The equations which describe the time evolution of the matrix elements of this density operator are called master equations, and we must use them instead of the Schrödinger equation. We begin by reviewing the rudiments of the density matrix theory.

37.2.1 The density operator

We define the *statistical operator* or *density operator* [3],

$$\boxed{\hat{\rho} \equiv \sum_k p_k \hat{P}_k \qquad \text{where} \qquad \hat{P}_k \equiv |\psi_k\rangle\langle\psi_k|} \ , \tag{37.11}$$

where $\{|\psi_k\rangle\}$ is a complete set of orthonormal states of the system under study. We consider a statistical distribution of these states with p_j being the probability of finding $|\psi_j\rangle$ in the set. Obviously, $\sum_k p_k = 1$. That is, the density operator acts on a member of the set $\{|\psi_k\rangle\}$ in a way to extract the probability of finding the system in $|\psi_j\rangle$,

$$\hat{\rho}|\psi_j\rangle = \sum_k p_k |\psi_k\rangle\langle\psi_k|\psi_j\rangle = p_j|\psi_j\rangle \ . \tag{37.12}$$

If all members of the set are in the same state, for example $|\psi_k\rangle$, the density operator reduces to,

$$\hat{\rho} = |\psi_k\rangle\langle\psi_k| \ , \tag{37.13}$$

and the system is in a *pure state* with $p_k = \delta_{1k}$. Each time a quantum state can be expressed by a single wave function, it is a pure state, but it does not have to be an eigenstate. Starting from the equation (37.12) we find,

$$\langle\psi_k|\hat{\rho}|\psi_j\rangle = p_j \delta_{kj} \ . \tag{37.14}$$

The diagonal elements of the density matrix are the probabilities of finding the system in $|\psi_j\rangle$, and assuming that all $|\psi_k\rangle$ are orthonormal, the non-diagonal elements of the incoherent sum (37.11) are necessarily zero [4], Besides that,

$$\sum_k \langle\psi_k|\hat{\rho}|\psi_k\rangle = 1 \ , \tag{37.15}$$

so that $\hat{\rho}$ contains all *available* information about the system, that is, our *knowledge* about its state. When the state of the system is unknown, $\hat{\rho}$ describes the probability

[3] In the presence of degeneracy or a continuous spectrum we can generalize the definition:

$$\hat{\rho} \equiv \sum_k p_k \hat{P}_k + \int p_\lambda \hat{P}_\lambda d\lambda \quad \text{where} \quad \hat{P}_k \equiv \sum_m |km\rangle\langle km| \quad \text{and} \quad \hat{P}_\lambda \equiv \int |\lambda\mu\rangle\langle\lambda\mu| d\mu \ .$$

Here, m and μ are degenerate quantum numbers, m, n are discrete, and λ, μ are continuous quantum numbers. The set of quantum numbers is complete, when

$$\sum\nolimits_{k,m} |km\rangle\langle km| = \mathbb{I} = \int |\lambda\mu\rangle\langle\lambda\mu| d\lambda d\mu \ .$$

The degree of degeneracy of a state $|k\rangle$ is $\mathrm{Tr}\,\hat{P}_k = \sum_m 1$. The probability of finding the system in the state $|k\rangle$ is $\langle\hat{P}_k\rangle = p_n \sum_m 1$.

[4] This is simply because we constructed the density operator to be diagonal in the basis $\{|\psi_k\rangle\}$. It does not mean, that the density operator cannot have non-diagonal elements in another basis.

of finding the system in each state. When the state is fully known, $\hat{\rho}$ describes a pure state, that is, a vector in the Hilbert space, which is unequivocally determined by a complete set of observables with their respective quantum numbers.

The properties of the density operator are,

$$\boxed{\begin{array}{rcll} \hat{\rho} & = & \hat{\rho}^\dagger & \\ \langle\hat{\rho}\rangle & \geq & 0 & \\ \mathrm{Tr}\,\hat{\rho} & = & 1 & \\ \mathrm{Tr}\,\hat{\rho}^2 & \leq & 1 & \\ \det\hat{\rho} & = & 0 & \\ \hat{\rho} & = & \hat{\rho}^2 & \text{for a pure state} \end{array}} \ . \tag{37.16}$$

Example 258 (*Inhomogeneous atomic clouds*): For example, a thermal atomic cloud of N two-level atoms needs in general to be described by a density operator, because the state of every atom is independent of the state of the other atoms. If we knew that all atoms behave exactly in the same way, for instance, when exposed to a radiation field, we could restrict to calculating the evolution of a single atom and extrapolate to N atoms. However, atomic motion and interatomic interactions often influence the dynamics in a way that the atoms behave differently.

37.2.2 Matrix formalism

The next step is to develop matrix representations of the density operator by expanding the state vectors $|\psi_k\rangle$ in a complete orthonormal basis,

$$|\psi_k\rangle = \sum_n c_{nk}|n\rangle = \sum_n |n\rangle\langle n|\psi_k\rangle \ , \tag{37.17}$$

using the *completeness relation* (23.183), that is, $\sum_n |n\rangle\langle n| = \mathbb{I}$, and defining,

$$c_{nk} \equiv \langle n|\psi_k\rangle \tag{37.18}$$

as the projection of the state vector $|\psi_k\rangle$ on the basis vector $|n\rangle$. Now, we can write the density operator matrix representation within the basis $\{|n\rangle\}$ using the definition of $\hat{\rho}$ in Eq. (37.11) and replacing $|\psi_k\rangle$ and $\langle\psi_k|$ by their expansions (37.17):

$$\hat{\rho} = \sum_k p_k|\psi_k\rangle\langle\psi_k| = \sum_k p_k \sum_{m,n} |n\rangle\langle n|\psi_k\rangle\langle\psi_k|m\rangle\langle m| = \sum_k p_k \sum_{m,n} c_{nk}c^*_{mk}|n\rangle\langle m| \ . \tag{37.19}$$

The matrix elements of $\hat{\rho}$ in this representation are

$$\rho_{nm} \equiv \langle n|\hat{\rho}|m\rangle = \sum_k p_k c_{nk}c^*_{mk} \tag{37.20}$$

with the diagonal elements $\langle n|\hat{\rho}|n\rangle = \sum_k p_k|c_{nk}|^2$ and,

$$\rho^*_{nm} = \langle n|\hat{\rho}|m\rangle^* = \sum_k p_k c^*_{nk}c_{mk} = \sum_k p_k\langle m|\psi_k\rangle\langle\psi_k|n\rangle = \langle m|\rho|n\rangle = \rho_{mn} \ , \tag{37.21}$$

which means that the operator $\hat{\rho}$ is Hermitian.

Example 259 (*Density operator for a single atom*): For a very simple system such as a single atom with several levels, that without spontaneous emission can be described by a single wavefunction $|\psi_1\rangle$, we can let $p_k = \delta_{1k}$. That is, the equations (37.19) and (37.21) reduce to,

$$\hat{\rho} = \sum_{m,n} c_{n1} c_{m1}^* |n\rangle\langle m| \qquad \text{and} \qquad \langle n|\rho|m\rangle = c_{n1} c_{m1}^* \ . \tag{37.22}$$

37.2.3 Measurement and trace

The sum of the diagonal elements of a matrix representing an operator is called the *trace*. This quantity represents a fundamental property of the density operator, since it is invariant with respect to any unitary transformation:

$$\mathrm{Tr}\,\hat{\rho} \equiv \sum_n \langle n|\hat{\rho}|n\rangle \ . \tag{37.23}$$

With the definition of the density operator (37.11) we can write the Eq. (37.23) as,

$$\mathrm{Tr}\,\hat{\rho} \equiv \sum_{n,k} p_k \langle n|\psi_k\rangle\langle\psi_k|n\rangle \ . \tag{37.24}$$

Now, using the completeness relation,

$$\mathrm{Tr}\,\hat{\rho} \equiv \sum_{n,k} p_k \langle\psi_k|n\rangle\langle n|\psi_k\rangle = \sum_k p_k \langle\psi_k|\psi_k\rangle = 1 \ , \tag{37.25}$$

which shows that the trace of the density operator representation is always 1 regardless of the basis of the matrix representation.

Example 260 (*Density operator for a statistical mixture*): Let us imagine an experiment with a single three-level atom coupling a state $|1\rangle$ to two other possible states $|2\rangle$ and $|3\rangle$ via a $\frac{\pi}{2}$-pulse, such that one of the two states,

$$|\psi_1\rangle = \tfrac{1}{\sqrt{2}}(|1\rangle + |2\rangle) \qquad \text{or} \qquad |\psi_2\rangle = \tfrac{1}{\sqrt{2}}(|1\rangle + |3\rangle)$$

be generated with equal probability. We also suppose that the performed experiment doesn't tell us which one of the two states was generated, so that we have to describe the system by a density operator,

$$\hat{\rho} = \sum_{k=1,2} \tfrac{1}{2}|\psi_k\rangle\langle\psi_k| = \tfrac{1}{2}\left[\frac{|1\rangle + |2\rangle}{\sqrt{2}}\,\frac{\langle 1| + \langle 2|}{\sqrt{2}}\right] + \tfrac{1}{2}\left[\frac{|1\rangle + |3\rangle}{\sqrt{2}}\,\frac{\langle 1| + \langle 3|}{\sqrt{2}}\right] \ .$$

Choosing an obvious basis, we can represent the density operator by a matrix,

$$\hat{\rho} = \begin{pmatrix} \frac{1}{2} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & 0 \\ \frac{1}{4} & 0 & \frac{1}{4} \end{pmatrix} \ ,$$

for which we verify,

$$\hat{\rho} = \hat{\rho}^\dagger \qquad \text{and} \qquad \mathrm{Tr}\,\hat{\rho} = 1 \ ,$$

but,

$$\hat{\rho}^2 \neq \hat{\rho} \qquad \text{and} \qquad \mathrm{Tr}\,\hat{\rho}^2 = \tfrac{5}{8} \leq 1 \ .$$

Hence the state is not pure.

Expectation values of observables are expressed by,

$$\langle \hat{A} \rangle = \sum_k p_k \langle \psi_k | \hat{A} | \psi_k \rangle \ . \tag{37.26}$$

On the other hand,

$$\hat{\rho}\hat{A} = \sum_k p_k |\psi_k\rangle\langle\psi_k|\hat{A} \ , \tag{37.27}$$

and in the basis $\{|n\rangle\}$,

$$\langle n|\hat{\rho}\hat{A}|m\rangle = \langle n| \sum_k p_k |\psi_k\rangle\langle\psi_k|\hat{A}|m\rangle = \sum_k p_k \langle n|\psi_k\rangle\langle\psi_k|\hat{A}|m\rangle = \sum_k p_k \langle\psi_k|\hat{A}|m\rangle\langle n|\psi_k\rangle \ . \tag{37.28}$$

Now, along the diagonal, we have,

$$\langle n|\hat{\rho}\hat{A}|n\rangle = \sum_k p_k \langle\psi_k|n\rangle\langle n|\hat{A}|\psi_k\rangle \ . \tag{37.29}$$

With the closure relation in the basis $\{|n\rangle\}$, we now have [5],

$$\boxed{\mathrm{Tr}\,\hat{\rho}\hat{A} = \sum_k p_k \langle\psi_k|\hat{A}|\psi_k\rangle = \langle\hat{A}\rangle} \ . \tag{37.30}$$

The Eq. (37.30) says that the ensemble average of any dynamic observable $\hat{A}$ can be calculated from the diagonal elements of the operator matrix $\hat{\rho}\hat{A}$: Since the trace is independent of the basis (this will be shown in Exc. 37.2.4.1), each unitary transformation taking the matrix representation from a basis $\{|n\rangle\}$ to another one $\{|t\rangle\}$ leaves the trace invariant. Using the definition of a unitary transformation we can easily show that the trace of a cyclic permutation of a product is invariant. For example,

$$\mathrm{Tr}\,[\hat{A}\hat{B}\hat{C}] = \mathrm{Tr}\,[\hat{C}\hat{A}\hat{B}] = \mathrm{Tr}\,[\hat{B}\hat{A}\hat{C}] \ , \tag{37.31}$$

and in particular

$$\mathrm{Tr}\,[\hat{\rho}\hat{A}] = \mathrm{Tr}\,[\hat{A}\hat{\rho}] = \langle\hat{A}\rangle \ . \tag{37.32}$$

In the Excs. 37.2.4.2 and 37.2.4.3 we apply the density operator to pure and mixed states of a two-level system. In Excs. 37.2.4.4 and 37.2.4.5 we study thermal mixtures and Exc. 37.2.4.6 Glauber states.

37.2.3.1 Measurement process

If an observable $\hat{A}$ has a spectral representation $\hat{A} = \sum_n a_n |a_n\rangle\langle a_n| = \sum_n a_n \hat{P}_n$, with $\hat{P}_n = |a_n\rangle\langle a_n|$, the measurement process will transform the density operator to,

$$\hat{\rho}' = \sum_n \hat{P}_n \hat{\rho} \hat{P}_n \ . \tag{37.33}$$

[5] In the presence of degeneracy or a continuous part of the spectrum we can generalize the definition of the expectation,

$$\langle\hat{X}\rangle \equiv \mathrm{Tr}\,\hat{\rho}\hat{X} = \sum_{k,m} \langle km|\hat{\rho}\hat{X}|km\rangle \ .$$

That is, after the *measurement*, the density operator becomes diagonal on the basis of the eigenvalues of $\hat{A}$ [6], as explained in Sec. 23.4.7. The expression can be thought of as the mathematical formulation of von Neumann's state reduction postulate.

We note that the density operator (37.33) describes the whole ensemble after the measurement. The sub-ensemble corresponding to a particular result a_n of the measurement is described by a different density operator,

$$\hat{\rho}'_n = \frac{\hat{P}_n \hat{\rho} \hat{P}_n}{\mathrm{Tr}\,[\hat{\rho}\hat{P}_n]} \ . \tag{37.34}$$

This is true, when $|a_n\rangle$ is the only eigenvector with the eigenvalue a_n. If not, $\hat{P}_n$ in the expression (37.34) should be replaced by the projection operator onto the sub-space of a_n [7]. In Exc. 37.2.4.7 we study the projection of Glauber states and in Exc. 37.2.4.8 of entangled states.

37.2.3.2 Entropy

In a very general sense, the *entropy* determines in what direction a reversible process will take place. It is related to the size of the available phase space on both sides of the reaction. For example, the coupling of discrete and continuous modes is governed by entropy considerations.

Entropy measures of the lack of information about a system from which we only know $\langle \hat{H} \rangle$,

$$S \equiv -k_{\mathrm{B}} \langle \ln \hat{\rho} \rangle = -k_{\mathrm{B}}\ \mathrm{Tr}\,(\hat{\rho} \ln \hat{\rho}) \ . \tag{37.35}$$

The *information entropy* (or *von Neumann entropy*) of statistically independent systems $\hat{\rho} \equiv \hat{\rho}_1 \otimes \hat{\rho}_2$ is additive $S = S_1 + S_2$. We can also define absolute temperatures by $T^{-1} \equiv \partial S / \partial \langle \hat{H} \rangle$. The entropy of a pure state is 0. Hamiltonian processes conserve entropy, for they correspond to non-dissipative unitary transformations. On the other side, relaxation increases the entropy and the phase space volume. Another common definition is the so-called *purity* or *Renyi entropy*,

$$S_R \equiv \langle 1 - \hat{\rho} \rangle = 1 - \mathrm{Tr}\,(\hat{\rho}^2) \ . \tag{37.36}$$

Quantum states can exhibit coherences. For example, if we express a state $|\psi\rangle$ on a basis of eigenstates $|1\rangle$ and $|2\rangle$:

$$\hat{\rho} = |\psi\rangle\langle\psi| = \begin{pmatrix} |\langle\psi|1\rangle|^2 & \langle 1|\psi\rangle\langle\psi|2\rangle \\ \langle 2|\psi\rangle\langle\psi|1\rangle & |\langle\psi|2\rangle|^2 \end{pmatrix} \ . \tag{37.37}$$

[6] A projective measure always increases entropy. The entropy of a pure state is zero, while that of a mixture is always greater than zero. Therefore, a pure state can be converted into a mixture by a measurement, but the reverse can not happen. Thus, the action of measuring induces an irreversible change in the density matrix reminiscent of the collapse of the wavefunction. Strangely, the measurement *reduces* the amount of information by quenching the quantum interference of the compound system in a process called quantum decoherence. A subsystem can be taken from a mixed state to a pure state only at the price of increasing the von Neumann entropy elsewhere in the global system.

[7] In general, assuming that f is a function associating each observable $\hat{A}$ with a number $f(\hat{A})$ (which we may imagine as the expectation value), we can state the following: If f satisfies some natural properties (such as the one to produce positive values for positive operators), then there exists a unique density matrix $\hat{\rho}$, such that $f(\hat{A}) = \mathrm{Tr}\,(\hat{\rho}\hat{A})$ for all $\hat{A}$. That is, every reasonable 'family' of expectation values' can be represented by a density matrix, which suggests that the density matrix provides the most general description of a quantum state.

The evolution of such a state is described by the von Neumann equation,

$$i\hbar\partial_t\hat{\rho}(t) = [\hat{H}, \hat{\rho}(t)] \ . \tag{37.38}$$

The measurement process is not described by this equation. A pure state will always remain pure. If the eigenstates do not interact, the density operator will remain diagonal. The von Neumann equation conserves the properties of hermiticity, $\hat{\rho} = \hat{\rho}^\dagger$, completeness, $\mathrm{Tr}\,\hat{\rho} = 1$, and purity $\det\hat{\rho} = 0$.

The density operator for a *statistical mixture* in a canonical ensemble (where S is maximum, U is variable, and N is fixed) follows from a variational problem with the Lagrange parameters $\delta(S - k_\mathrm{B}\alpha\langle\mathbb{I}\rangle - k_\mathrm{B}\beta\langle\hat{H}\rangle) = 0$, since $\mathrm{Tr}\,\hat{\rho}$ and $\langle\hat{H}\rangle$ are fixed by boundary conditions. We find,

$$\boxed{\hat{\rho} = \frac{1}{Z}e^{-\hat{H}/k_\mathrm{B}T} \qquad \text{with} \qquad Z \equiv \mathrm{Tr}\,e^{-\hat{H}/k_\mathrm{B}T}} \ . \tag{37.39}$$

We also have the expectation values, $\langle H\rangle = -\partial\ln Z/\partial\beta$ and $(\Delta H)^2 = -\partial\langle\hat{H}\rangle/\partial\beta$ with the abbreviation $\beta \equiv (k_\mathrm{B}T)^{-1}$. All quantities are fixed, except the kinetic energy, which balances the interaction with a heat bath. T is the only equilibrium parameter. The density operator satisfies a Boltzmann distribution [8],

$$U = \langle\hat{H}\rangle = \frac{p^2}{2m} = -\frac{\partial}{\partial(1/k_\mathrm{B}T)}\ln\int e^{-p^2/2mk_\mathrm{B}T}dp = \frac{k_\mathrm{B}}{2}T \ . \tag{37.40}$$

37.2.3.3 Systems and subsystems

Density operators are very useful for playing with systems and subsystems. Let us, for instance, assume that we have two quantum systems defined on the Hilbert spaces $\mathcal{H}_1$ and $\mathcal{H}_2$. The composite system is then the tensor product $\mathcal{H}_1 \otimes \mathcal{H}_2$. We now suppose that the compound system is in a pure state, $|\psi\rangle \in \mathcal{H}_1 \otimes \mathcal{H}_2$. If the state can be written in the form $|\psi\rangle = |\psi_1\rangle \otimes |\psi_2\rangle$, this means that the state of the first subsystem is $|\psi_1\rangle$. However, in general, $|\psi\rangle$ does not decompose like this. Of course, every vector in $\mathcal{H}_1 \otimes \mathcal{H}_2$ is a linear combination of tensorial products of $\mathcal{H}_1$ and $\mathcal{H}_2$. If $|\psi\rangle$ can not be decomposed as a tensor product, we say that the two systems are *entangled*. In this case, there is no reasonable way of associating a pure state $|\psi_1\rangle \in \mathcal{H}_1$ to the state $\psi \in \mathcal{H}_1 \otimes \mathcal{H}_2$. If, for example, in the case of a two particle wavefunction $\Psi(x_1, x_2)$ there is no way to construct a wavefunction (i.e. a pure state) $\psi_1(x_1)$ describing the state of the first particle, then $\Psi(x_1, x_2) \neq \psi_1(x_1)\psi_2(x_2)$.

The point of the discussion is that, even if the total system is in a pure state, the various subsystems that compose it will normally be in mixed states. On the other hand, regardless of whether the composite system is in a pure or mixed state, we can perfectly construct a density matrix that describes the state. Therefore, the use of density matrices is inevitable. Let $\hat{\rho}$ be the density matrix of the system composed of two subsystems. Then the state in $\mathcal{H}_2$ is described by a reduced density operator given by the partial trace of $\hat{\rho}$ over $\mathcal{H}_2$. In the particular case, where the state the

[8] The von Neumann entropy S of a mixture can be expressed in terms of the eigenvalues or in terms of the trace and the logarithm of the density operator $\hat{\rho}$. Since $\hat{\rho}$ is a semi-definite positive operator, its spectrum λ_i, given by $\rho = \sum_i \lambda_i|\varphi_i\rangle\langle\varphi_i|$ where $\{|\varphi_i\rangle\}$ is an orthonormal basis, satisfies $\lambda_i > 0$ and $\sum\lambda_i = 1$. Then the entropy becomes $S = -\sum_i \lambda_i \ln\lambda_i = -\mathrm{Tr}\,(\rho\ln\rho)$.

density matrix has the form $\hat{\rho} = \hat{\rho}_1 \otimes \hat{\rho}_2$, where $\hat{\rho}_1$ and $\hat{\rho}_2$ are the density matrices in $\mathcal{H}_1$ and $\mathcal{H}_2$, then the partial trace is simply, $\mathrm{Tr}_{\mathcal{H}_2} \hat{\rho}\hat{\rho}_1$.

37.2.4 Exercises

37.2.4.1 Ex: Trace of an operator

The trace of an operator $\hat{A}$ is defined by $\mathrm{Tr}\,\hat{A} = \sum_n \langle n|\hat{A}|n\rangle$.
a. Show that the trace is independent of the chosen basis!
b. Show that $\mathrm{Tr}\,\hat{A}\hat{B} = \mathrm{Tr}\,\hat{B}\hat{A}$!

37.2.4.2 Ex: Pure states and mixtures

Consider a system of two levels coupled by a light mode. The Hamiltonian can be written ($\hbar \equiv 1$),

$$\hat{H} = \begin{pmatrix} 0 & \frac{1}{2}\Omega \\ \frac{1}{2}\Omega & \omega_0 \end{pmatrix} .$$

Calculate $\hat{\rho}$, $\hat{\rho}^2$ and $\langle \hat{H} \rangle$ for the following two cases:
a. The atom is in a superposition state, $|\psi\rangle = \alpha|1\rangle + \beta|2\rangle$ and
b. the atom is a statistical mixture of eigenstates, $\hat{\rho} = \mu|1\rangle\langle 1| + \nu|2\rangle\langle 2|$.

37.2.4.3 Ex: Mixture of states

A two-level atom is initially in a superposition of two states $|\psi\rangle = \frac{1}{\sqrt{2}}|1\rangle + \frac{1}{\sqrt{2}}|2\rangle$. An apparatus measures the populations of the states, but the experimenter forgot to read the indicated result.
a. Describe the state the atom by the density operator.
b. Now the experimenter returns to the device. Calculate with which probability he reads the state $|1\rangle$.

37.2.4.4 Ex: Thermal mixture

We consider a thermal non-interacting atomic gas in one dimension. Instead of describing the state of the atomic ensemble, we can consider a single atom with a distributed probability of having a given velocity v. The density operator of the continuous degree of freedom can be written,

$$\hat{\rho} = \int dv \sqrt{\frac{m}{2\pi k_\mathrm{B} T}} e^{-mv^2/2k_\mathrm{B}T} |v\rangle\langle v| ,$$

and the trace of an arbitrary observable $\hat{A}$,

$$\langle \hat{A} \rangle = \mathrm{Tr}\,\hat{\rho}A = \int du \langle u|\hat{\rho}\hat{A}|u\rangle .$$

Now imagine a device capable of measuring the speed of a single atom randomly chosen within the cloud.
a. Express the probability of measuring a specific velocity v' for this atom using the density operator.
b. Express the expectation value of the average velocity by the density operator.

37.2.4.5 Ex: Thermal population of a harmonic oscillator

In thermal equilibrium the energy states of a system are populated following Boltzmann's law,

$$P_n = \frac{e^{-n\beta\hbar\omega}}{\sum_m e^{-m\beta\hbar\omega}} \qquad \text{with} \qquad \beta \equiv \frac{1}{k_\mathrm{B}T} \ .$$

a. Consider a one-dimensional harmonic oscillator characterized by the secular frequency ω and, using the density operator, calculate the mean quantum number of the population and the mean energy.
b. For an energy spacing of $\omega/2\pi = 10\,\mathrm{MHz}$, how many levels of the harmonic oscillator are necessary at room temperature to accumulate a population of at least 50%. How many for an energy spacing of $\omega/2\pi = 10\,\mathrm{GHz}$. Repeat the calculation for a $1\,\mu\mathrm{K}$ cold atomic cloud.

37.2.4.6 Ex: Density operator of a Glauber state

a. Write down the density operator of a Glauber state and calculate its purity.
b. How does the density operator look after a measurement of its vibrational level before acknowledging the result? Is it pure?
c. How does it look having acknowledged the result? Is it pure?

37.2.4.7 Ex: Reduced density operator of a Glauber state

Project the density operator of a Glauber state onto its two lowest Fock states using the formula (37.34). Show that the resulting density operator is pure.

37.2.4.8 Ex: Partial measurements

Consider the density operator describing the quantum state of two spins, $|\Psi\rangle = |\psi_a\rangle \otimes |\psi_b\rangle$, with $|\psi_a\rangle = a_1|\uparrow\rangle + a_2|\downarrow\rangle$ and $|\psi_b\rangle = b_1|\rightarrow\rangle + b_2|\leftarrow\rangle$.
a. Write down the density operator for the complete system in terms of the expansion coefficients $c_{ij} = a_i b_j$.
b. Assume that the spin $|\psi_b\rangle$ is measured and verify whether the new density operator describing our knowledge of the system is pure.
c. Now consider the entangled state $|\Psi_e\rangle = c_{11}|\uparrow\rangle|\rightarrow\rangle + c_{22}|\downarrow\rangle|\leftarrow\rangle$. Write down again the density operator for the complete system, measure the spin $|\psi_b\rangle$, and verify whether the new density operator describing our knowledge of the system is pure.

37.3 (Quasi-)probability distribution functions of the coherent state basis

In the previous section we have seen that a light mode can be identified with a harmonic oscillator, which enabled us to harness the whole powerful formalism developed in Secs. 24.5 and 24.6 for the characterization of the quantum states of light. As we have seen in those sections, quantum observables are intrinsically affected by quantum noise, which leads to a spreading of their representation in phase space. For the case of Glauber states of a harmonic oscillator we illustrated in Fig. 24.14 the uncertainty

of conjugate variables by circles around their expectation values whose areas are determined by the Heisenberg uncertainty relation. These circular areas represent phase space probability distribution functions. These are distribution functions measuring the probability to encounter the observables at specific points in phase space.

States other than Glauber states are possible, for instance Fock or cat states. Some of these states may exhibit quantum correlations, which we would like to identify in probability distributions. Quantum correlations in systems with small Hilbert spaces, such as the two-level atom, are conveniently represented by a density operator or by the Bloch vector introduced in Eq. (23.154). Large or infinite Hilbert spaces require different approaches. We have seen in Sec. 24.6.1 how to expand the state of a harmonic oscillator on a Fock state basis. On the other hand, we have seen that Glauber states are more 'natural' states for a harmonic oscillator, so that we would like to visualize expansions of arbitrary states into a coherent state basis.

The following sections are devoted to introducing various such distribution functions [835, 823] and to calculating them for a selection of particular states, such as the Fock and the Glauber state, the thermal state, and the Schrödinger cat state. We will mostly restrict the discussion to pure states, postponing a discussion of the representation of statistical mixtures to Sec. 40.2, where we will also extend the discussion to quantum correlations in light fields resulting from a Jaynes-Cummings type interaction of an atom with a light mode.

37.3.1 The density operator and distribution functions

37.3.1.1 The density operator

We define the *density operator* for a pure state as,

$$\hat{\rho} \equiv |\psi\rangle\langle\psi| \ . \tag{37.41}$$

A detailed discussion of the density operator for non pure states, that is, statistical mixtures has been given in Sec. 37.2. The definition (37.41) is independent from a chosen basis, but a proper representation can be found by simply expanding the state $|\psi\rangle$ on a proper basis. The expansion we had in mind in Sec. 37.2.2 was on eigenstates of atomic excitations, which are typically discrete and limited in number. The expansion of the density operator in the infinite but discrete spectrum of Fock states is essentially the same as for atomic excitations and thus straightforward,

$$\begin{aligned} \hat{\rho} &= \sum_n \hat{\rho}|n\rangle\langle n| \equiv \sum_n p_n |n\rangle\langle n| \\ \Longrightarrow p_m = \langle m|\hat{\rho}|m\rangle &= \sum_n p_n |\langle m|n\rangle|^2 \\ &= \sum_n p_n \delta_{mn} = p_m \ , \end{aligned} \tag{37.42}$$

where the first line can be read as a definition of the photon number distribution function p_n. An analogous expansion in the continuous Glauber basis is, however,

more complicated, because the coherent states are not orthogonal,

$$\hat{\rho} = \tfrac{1}{\pi}\int \hat{\rho}|\alpha\rangle\langle\alpha| d^2\alpha \equiv \int P(\alpha,\alpha^*)|\alpha\rangle\langle\alpha| d^2\alpha \tag{37.43}$$

$$\begin{aligned}\Longrightarrow \pi Q(\beta,\beta^*) \equiv \langle\beta|\hat{\rho}|\beta\rangle &= \int P(\alpha,\alpha^*)|\langle\beta|\alpha\rangle|^2 d^2\alpha \\ &= \int P(\alpha,\alpha^*) e^{-|\alpha-\beta|^2} d^2\alpha \neq P(\beta,\beta^*)\ .\end{aligned}$$

That is, we end up with two distribution functions, the so-called *P-function* $P(\alpha,\alpha^*)$ (or *Glauber-Sudarshan representation*) and the *Q-function* $Q(\alpha,\alpha^*)$ (or *Husimi representation*) which, according to (37.43) they are not equal. Before we deepen the discussion in the upcoming sections let us already state here, that the reason for the complication is rooted in the non-commutativity of the field operators $[\hat{a},\hat{a}^\dagger] = 1$. Indeed, expressing the density operator of a system as a function of field operators we have (at least) two choices called the *normal-ordered* arrangement (label N) and the *antinormal-ordered* arrangement (label A) [9],

$$\hat{\rho}_{\rm N}(\hat{a},\hat{a}^\dagger) = \sum_{m,n} c_{m,n}\hat{a}^{\dagger m}\hat{a}^n \qquad \text{and} \qquad \hat{\rho}_{\rm A}(\hat{a},\hat{a}^\dagger) = \sum_{m,n} c'_{m,n}\hat{a}^m\hat{a}^{\dagger n}\ . \tag{37.44}$$

Although both expressions can be converted into each other, the functional form of the density operator depends on the arrangement. We will show in Exc. 37.3.5.1 that the $P(\alpha,\alpha^*)$-function defined by the first line of (37.43) is more natural for the antinormal-ordered density operator $\hat{\rho}_{\rm A}$, while the $Q(\alpha,\alpha^*)$-function defined by the second line of (37.43) is more natural for the normal-ordered density operator $\hat{\rho}_{\rm N}$:

$$\rho_{\rm N}(\alpha,\alpha^*) = \tfrac{1}{\pi}Q(\alpha,\alpha^*) \qquad \text{and} \qquad \rho_{\rm A}(\alpha,\alpha^*) = \pi P(\alpha,\alpha^*)\ . \tag{37.45}$$

We will discuss the distribution functions more deeply in the upcoming sections.

To prepare the subsequent derivations, let us define the two-dimensional complex Fourier transform by,

$$(\mathcal{F}\chi)(\beta,\beta^*) = \tfrac{1}{\pi}\int \chi(\alpha,\alpha^*) e^{\beta\alpha^*-\beta^*\alpha} d^2\alpha\ , \tag{37.46}$$

with $d^2\lambda = d\mathfrak{Re}\,\lambda\; d\mathfrak{Im}\,\lambda = dr_\lambda dp_\lambda$. Twofold application of the Fourier transform reproduces the original function,

$$\begin{aligned}(\mathcal{F}\mathcal{F}\chi)(\gamma,\gamma^*) &= \tfrac{1}{\pi}\int (\mathcal{F}\chi)(\beta,\beta^*) e^{\gamma\beta^*-\gamma^*\beta} d^2\beta \\ &= \tfrac{1}{\pi^2}\int \chi(\alpha,\alpha^*)\int e^{\beta^*(\gamma-\alpha)-\beta(\gamma^*-\alpha^*)} d^2\beta d^2\alpha \\ &= \tfrac{1}{\pi^2}\int \chi(\alpha,\alpha^*)\pi^2\delta^{(2)}(\gamma-\alpha) d^2\alpha = \chi(\gamma,\gamma^*)\ ,\end{aligned} \tag{37.47}$$

[9] Normal ordering is often denoted by double colons $:\ldots:$. For example, $:\hat{a}\hat{a}^\dagger: = \hat{a}^\dagger\hat{a} = \hat{a}\hat{a}^\dagger - 1$, and for an arbitrary density operator $\hat{\rho}(\hat{a},\hat{a}^\dagger)$ the normal-ordered counterpart is, $\hat{\rho}_{\rm N}(\hat{a},\hat{a}^\dagger) = :\hat{\rho}(\hat{a},\hat{a}^\dagger):$.

where we used,

$$\delta^{(2)}(\alpha) = \tfrac{1}{\pi^2} \int e^{\lambda^*\alpha - \lambda\alpha^*} d^2\lambda \ . \tag{37.48}$$

The formula (37.48) can be extended to include field operators [835],

$$\delta(\alpha^* - \hat{a}^\dagger)\delta(\alpha - \hat{a}) = \tfrac{1}{\pi^2} \int e^{-\lambda(\alpha^* - \hat{a}^\dagger)} e^{\lambda^*(\alpha - \hat{a})} d^2\lambda \tag{37.49}$$

$$\delta(\alpha - \hat{a})\delta(\alpha^* - \hat{a}^\dagger) = \tfrac{1}{\pi^2} \int e^{\lambda^*(\alpha - \hat{a})} e^{-\lambda(\alpha^* - \hat{a}^\dagger)} d^2\lambda \ ,$$

which will be useful in the following.

37.3.1.2 The Glauber-Sudarshan P-distribution

The Glauber-Sudarshan P-function can be formally defined by [835],

$$\boxed{P(\alpha, \alpha^*) \equiv \mathrm{Tr}\ \hat{\rho}\delta(\alpha^* - \hat{a}^\dagger)\delta(\alpha - \hat{a})} \ . \tag{37.50}$$

The definition (37.43) of the P-function, that is,

$$\boxed{\hat{\rho} \equiv \int P(\alpha, \alpha^*)|\alpha\rangle\langle\alpha| d^2\alpha} \ , \tag{37.51}$$

is equivalent to the definition (37.50), as will be verified in Exc. 37.3.5.2. From (37.51) we see, that the Glauber-Sudarshan P-function is just the distribution that leaves the density matrix diagonal in the coherent state basis. Since $\hat{\rho}$ is Hermitian, $P(\alpha, \alpha^*)$ is real, and since $\mathrm{Tr}\ \hat{\rho} = 1$, it is normalized, $\int P(\alpha, \alpha^*) d^2\alpha = 1$. Hence, the P-distribution functions can be interpreted as the probability of finding the coherent state $|\alpha\rangle$ within the statistical mixture given by (37.51).

In order to unravel its properties let us consider an arbitrary operator $\hat{O}$ being a function of the field operators $\hat{a}$ and $\hat{a}^\dagger$. Using the commutation rule $[\hat{a}, \hat{a}^\dagger] = 1$ the operator can always be brought in normal-ordered form,

$$\hat{O}_{\mathrm{N}}(\hat{a}, \hat{a}^\dagger) = \sum_{m,n} o_{m,n} \hat{a}^{\dagger m} \hat{a}^n \ . \tag{37.52}$$

The expectation value of this operator is,

$$\langle \hat{O}_{\mathrm{N}}(\hat{a}, \hat{a}^\dagger)\rangle = \mathrm{Tr}\ \hat{\rho}\hat{O}_{\mathrm{N}}(\hat{a}, \hat{a}^\dagger) = \int P(\alpha, \alpha^*) O_{\mathrm{N}}(\alpha, \alpha^*) d^2\alpha \ , \tag{37.53}$$

as we will show in Exc. 37.3.5.3.

37.3.1.3 The Husimi Q-distribution

The Husimi Q-function is formally defined by [835],

$$\boxed{Q(\alpha, \alpha^*) \equiv \mathrm{Tr}\ \hat{\rho}\delta(\alpha - \hat{a})\delta(\alpha^* - \hat{a}^\dagger)} \ . \tag{37.54}$$

The definition (37.43) of the Q-function, that is,

$$\boxed{\langle\alpha|\hat{\rho}|\alpha\rangle = \pi Q(\alpha,\alpha^*)} \ , \tag{37.55}$$

is equivalent to the definition (37.50), as will be verified in Exc. 37.3.5.2. From (37.55) we see, that the Q-distribution function can be interpreted as the expectation value of the density operator (37.41).

The expression resembles Eq. (37.50) except for the order of the δ-functions. We now consider the same arbitrary operator $\hat{O}$ as in (37.52), but now expressed in antinormal ordered form of the field operators $\hat{a}$ and $\hat{a}^\dagger$,

$$\hat{O}_{\mathrm{A}}(\hat{a},\hat{a}^\dagger) = \sum_{m,n} o_{m,n}\hat{a}^m\hat{a}^{\dagger n} \ . \tag{37.56}$$

As we will show in Exc. 37.3.5.3, the expectation value of this operator is,

$$\langle\hat{O}_{\mathrm{A}}(\hat{a},\hat{a}^\dagger)\rangle = \mathrm{Tr}\ \hat{\rho}\hat{O}_{\mathrm{A}}(\hat{a},\hat{a}^\dagger) = \int Q(\alpha,\alpha^*)O_{\mathrm{A}}(\alpha,\alpha^*)d^2\alpha \ . \tag{37.57}$$

37.3.1.4 The Wigner-Weyl distribution

The *Wigner function* represents something like the spectrum of two-dimensional phase-space correlation function. For a pure state and a one-dimensional system it is defined by,

$$W(x,p) \equiv \tfrac{1}{\pi}\int_{-\infty}^{\infty}\langle\psi|x+y\rangle\langle x-y|\psi\rangle e^{2\imath py/\hbar}dy \ . \tag{37.58}$$

Example 261 (*Wigner function of a free particle in 3D*): For example, for a free particle described by the wavefunction in three-dimensional space,

$$\langle\mathbf{r}|\psi\rangle = \tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ ,$$

the Wigner function is,

$$\begin{aligned} W(\mathbf{r},\mathbf{p}) &= \frac{1}{\pi^3}\int_{-\infty}^{\infty}\tfrac{1}{\sqrt{V}}e^{-\imath\mathbf{k}\cdot(\mathbf{r}+\mathbf{x})}\tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot(\mathbf{r}-\mathbf{x})}e^{(2\imath/\hbar)\mathbf{p}\cdot\mathbf{x}}d^3x \\ &= \frac{1}{\pi^3 V}\int_{-\infty}^{\infty}e^{-2\imath(\mathbf{k}-\mathbf{p}/\hbar)\cdot\mathbf{x}}d^3x = \tfrac{1}{V}\delta^3(\mathbf{p}-\hbar\mathbf{k}) \ . \end{aligned}$$

For a harmonic oscillator, we would like to embed the Wigner function into the formalism of the coherent states distribution functions, such that it can be used to evaluate expectation values,

$$\langle\hat{O}_{\mathrm{S}}(\hat{a},\hat{a}^\dagger)\rangle = \mathrm{Tr}\ \hat{\rho}\hat{O}_{\mathrm{S}}(\hat{a},\hat{a}^\dagger) = \int W(\alpha,\alpha^*)O_{\mathrm{S}}(\alpha,\alpha^*)d^2\alpha \ , \tag{37.59}$$

where the index S denotes *symmetric order*. How this can be done will be detailed in the next section and in Exc. 37.3.5.3.

Example 262 (*Symmetric order*): Simple examples for Wigner-Weyl ordering are,

$$\begin{aligned}
\hat{a}\hat{a}^\dagger &= \tfrac{1}{2}(\hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a}) - \tfrac{1}{2} \\
\hat{a}^\dagger\hat{a} &= \tfrac{1}{2}(\hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a}) + \tfrac{1}{2} \\
\hat{a}^2\hat{a}^\dagger &= \tfrac{1}{2}(\hat{a}^2\hat{a}^\dagger + \hat{a}^\dagger\hat{a}^2) + \hat{a} \\
\hat{a}\hat{a}^\dagger\hat{a} &= \tfrac{1}{2}(\hat{a}^2\hat{a}^\dagger + \hat{a}^\dagger\hat{a}^2) \\
\hat{a}^\dagger\hat{a}^2 &= \tfrac{1}{2}(\hat{a}^2\hat{a}^\dagger + \hat{a}^\dagger\hat{a}^2) - \hat{a}\ .
\end{aligned}$$

37.3.2 Relation between the P, Q, and Wigner distributions

All three distribution function studied here, the P, the Q, and the Wigner distributions can be brought into a common generic shape writing the density operator as [835],

$$\boxed{\begin{aligned}
\hat{\rho} &= \pi \int F_X(\alpha,\alpha^*)\Delta_X(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger)d^2\alpha \\
\text{with} \quad & \Delta_{\mathrm{N}}(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger) = \tfrac{1}{\pi^2}\int e^{-\lambda(\alpha^*-\hat{a}^\dagger)+\lambda^*(\alpha-\hat{a})}e^{-|\lambda|^2/2}d^2\lambda \\
& \Delta_{\mathrm{S}}(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger) = \tfrac{1}{\pi^2}\int e^{-\lambda(\alpha^*-\hat{a}^\dagger)+\lambda^*(\alpha-\hat{a})}d^2\lambda \\
& \Delta_{\mathrm{A}}(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger) = \tfrac{1}{\pi^2}\int e^{-\lambda(\alpha^*-\hat{a}^\dagger)+\lambda^*(\alpha-\hat{a})}e^{|\lambda|^2/2}d^2\lambda
\end{aligned}} \ , \tag{37.60}$$

with the indices $X = N, S, A$ and the respective distribution functions $F_{\mathrm{N}} = P$, $F_{\mathrm{S}} = W$, and $F_{\mathrm{A}} = Q$. A useful formula helping us to break down the exponential functions is obtained from Glauber's formula (23.312) applied to the displacement operator $D(\alpha) = e^{\lambda\hat{a}^\dagger - \lambda^*\hat{a}}$ defined in (24.130),

$$e^{\lambda\hat{a}^\dagger-\lambda^*\hat{a}} = e^{-\lambda^*\hat{a}}e^{\lambda\hat{a}^\dagger}e^{|\lambda|^2/2} = e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}e^{-|\lambda|^2/2}\ . \tag{37.61}$$

as it allows us to rewrite the formulas (37.60) as,

$$\begin{aligned}
\Delta_{\mathrm{N}}(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger) &= \mathcal{F}[e^{-\lambda^*\hat{a}}e^{\lambda\hat{a}^\dagger}] \\
\Delta_{\mathrm{S}}(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger) &= \mathcal{F}[e^{\lambda\hat{a}^\dagger-\lambda^*\hat{a}}] \\
\Delta_{\mathrm{A}}(\alpha-\hat{a},\alpha^*-\hat{a}^\dagger) &= \mathcal{F}[e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}]\ .
\end{aligned} \tag{37.62}$$

Inserting the density operator (37.60) into definition (37.50) of the Glauber-Sudarshan P-function we calculate,

$$\begin{aligned}
P(\alpha,\alpha^*) &= \mathrm{Tr}\ \hat{\rho}\delta(\alpha^*-\hat{a}^\dagger)(\alpha-\hat{a}) \\
&= \tfrac{1}{\pi^2}\int e^{\lambda^*\alpha-\lambda\alpha^*}\,\mathrm{Tr}\ \hat{\rho}e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}d^2\lambda = \mathcal{F}[\chi_{\mathrm{N}}(\lambda,\lambda^*)]\ ,
\end{aligned} \tag{37.63}$$

where we defined the so-called normal-ordered *characteristic function* $\chi_{\rm N} \equiv {\rm Tr}\ \hat{\rho} e^{\lambda \hat{a}^\dagger} e^{-\lambda^* \hat{a}}$. Similarly, inserting the density operator (37.60) into definition (37.54) of the Husimi Q-function we calculate,

$$\begin{aligned} Q(\alpha, \alpha^*) &= {\rm Tr}\ \hat{\rho} \delta(\alpha - \hat{a})(\alpha^* - \hat{a}^\dagger) \\ &= \tfrac{1}{\pi^2} \int e^{\lambda^* \alpha - \lambda \alpha^*} {\rm Tr}\ \hat{\rho} e^{-\lambda^* \hat{a}} e^{\lambda \hat{a}^\dagger} d^2\lambda = \mathcal{F}[\chi_{\rm A}(\lambda, \lambda^*)] \ , \end{aligned} \tag{37.64}$$

where we defined the antinormal-ordered characteristic function $\chi_{\rm A} \equiv {\rm Tr}\ \hat{\rho} e^{-\lambda^* \hat{a}} e^{\lambda \hat{a}^\dagger}$. By analogy we find for the Wigner distribution,

$$W(\alpha, \alpha^*) = \mathcal{F}[\chi_{\rm A}(\lambda, \lambda^*)] = \tfrac{1}{\pi^2} \int e^{\lambda^* \alpha - \lambda \alpha^*} {\rm Tr}\ \hat{\rho} e^{\lambda \hat{a}^\dagger - \lambda^* \hat{a}} d^2\lambda \ . \tag{37.65}$$

In summary, the three coherent distribution functions are expressed by inverse Fourier transforms of the following characteristic functions [10],

$$\boxed{\begin{array}{lclcrcl} \chi_{\rm N}(\lambda, \lambda^*) & = & {\rm Tr}\ \hat{\rho} e^{\lambda \hat{a}^\dagger} e^{-\lambda^* \hat{a}} & , & P & = & \mathcal{F}\chi_{\rm N} \\ \chi_{\rm S}(\lambda, \lambda^*) & = & {\rm Tr}\ \hat{\rho} e^{\lambda \hat{a}^\dagger - \lambda^* \hat{a}} & , & W & = & \mathcal{F}\chi_{\rm S} \\ \chi_{\rm A}(\lambda, \lambda^*) & = & {\rm Tr}\ \hat{\rho} e^{-\lambda^* \hat{a}} e^{\lambda \hat{a}^\dagger} & , & Q & = & \mathcal{F}\chi_{\rm A} \end{array}} \ . \tag{37.66}$$

We see that the distribution functions $\chi_{N,S,A}$ are related to each other via (37.61). We derive in Exc. 37.3.5.4 the so-called disentangling theorem [352],

$$e^{-|\lambda|^2/2} \chi_{\rm N}(\lambda) = \chi_{\rm S}(\lambda) = e^{|\lambda|^2/2} \chi_{\rm A}(\lambda) \ . \tag{37.67}$$

Thus, Q-function corresponds to a smoothed Wigner function, which in turn corresponds to a smoothed P-function. The inverse complex Fourier transformation converts the products in (37.67) into convolutions. Exploiting the useful integral formula,

$$\tfrac{1}{\pi} \int e^{-a|\lambda|^2 + b\lambda + c\lambda^*} d^2\lambda = \tfrac{1}{a} e^{bc/a} \ , \tag{37.68}$$

we find,

$$W = P \star \frac{2}{\pi} e^{-2|\lambda|^2} \qquad \text{and} \qquad Q = W \star \frac{2}{\pi} e^{-2|\lambda|^2} = P \star \frac{1}{\pi} e^{-|\lambda|^2} \ . \tag{37.69}$$

What still needs to be proven is, that the generic definition of the distribution function (37.63), (37.64), and (37.65) coincides with the earlier definitions (37.50), (37.54), and (37.58). This will be done in Exc. 37.3.5.5. Also solve the Excs. 37.3.5.6 to 37.3.5.7.

Example 263 (*Generalized phase space representations*): The fact that the probability distributions Q, W, and P are intrinsically connected suggests setting up a generalized formalism based on the displacement operator

[10] For pure states, the definition of the characteristic functions is simplified to,

$$\chi_X(\lambda, \lambda^*) = \langle \psi | ... | \psi \rangle \ .$$

$\mathcal{D}(\alpha)|0\rangle = e^{\lambda\hat{a}^\dagger - \lambda^*\hat{a}}|0\rangle = |\alpha\rangle$ introduced in (24.130) and the parity operator Π_s [524]. Defining the s-parametrized probability distribution,

$$X_\rho(\alpha, s) = \mathrm{Tr}\ \hat{\rho}\mathcal{D}(\alpha)\Pi_s\mathcal{D}^\dagger(\alpha) \longrightarrow \langle\psi|\mathcal{D}(\alpha)\Pi_s\mathcal{D}^\dagger(\alpha)|\psi\rangle\ , \tag{37.70}$$

where the second expression holds for pure states, we recover the probability distributions Q, W, and P from,

$$Q_\rho(\alpha) \equiv X_\rho(\alpha, -1) \qquad \text{with} \qquad \Pi_{-1} = \sum_{m,n}\delta_{n0}\delta_{mn}|m\rangle\langle n| \tag{37.71}$$

$$W_\rho(\alpha) \equiv X_\rho(\alpha, 0) \qquad \text{with} \qquad \Pi_0 = \sum_{m,n} 2e^{\imath\pi n}\delta_{mn}|m\rangle\langle n|$$

$$\text{so that} \qquad \Pi_0|\alpha\rangle = \sum_n 2e^{\imath\pi n}|n\rangle\langle n|\alpha\rangle = \sum_n 2e^{-|\alpha|^2/2}\frac{(-\alpha)^n}{\sqrt{n!}}|n\rangle = 2|-\alpha\rangle$$

$$P_\rho(\alpha) \equiv X_\rho(\alpha, 1) \qquad \text{with} \qquad \Pi_1 = \sum_{m,n}\infty\delta_{mn}|m\rangle\langle n|\ .$$

In particular, for the vacuum state we calculate,

$$Q_{|0\rangle}(\alpha) = \sum_n \langle 0|\mathcal{D}(\alpha)\delta_{n0}|n\rangle\langle n|\mathcal{D}^\dagger(\alpha)|0\rangle = |\langle 0|-\alpha\rangle|^2 = e^{-|\alpha|^2} \tag{37.72}$$

$$W_{|0\rangle}(\alpha) = \sum_n \langle 0|\mathcal{D}(\alpha)2e^{\imath\pi n}|n\rangle\langle n|\mathcal{D}^\dagger(\alpha)|0\rangle = 2\sum_n e^{\imath\pi n}|\langle n|-\alpha\rangle|^2 = 2e^{-2|\alpha|^2}$$

$$P_{|0\rangle}(\alpha) = ... = \delta^{(2)}(\alpha)\ .$$

The convolution of distribution functions yields,

$$[Y \star X](\alpha) = \int [\mathcal{D}^{-1}(\alpha)Y(\alpha')]X(\alpha')d\alpha' = \int Y(\alpha'-\alpha)X(\alpha')d\alpha'$$

$$X_{|0\rangle}(\alpha, s') \star X_\rho(\alpha, s) = X_\rho(\alpha, s+s'-1)\ . \tag{37.73}$$

For example,

$$P_{|0\rangle}(\alpha) \star X_\rho(\alpha, s) = X_{|0\rangle}(\alpha, 1) \star X_\rho(\alpha, s) = X_\rho(\alpha, s)\ . \tag{37.74}$$

identifying the Glauber-Sudarshan distribution as the identity operator, and

$$W_{|0\rangle}(\alpha) \star W_\rho(\alpha) = X_{|0\rangle}(\alpha, 0) \star X_\rho(\alpha, 0) = X_\rho(\alpha, -1) = Q_\rho(\alpha)\ . \tag{37.75}$$

37.3.3 Characteristic functions for arbitrary HO states in the Fock basis

The various states that a light field can adopt can now be expressed either by photon number distribution in a Fock state basis, or by two-dimensional weighting functions P, Q, W in a coherent state basis. Here, are some examples for these representations.

If a state of a harmonic oscillator can be expanded into Fock states,

$$|\psi\rangle = \sum_n c_n|n\rangle\ , \tag{37.76}$$

the normal-ordered characteristic function (37.66) will be composed of terms like $\langle m|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n\rangle$. To evaluate these terms, we begin calculating [11],

$$\hat{a}^k|n\rangle = \sqrt{\frac{n!}{(n-k)!}}|n-k\rangle \quad \text{for} \quad k \le n \qquad \text{and} \qquad \hat{a}^k|n\rangle = 0 \quad \text{for} \quad k \ge n \ , \tag{37.77}$$

and,

$$e^{-\lambda^*\hat{a}}|n\rangle = \sum_{k=0}^{\infty}\frac{(-\lambda^*\hat{a})^k}{k!}|n\rangle = \sum_{k=0}^{n}\frac{(-\lambda^*)^k}{\sqrt{k!}}\sqrt{\binom{n}{k}}|n-k\rangle \ . \tag{37.78}$$

Hence, assuming $m \ge n$,

$$\begin{aligned}\langle m|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n\rangle &= \sum_{k=0}^{n}\frac{(-\lambda^*)^k\lambda^{m-n+k}}{\sqrt{k!(m-n+k)!}}\sqrt{\binom{n}{k}\binom{m}{m-n+k}} \\ &= \sqrt{\frac{n!}{m!}}\lambda^{m-n}\sum_{k=0}^{n}\binom{m}{k+m-n}\frac{(-|\lambda|^2)^k}{k!} = \sqrt{\frac{n!}{m!}}\lambda^{m-n}L_n^{m-n}(|\lambda|^2) \ ,\end{aligned} \tag{37.79}$$

where L_n^{m-n} are Laguerre polynomials. Now, exploiting the fact that

$$\begin{aligned}\langle m|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n\rangle &= (\langle n|e^{-\lambda\hat{a}^\dagger}e^{\lambda^*\hat{a}}|m\rangle)^\dagger = \overline{\langle n|e^{-\lambda\hat{a}^\dagger}e^{\lambda^*\hat{a}}|m\rangle} \\ &= \sqrt{\frac{m!}{n!}}(-\lambda^*)^{n-m}L_n^{n-m}(|\lambda|^2) \ ,\end{aligned} \tag{37.80}$$

and with the expansion (37.76) we obtain for the normally-ordered characteristic function,

$$\begin{aligned}\chi_{\mathrm{N}}(\lambda) &= \sum_{m,n}c_m^*c_n\langle m|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n\rangle \\ &= \sum_{m\ge n}(1-\tfrac{1}{2}\delta_{m,n})\left(c_m^*c_n\langle m|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n\rangle + \overline{c_m^*c_n\langle m|e^{-\lambda\hat{a}^\dagger}e^{\lambda^*\hat{a}}|n\rangle}\right) \ .\end{aligned} \tag{37.81}$$

finally yielding,

$$\boxed{\chi_{\mathrm{N}}(\lambda) = \sum_{m\ge n}(1-\tfrac{1}{2}\delta_{m,n})\left[c_m^*c_n\lambda^{m-n} + c_mc_n^*(-\lambda^*)^{m-n}\right]\sqrt{\tfrac{n!}{m!}}L_n^{m-n}(|\lambda|^2)} \ . \tag{37.82}$$

Remembering that the symmetrically ordered function is given by $\chi_{\mathrm{S}}(\lambda) = e^{-|\lambda|^2}\chi_{\mathrm{N}}(\lambda)$ we may obtain the Wigner function by a numerical two-dimensional FFT,

$$W(\alpha) = \tfrac{1}{\pi^2}\int e^{-|\lambda|^2}\chi_{\mathrm{N}}(\lambda)e^{\lambda^*\alpha-\lambda\alpha^*}d^2\lambda \ . \tag{37.83}$$

We will use this result in Sec. 40.2.3 to characterize correlations in an optical mode emanating from a Jaynes-Cummings type coupling to an atom. In Exc. 37.3.5.8 we will try to find an analytic solution for this integral.

[11] See also 24.6.6.7.

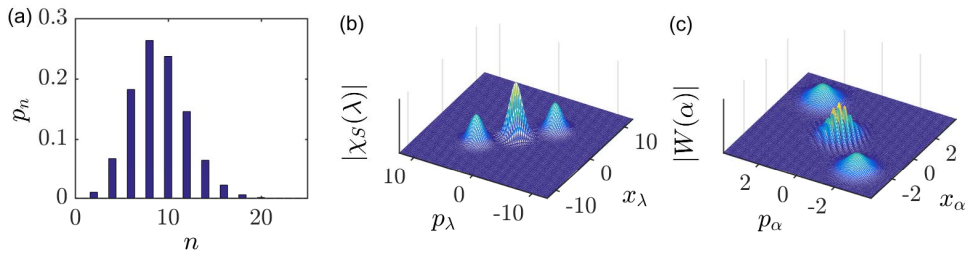


Figure 37.1: (code) Starting from a cat-state photon distribution, as shown in (a), we calculate the symmetrically ordered characteristic function (b) from the expression (37.81), and the Wigner function (c) by an FFT.

37.3.4 Representation of particular states in the Fock and Glauber basis

37.3.4.1 Representations of Glauber states

We have seen earlier that coherent states $|\beta\rangle$ can be expanded on a Fock state basis $|n\rangle$. For the state function, the density operator, and the photon number distribution we have,

Glauber states in the Fock basis

$$\begin{aligned} |\beta\rangle &= e^{-|\beta|/2}\sum_n \frac{\beta^n}{\sqrt{n!}}|n\rangle \\ \hat{\rho} &= |\beta\rangle\langle\beta| = e^{-|\beta|^2}\sum_{m,n}\frac{\beta^n\beta^{*m}}{\sqrt{m!n!}}|n\rangle\langle m| \\ P_n &= |\langle n|\beta\rangle|^2 = e^{-|\beta|^2}\frac{|\beta|^{2n}}{n!} \end{aligned} \tag{37.84}$$

Expanding a coherent state on a basis of Glauber states, we will derive in Exc. 37.3.5.9 the P-function, the density matrix, the Q-function, and the Wigner function,

Glauber states in the Glauber basis

$$\begin{aligned} |\beta\rangle &= \mathcal{D}(\beta)|0\rangle \\ \hat{\rho} &= |\beta\rangle\langle\beta| = \int \delta^{(2)}(\alpha-\beta)|\alpha\rangle\langle\alpha|d^2\alpha \\ P_{|\beta\rangle}(\alpha) &= \delta^{(2)}(\alpha-\beta) \\ Q_{|\beta\rangle}(\alpha) &= \tfrac{1}{\pi}e^{-|\alpha-\beta|^2} \\ W_{|\beta\rangle}(\alpha) &= \tfrac{2}{\pi}e^{-2|\alpha-\beta|^2} \end{aligned} \tag{37.85}$$

Example 264 (*State of a laser*): Following [978, 802], the correct *state of a*

laser beam is not simply a coherent state, but rather,

$$\hat{\rho} = \int |\alpha e^{\imath\varphi}\rangle\langle\alpha e^{\imath\varphi}| \frac{d\varphi}{2\pi} \ . \tag{37.86}$$

After averaging, this state can be written as a superposition of Fock states [211],

$$\hat{\rho} = \sum_n P_n |n\rangle\langle n| \qquad \text{with} \qquad P_n = \frac{e^{-|\alpha|^2}|\alpha|^2 n}{n!} \ , \tag{37.87}$$

but without a specific phase,

$$\hat{\rho} \neq \sum_{m,n} c_m^* c_n |m\rangle\langle n| \ . \tag{37.88}$$

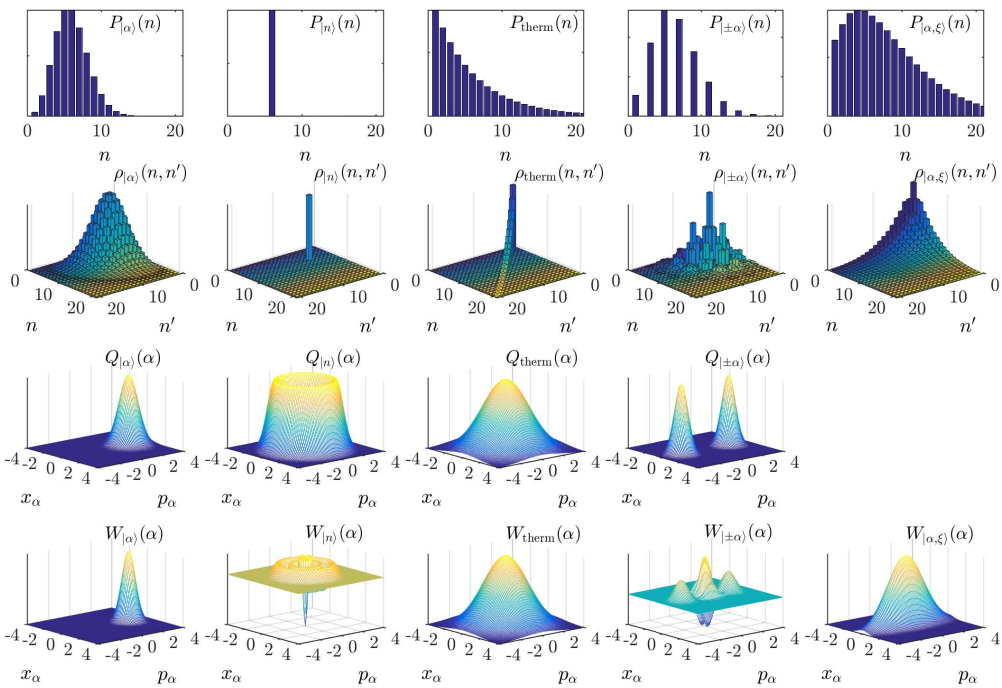

Figure 37.2: (code) (upper row) Photon number distributions $P(n)$, (second row) density matrices ρ, (third row) Q functions, and (lower row) Wigner functions of (first column) a Glauber state, (second column) a Fock state, (third column) a thermal state, (forth column) a Schrödinger cat state, and (last column) a squeezed state.

37.3.4.2 Representations of Schrödinger cat states

Schrödinger cat states are correlated states of many particles (or quasi-particles). The expansion of the *Schrödinger cat state* $|\beta_0\rangle \pm |\beta_1\rangle$ on a Fock state basis yields, as we have seen in Exc. 24.6.6.6,

Schrödinger cat states in the Fock basis

$$\begin{aligned}
|\psi_\pm\rangle &= \sum_n \frac{e^{-|\beta_0|^2/2}\beta_0^n \pm e^{-|\beta_1|^2/2}\beta_1^n}{\sqrt{2n!}}|n\rangle \\
\hat\rho &= |\psi_\pm\rangle\langle\psi_\pm| \\
P_n &= |\langle n|\psi_\pm\rangle|^2 \longrightarrow e^{-|\beta_0|^2}\frac{|\beta_0|^{2n}}{n!}\frac{|1\pm(-1)^n|^2}{2} \qquad \text{for} \quad \beta_0 = -\beta_1
\end{aligned} \tag{37.89}$$

Expanding a Schrödinger cat state on a basis of Glauber states, we will derive in Exc. 37.3.5.10 the P-function, the density matrix, the Q-function, and the Wigner function,

Schrödinger cat states in the Glauber basis

$$\begin{aligned}
|\psi_\pm\rangle &= \tfrac{1}{C}(|\beta_0\rangle \pm |\beta_1\rangle) \qquad \text{with} \qquad C = \sqrt{2 \pm 2e^{-|\beta_0-\beta_1|^2}} \\
\hat\rho &= |\psi_\pm\rangle\langle\psi_\pm| \\
P_{|\beta_0\rangle|\beta_1\rangle}(\alpha) &= \delta^{(2)}(\alpha-\beta_0) + \delta^{(2)}(\alpha-\beta_1) \\
Q_{|\beta_0\rangle|\beta_1\rangle}(\alpha) &= \tfrac{1}{\pi}e^{-|\alpha-\beta_0|^2} + \tfrac{1}{\pi}e^{-|\alpha-\beta_1|^2} \\
W_{|\beta_0\rangle|\beta_1\rangle}(\alpha) &= \tfrac{2}{C^2\pi}\Big(e^{-2|\alpha-\beta_0|^2} + e^{-2|\alpha-\beta_1|^2} \\
&\pm 2e^{-|\beta_0|^2/2-|\beta_1|^2/2}\mathfrak{Re}\, e^{-2(\beta_1-\alpha)(\beta_0^*-\alpha^*)+\beta_0^*\beta_1}\Big)
\end{aligned} \tag{37.90}$$

We know from microscopic systems, for instance a two-level atom, that they can live in superposition states $|1\rangle + |2\rangle$. In contrast, the Schrödinger cat states discussed above occur in continuous Schrödinger fields involving many particles. Macroscopic quantum interferences (i.e. interferences that are detectable with macroscopic apparatuses, for example in heterodyne schemes) are named *fuzzy Schrödinger cats*, if the interfering states are conspicuously separated in phase space.

At this point, we have to emphasize the fundamental difference between Schrödinger cats and superpositions of modes,

$$\begin{aligned}
|\psi\rangle &= |\alpha\rangle + |\beta\rangle && \neq |\alpha\rangle|\beta\rangle \\
\hat\rho &= |\alpha\rangle\langle\alpha| + |\beta\rangle\langle\beta| + |\alpha\rangle\langle\beta| + |\beta\rangle\langle\alpha| && \neq |\alpha\beta\rangle\langle\alpha\beta|
\end{aligned} \quad . \tag{37.91}$$

Schrödinger cats exhibit interferences in phase space, whereas for mode superpositions, interferences only appear when a parameter is varied (e.g., the length of an interferometer arm).

Schrödinger cat states are very sensitive to dissipation and easily converted into statistical mixtures. For example, $|\alpha\rangle \pm |-\alpha\rangle$ contains only odd (even) photon numbers in the distribution function P_n. After some time $\sim \tau_{cav}/N$, the distribution is converted into a Poisson distribution. The higher the particle number N, the faster the decoherence will be. Consequently, *truely macroscopic* cat states have never been observed.

37.3.4.3 Representations of Fock states

On the Fock state basis $|n\rangle$, a number state is characterized by,

Fock states in the Fock basis

$$\begin{aligned} |n\rangle &= \tfrac{(\hat{a}^\dagger)^n}{\sqrt{n!}}|0\rangle \\ \hat{\rho} &= |n\rangle\langle n| = \tfrac{1}{n!}(\hat{a}^\dagger)^n|0\rangle\langle 0|\hat{a}^n \\ P_k &= \delta_{nk} \end{aligned} \tag{37.92}$$

This state can be expanded into Glauber states $|\alpha\rangle$ by following procedure. For large n we first calculate the P-distribution function,

$$P_{|n\rangle}(\alpha) = \delta^{(1)}(|\alpha| - \sqrt{n}) \ , \tag{37.93}$$

because it allows us to derive the density matrix via the formula (37.51),

$$\begin{aligned} \hat{\rho}_{|n\rangle} &= \int \delta^{(1)}(|\alpha| - \sqrt{n})|\alpha\rangle\langle\alpha| d^2\alpha \\ &= \int_0^\infty \int_0^{2\pi} \delta^{(1)}(|\alpha| - \sqrt{n})|\alpha\rangle\langle\alpha| \ |\alpha| d|\alpha| d\varphi_\alpha = \sqrt{n}\int_0^{2\pi} |\alpha\rangle\langle\alpha| d\varphi_\alpha \ . \end{aligned} \tag{37.94}$$

The Q-distribution function becomes, inserting the density operator obtained in (37.94),

$$\begin{aligned} Q_{|n\rangle}(\alpha) &= \tfrac{1}{\pi}\langle\alpha|\hat{\rho}_{|n\rangle}|\alpha\rangle \\ &= \tfrac{1}{\pi} n \int_0^{2\pi} |\langle\alpha|\beta\rangle|^2 d\varphi_\beta = \frac{1}{\pi} n \int_0^{2\pi} e^{-|\alpha - |\beta| e^{\imath\varphi_\beta}|^2} d\varphi_\beta \triangleq \frac{|\alpha|^{2n}}{\pi n!} e^{-|\alpha|^2} \ , \end{aligned} \tag{37.95}$$

and finally the Wigner function is,

$$W_{|n\rangle}(\alpha) = \frac{2}{\pi} e^{-2|\alpha|^2} (-1)^n \sum_{m=0}^{n} \binom{n}{m} \frac{(-4|\alpha|^2)^m}{m!} = \frac{2}{\pi} e^{-2|\alpha|^2} (-1)^n L_n(4|\alpha|^2) \ , \tag{37.96}$$

where $L_m(4|\alpha|^2)$ are Laguerre polynomials. In Excs. 37.3.5.11 and 37.3.5.12 we will learn how to derive the above distribution functions directly from the characteristic functions. In summary, we have [477],

Fock states in the Glauber basis

$$\begin{aligned}
|n\rangle &= \frac{\sqrt{n!}}{2\pi r^n} e^{r^2/2} \int_0^{2\pi} e^{-\imath n\varphi_\alpha} |\alpha\rangle d\varphi_\alpha \\
\hat{\rho} &= \sqrt{n} \int_0^{2\pi} |\alpha\rangle\langle\alpha| d\varphi_\alpha \\
P_{|n\rangle}(\alpha) &= \delta^{(1)}(|\alpha| - \sqrt{n}) \\
Q_{|n\rangle}(\alpha) &= \frac{|\alpha|^{2n}}{\pi n!} e^{-|\alpha|^2} \\
W_{|n\rangle}(\alpha) &= \tfrac{2}{\pi} e^{-2|\alpha|^2} (-1)^n L_n(4|\alpha|^2)
\end{aligned} \tag{37.97}$$

37.3.4.4 Representations of thermal states

A light mode in a *thermal mixture can not be represented by a pure state*, but requires a density matrix description beyond (37.41). The concept of statistical mixtures has been introduced in Sec. 37.2. The following formulas will be derived in Exc. 37.3.5.13 [835],

thermal states in the Fock basis

$$\begin{aligned}
\hat{\rho} &= \sum_n \frac{\bar{n}^n}{(1+\bar{n})^{1+n}} |n\rangle\langle n| \\
P_n &= \tfrac{\bar{n}^n}{(1+\bar{n})^{1+n}}
\end{aligned} \tag{37.98}$$

The coherent distribution P-function is,

thermal states in the Glauber basis

$$\begin{aligned}
\hat{\rho} &= \frac{1}{\pi\bar{n}} \int e^{-|\alpha|^2/\bar{n}} |\alpha\rangle\langle\alpha| d^2\alpha \\
P_{\text{therm}}(\alpha) &= \tfrac{1}{\pi\bar{n}} e^{-|\alpha|^2/\bar{n}} \\
Q_{\text{therm}}(\alpha) &= \tfrac{1}{\pi(\bar{n}+1)} e^{-|\alpha|^2/(\bar{n}+1)} \\
W_{\text{therm}}(\alpha) &= \tfrac{1}{\pi(\bar{n}+1/2)} e^{-|\alpha|^2/(\bar{n}+1/2)}
\end{aligned} \tag{37.99}$$

Resolve the Excs. 37.3.5.14 and 37.3.5.15.

37.3.5 Exercises

37.3.5.1 Ex: Glauber-Sudarshan and Husimi distribution

a. Show that $\rho_{\text{A}}(\alpha, \alpha^*) = \pi P(\alpha, \alpha^*)$ for an anti-normally ordered density operator $\hat{\rho}_{\text{A}}(\hat{a}, \hat{a}^\dagger)$.

b. Show that $\rho_{\mathrm{N}}(\alpha,\alpha^*) = \frac{1}{\pi}Q(\alpha,\alpha^*)$ for a normally ordered density operator $\hat{\rho}_{\mathrm{N}}(\hat{a},\hat{a}^\dagger)$.

37.3.5.2 Ex: Glauber-Sudarshan and Husimi distribution

a. Show that the definitions of the Glauber-Sudarshan distribution given by (37.60) and (37.51) are equivalent.
b. Show that the definitions of the Husimi distribution given by (37.60) and (37.55) are equivalent.

37.3.5.3 Ex: Moments of Glauber states

a. Prove Eq. (37.53).
b. Prove Eq. (37.57).
c. Prove $\frac{1}{2}\langle\hat{a}\hat{a}^\dagger + \hat{a}^\dagger\hat{a}\rangle = \int W(\alpha,\alpha^*)\alpha\alpha^* d^2\alpha$.
d. Prove $\langle\{\hat{a}_j^{\dagger m}\hat{a}_k^n\}_{\mathrm{S}}\rangle = \int W(\alpha)\alpha_j^m\alpha_k^{*n}\ d\alpha$, where the index S denotes *symmetric ordering*. Symmetric or *Weyl ordering* means that all products $\hat{r}\hat{p}$ must be replaced by the symmetric expressions, such as $(\hat{r}\hat{p}+\hat{p}\hat{r})/2$.
e. Then prove Eq. (37.59).

37.3.5.4 Ex: Relationship between the characteristic functions

Derive the disentangling theorem (37.67) between the characteristic functions of the Glauber state basis.

37.3.5.5 Ex: General form of the distribution functions

Show that from the definition (37.60) the common definition of the distribution functions (37.51) and (37.55) are recovered.

37.3.5.6 Ex: Characteristic functions

a. Evaluate the expression $\left.\frac{\partial^{m+n}\chi_X(\lambda)}{\partial\lambda^{*m}\partial(-\lambda)^n}\right|_{\lambda=0}$ for $X = N, S, A$.
b. Consider the particular case of a coherent state.

37.3.5.7 Ex: Calculating with Wirtinger derivatives

Prove the following identities called *Wirtinger derivatives* [352],

$$\hat{a}^\dagger - \alpha^* = \frac{\partial}{\partial\underset{\rightarrow}{\alpha}} \qquad \text{and} \qquad \hat{a}^\dagger - \alpha = \frac{\partial}{\partial\underset{\leftarrow}{\alpha}^*}\ .$$

Note, that with the bosonic operators we can construct the observables,

$$\hat{x} + \imath\hat{p} = \sqrt{2}\hat{a} \quad , \quad \partial_x - \imath\partial_p = 2\underset{\rightarrow}{\partial_\alpha} \quad , \quad \partial_x + \imath\partial_p = 2\underset{\leftarrow}{\partial_{\alpha^*}}\ .$$

In two dimensions [314], $d^2\alpha = d(\mathfrak{Re}\,\alpha)d(\mathfrak{Im}\,\alpha) = dxdp$.

37.3.5.8 Ex: Wigner function for arbitrary HO states in the Fock basis

Search an analytic solution for the integral (37.82).

37.3.5.9 Ex: P-, Q-, and Wigner distribution functions for Glauber states

Starting from the characteristic functions $\chi_{A,S,N}(\lambda)$ derive for a coherent state $|\beta\rangle$ (a) the Husimi representation, (b) the Glauber-Sudarshan representation, and (c) the Wigner representation.

37.3.5.10 Ex: P-, Q-, and Wigner distribution functions for cat states

Starting from the characteristic functions $\chi_{A,S,N}(\lambda)$ derive for a normalized cat state $C^{-1}(|\beta_0\rangle + |\beta_1\rangle)$ (a) the Husimi representation, (b) the Glauber-Sudarshan representation, and (c) the Wigner representation.

37.3.5.11 Ex: P-, Q-, and Wigner distribution functions for Fock states

Starting from the characteristic functions $\chi_{A,S,N}(\lambda)$ derive for a number state $|n\rangle$ (a) the Husimi representation, (b) the Glauber-Sudarshan representation, and (c) the Wigner representation.

37.3.5.12 Ex: Wigner distribution function of a Fock state

Calculate the Wigner function for a harmonic oscillator in a Fock state from its wavefunction $\langle x|n\rangle$.

37.3.5.13 Ex: Thermal state

a. Show that $\langle -\beta|\hat{\rho}|\beta\rangle e^{|\beta|^2}$ and $P(\alpha,\alpha^*)e^{-|\alpha|^2}$ are related by Fourier transform.
b. Using the relationship of (a), derive the density operator and the distribution function of the Fock and the Glauber basis for a thermal state.

37.3.5.14 Ex: Phase space distributions

1. Compute the three characteristic functions for the coherent state $\alpha\rangle$.
2. Show that $Q_{[\rho]}(\alpha) = \frac{1}{\pi}\langle 0|\mathcal{D}(-\alpha)\rho\mathcal{D}(\alpha)|0\rangle = \frac{1}{\pi}\mathrm{Tr}[|0\rangle\langle 0|\mathcal{D}(-\alpha)\rho\mathcal{D}(\alpha)|0\rangle]$. **Hint:** use linearity of the trace, the closure relations of coherent states.
3. Compute the Q function of a coherent state and of a Fock state.
4. **Difficult:** Show that $W(x,p) = \frac{1}{\pi}\int du\langle \frac{u}{2}|\mathcal{D}(-\alpha)\rho\mathcal{D}(\alpha)\mathcal{P}|\frac{u}{2}\rangle = \frac{2}{\pi}\mathrm{Tr}\,[\mathcal{D}(-\alpha)\rho\mathcal{D}(\alpha)\mathcal{P}]$.

37.3.5.15 Ex: Kerr states

Here, we study the so called optical *Kerr state* generated by the unitary operator

$$\mathcal{U}_{\mathrm{Kerr}}(\tau) = e^{\imath(\tau/2)\hat{a}^{\dagger 2}\hat{a}^2} \ . \tag{37.100}$$

a. Show that the Fock states are eigenstates of this operator and determine the eigenvalues.

b. How does the operator act on Glauber states?
c. Verify the transformation rule,

$$U^\dagger_{\text{Kerr}}\hat{a}U_{\text{Kerr}} = e^{\imath\tau\hat{n}}\hat{a} \ . \tag{37.101}$$

37.4 Squeezed states of the harmonic oscillator

37.4.1 The squeezing operator

Let us consider a Hamiltonian of the following form,

$$\boxed{\hat{H}_{\text{sqz}} = \hbar\omega\hat{a}^\dagger\hat{a} + \tfrac{\imath}{2}\hbar\xi\hat{a}^{\dagger 2} - \tfrac{\imath}{2}\hbar\xi^*\hat{a}^2} \ . \tag{37.102}$$

leading to the equation of motion,

$$\dot{\hat{a}} = -\imath\omega\hat{a} + 2g\hat{a}^\dagger \ . \tag{37.103}$$

The non-linear, i.e. quadratic, appearance of the field operators suggests that the interaction should include correlated pair production, as is the case for parametric processes or four-wave mixing. We will see later that cavities are good for generating squeezing. However, the unused ports of a cavity let uncorrelated vacuum fluctuations enter, which partially overrule squeezing.

For now, we study, in analogy with the displacement operator (24.130), the propagator $e^{-\imath\hat{H}_{\text{sqz}}t/\hbar}$, i.e the operator given by,

$$\mathcal{S}(\xi) \equiv e^{\xi^*\hat{a}^2/2 - \xi\hat{a}^{\dagger 2}/2} \ , \tag{37.104}$$

which we will call the *squeezing operator* because, applied to the vacuum state, $|\xi\rangle = S(\xi)|0\rangle$, this operator will compress the uncertainty of one quadrature component, as we will see shortly. It is easy to see that [352],

$$\mathcal{S}^\dagger(\xi) = \mathcal{S}(-\xi) = \mathcal{S}^{-1}(\xi) \ . \tag{37.105}$$

In analogy with the calculation (24.131), using the commutation rules, it is possible to verify the unitarity of this operator [592] (see Exc. 37.4.4.1). In particular, using the relationship (23.279) and the abbreviation $\hat{A} \equiv -\frac{\xi^*}{2}\hat{a}^2 + \frac{\xi}{2}\hat{a}^{\dagger 2}$, we can show [889] (see Exc. 37.4.4.2),

$$\begin{aligned}\mathcal{S}^\dagger(\xi)\hat{a}\mathcal{S}(\xi) &= e^{\hat{A}}\hat{a}e^{-\hat{A}} = \hat{a} + [\hat{A},\hat{a}] + \tfrac{1}{2!}[\hat{A},[\hat{A},\hat{a}]] + \tfrac{1}{3!}\left[\hat{A},[\hat{A},[\hat{A},\hat{a}]]\right] + ... \\ &= \hat{a} - \xi\hat{a}^\dagger + \tfrac{1}{2!}\xi\xi^*\hat{a} - \tfrac{1}{3!}\xi\xi^*\xi\hat{a}^\dagger + ... = \hat{a}\cosh|\xi| - \tfrac{|\xi|}{\xi^*}\hat{a}^\dagger\sinh|\xi| \ ,\end{aligned} \tag{37.106}$$

and similarly for $\hat{a}^\dagger$, such that with $\xi \equiv re^{\imath\varphi}$,

$$\mathcal{S}^\dagger(\xi)\hat{a}\mathcal{S}(\xi) = \hat{a}\cosh r - \hat{a}^\dagger e^{\imath\varphi}\sinh r \ . \tag{37.107}$$

The formulas (37.107) describe a *Bogolubov transform*, as they can be cast into the form,

$$\boxed{\hat{b} \equiv u\hat{a} + v\hat{a}^\dagger \qquad , \qquad \hat{b}^\dagger \equiv u^*\hat{a}^\dagger + v^*\hat{a}} \ , \tag{37.108}$$

for complex numbers u and v. By postulating the same commutation relation for new operators, $[\hat{b}, \hat{b}^\dagger] = 1$, we immediately get the condition,

$$|u|^2 - |v|^2 = 1 \ . \tag{37.109}$$

Comparing with the hyperbolic identity $\cosh^2 r - \sinh^2 r = 1$, we can parametrize the constants as,

$$u = \cosh r \qquad \text{and} \qquad v = e^{\imath\varphi} \sinh r \ . \tag{37.110}$$

This is interpreted as a linear simplectic transformation in phase space between pairs of annihilation and creation operators satisfying the same commutation relation $[\hat{a}, \hat{a}^\dagger] = 1$.

37.4.1.1 Relation between squeezing and displacement operator

The squeezing operator *does not commute* with the displacement operator. However, in Exc. 37.4.4.3 we derive the following simple relation,

$$\mathcal{S}(\xi)\mathcal{D}(\alpha) \neq \mathcal{D}(\alpha)\mathcal{S}(\xi) = \mathcal{S}(\xi)\mathcal{D}(\alpha\cosh r + \alpha^* e^{\imath\varphi}\sinh r) \ . \tag{37.111}$$

Squeezed coherent states are generated by coherent displacement of a *squeezed vacuum*,

$$\boxed{|\alpha, \xi\rangle = \mathcal{D}(\alpha)|0, \xi\rangle = \mathcal{D}(\alpha)\mathcal{S}(\xi)|0\rangle} \ . \tag{37.112}$$

On the other hand, from (37.111),

$$\begin{aligned} \mathcal{D}(\alpha)\mathcal{S}(\xi)|0\rangle &= \mathcal{S}(\xi)\mathcal{D}(\alpha\cosh r + \alpha^* e^{\imath\varphi}\sinh r)|0\rangle \\ &= \mathcal{S}(\xi)|\alpha\cosh r + \alpha^* e^{\imath\varphi}\sinh r\rangle \ . \end{aligned} \tag{37.113}$$

In Exc. 37.4.4.4 we show that the coherent squeezed state $|\alpha, \xi\rangle$ is an eigenstate of the operator $\hat{a}\cosh r + \hat{a}^\dagger e^{\imath\varphi}\sinh r$. That is,

$$\begin{aligned} \mathcal{S}(\xi)\hat{a}\mathcal{S}^\dagger(\xi)|\alpha, \xi\rangle &= (\hat{a}\cosh r + \hat{a}^\dagger e^{\imath\varphi}\sinh r)|\alpha, \xi\rangle \\ &= (\alpha\cosh r + \alpha^* e^{\imath\varphi}\sinh r)|\alpha, \xi\rangle \ . \end{aligned} \tag{37.114}$$

The squeezed states form a complete basis with the closure relation,

$$\tfrac{1}{\pi}\int |\alpha, \xi\rangle\langle\alpha, \xi| d^2\alpha = \mathbb{I} \ . \tag{37.115}$$

37.4.1.2 Squeezing of the uncertainty relation

Let us consider a squeezed mode $\hat{b}$ generated by application of the transformation (37.107). The real and imaginary parts defined by $\hat{b} = \hat{x}_b + \imath\hat{p}_b$, are Hermitian and satisfy the Heisenberg uncertainty relation (23.201),

$$[\hat{x}_b, \hat{p}_b] = \tfrac{\imath}{2} \qquad \text{and} \qquad \Delta\hat{x}_b\Delta\hat{p}_b \geq \tfrac{1}{2\imath}\langle[\hat{x}_b, \hat{p}_b]\rangle = \tfrac{1}{4} \ . \tag{37.116}$$

However, let us take a look at the uncertainties separately. They relate to the Glauber mode via,

$$\begin{aligned}\hat{x}_b &= \tfrac{1}{2}(\hat{b}+\hat{b}^\dagger) = \tfrac{1}{2}(\hat{a}\cosh r - \hat{a}^\dagger e^{\imath\varphi}\sinh r) + \tfrac{1}{2}(\hat{a}^\dagger\cosh r - \hat{a}e^{-\imath\varphi}\sinh r) \\ &= \hat{x}_a\cosh r - \tfrac{1}{2}\sinh r(\hat{a}^\dagger e^{\imath\varphi} + \hat{a}e^{-\imath\varphi}) \xrightarrow{\varphi=0} \hat{x}_a e^r \\ \hat{p}_b &= \tfrac{1}{2\imath}(\hat{b}-\hat{b}^\dagger) = \tfrac{1}{2\imath}(\hat{a}\cosh r - \hat{a}^\dagger e^{\imath\varphi}\sinh r) - \tfrac{1}{2\imath}(\hat{a}^\dagger\cosh r - \hat{a}e^{-\imath\varphi}\sinh r) \\ &= \hat{p}_a\cosh r - \tfrac{1}{2\imath}\sinh r(\hat{a}^\dagger e^{\imath\varphi} - \hat{a}e^{-\imath\varphi}) \xrightarrow{\varphi=0} \hat{p}_a e^{-r}\ .\end{aligned} \tag{37.117}$$

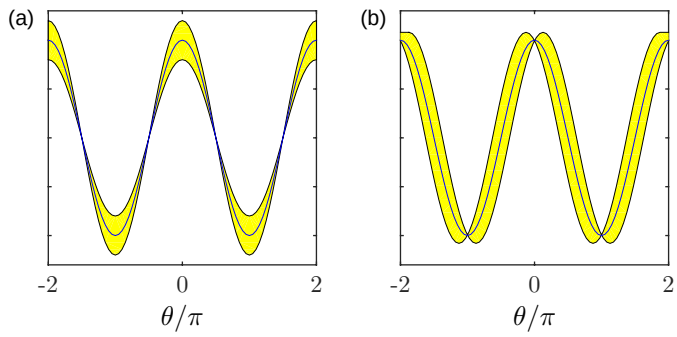

Figure 37.3: (code) Illustration of (a) amplitude squeezing and (b) phase squeezing.

The individual fluctuations are (assuming $\varphi = 0$),

$$\begin{aligned}\Delta\hat{x}_b^2 &= \langle\hat{x}_b^2\rangle - \langle\hat{x}_b\rangle^2 = e^{2r}\left(\langle\hat{x}_a^2\rangle - \langle\hat{x}_a\rangle^2\right) \\ &= \tfrac{1}{4}e^{2r}\left(1 + \langle\hat{a}^2\rangle + \langle\hat{a}^\dagger\rangle^2 + 2\langle\hat{a}^\dagger\hat{a}\rangle - \langle\hat{a}\rangle^2 - \langle\hat{a}^\dagger\rangle^2 - 2\langle\hat{a}^\dagger\rangle\langle\hat{a}\rangle\right)\ .\end{aligned} \tag{37.118}$$

Considering coherent vacuum, $|\alpha\rangle = |0\rangle$ so that $\hat{a}|\alpha\rangle = 0$,

$$\begin{aligned}\Delta\hat{x}_b^2 &= e^{2r}\left(\tfrac{1}{2}\mathfrak{Re}\,\langle\hat{a}^2\rangle + \tfrac{1}{4} + \tfrac{1}{2}\langle\hat{a}^\dagger\hat{a}\rangle\right) \\ \Delta\hat{p}_b^2 &= e^{-2r}\left(-\tfrac{1}{2}\mathfrak{Re}\,\langle\hat{a}^2\rangle + \tfrac{1}{4} + \tfrac{1}{2}\langle\hat{a}^\dagger\hat{a}\rangle\right)\ .\end{aligned} \tag{37.119}$$

hence,

$$\Delta\hat{x}_b = \tfrac{1}{2}e^r \qquad \text{and} \qquad \Delta\hat{p}_b = \tfrac{1}{2}e^{-r}\ , \tag{37.120}$$

and the squeezed state is at the uncertainty minimum.

Example 265 (*Detection of squeezing*): One method of detecting squeezing in a light mode is via balanced homodyne detection (see Sec. 55.4.2). The idea consists in mixing the squeezed light mode with a strong local oscillator at a 50% beam splitter, as will be discussed in Sec. 37.5.3.

37.4.2 Squeezed state in the Fock basis

The number of photons in the squeezed state is [592],

$$\langle n|\alpha,\xi\rangle = \frac{(\zeta/2)^{n/2}}{\sqrt{n!\cosh r}}e^{-\frac{1}{2}(|\alpha|^2+\alpha^*\zeta)}H_n\left(\frac{\alpha+\alpha^*\zeta}{\sqrt{2\zeta}}\right)\ , \tag{37.121}$$

with the abbreviation $\zeta \equiv e^{\imath\theta}\tanh r$. For squeezed vacuum $\alpha = 0$, noting that $H_n(0) = (-2)^{n/2}(n-1)!!$ for even n and $H_n(0) = 0$ for odd n, we find,

$$\langle n|0,\xi\rangle = \frac{(-\zeta)^{n/2}(n-1)!!}{\sqrt{n!\cosh r}} \tag{37.122}$$

for even photon number. Odd photon numbers are excluded. Hence,

squeezed states in the Fock basis

$$\begin{aligned} |\alpha,\xi\rangle &= \sum_n |n\rangle\langle n|\alpha,\xi\rangle \\ \hat{\rho} &= |\alpha,\xi\rangle\langle\alpha,\xi| \\ P_n &= |\langle n|\alpha,\xi\rangle|^2 \end{aligned} \quad . \tag{37.123}$$

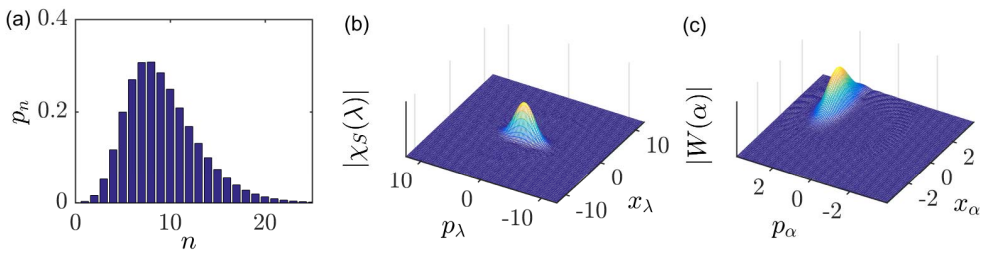

Figure 37.4: (code) Starting from a squeezed state photon distribution with $r = 0.5$, as shown in (a), we calculate the symmetrically ordered characteristic function (b) from the expression (37.82), and the Wigner function (c) by an FFT.

In the photon representation, as shown in Exc. 37.4.4.2, the squeezed vacuum is (unlike the coherent and the Fock vacuum) not empty,

$$\begin{aligned} \langle\alpha,\xi|\hat{n}|\alpha,\xi\rangle &= |\alpha|^2 + \sinh^2|\xi| &&\xrightarrow{\alpha\to 0} \sinh^2|\xi| \\ \Delta_{\alpha,\xi}\hat{n} &= |\alpha| + 2\cosh^2|\xi|\sinh^2|\xi| &&\xrightarrow{\alpha\to 0} 2\cosh^2|\xi|\sinh^2|\xi| \end{aligned} \quad . \tag{37.124}$$

Squeezed vacuum contains contributions from many $|n\rangle$.

For the squeezed vacuum state the photon number distribution displays odd-even-oscillations. This can be explained by the mathematical form of the squeezing operator, that resembles the operator for two-photon generation and annihilation processes. Photons in a squeezed vacuum state are more likely to appear in pairs.

37.4.3 Squeezed state in the Glauber basis

The *squeezed state* contains non-classical quantum correlations, as we will show in Exc. 37.4.4.5 by calculating $g^{(2)}$ for squeezed states,

$$g^{(2)}(\tau) = \frac{\langle\hat{b}^\dagger\hat{b}^\dagger(\tau)\hat{b}(\tau)\hat{b}\rangle}{\langle\hat{b}^\dagger\rangle^2\langle\hat{b}\rangle^2} \xrightarrow{\tau\to 0} 3 + \frac{1}{\sinh^2 r} \quad . \tag{37.125}$$

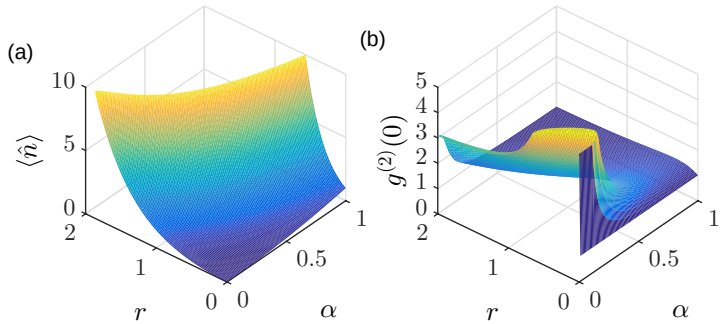

Figure 37.5: (code) (a) Photon number and (b) correlation function $g^{(2)}$ as a function of amplitude and squeezing parameter.

The distribution functions in the coherent representation are,

squeezed states in the Glauber basis

$$
\begin{aligned}
|\psi\rangle &= |\beta,\xi\rangle \\
\hat{\rho} &= |\beta,\xi\rangle\langle\beta,\xi| \\
P_{|\beta\rangle}(\alpha) &= \\
Q_{|\beta\rangle}(\alpha) &= \frac{\operatorname{sech} r}{\pi}\, e^{-(|\alpha|^2+|\beta|^2)+2\Re\mathfrak{e}\,(\alpha^*\beta)\operatorname{sech} r-\frac{1}{2}\left[e^{\imath\theta}(\alpha^{*2}-\beta^{*2})+e^{-\imath\theta}(\alpha^2-\beta^2)\right]\tanh r} \\
W_{|\beta\rangle}(\alpha) &= \frac{1}{2\pi}\exp\left(-\frac{(\alpha+\alpha^*)^2}{2e^{-2r}}+\frac{(\alpha-\alpha^*)^2}{2e^{2r}}\right)
\end{aligned}
\tag{37.126}
$$

37.4.4 Exercises

37.4.4.1 Ex: Unitarity of the squeezing operator

Verify the unitarity of the squeezing operator.

37.4.4.2 Ex: Transformation by the squeezing operator

a. Demonstrate the relationships (37.106).
b. Using them, calculate $\langle\alpha,\xi|\hat{n}|\alpha,\xi\rangle$ and show with $\alpha\to 0$, that the squeezed vacuum is not empty.

37.4.4.3 Ex: Studying the squeezing operator

Using the Baker-Campbell-Hausdorff braiding identity,

$$e^{\hat{x}}e^{\hat{y}}e^{-\hat{x}} = e^{\hat{y}+[\hat{x},\hat{y}]+\frac{1}{2!}[\hat{x},[\hat{x},\hat{y}]]+\ldots}$$

a. demonstrate the relationship (37.111) and
b. evaluate the expression $e^{\hat{a}^{\dagger 2}/2}e^{\hat{a}^2/2}e^{-\hat{a}^{\dagger 2}/2}$.

37.4.4.4 Ex: Squeezed states

a. Verify that the squeezed coherent states $|\alpha, \xi\rangle$ are eigenstates of the operator $\hat{a}\cosh r + e^{\imath\varphi}\hat{a}^\dagger \sinh r$.
b. Show that the squeezed vacuum state

$$|0, \xi\rangle = |0, re^{\imath\varphi}\rangle = \frac{1}{\sqrt{\cosh r}} \sum_{n=0}^{\infty} (-1)^n \frac{\sqrt{(2n)!}}{2^n n!} e^{\imath n\varphi} \tanh^n r |2n\rangle$$

is an eigenstate of the operator

$$\hat{a}\cosh r + \hat{a}^\dagger e^{\imath\varphi} \sinh r$$

with eigenvalue 0.

37.4.4.5 Ex: Correlation function of squeezed states

a. Calculate the photon number $\langle \hat{n} \rangle$, its variance $\delta\hat{n}$, and the correlation function $g^{(2)}(0)$ of coherent states $|\beta\rangle$.
b. Calculate the same quantities for of squeezed vacuum states $|0, \xi\rangle$.
c. Generalize the calculation for squeezed coherent states $|\alpha, \xi\rangle$.

37.5 Beam splitting, quantum amplification, and non-linear mode coupling

The beam splitter is one of the most important devices not only in practical optical setups, but also for its conceptual role in quantum mechanics. It thus deserves a dedicated section.

A classical beam splitter divides a beam of light into two branches, which are distinct by their orientation in space or by other degrees of freedom. On the other hand, a photonic picture obviously requires a quantum description. For one reason, the photon numbers scattered into the two branches are quantum mechanically entangled. Furthermore, the very concept of the beam splitter necessitates a second entrance port which, even if empty, unavoidably introduces quantum noise. Finally, in quantum mechanics, as we already learned for the case of measurement devices, the beam splitting device needs to be included in a full description of the beam splitting dynamics, which has important concequences. In fact, quantum mechanically the beam splitting resembles more a scattering problem, where the light beam represents one entrance and output channel and the physical beam splitter the other one (see Fig. 37.6).

This section is organized as follows. In Secs. 37.5.1 and 37.5.2 we discuss beam splitting at a macroscopic splitting device, i.e. we neglect backaction of the beam splitting event on the splitting device (e.g. recoil or transitions between electronic levels). Backaction on the splitting device is then treated in 37.5.6.

37.5.1 The beam splitter in various representations

We have learned in Sec. 40.2 how a two-level quantum systems couples to a harmonic oscillator via terms in the Hamiltonian containing expressions such as $\hat{\sigma}_+\hat{a}$. We will

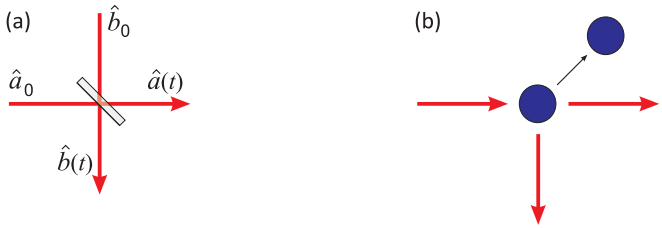

Figure 37.6: (a) Classical beam splitting. (b) Scattering of two modes.

now see how two quantum harmonic oscillators couple together via terms such as $\hat{a}^\dagger\hat{b}$, where $\hat{a}$ and $\hat{b}$ are the field operators of two oscillator modes. A device providing such a coupling is called *beam splitter*. It *mixes two modes* according to the Hamiltonian,

$$\boxed{\hat{H} = \tfrac{\hbar}{2}\Omega(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b})} \ . \tag{37.127}$$

The beam splitter can be described in the Schrödinger or the Heisenberg picture exploiting the formalism introduced in Sec. 24.5.

37.5.1.1 Schrödinger picture

In the Schrödinger picture, if $|\psi_0\rangle = |\alpha_0\rangle|\beta_0\rangle$ is the state of the modes before the beam splitter, the Schrödinger equation, $\imath\hbar\partial_t|\psi(t)\rangle = \hat{H}|\psi(t)\rangle$, gives us the state after the splitter via its solution,

$$\boxed{|\psi(t)\rangle = e^{\imath\Omega t/2(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b})}|\psi_0\rangle} \ . \tag{37.128}$$

A 50% beam splitter corresponds to a $\Omega t = \pi/2$ pulse.

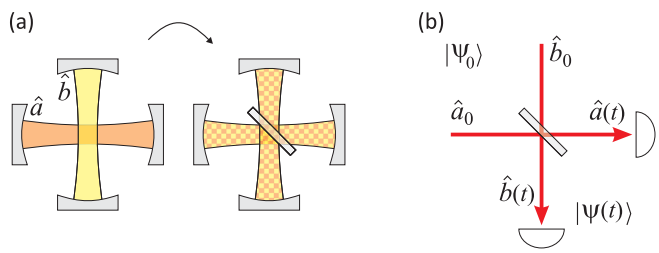

Figure 37.7: (a) Coupling of two cavity modes by insertion of a beam splitter. (b) Beam splitter mixing two propagating modes.

37.5.1.2 Heisenberg picture

We can also describe the beam splitter in the Heisenberg picture. With the commutation rules,

$$[\hat{a}, \hat{a}^\dagger] = 1 = [\hat{b}, \hat{b}^\dagger] \quad , \quad [\hat{a}, \hat{b}] = 0 = [\hat{a}, \hat{b}^\dagger] \ , \tag{37.129}$$

and the Heisenberg equations,

$$\begin{aligned}\dot{\hat{a}} &= \tfrac{\imath}{\hbar}[\hat{H},\hat{a}] = \tfrac{\imath}{2}\Omega[(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b}),\hat{a}] = -\tfrac{\imath}{2}\Omega\hat{b} \\ \dot{\hat{b}} &= \tfrac{\imath}{\hbar}[\hat{H},\hat{b}] = \tfrac{\imath}{2}\Omega[(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b}),\hat{b}] = -\tfrac{\imath}{2}\Omega\hat{a}\ ,\end{aligned} \tag{37.130}$$

we calculate,

$$\ddot{\hat{a}} = -\tfrac{1}{4}\Omega^2\hat{a} \qquad \text{and} \qquad \ddot{\hat{b}} = -\tfrac{1}{4}\Omega^2\hat{b}\ , \tag{37.131}$$

the solution of which is,

$$\begin{pmatrix}\hat{a}(t)\\ \hat{b}(t)\end{pmatrix} = \begin{pmatrix}\cos\frac{1}{2}\Omega t & -\imath\sin\frac{1}{2}\Omega t\\ -\imath\sin\frac{1}{2}\Omega t & \cos\frac{1}{2}\Omega t\end{pmatrix}\begin{pmatrix}\hat{a}_0\\ \hat{b}_0\end{pmatrix}\ . \tag{37.132}$$

The matrix in (37.132) represents a unitary transformation, and it is easy to verify $[\hat{a}(t),\hat{b}(t)] = [\hat{a}_0,\hat{b}_0]$.

Introducing the abbreviation $\eta \equiv \cos^2(\Omega t/2)$, we can describe the evolution as,

$$\boxed{\begin{pmatrix}\hat{a}(t)\\ \hat{b}(t)\end{pmatrix} = \begin{pmatrix}\sqrt{\eta} & -\imath\sqrt{1-\eta}\\ -\imath\sqrt{1-\eta} & \sqrt{\eta}\end{pmatrix}\begin{pmatrix}\hat{a}_0\\ \hat{b}_0\end{pmatrix}}\ . \tag{37.133}$$

For a $\Omega t = \pi/2$ pulse, we get,

$$\begin{pmatrix}\hat{a}(t)\\ \hat{b}(t)\end{pmatrix} = \sqrt{\tfrac{1}{2}}\begin{pmatrix}1 & -\imath\\ -\imath & 1\end{pmatrix}\begin{pmatrix}\hat{a}_0\\ \hat{b}_0\end{pmatrix}\ . \tag{37.134}$$

that each the reflected beam suffers a phase shift of $\pi/2$ [12]. Resolve the Excs. 37.5.8.1 to 37.5.8.3.

37.5.1.3 Glauber representation

In the Heisenberg picture, the wavefunctions of the quantum states (and hence the density operator and the Wigner function) remain unchanged during the evolution, i.e.,

$$\begin{aligned}|\psi\rangle \equiv |\alpha\rangle|\beta\rangle = |\alpha_0\rangle|\beta_0\rangle \equiv |\psi_0\rangle\ , \\ \rho_{|\psi\rangle} = \rho_{|\psi_0\rangle}\ , \\ W_{|\psi\rangle}(\gamma) = W_{|\psi_0\rangle}(\gamma)\ , \\ P_{|\psi\rangle}(\gamma) = P_{|\psi_0\rangle}(\gamma)\ , \\ Q_{|\psi\rangle}(\gamma) = Q_{|\psi_0\rangle}(\gamma)\ ,\end{aligned} \tag{37.135}$$

where the $|\psi\rangle$ are arbitrary quantum states and the $|\gamma\rangle$ are Glauber's states. This means that two field modes mixed at a beam splitter do not interfere with phase space, i.e. do not develop quantum correlations. Of course, that would be too easy,

[12] This fact is a consequence of *time-reversal invariance* at the beam splitter. We will see later that, in fact, only the beam reflected at the surface of an optically denser medium suffers a phase-shift of π, while the beam reflected at an optically thinner medium does not suffer any phase shift.

indeed; we will soon see in Sec. 37.4, that we need to work a little harder to produce quantum correlations.

Setting $\theta \equiv \Omega t/2$ and $\hat{b} \curvearrowright -\imath\hat{b}$ in the propagator of Eq. (37.128), we may define a beam splitting operator in analogy to the displacement operator (24.130),

$$\mathcal{B}(\theta) \equiv e^{\theta(\hat{a}^\dagger\hat{b}-\hat{a}\hat{b}^\dagger)} \ , \tag{37.136}$$

which is an equivalent beam splitter description. We find,

$$\begin{aligned} \mathcal{B}(\theta)^\dagger\hat{a}\mathcal{B}(\theta) &= \hat{a}\cos\theta + \hat{b}\sin\theta \\ \mathcal{B}(\theta)^\dagger\hat{b}\mathcal{B}(\theta) &= -\hat{a}\sin\theta + \hat{b}\cos\theta \end{aligned} \ , \tag{37.137}$$

as will be shown in Exc. 37.5.8.4 [13].

37.5.1.4 Fock representation

Alternatively, we can describe the beam splitter in the Fock representation [14]. The Hamiltonian of the beam splitter couples two modes of harmonic oscillators. Expanding on a two-dimensional Fock basis via $|\psi\rangle \equiv (...|0\rangle|n_a\rangle....|n_b\rangle|0\rangle...)$ we can gain more insight:

$$\begin{aligned} \hat{H} &= \tfrac{\hbar}{2}\Omega(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b}) \\ &= \tfrac{\hbar}{2}\Omega\sum_{n_a,n_b}\sqrt{n_a(n_b+1)}|n_a-1,n_b+1\rangle\langle n_a,n_b| + \sqrt{(n_a+1)n_b}|n_a+1,n_b-1\rangle\langle n_a,n_b| \\ &= \sum_{n_a+n_b}\hat{H}_{a+b} \ , \end{aligned} \tag{37.138}$$

where,

$$\hat{H}_{a+b} = \tfrac{\hbar}{2}\Omega\begin{pmatrix} 0 & \sqrt{1n_b} & & & \\ \sqrt{1n_b} & 0 & \sqrt{2(n_b-1)} & & \\ & \sqrt{2(n_b-1)} & \ddots & & \\ & & & \ddots & \sqrt{n_a 1} \\ & & & \sqrt{n_a 1} & 0 \end{pmatrix} . \tag{37.139}$$

The sub-spaces with n_a+n_b+1 photons are completely degenerate, since $\det(\lambda\mathbb{I}_{a+b} - \hat{H}_{a+b}) = \lambda^{n_a+n_b+1} = 0$. The degeneracy is removed, when we introduce loss mechanisms into one of the modes. Thus, the Hamiltonian can be understood as a Dicke system with the multiplicity $\frac{1}{2}\widehat{(n_a+n_b)} = n_a+n_b+1$. See also Exc. 37.5.8.2.

Example 266 (*Beam splitter with 0 or 1 photons*): As an example, we consider $n_a, n_b = 0, 1$. Then, in the basis $\begin{pmatrix}|0,0\rangle & |0,1\rangle & |1,0\rangle & |0,2\rangle & |1,1\rangle & |2,0\rangle & \cdots\end{pmatrix}^t$

[13] Compare to the formulas (24.128), (24.133), and (37.107).
[14] A more in-depth discussion is found in Ref. [567].

the matrix of the Hamiltonian becomes,

$$\hat{H} = \tfrac{1}{2}\Omega \begin{pmatrix} 0 & & & & & \\ & 0 & 1 & & & \\ & 1 & 0 & & & \\ & & & 0 & \sqrt{2} & 0 \\ & & & \sqrt{2} & 0 & \sqrt{2} \\ & & & 0 & \sqrt{2} & 0 \end{pmatrix} .$$

It is easily verified that the matrix of eigenvectors and the matrix of eigenvalues,

$$U = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -\frac{1}{2}\sqrt{2} & -1 & \frac{1}{2}\sqrt{2} \\ 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & -\frac{1}{2}\sqrt{2} & 1 & \frac{1}{2}\sqrt{2} \end{pmatrix} \quad \text{respectively} \quad E = \tfrac{\hbar}{2}\Omega \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2 \end{pmatrix}$$

satisfy $U^{-1}HU = E$. Hence,

$$|\psi\rangle = U^{-1}e^{\imath Et}U|\psi_0\rangle \ ,$$

and we find, that the state $|1,1\rangle = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}^T$ is transformed into a superposition,

$$\begin{pmatrix} 0 & 0 & 0 & \frac{1}{\sqrt{2}}\imath\sin\Omega t & \cos\Omega t & \frac{1}{\sqrt{2}}\imath\sin\Omega t \end{pmatrix}^T \xrightarrow{\Omega t=\pi/2} \frac{\imath}{\sqrt{2}}(|0,2\rangle + |2,0\rangle) \ .$$

Similarly, we find that the superposition state $\frac{1}{\sqrt{2}}(|1,0\rangle+|0,1\rangle) = \begin{pmatrix} 0 & 1 & -1 & 0 & 0 & 0 \end{pmatrix}^T$ is transformed into,

$$e^{-\frac{1}{2}\imath\Omega t}\begin{pmatrix} 0 & 1 & -1 & 0 & 0 & 0 \end{pmatrix}^T \xrightarrow{\Omega t=\pi/2} e^{-\imath\pi/4}\frac{1}{\sqrt{2}}(|1,0\rangle + |0,1\rangle) \ .$$

37.5.2 Fock and Glauber states at a beam splitter

A beam splitter divides a Fock state containing N photons into two Glauber states,

$$\begin{aligned} |\psi\rangle &= \frac{1}{2^{N/2}\sqrt{N!}}(\hat{a}_1^\dagger + \hat{a}_2^\dagger)^N|0,0\rangle = \frac{1}{2^{N/2}\sqrt{N!}}\sum_{n=0}^{N}\binom{N}{n}(\hat{a}_1^\dagger)^n(\hat{a}_2^\dagger)^{N-n}|0,0\rangle \qquad (37.140) \\ &= \frac{1}{2^{N/2}}\sum_{n=0}^{N}\sqrt{\binom{N}{n}}|n,N-n\rangle = \sum_{n=0}^{N}\sqrt{\binom{N}{n}0.5^n 0.5^{N-n}}|n,N-n\rangle \\ &\simeq \sum_{n=0}^{N}\sqrt{\frac{(N/2)^n}{n!}e^{-N/2}}|n,N-n\rangle = e^{-|\alpha|/2}\sum_{n=0}^{N}\frac{\alpha^n}{\sqrt{n!}}|n,N-n\rangle \ , \end{aligned}$$

approximating the binomial distribution by the Poisson distribution,

$$\binom{N}{n}p^n(1-p)^{N-n} \xrightarrow{N\to\infty} \frac{(pN)^n}{n!}e^{-pN} \ . \qquad (37.141)$$

and defining $\alpha \equiv N/2$. The normalization is $\langle\psi|\psi\rangle = 1$. The population in an individual mode is,

$$\langle\hat{n}_1\rangle = \langle\psi|\hat{a}_1^\dagger\hat{a}_1|\psi\rangle = \frac{1}{2^N}\langle m, N-m| \sum_{n,m=0}^{N} \sqrt{\binom{N}{m}}\hat{a}_1^\dagger\hat{a}_1\sqrt{\binom{N}{n}}|n, N-n\rangle \quad (37.142)$$
$$= \frac{1}{2^N}\sum_{n=0}^{N}\binom{N}{n}n = \frac{N}{2} \ .$$

The result (37.140) shows that, ignoring (tracing over) one of the modes, the other mode automatically becomes a Glauber state [15].

Besides that,

$$\langle\hat{n}_1^2\rangle = \frac{1}{2^n}\sum_{n=0}^{n}\binom{N}{n}n^2 = \frac{N}{2^n}\sum_{n=0}^{N-1}\binom{N}{n}(n+1) = \frac{N(N+1)}{4} \quad (37.143)$$
$$\langle\hat{n}_1\hat{n}_2\rangle = \frac{1}{2^n}\sum_{n=0}^{n}\sqrt{\binom{N}{n}}n(N-n) = N\langle\hat{n}_1\rangle - \langle\hat{n}_1^2\rangle = \frac{N(N-1)}{4}$$

The squeezing parameter is,

$$\xi_{12} = \frac{\sigma^2(\hat{n}_1-\hat{n}_2)}{\langle\hat{n}_1\rangle+\langle\hat{n}_2\rangle} = \frac{\langle\hat{n}_1^2 - 2\hat{n}_1\hat{n}_2 + \hat{n}_2^2\rangle}{N} = \frac{2\langle\hat{n}_1^2\rangle - 2\langle\hat{n}_1\hat{n}_2\rangle}{N} = 1 \ . \quad (37.144)$$

The correlation functions at equal times are,

$$g_{11} = \frac{\left\langle\hat{a}_1^\dagger\hat{a}_1^\dagger\hat{a}_1\hat{a}_1\right\rangle}{\langle\hat{n}_1\rangle^2} = \frac{1}{\langle\hat{n}_1\rangle^2}\frac{1}{2^n}\sum_{n=2}^{n}\binom{N}{n}n(n-1) = \frac{\langle\hat{n}_1^2\rangle - \langle\hat{n}_1\rangle}{\langle\hat{n}_1\rangle^2} = 1 \quad (37.145)$$
$$g_{12} = \frac{\left\langle\hat{a}_1^\dagger\hat{a}_2^\dagger\hat{a}_2\hat{a}_1\right\rangle}{\langle\hat{n}_1\rangle\langle\hat{n}_2\rangle} = \frac{1}{\langle\hat{n}_1\rangle^2}\frac{1}{2^n}\sum_{n=0}^{N}\binom{N}{n}n(N-n) = \frac{N\langle\hat{n}_1\rangle - \langle\hat{n}_1^2\rangle}{\langle\hat{n}_1\rangle^2} = \frac{N-1}{N}$$

The Cauchy-Schwarz inequality and the quantum inequality are both met,

$$g_{12} \le \sqrt{g_{11}g_{22}} \quad (37.146)$$
$$g_{12} \le \sqrt{\left(g_{11} + \frac{1}{\langle\hat{n}_1\rangle}\right)\left(g_{22} + \frac{1}{\langle\hat{n}_2\rangle}\right)}$$

In comparison, a Glauber state is normally divided,

$$|\psi\rangle = |\alpha_1\rangle|\alpha_2\rangle = e^{-|\alpha_1|^2/2}\sum_n \frac{\alpha_1^n}{\sqrt{n!}}|n\rangle e^{-|\alpha_2|^2/2}\sum_m \frac{\alpha_2^m}{\sqrt{m!}}|m\rangle \quad (37.147)$$
$$= e^{-|\alpha_1|^2/2-|\alpha_2|^2/2}\sum_{n,m}\frac{\alpha_1^n\alpha_2^m}{\sqrt{n!}\sqrt{m!}}|n\rangle|m\rangle \ .$$

[15] This does not mean that the output modes are uncorrelated. For instance, if we measure n photons in one mode, we know that the other must contain exactly $N-n$ photons. However, the correlations are so dense in phase space that they are not resolvable or decohere rapidly. In fact, it can be shown that coherent states are the only pure states that produce uncorrelated outputs when mixed by a passive linear-optics device [10, 9].

37.5.2.1 Density matrix representation

The density matrix for a pure state is,

$$\hat{\rho} = |\psi\rangle\langle\psi| = \begin{pmatrix} |\langle\psi|1\rangle|^2 & \langle 1|\psi\rangle\langle\psi|2\rangle \\ \langle 2|\psi\rangle\langle\psi|1\rangle & |\langle\psi|2\rangle|^2 \end{pmatrix} . \tag{37.148}$$

The evolution of such a state is described by the von Neumann equation:

$$\imath\hbar\partial_t\hat{\rho}(t) = [\hat{H}, \hat{\rho}(t)] . \tag{37.149}$$

For the beam splitter we obtain,

$$\hat{\rho} = |\psi\rangle\langle\psi| = \begin{pmatrix} |\langle\psi|0,0\rangle|^2 & \langle 0,0|\psi\rangle\langle\psi|0,1\rangle & \langle 0,0|\psi\rangle\langle\psi|1,0\rangle & \\ \langle 0,1|\psi\rangle\langle\psi|0,0\rangle & |\langle\psi|0,1\rangle|^2 & \langle 0,1|\psi\rangle\langle\psi|1,0\rangle & \\ \langle 1,0|\psi\rangle\langle\psi|0,0\rangle & \langle 1,0|\psi\rangle\langle\psi|0,1\rangle & |\langle\psi|1,0\rangle|^2 & \\ & & & \ddots \end{pmatrix} . \tag{37.150}$$

Example 267 (*Density matrix for the beam splitter with 0 or 1 photons*): For the case of the superposition states, $|\psi\rangle = \frac{1}{\sqrt{2}}(|0,1\rangle \pm |1,0\rangle)$,

$$\hat{\rho} = \begin{pmatrix} 0 & 0 & 0 & \\ 0 & \frac{1}{2} & \pm\frac{1}{2} & \\ 0 & \pm\frac{1}{2} & \frac{1}{2} & \\ & & & \ddots \end{pmatrix} .$$

Obviously, $\hat{\rho} = \hat{\rho}^2$. For the above superposition state, $\partial_t\hat{\rho}(t) = 0$.

37.5.3 Ordinary and balanced homodyne detection

In Secs. 24.5.1 and 24.6.1 we have calculated the quantum noise of a harmonic oscillator in the Fock and the Glauber basis. We will now discuss a method to measure this noise called *homodyne detection* or *phase-sensitive detection*. The signal is obtained by superposing the field mode of interest with a local oscillator with a relative phase θ at a 50% beam splitter and a subtraction of the photo currents in the two ports of the interferometer.

To begin with, let us describe both the field mode $\hat{a}$ and the local oscillator $\hat{b}$ on equal footings as quantized modes [see Fig. 37.8(a)]. The *ordinary homodyne signal* is obtained by superposing the field mode of interest with a local oscillator with a relative phase θ at a beam splitter and measuring the photo currents in the two ports $\hat{c}$ and $\hat{d}$ of the interferometer. From Eq. (37.134) we obtain for a 50% beam splitter,

$$\hat{c} = \frac{1}{\sqrt{2}}(\hat{a} - \imath\hat{b}) \quad , \quad \hat{d} = \frac{1}{\sqrt{2}}(-\imath\hat{a} + \hat{b}) \tag{37.151}$$

and

$$\begin{aligned} \hat{I}_c &= \hat{c}^\dagger\hat{c} = \tfrac{1}{2}(\hat{a}^\dagger\hat{a} + \hat{b}^\dagger\hat{b} - \imath\hat{a}^\dagger\hat{b} + \imath\hat{b}^\dagger\hat{a}) \\ \hat{I}_d &= \hat{d}^\dagger\hat{d} = \tfrac{1}{2}(\hat{a}^\dagger\hat{a} + \hat{b}^\dagger\hat{b} + \imath\hat{a}^\dagger\hat{b} - \imath\hat{b}^\dagger\hat{a}) . \end{aligned} \tag{37.152}$$

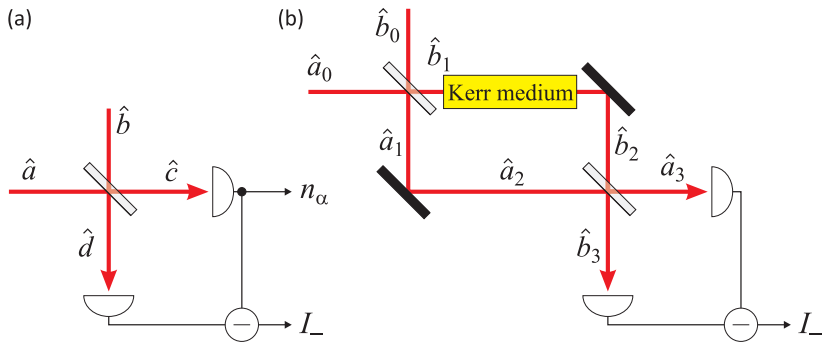

Figure 37.8: (a) Homodyne detection scheme. Output n_α delivers the *ordinary homodyne signal*, and output I_- the *balanced homodyne signal*. (b) Homodyne detection of squeezing in a Mach-Zehnder interferometer.

To obtain the *balanced homodyne signal* we add or subtract both photo currents,

$$\begin{aligned} \hat{I}_+ &= \hat{I}_c + \hat{I}_d = \hat{a}^\dagger \hat{a} + \hat{b}^\dagger \hat{b} \\ \hat{I}_- &= \hat{I}_c - \hat{I}_d = \imath(\hat{b}^\dagger \hat{a} - \hat{a}^\dagger \hat{b}) \ . \end{aligned} \tag{37.153}$$

In order to quantify the intensity noise, we also need to calculate the square values [318],

$$\begin{aligned} \hat{I}_+^2 &= \quad (\hat{a}^\dagger \hat{a} + \hat{b}^\dagger \hat{b})^2 = (\hat{n}_a + \hat{n}_b)^2 \\ \hat{I}_-^2 &= -(\hat{b}^\dagger \hat{a} - \hat{a}^\dagger \hat{b})^2 = -\hat{a}^2 \hat{b}^{\dagger 2} - \hat{a}^{\dagger 2} \hat{b}^2 + \hat{a}\hat{a}^\dagger \hat{b}^\dagger \hat{b} + \hat{a}^\dagger \hat{a} \hat{b} \hat{b}^\dagger \ , \end{aligned} \tag{37.154}$$

yielding,

$$\begin{aligned} \Delta I_+^2 &= \langle \hat{I}_+^2 \rangle - \langle \hat{I}_+ \rangle^2 = \Delta \hat{n}_a^2 + \Delta \hat{n}_b^2 \\ \Delta I_-^2 &= \langle \hat{I}_-^2 \rangle - \langle \hat{I}_- \rangle^2 \\ &= -\Delta \hat{a}^2 \langle \hat{b}^{\dagger 2} \rangle - \Delta \hat{a}^{\dagger 2} \langle \hat{b} \rangle^2 + \langle \hat{a}\hat{a}^\dagger \rangle \langle \hat{b}^\dagger \hat{b} \rangle + \langle \hat{a}^\dagger \hat{a} \rangle \langle \hat{b}\hat{b}^\dagger \rangle - 2\langle \hat{a}^\dagger \rangle \langle \hat{a} \rangle \langle \hat{b}^\dagger \rangle \langle \hat{b} \rangle \ . \end{aligned} \tag{37.155}$$

Assuming the local oscillator in a coherent state, $|\beta\rangle = ||\beta| e^{\imath(\pi/2-\theta)}\rangle$, we obtain,

$$\boxed{\begin{aligned} \Delta I_+^2 &\xrightarrow{|\beta\rangle} \Delta \hat{n}_a^2 + |\beta|^2 \\ \Delta I_-^2 &\xrightarrow{|\beta\rangle} |\beta|^2 e^{\imath 2\theta} \Delta \hat{a}^2 + |\beta|^2 e^{-\imath 2\theta} \Delta \hat{a}^{\dagger 2} + 2|\beta|^2 (\langle \hat{n}_a \rangle - \langle \hat{a}^\dagger \rangle \langle \hat{a} \rangle) + \langle \hat{n}_a \rangle + |\beta|^2 \end{aligned}} \ . \tag{37.156}$$

To determine the shot noise, we simply block the local oscillator $\hat{b}$ and obtain,

$$\Delta I_+^2 \xrightarrow{\beta=0} \Delta n_a^2 \qquad \text{and} \qquad \Delta I_-^2 \xrightarrow{\beta=0} \langle \hat{n}_a \rangle \ . \tag{37.157}$$

Hence, Δn_a^2 is the intensity noise of mode $\hat{a}$, and $\langle \hat{n}_a \rangle$ is the shot noise, which is present even though the intensities I_c and I_d are perfectly balanced and should cancel out in subtraction (see the Exc. 37.5.8.5).

37.5.3.1 Phase-dependent noise for specific probe light fields

Now, let us consider specific light fields. For a coherent probe, $|\psi\rangle \equiv |\alpha\rangle$,

$$\Delta\hat{I}_+^2 \overset{|\psi\rangle\equiv|\alpha\rangle}{\longrightarrow} |\alpha|^2 + |\beta|^2 \overset{|\psi\rangle\equiv|\alpha\rangle}{\longleftarrow} \Delta\hat{I}_-^2 \ . \tag{37.158}$$

That is, as illustrated in Fig. 37.9, the noise of neither the sum nor difference intensities vary with the phase of the local oscillator. Note that here, the coherent light modes of neither the probe nor the local oscillator are treated as classical; otherwise the noise should disappear.

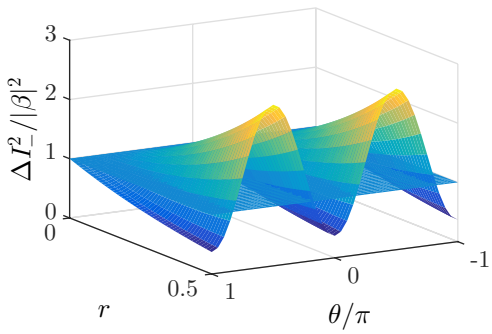

Figure 37.9: (code) Noise in the subtracted intensities ΔI_-^2 as a function of squeezing parameter r and homodyning phase θ. The plane at $\Delta I_-^2/|\beta|^2 = 1$ corresponds to coherent vacuum, the modulated curve to squeezed vacuum.

Now, for squeezed vacuum, $|\psi\rangle \equiv |0,\xi\rangle = \mathcal{S}(\xi)|0\rangle$, using the results of Exc. 37.4.4.5, namely,

$$\begin{aligned}
\langle\hat{a}\rangle &= 0 = \langle\hat{a}^\dagger\rangle \qquad (37.159)\\
\langle\hat{n}_a\rangle &= \sinh^2 r \\
\langle 0,\xi|\hat{a}^2|0,\xi\rangle &= \langle 0|\mathcal{S}^\dagger(\xi)\hat{a}\mathcal{S}(\xi)\mathcal{S}^\dagger(\xi)\hat{a}\mathcal{S}(\xi)|0\rangle \\
&= \langle 0|(\hat{a}\cosh r - \hat{a}^\dagger e^{\imath\varphi}\sinh r)^2|0\rangle = -e^{\imath\varphi}\sinh r\cosh r \\
\langle 0,\xi|\hat{a}^{\dagger 2}|0,\xi\rangle &= -e^{-\imath\varphi}\sinh r\cosh r \ , \qquad (37.160)
\end{aligned}$$

we get,

$$\begin{aligned}
\Delta\hat{I}_+^2 &\overset{|\psi\rangle\equiv|0,\xi\rangle}{\longrightarrow} 2\sinh^2 r\cosh^2 r \qquad (37.161)\\
\Delta\hat{I}_-^2 &\overset{|\psi\rangle\equiv|0,\xi\rangle}{\longrightarrow} -2|\beta|^2\cos(2\theta+\varphi)\sinh r\cosh r + 2|\beta|^2\sinh^2 r + \sinh^2 r + |\beta|^2 \ .
\end{aligned}$$

We see that $\Delta\hat{I}_-^2$ depends on the phase of the local oscillator and, as illustrated in Fig. 37.9 can have values below that expected for coherent vacuum.

The generalization to squeezed coherent light, $|\psi\rangle \equiv |\alpha,\xi\rangle = \mathcal{D}(\alpha)|0,\xi\rangle = \mathcal{D}(\alpha)\mathcal{S}(\xi)|0\rangle$ is simple. We just need to separate the probe mode into a classical and a quantum part, $\hat{a} = \alpha + \delta\hat{a}$. Obviously, $\langle\delta\hat{a}\rangle = 0$ and $\Delta\hat{a}^2 = \Delta(\delta\hat{a})^2$, so that the only modification expected for $\Delta\hat{I}_-^2$ is an additional term $|\alpha|^2$, which however is negligible if the local oscillator $|\beta|^2$ is much stronger.

37.5.3.2 Shot noise

Like any quantized degree of freedom, a light mode is subject to intrinsic quantum noise imposed by the Heisenberg uncertainty relation, as we have seen for the harmonic oscillator (24.138). In the case of a light mode the quantum noise originates in the fact, that any power measurement based on photon counting involves *projection* onto a discrete number of photons. Often the light mode will be in a 'classical' coherent state, which is not an eigenstate of the photon number measurement operator. The projection onto Fock states introduces unavoidable *quantum projection noise* in this case is called *shot noise* and introduces the Heisenberg limit in the quadrature phases of the light intensity.

37.5.3.3 Inverse Radon transform

The expectation value of $\Delta\hat{I}_-$ is afflicted with the Heisenberg uncertainty and can be expressed as the first moment of the Wigner function $W(\alpha)$:

$$\begin{aligned}\langle\psi|\hat{I}_-|\psi\rangle &= \int W_{|\psi\rangle}(\alpha)\hat{I}_- d^2\alpha \\ &= \sqrt{2}|\beta_{\rm LO}|\int W_{|\psi\rangle}(x_\theta,p_\theta)x_\theta dx_\theta dp_\theta = \sqrt{2}|\beta_{\rm LO}|\int_{-\infty}^{\infty} w_\theta(x_\theta)x_\theta dx_\theta \ .\end{aligned} \tag{37.162}$$

Here, the distribution function integrated over a rotated quadrature component p_θ is given by,

$$w_\theta(x_\theta) \equiv \int_{-\infty}^{\infty} W_\theta(x_\theta,p_\theta)dp_\theta \ . \tag{37.163}$$

This is called the *radon transform*. The distribution function $w_\theta(p_\theta)$ as well as the Wigner function are normalized to 1. Multiple measurements of the expectation value $x_\theta = \langle\psi|\hat{x}_\theta|\psi\rangle$ now yields a histogram $H_{|\psi\rangle}(x_\theta)$ reflecting, if normalized, $w_{|\psi\rangle}(x_\theta) = H_{|\psi\rangle}(x_\theta)/\int H_{|\psi\rangle}(x_\theta)$ exactly the distribution function.

Considering the finite detector efficiency [567] $w_\theta(x_\theta)$ must be generalized to a convolution with an apparatus function $\zeta(x)$:

$$w_\theta^{\rm real}(\sqrt{\eta}x_\theta) = (w_\theta^{\rm ideal}\star\zeta) \qquad \text{where} \qquad \zeta(x) = \frac{1}{\sqrt{\pi(1-\eta)}}e^{-\eta\alpha^2/(1-\eta)} \ . \tag{37.164}$$

A finite detector efficiency degrades the contrast of the quantum interference structures.

With the procedure of optical *homodyne tomography* or *quantum state endoscopy* the Wigner function for e.g. a Schrödinger cat state can be reconstructed from a set of distribution functions $w_\theta(x_\theta) = \int W(\alpha e^{\imath\theta})dp_\theta$ measured for various phases θ [567]. To do this the data set is exposed to an inverse *radon transform*:

$$W(\alpha) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_0^{\pi}\int_{-\infty}^{\infty} w_\theta(x_\theta)|\zeta|e^{\imath\zeta\left[\mathfrak{Re}\,(2^{-1/2}\alpha e^{-\imath\theta})-x_\theta\right]}dx d\theta d\zeta \ . \tag{37.165}$$

In contrast to the conventional homodyne detection, where the phase dependency of amplitude noise is recorded, the homodyne tomography allows the complete reconstruction of a quantum state through measurement of the distribution of the amplitude

noise power,

$$P_s = \frac{\omega_s}{2\pi} \int_0^{\omega_s/2\pi} dt |\langle I(t) \rangle|^2 \tag{37.166}$$

for various phases.

Alternatively, to the homodyne method, one may reconstruct the photon distribution in field modes from their temporal evolution [950]. Another method could be to use atoms as sensors for the quantum state of a light field in a Jaynes-Cummings type dynamics.

37.5.4 Quantum amplifier

We will call in the following as *quantum signals* degrees of freedom subject to quantum noise. Typically a quantum signal will be a mode of an electric field, represented by an annihilation operator $\hat{a}$. Such a mode can be enhanced by *quantum amplifier*, which is a device amplifying quantum signals according to the rules of quantum mechanics. Examples include the active elements of lasers and optical parametric amplifiers. A quantum amplifier is characterized by its gain and its own intrinsic quantum noise, which are interdependent parameters; the higher the gain, the larger the uncertainty noise. In the case of lasers, the uncertainty corresponds to the amplified spontaneous emission of the active medium.

Quantum amplification is a unitary transformation $\hat{U}$, acting in an initial state $|\text{in}\rangle$ and producing (in the Schrödinger figure) the amplified state,

$$|\text{out}\rangle = \hat{U}|\text{in}\rangle \ . \tag{37.167}$$

The amplification depends on the mean value $\langle \hat{a} \rangle$ of the annihilation operator and its dispersion $\langle \hat{a}^\dagger \hat{a} \rangle - \langle \hat{a}^\dagger \rangle \langle \hat{a} \rangle$. A coherent state is a state with minimal uncertainty; when the state is transformed, the uncertainty may increase. This increase can be interpreted as noise in the amplifier. The gain G can be defined as follows:

$$G = \frac{\langle \hat{a} \rangle_{\text{out}}}{\langle \hat{a} \rangle_{\text{in}}} \ . \tag{37.168}$$

The quantum amplifier can also be described in the Heisenberg picture; the changes are attributed to the amplification of the field operator. Thus, the evolution of the operator $\hat{a}_{\text{out}}$ is given by

$$\hat{a}_{\text{out}} = \hat{U}^\dagger \hat{a} \hat{U} \ , \tag{37.169}$$

while the state vector remains unchanged. The gain is then given by,

$$G = \frac{\langle \hat{a}_{\text{out}} \rangle_{\text{in}}}{\langle \hat{a} \rangle_{\text{in}}} \ . \tag{37.170}$$

In general, the gain G may be complex, and it may depend on the initial state. For laser applications, the amplification of coherent states is important. Therefore, it is usually assumed that the initial state is a coherent state characterized by a complex-valued initial parameter α, such that $|\text{in}\rangle = |\alpha\rangle$. Even with such a restriction, the gain may depend on the amplitude or phase of the initial field.

In the following, the Heisenberg representation is used; all brackets are assumed to be evaluated with respect to the initial coherent state,

$$\text{noise} = \langle \hat{a}^\dagger_{\text{out}} \hat{a}_{\text{out}} \rangle - \langle \hat{a}^\dagger_{\text{out}} \rangle \langle \hat{a}_{\text{out}} \rangle - (\langle \hat{a}^\dagger \hat{a} \rangle - \langle \hat{a}^\dagger \rangle \langle \hat{a} \rangle) \ . \tag{37.171}$$

The expectation values are assumed to be evaluated with respect to the initial coherent state. This quantity characterizes the increase of the uncertainty of the field due to amplification. As the uncertainty of the field operator does not depend on its parameter, the quantity above shows how much output field differs from a coherent state.

37.5.4.1 Linear phase-invariant amplifier

Linear phase-invariant amplifiers may be described as follows. Assume that the unitary operator U amplifies in such a way that the input $\hat{a}$ and the output $\hat{a}_{\text{out}} = \hat{U}^\dagger \hat{a} \hat{U}$, are related by a linear equation,

$$\hat{a}_{\text{out}} = c\hat{a} + s\hat{b}^\dagger \ , \tag{37.172}$$

where c and s are c-numbers and $\hat{b}^\dagger$ is a creation operator characterizing the amplifier. Without loss of generality, it may be assumed that c and s are real. The commutator of the field operators is invariant under unitary transformation U:

$$[\hat{a}_{\text{out}}, \hat{a}^\dagger_{\text{out}}] = 1 = [\hat{a}, \hat{a}^\dagger] \quad , \quad [\hat{a}_{\text{in}}, \hat{a}^\dagger_{\text{out}}] = 0 = [\hat{a}_{\text{out}}, \hat{a}^\dagger_{\text{in}}] \ . \tag{37.173}$$

From the unitarity of U, it follows that $\hat{b}$ satisfies the same commutation relations. The c-numbers are then $c^2 - s^2 = 1$. Hence, the phase-invariant amplifier acts by introducing an additional mode to the field, with a large amount of stored energy, behaving as a boson. Calculating the gain and the noise of this amplifier, one finds $G = c$, and

$$\text{noise} = \text{c}^2 - 1 \ . \tag{37.174}$$

The coefficient $g = |G|^2$ is sometimes called the intensity amplification coefficient. The noise of the linear phase-invariant amplifier is given by $g - 1$. The gain can be dropped by splitting the beam; the estimate above gives the minimal possible noise of the linear phase-invariant amplifier. The linear amplifier has an advantage over the multi-mode amplifier: if several modes of a linear amplifier are amplified by the same factor, the noise in each mode is determined independently; that is, modes in a linear quantum amplifier are independent.

To obtain a large amplification coefficient with minimal noise, one may use homodyne detection, constructing a field state with known amplitude and phase, corresponding to the linear phase-invariant amplifier. The uncertainty principle sets the lower bound of quantum noise in an amplifier. In particular, the output of a laser system and the output of an optical generator are not coherent states.

The multiplicative amplifier $\mathcal{D}$ also adds additive noise F. We have $\mathcal{D}\mathcal{D}^\dagger = 1$,

$$\begin{pmatrix} \hat{a}^\dagger_{\text{out}} \\ \hat{a}_{\text{out}} \end{pmatrix} = \mathcal{D} \begin{pmatrix} \hat{a}^\dagger_{\text{in}} \\ \hat{a}_{\text{in}} \end{pmatrix} + \begin{pmatrix} F_1 \\ F_2 \end{pmatrix} \ . \tag{37.175}$$

37.5.5 Coupled quantum oscillators with/out counter-rotating terms

The Hamiltonian of a beam splitter resembles the one of a system of two *coupled oscillators* with identical eigenfrequencies. Here, we are interested in calculating the time evolution of such a system. We rewrite the Hamiltonian in terms of the *normal modes*. We start from the Hamiltonian with counter-rotating terms [303],

$$\boxed{\hat{H} = \hbar\omega(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}) + \hbar\omega(\hat{b}^\dagger\hat{b} + \tfrac{1}{2}) + \tfrac{\hbar\Omega}{2}(\hat{a} + \hat{a}^\dagger)(\hat{b} + \hat{b}^\dagger)} \,, \tag{37.176}$$

which we rewrite in terms of the quadrature components given by,

$$\begin{pmatrix} \hat{x}_a \\ \hat{p}_a \\ \hat{x}_b \\ \hat{p}_b \end{pmatrix} = \mathcal{T}_{ab} \begin{pmatrix} \hat{a} \\ \hat{a}^\dagger \\ \hat{b} \\ \hat{b}^\dagger \end{pmatrix} \qquad \text{with} \qquad \mathcal{T}_{ab} \equiv \sqrt{\frac{\hbar\omega}{2}} \begin{pmatrix} \omega^{-1} & \omega^{-1} & 0 & 0 \\ \imath & -\imath & 0 & 0 \\ 0 & 0 & \omega^{-1} & \omega^{-1} \\ 0 & 0 & \imath & -\imath \end{pmatrix} \,, \tag{37.177}$$

as

$$\hat{H} = \tfrac{1}{2}(\hat{p}_a^2 + \omega^2\hat{x}_a^2) + \tfrac{1}{2}(\hat{p}_b^2 + \omega^2\hat{x}_b^2) + \Omega\omega\hat{x}_a\hat{x}_b \,. \tag{37.178}$$

Setting $\omega_\pm = \sqrt{\omega^2 \pm \Omega\omega}$ allows us to rewrite the Hamiltonian as,

$$\hat{H} = \tfrac{1}{4}(\hat{p}_a + \hat{p}_b)^2 + \tfrac{1}{4}\omega_+^2(\hat{x}_a + \hat{x}_b)^2 + \tfrac{1}{4}(\hat{p}_a - \hat{p}_b)^2 + \tfrac{1}{4}\omega_-^2(\hat{x}_a - \hat{x}_b)^2 \,. \tag{37.179}$$

Now, we apply the transform,

$$\begin{pmatrix} \hat{x}_A \\ \hat{p}_A \\ \hat{x}_B \\ \hat{p}_B \end{pmatrix} = \mathcal{M} \begin{pmatrix} \hat{x}_a \\ \hat{p}_a \\ \hat{x}_b \\ \hat{p}_b \end{pmatrix} \qquad \text{with} \qquad \mathcal{M} \equiv \sqrt{\frac{1}{2}} \begin{pmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{pmatrix} = M^{-1} \,, \tag{37.180}$$

and rewrite the Hamiltonian again as,

$$\hat{H} = \tfrac{1}{2}(\hat{p}_A^2 + \omega_+^2\hat{x}_A^2) + \tfrac{1}{2}(\hat{p}_B^2 + \omega_-^2\hat{x}_B^2) \,. \tag{37.181}$$

We go back from the quadrature components to the field mode operators via,

$$\begin{pmatrix} \hat{x}_A \\ \hat{p}_A \\ \hat{x}_B \\ \hat{p}_B \end{pmatrix} = \mathcal{T}_{AB} \begin{pmatrix} \hat{A} \\ \hat{A}^\dagger \\ \hat{B} \\ \hat{B}^\dagger \end{pmatrix} \qquad \text{with} \qquad \mathcal{T}_{AB} \equiv \sqrt{\frac{\hbar}{2}} \begin{pmatrix} 1/\sqrt{\omega_+} & 1/\sqrt{\omega_+} & 0 & 0 \\ \imath\sqrt{\omega_+} & -\imath\sqrt{\omega_+} & 0 & 0 \\ 0 & 0 & 1/\sqrt{\omega_-} & 1/\sqrt{\omega_+} \\ 0 & 0 & \imath\sqrt{\omega_-} & -\imath\sqrt{\omega_+} \end{pmatrix} \,, \tag{37.182}$$

and finally obtain,

$$\boxed{\hat{H} = \hbar\omega_+(\hat{A}^\dagger\hat{A} + \tfrac{1}{2}) + \hbar\omega_-(\hat{B}^\dagger\hat{B} + \tfrac{1}{2})} \,. \tag{37.183}$$

The Heisenberg equations of motion for the oscillator modes,

$$\frac{d}{dt}\begin{pmatrix} \hat{a} \\ \hat{a}^\dagger \\ \hat{b} \\ \hat{b}^\dagger \end{pmatrix} = -\tfrac{\imath}{\hbar}\left[\begin{pmatrix} \hat{a} \\ \hat{a}^\dagger \\ \hat{b} \\ \hat{b}^\dagger \end{pmatrix}, \hat{H}\right] = \mathcal{X}\begin{pmatrix} \hat{a} \\ \hat{a}^\dagger \\ \hat{b} \\ \hat{b}^\dagger \end{pmatrix} \qquad \text{with} \qquad \mathcal{X} \equiv \begin{pmatrix} -\imath\omega & 0 & -\frac{\imath\Omega}{2} & -\frac{\imath\Omega}{2} \\ 0 & \imath\omega & \frac{\imath\Omega}{2} & \frac{\imath\Omega}{2} \\ -\frac{\imath\Omega}{2} & -\frac{\imath\Omega}{2} & -\imath\omega & 0 \\ \frac{\imath\Omega}{2} & \frac{\imath\Omega}{2} & 0 & \imath\omega \end{pmatrix} \,, \tag{37.184}$$

are difficult to integrate. In contrast, the Heisenberg equations for the normal modes,

$$\frac{d}{dt}\begin{pmatrix}\hat{A}\\ \hat{A}^\dagger\\ \hat{B}\\ \hat{B}^\dagger\end{pmatrix} = -\tfrac{\imath}{\hbar}\left[\begin{pmatrix}\hat{A}\\ \hat{A}^\dagger\\ \hat{B}\\ \hat{B}^\dagger\end{pmatrix}, \hat{H}\right] = E_{\mathcal{X}}\begin{pmatrix}\hat{A}\\ \hat{A}^\dagger\\ \hat{B}\\ \hat{B}^\dagger\end{pmatrix} \tag{37.185}$$

$$\text{with}\qquad E_{\mathcal{X}} = U_{\mathcal{X}}^{-1}\mathcal{X}U_{\mathcal{X}} = \begin{pmatrix}-\imath\omega_+ & 0 & 0 & 0\\ 0 & \imath\omega_+ & 0 & 0\\ 0 & 0 & -\imath\omega_- & 0\\ 0 & 0 & 0 & \imath\omega_-\end{pmatrix}$$

$$\text{and}\qquad U_{\mathcal{X}} = \begin{pmatrix}-1-\frac{2}{\Omega}(\omega+\omega_+) & -1-\frac{2}{\Omega}(\omega-\omega_+) & 1-\frac{2}{\Omega}(\omega+\omega_-) & 1-\frac{2}{\Omega}(\omega-\omega_-)\\ 1 & 1 & -1 & -1\\ -1-\frac{2}{\Omega}(\omega+\omega_+) & -1-\frac{2}{\Omega}(\omega-\omega_+) & -1+\frac{2}{\Omega}(\omega+\omega_-) & -1+\frac{2}{\Omega}(\omega-\omega_-)\\ 1 & 1 & 1 & 1\end{pmatrix},$$

are easily solved by,

$$\begin{pmatrix}\hat{A}(t)\\ \hat{A}^\dagger(t)\\ \hat{B}(t)\\ \hat{B}^\dagger(t)\end{pmatrix} = e^{E_{\mathcal{X}}t}\begin{pmatrix}\hat{A}(0)\\ \hat{A}^\dagger(0)\\ \hat{B}(0)\\ \hat{B}^\dagger(0)\end{pmatrix}\qquad\text{with}\qquad e^{E_{\mathcal{X}}t} \equiv \begin{pmatrix}e^{-\imath\omega_+t} & 0 & 0 & 0\\ 0 & e^{\imath\omega_+t} & 0 & 0\\ 0 & 0 & e^{-\imath\omega_-t} & 0\\ 0 & 0 & 0 & e^{\imath\omega_-t}\end{pmatrix}. \tag{37.186}$$

Hence, the oscillator modes evolve as,

$$\begin{pmatrix}\hat{a}(t)\\ \hat{a}^\dagger(t)\\ \hat{b}(t)\\ \hat{b}^\dagger(t)\end{pmatrix} = e^{\mathcal{X}t}\begin{pmatrix}\hat{a}(0)\\ \hat{a}^\dagger(0)\\ \hat{b}(0)\\ \hat{b}^\dagger(0)\end{pmatrix}\qquad\text{with}\qquad e^{\mathcal{X}t} = \mathcal{T}_{ab}^{-1}\mathcal{M}^{-1}\mathcal{T}_{AB}e^{E_{\mathcal{X}}t}\mathcal{T}_{AB}^{-1}\mathcal{M}\mathcal{T}_{ab} = U_{\mathcal{X}}e^{E_{\mathcal{X}}t}U_{\mathcal{X}}^{-1}. \tag{37.187}$$

37.5.5.1 Rotating-wave approximation

The rotating-wave approximation is performed via $\omega_\pm \simeq \omega \pm \frac{1}{2}\Omega$. It leads to the Hamiltonian,

$$\boxed{\hat{H} = \hbar\omega(\hat{a}^\dagger\hat{a}+\tfrac{1}{2}) + \hbar\omega(\hat{b}^\dagger\hat{b}+\tfrac{1}{2}) + \tfrac{\hbar\Omega}{2}(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b})}\,. \tag{37.188}$$

In this approximation, we find $\mathcal{T}_{AB}^{-1}\mathcal{M}\mathcal{T}_{ab} \simeq \mathcal{M}$ and the transformation defined in (37.180),

$$\begin{pmatrix}\hat{A}\\ \hat{A}^\dagger\\ \hat{B}\\ \hat{B}^\dagger\end{pmatrix} = \mathcal{M}\begin{pmatrix}\hat{a}\\ \hat{a}^\dagger\\ \hat{b}\\ \hat{b}^\dagger\end{pmatrix}, \tag{37.189}$$

takes us directly from the Hamiltonian (37.188) to [16],

$$\boxed{\hat{H} = (\hbar\omega + \tfrac{\hbar\Omega}{2})(\hat{A}^\dagger\hat{A} + \tfrac{1}{2}) + (\hbar\omega - \tfrac{\hbar\Omega}{2})(\hat{B}^\dagger\hat{B} + \tfrac{1}{2})} \,. \tag{37.190}$$

Do the Excs. 37.5.8.6 and 37.5.8.7.

Note, that two coupled oscillator model becomes *criticality*, when the atom-field coupling strength exceeds the frequencies of the mode and the atomic two-level system.

37.5.6 Backaction on the splitting device

In all above considerations we treated the beam splitter as a classical device splitting or combining modes, which can be quantized. This is, of course, an idealization, because the action of splitting and combination requires interaction between the modes and the beam splitter. That is, the beam splitter itself must be considered as a (potentially quantized) degree of freedom and included into a global description. In a complete quantum picture beam splitting invloves at least an interaction between two degrees of freedom: the mode suffering the splitting (which we already treated quantum mechanically in the preceding sections), and the splitting device (which we will treat as an ancilla in the following, similarly as we did for a quantum measurement). In classical beam splitters, the dynamics of the ancilla is neglected, but in quantum beam splitters the ancilla serves as a witness of a splitting event. In practice, it can be a recoiling atom, a phase shift of an internal atomic state, or something else.

A complete generic model should allow to describe quantum mechanically (i) strong measurement directly on the system or (ii) weak measurements via an ancilla. For simplicity, we will assume the beam splitting device to be a two-level atom including its internal and external degrees of freedom. The light mode may then interact with the atom (or not) and be scattered into different directions of space. In order to emulate a beam splitter we need to ensure the existence of only two scattered exit modes. This can be done by putting the atom in a ring cavity, where the only modes available are the forward and the backward scattered mode. It is fair to say that this model represents the simplest possible beam splitter description including backaction. In the same time, the system exhibits a dynamics known as collective atomic recoil lasing (CARL), which is extensively discussed in Chp. 48.

37.5.6.1 Interaction-free measurement

Beam splitters and coupled cavities have been proposed for the realization of *interaction-free measurements* 37.5.8.8 and 37.5.8.9 [292, 932, 549, 531]. Resolve also the Excs. 37.5.8.11 to 37.5.8.12.

[16] Note the different behavior of a beam splitter under this transformation,

$$\begin{aligned}\hat{H} &= \hbar\omega(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}) + \hbar\omega(\hat{b}^\dagger\hat{b} + \tfrac{1}{2}) + \tfrac{\hbar\Omega}{2}\left(\hat{a}\hat{b}^\dagger - \hat{a}^\dagger\hat{b}\right) \\ &= \hbar\omega(\hat{A}^\dagger\hat{A} + \tfrac{1}{2}) + \hbar\omega(\hat{B}^\dagger\hat{B} + \tfrac{1}{2}) + \tfrac{\hbar\Omega}{2}(-\hat{A}\hat{B}^\dagger + \hat{A}^\dagger\hat{B}) \,.\end{aligned}$$

37.5.7 Multimode squeezing

We have seen earlier that a beam splitting operator (37.136) can be defined, which mixes two modes in a linear fashion. By analogy we may define a squeezing operator mixing two modes in a non-linear way.

We define,

$$\hat{b} = \mu\hat{a} + \nu\hat{c}^\dagger \ . \tag{37.191}$$

Again using $\mu^2 - \nu^2 = 1$, the standard commutation rules for $\hat{a}$ and $\hat{c}$ give,

$$\begin{aligned} [\hat{b}, \hat{b}^\dagger] &= 1 \\ [\hat{b}_r, \hat{b}_p] &= \tfrac{\imath}{2} \ . \end{aligned} \tag{37.192}$$

The individual variances read,

$$\begin{aligned} \Delta\hat{b}_r^2 &= \langle \hat{b}_r^2 \rangle - \langle \hat{b}_r \rangle^2 \\ &= \tfrac{1}{4}\langle (\hat{b} + \hat{b}^\dagger)^2 \rangle - \tfrac{1}{4}\langle \hat{b} + \hat{b}^\dagger \rangle^2 \\ &= \tfrac{1}{4}\langle (\mu\hat{a} + \mu\hat{a}^\dagger + \nu\hat{c} + \nu\hat{c}^\dagger)^2 \rangle \\ &= \tfrac{1}{4}\mu^2 + \tfrac{1}{4}\nu^2 + \tfrac{1}{2}\mu^2\langle \hat{a}^\dagger\hat{a} \rangle + \tfrac{1}{2}\nu^2\langle \hat{c}^\dagger\hat{c} \rangle + \tfrac{1}{2}\mu\nu \left(\langle \hat{a}\hat{c} \rangle + \langle \hat{a}^\dagger\hat{c}^\dagger \rangle \right) \rangle \ . \end{aligned} \tag{37.193}$$

using $\langle \hat{a} \rangle = \langle \hat{c} \rangle = \langle \hat{a}^\dagger\hat{c} \rangle = 0$.

Two-mode squeezing can exist even if the individual modes are not squeezed,

$$|r, \phi\rangle = \cosh^{-1} r \sum\nolimits_n \tanh^n r e^{\imath n\phi} |r, \phi\rangle_a |r, \phi\rangle_b \ . \tag{37.194}$$

A *two-mode squeezed vacuum state* can be generated by the squeezing operator,

$$\boxed{\mathcal{S}(\xi) \equiv e^{\xi^* \hat{a}\hat{b}/2 - \xi\hat{a}^\dagger b^\dagger/2} \ .} \tag{37.195}$$

Remember that the single-mode squeezing is obtained if $\hat{a} = \hat{b}$. In a number state base,

$$|r, \phi\rangle = \frac{1}{\cosh r} \sum\nolimits_n (\tanh r)^n e^{\imath n\phi} |n\rangle_a |n\rangle_b \ . \tag{37.196}$$

Two-mode relative number squeezing parameter

$$\xi_{i,j} = \frac{\sigma^2(n_i - \langle n_j \rangle)}{\langle n_i \rangle + \langle n_j \rangle} \ . \tag{37.197}$$

37.5.8 Exercises

37.5.8.1 Ex: Conservation law at a beam splitter 1

Show that the beam-splitting transformation

$$\begin{pmatrix} \hat{c} \\ \hat{d} \end{pmatrix} = \begin{pmatrix} t & -r \\ r & t \end{pmatrix} \begin{pmatrix} \hat{a} \\ \hat{b} \end{pmatrix}$$

preserves the commutations relations and the photon number. More generally,

$$\begin{pmatrix} \hat{c} \\ \hat{d} \end{pmatrix} = \mathcal{U} \begin{pmatrix} \hat{a} \\ \hat{b} \end{pmatrix} \qquad \Longrightarrow \qquad [\hat{c}, \hat{d}] = [\hat{a}, \hat{b}] \det U \ .$$

37.5.8.2 Ex: Conservation law at a beam splitter 2

Derive from the Hamiltonian (37.127) that $\hat{a}^\dagger\hat{a} + \hat{b}^\dagger\hat{b} = const.$

37.5.8.3 Ex: Beam splitter

Show that $\hat{B}|1,0\rangle = \cos\theta|1,0\rangle - \sin\theta|0,1\rangle$ and $\hat{B}|0,n\rangle = \sum_{k=0}^{\infty}\sqrt{\binom{n}{k}}\cos^k\theta\sin^{n-k}\theta|n-k,k\rangle$.

37.5.8.4 Ex: Beam splitter

Show that for $\hat{B} \equiv e^{\theta(\hat{a}\hat{b}^\dagger - \hat{a}^\dagger\hat{b})}$ holds,

$$\hat{B}\hat{a}\hat{B}^\dagger = \hat{a}\cos\theta + \hat{b}\sin\theta \qquad \text{and} \qquad \hat{B}\hat{b}\hat{B}^\dagger = -\hat{a}\sin\theta + \hat{b}\cos\theta\ .$$

37.5.8.5 Ex: Homodyne detection of squeezing

Consider the beam bath shown in Fig. 37.8(b), where the Kerr medium is assumed to generate squeezing in the mode $\hat{a}_1$. Calculate the balanced homodyne signal $\hat{a}_3^\dagger\hat{a}_3 - \hat{b}_3^\dagger\hat{b}_3$.

37.5.8.6 Ex: Coupled harmonic oscillators with different eigenfrequencies and damping

Here, we generalize the calculation of Sec. 37.5.5 for coupling of oscillators with different eigenfrequencies.
a. From,

$$\hat{H} = \hbar\omega_a(\hat{a}^\dagger\hat{a} + \tfrac{1}{2}) + \hbar\omega_b(\hat{b}^\dagger\hat{b} + \tfrac{1}{2}) + \tfrac{\hbar\Omega}{2}(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b}) + \tfrac{\hbar\Omega'}{2}(\hat{a}\hat{b} + \hat{a}^\dagger\hat{b}^\dagger)$$

derive the Hamiltonian in terms of the quadrature components $\hat{x}_{a,b}$ and $\hat{p}_{a,b}$.
b. Set up the Heisenberg equations for the field operators $\hat{a}$, $\hat{a}^\dagger$, $\hat{b}$, and $\hat{b}^\dagger$ and determine the eigenvalues of the matrix $\mathcal{X}$ defined by,

$$\frac{d}{dt}\begin{pmatrix}\hat{a}\\ \hat{a}^\dagger\\ \hat{b}\\ \hat{b}^\dagger\end{pmatrix} = X\begin{pmatrix}\hat{a}\\ \hat{a}^\dagger\\ \hat{b}\\ \hat{b}^\dagger\end{pmatrix}\ .$$

c. Extend the Heisenberg equations by including loss terms for the cavity modes κ_a and κ_b and determine the corresponding matrix $\mathcal{X}_\kappa$, as well as its eigenvalues for the simplifying case $\Omega' \equiv \Omega$.

37.5.8.7 Ex: Equivalence of beam splitter and coupled oscillator models

Show that the beam splitter and the coupled oscillators model for degenerate frequencies are equivalent.

37.5.8.8 Ex: Elitzur and Vaidman bomb tester

a. Write down the beam splitter Hamiltonian in the Fock representation for a the case of a single photon, diagonalize it, and determine the propagator $e^{\imath \hat{H} t/\hbar}$ for a 50/50 beam splitter.
b. Based on the propagator derived in (a) draw an analogy between a Mach-Zehnder interferometer and a resonantly driven two-level system. Interpreting the interferometer as a qubit explain the *Elitzur and Vaidman bomb testing problem*. What is the probability?
c. Reformulate the interaction-free bomb tester in a quantum computing language.

37.5.8.9 Ex: Multiple beam splitters for improved bomb testing

In the original Elitzur and Vaidman bomb tester photons are sent through a single interferometer. Now, let the photons be sent repeatedly through the same beam splitter. Assume the photon wavepacket to be shorter than the length of the interferometer arms so that it *does not interfere with itself*. How many times must the photons be sent to the beam splitter to be totally transferred?

37.5.8.10 Ex: Hamiltonian approach to coupled cavities for improved bomb testing

a. Consider two identical weakly coupled cavities. Solving the Heisenberg equations with the Hamiltonian for two coupled oscillators calculate how the photon numbers evolve in each cavity (see Exc. 37.5.8.6). How do the field amplitudes change after one cavity round trip?
b. How does the photon number in cavity 'b' evolve if an absorber is inserted into the cavity 'a' [549]? How does the field amplitudes change in this case after one cavity round trip?
c. Now, we model the absorber by a two-level atom being in resonance with the light field and subject to spontaneous emission. Set up the Hamiltonian, derive the equations of motion, and solve them numerically. Interpret the results.
Comments: The multiple path model leading to the Airy formulas describes a physical process involving beam propagation and reflection and transmission at a real object like an atom or a beam splitter. The complete dynamics is only partially grasped by a Hamiltonian and a master equation treating the cavity as a closed system and being restricted to describing energy fluxes into and out of the system.
One manifestation of it is the necessity of approximating the Airy function close to resonance by a Lorentzian in order to link the cavity transmission to a decay rate.
Another manifestation is the discrepancy in the coupled cavity description via multiple paths and via Hamiltonian for coupled oscillators: The models only coincide of $r = \sqrt{R} \stackrel{!}{=} 1$.

37.5.8.11 Ex: Simulation of the quantum Zeno effect with qubit gates

Design a quantum circuit simulating the quantum Zeno effect ruling the bomb tester and its extension to multiple paths.

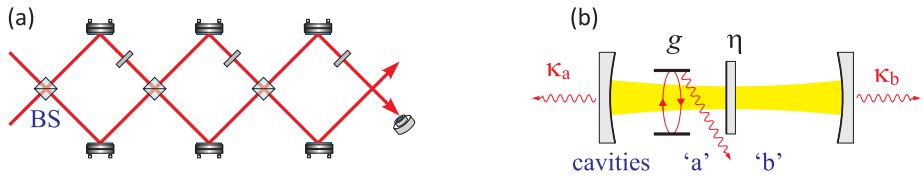

Figure 37.10: (a) Illustration of the multiple paths model and (b) the coupled cavities model for improved bomb testing.

37.5.8.12 Ex: Link between entanglement and squeezing

Prove that, if $\hat{a}_1$ and $\hat{a}_2$ are EPR-entangled beams with respect to quadrature components, then beams $\hat{b}_{1,2} = \frac{1}{\sqrt{2}}(\hat{a}_1 \pm \hat{a}_2)$ are squeezed with respect to two orthogonal quadrature components and vice versa [770, 771, 595].

Chapter 38

Optical cavities

So far we have considered the coherent dynamics between atoms and radiation fields in free space, and we extended the theory to take into account the dissipative coupling to the electromagnetic vacuum by spontaneous emission and atomic motion. The vacuum represents a homogeneous and isotropic reservoir characterized by a continuous white energy spectrum. The situation changes completely when we place the atom inside an optical cavity which breaks the translational and rotational symmetries and imprints a resonance structure into the density of photonic states. Obviously, the cavity will profoundly change the atomic coupling to the electromagnetic vacuum, and hence the way in which the atom reacts to incident light, as much with respect to light scattering as with respect to optical forces.

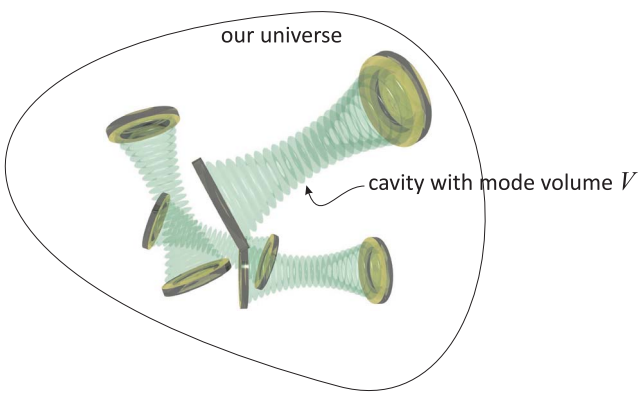

Figure 38.1: Illustration of the mode structure of empty space.

In this chapter we analyze the coupled dynamics of atoms interacting with the optical field modes of a cavity pumped by incident laser beams. We first concentrate in Sec. 38.2 on empty cavities. Later, in Chp. 45 we turn our attention to the impact of atoms on the cavity dynamics, in particular its transmission spectrum. Cooperative and collective effects that may be induced by cavities will be discussed in Chps. 47 and 48.

38.1 Open systems and the master equation

Let us now derive the master equation for an open quantum system. We assume that the environment (also called *bath* or *reservoir*) and the system under consideration are quantum systems in the sense that (1) the relevant degrees of freedom are completely characterized by state vectors (or density matrices), and (2) the temporal evolution of the total system is unitary $U(t) = e^{-\imath \hat{H} t}$. The total Hamiltonian, $\hat{H} = \hat{H}_{\rm sys} + \hat{H}_{\rm res} + V$ is assumed to be independent of time and consists of three parts, namely the Hamiltonian of the system $\hat{H}_{\rm sys}$, the Hamiltonian of the bath $\hat{H}_{\rm res}$, and the interaction V between the system and the bath. The purpose of the master equation is to find the dynamics of the system by tracing over all degrees of freedom of the bath. This is not always possible, and we will assume that the interaction V is sufficiently weak, so that perturbation theory is applicable.

38.1.1 Temporal evolution of the density operator

As shown in Secs. 23.6.2 to 23.6.4, the equations governing the temporal evolution of a quantum system depend on the choice of the picture, i.e. Schrödinger's (23.242), Heisenberg's (23.248), or the interaction picture (23.255). This, of course, also applies to a system represented by a density matrix.

Returning to the density operator definition (37.11), we can express its temporal dependence in terms of time-dependent quantum states and of the time evolution operator (23.245),

$$\hat{\rho}(t) = \sum_k p_k |\psi_k(t)\rangle\langle\psi_k(t)| = \sum_k p_k \mathcal{U}(t,t_0)|\psi_k(t_0)\rangle\langle\psi_k(t_0)|\mathcal{U}^\dagger(t,t_0) \ . \tag{38.1}$$

Writing,

$$\hat{\rho}(t_0) = \sum_k p_k |\psi_k(t_0)\rangle\langle\psi_k(t_0)| \ , \tag{38.2}$$

we see immediately,

$$\hat{\rho}(t) = \mathcal{U}(t,t_0)\hat{\rho}(t_0)\mathcal{U}^\dagger(t,t_0) \ , \tag{38.3}$$

where, for the common case of a time-independent Hamiltonian,

$$\mathcal{U}(t,t_0) = e^{-\imath \hat{H}(t-t_0)/\hbar} \ . \tag{38.4}$$

Now we find the time derivative of the density operator differentiating the two sides of (38.3) and substituting the Eqs.

$$\frac{d\mathcal{U}}{dt} = \frac{1}{\imath\hbar}\hat{H}\mathcal{U} \qquad \text{and} \qquad \frac{d\mathcal{U}^\dagger}{dt} = -\frac{1}{\imath\hbar}\mathcal{U}^\dagger\hat{H} \tag{38.5}$$

for the time derivatives $\mathcal{U}$ and $\mathcal{U}^\dagger$. The result is

$$\boxed{\frac{d\hat{\rho}(t)}{dt} = \frac{\imath}{\hbar}[\hat{\rho}(t), \hat{H}]} \ . \tag{38.6}$$

The commutator itself can be considered as a *superoperator* acting, not any more on states but on operators, that is, we can write,

$$\mathfrak{L}\hat{\rho}(t) \equiv \frac{\imath}{\hbar}[\hat{\rho}(t), \hat{H}] \ , \tag{38.7}$$

where $\mathfrak{L}$ is called *Liouville operator*. The equation (38.6) is called *Liouville equation* or *von Neumann equation*. The Liouville equation describes the *time evolution of the density operator* which, in turn, describes the distribution of an ensemble of quantum states. Even though the form of the Liouville equation resembles a Heisenberg equation, Eq. (38.1) shows that $\hat{\rho}(t)$ is in the *Schrödinger picture* [1].

In the interaction representation the evolution of the total density matrix $\hat{\rho}_{\rm tot}$ becomes,

$$\boxed{\imath\hbar\frac{d\tilde{\rho}_{\rm tot}}{dt} = [\tilde{V}(t), \tilde{\rho}_{\rm tot}]} \ . \tag{38.8}$$

where $\tilde{\rho}_{\rm tot}(t) \equiv U_0^\dagger \rho_{\rm tot} U_0$ and $\tilde{V}(t) \equiv U_0^\dagger V U_0$ and $U_0 = e^{-\imath(\hat{H}_{\rm sys}+\hat{H}_{\rm res})t/\hbar}$. This evolution is, for the time being, very general, and the solution can be formally written,

$$\tilde{\rho}_{\rm tot}(t) = \tilde{\rho}_{\rm tot}(0) + \frac{1}{\imath\hbar}\int_0^t dt_1[\tilde{V}(t_1), \tilde{\rho}_{\rm tot}(t_1)] \ . \tag{38.9}$$

Iterating once again:

$$\tilde{\rho}_{\rm tot}(t) = \tilde{\rho}_{\rm tot}(0)+\frac{1}{\imath\hbar}\int_0^t dt_1[\tilde{V}(t_1), \tilde{\rho}_{\rm tot}(0)]+\frac{1}{(\imath\hbar)^2}\int_0^t dt_1\int_0^{t_1} dt_2\left[\tilde{V}(t_1), [\tilde{V}(t_2), \tilde{\rho}_{\rm tot}(t_2]\right] \ . \tag{38.10}$$

In the following, we will call several approximations to simplify the calculations, in particular, the Born approximation, the assumption that the initial state is a product state and, later-on, the Markov approximation.

38.1.2 Born approximation for weak coupling

We will now assume the interaction $\tilde{V}$ to be weak. We can then expect that, repeating the iterative process, the series will converge and write the general solution as,

$$\tilde{\rho}_{\rm tot}(t) = \tilde{\rho}_{\rm tot}(0) + \sum_{n\geq 1}\frac{1}{(\imath\hbar)^n}\int_0^t dt_1 ... \int_0^{t_{n-1}} dt_n\left[\tilde{V}(t_1), ..., [\tilde{V}(t_n), \tilde{\rho}_{\rm tot}(0)]\right] \ . \tag{38.11}$$

This way of terminating an iterative equation by $\rho_{\rm tot}(0)$ is generally known as the *Born approximation*. Here, we will just go to second order in $\tilde{V}$. Tracing over the bath,

$$\tilde{\rho}_{\rm sys}(t) = {\rm Tr}_{\rm res}\ \tilde{\rho}_{\rm tot}(t) \ , \tag{38.12}$$

we extract the density matrix for only the system,

$$\begin{aligned}\tilde{\rho}_{\rm sys}(t) = \tilde{\rho}_{\rm sys}(0) &+ \frac{1}{\imath\hbar}\int_0^t dt_1 {\rm Tr}_{\rm res}[\tilde{V}(t_1), \tilde{\rho}_{\rm tot}(0)] \\ &+ \frac{1}{(\imath\hbar)^2}\int_0^t dt_1\int_0^{t_1} dt_2 {\rm Tr}_{\rm res}\left[\tilde{V}(t_1), [\tilde{V}(t_2), \tilde{\rho}_{\rm tot}(0)]\right] \ .\end{aligned} \tag{38.13}$$

[1] The Heisenberg equation for the density operator in the Schrödinger picture or the master equation in the Heisenberg picture are $d\hat{\rho}_H/dt = 0$.

38.1.3 Assumption of an initial product state

Next, we need to make the quite important assumption, that the initial state between the system and the environment are not correlated, or mathematically speaking, they can be written as product states,

$$\tilde{\rho}_{\rm tot}(0) = \tilde{\rho}_{\rm sys}(0) \otimes \rho_{\rm res}(0) \ . \tag{38.14}$$

Another assumption, which is not essential but often valid, is that $\mathrm{Tr}_{\rm res}[\tilde{V}(t_1), \tilde{\rho}_{\rm tot}(0)] = 0$. If this is the case, then the first-order term will vanish. In second order, we can write,

$$\begin{aligned} \tilde{\rho}_{\rm sys}(t) &= e^{\mathcal{M}(t)} \tilde{\rho}_{\rm sys}(0) \\ \text{where} \quad \mathcal{M}(t)\chi &\equiv \frac{1}{(i\hbar)^2} \int_0^t dt_1 \int_0^{t_1} dt_2 \mathrm{Tr}_{\rm res} \left[\tilde{V}(t_1), [\tilde{V}(t_2), \chi \otimes \rho_{\rm res}] \right] \ , \end{aligned} \tag{38.15}$$

is a *superoperator* acting on the operator density of the system. Taking the temporal derivative, we have the explicit master equation,

$$\boxed{\begin{aligned} \frac{d\tilde{\rho}_{\rm sys}(t)}{dt} = \mathcal{L}\rho_{\rm sys}(t) &= \frac{d}{dt}\left(\mathcal{M}(t)\tilde{\rho}_{\rm sys}(t)\right) \\ &= \frac{1}{(\imath\hbar)^2} \int_0^t d\tau \ \mathrm{Tr}_{\rm res} \left[\tilde{V}(t), [\tilde{V}(\tau), \tilde{\rho}_{\rm sys}(t) \otimes \rho_{\rm res}] \right] \end{aligned}} \ . \tag{38.16}$$

The superoperator $\mathcal{L}$ is called *Lindblad operator*.

38.1.4 Markov approximation for short memory

Here, we have to evaluate the terms involving the average with respect to the thermal bath, which is assumed to have a short memory, in the sense that the correlation time is very short. Mathematically,

$$\begin{aligned} \int_0^t d\tau \ \mathrm{Tr}_{\rm res} \left(\tilde{V}(t)\tilde{V}(\tau)\rho_{\rm res} \right) &= \int_0^t d\tau \ \mathrm{Tr}_{\rm res} \left(\tilde{V}(t-\tau)\tilde{V}(0)\rho_{\rm res} \right) \\ &\simeq \int_0^\infty d\tau \ \mathrm{Tr}_{\rm res} \left(\tilde{V}(t-\tau)\tilde{V}(0)\rho_{\rm res} \right) \ . \end{aligned} \tag{38.17}$$

In other words, the two-point correlation function is significant only, when $t \simeq \tau$, and it is valid to extend the upper bound to infinity. This is the *Markov approximation*.

38.1.5 Example: Damped harmonic quantum oscillator

As an example, we let us consider the master equation for the *Brownian motion of a quantum harmonic oscillator*. It can be written,

$$\frac{d\tilde{\rho}_{\rm sys}}{dt} = \frac{1}{(\imath\hbar)^2} \int_0^t d\tau \ \mathrm{Tr}_{\rm res} \left\{ \begin{array}{c} \tilde{V}(t)\tilde{V}(\tau)\tilde{\rho}(t) \otimes \rho_{\rm res} - \tilde{V}(t)\tilde{\rho}_{\rm sys}(t) \otimes \rho_{\rm res}\tilde{V}(\tau) \\ -\tilde{V}(\tau)\tilde{\rho}_{\rm sys}(t) \otimes \rho_{\rm res}\tilde{V}(t) + \tilde{\rho}_{\rm sys}(t) \otimes \rho_{\rm res}\tilde{V}(\tau)\tilde{V}(t) \end{array} \right\} \ . \tag{38.18}$$

The coupling of the system to the bath is assumed to be of the form,

$$\tilde{V} = \hbar \left(\hat{a}^\dagger \hat{\Gamma}(t) e^{\imath \Omega t} + \hat{a} \hat{\Gamma}^\dagger(t) e^{-\imath \Omega t} \right) \ , \tag{38.19}$$

where $\hat{\Gamma}(t) = \sum_k g_k \hat{b}_k e^{-\imath \omega_k t}$, the bosonic operators $\hat{a}$ and $\hat{b}_k$ act, respectively, on the system (with the frequency Ω) and the bath (with the frequency ω_k). Here, g_k characterizes the coupling force between the oscillators of the system and the bath. Hence,

$$\frac{d\tilde{\rho}_{\rm sys}}{dt} = -\int_0^t d\tau \, {\rm Tr}_{\rm res} \left\{ \begin{array}{l} \left(\hat{a}^\dagger \hat{\Gamma}(t) e^{\imath \Omega t} + \hat{a} \hat{\Gamma}^\dagger(t) e^{-\imath \Omega t} \right) \left(\hat{a}^\dagger \hat{\Gamma}(\tau) e^{\imath \Omega \tau} + \hat{a} \hat{\Gamma}^\dagger(\tau) e^{-\imath \Omega \tau} \right) \tilde{\rho}(t) \otimes \rho_{\rm res} \\ - \left(\hat{a}^\dagger \hat{\Gamma}(t) e^{\imath \Omega t} + \hat{a} \hat{\Gamma}^\dagger(t) e^{-\imath \Omega t} \right) \tilde{\rho}(t) \otimes \rho_{\rm res} \left(\hat{a}^\dagger \hat{\Gamma}(\tau) e^{\imath \Omega \tau} + \hat{a} \hat{\Gamma}^\dagger(\tau) e^{-\imath \Omega \tau} \right) \\ - \left(\hat{a}^\dagger \hat{\Gamma}(\tau) e^{\imath \Omega \tau} + a \hat{\Gamma}^\dagger(\tau) e^{-\imath \Omega \tau} \right) \tilde{\rho}(t) \otimes \rho_{\rm res} \left(\hat{a}^\dagger \hat{\Gamma}(t) e^{\imath \Omega t} + a \hat{\Gamma}^\dagger(t) e^{-\imath \Omega t} \right) \\ + \tilde{\rho}(t) \otimes \rho_{\rm res} \left(\hat{a}^\dagger \hat{\Gamma}(\tau) e^{\imath \Omega \tau} + \hat{a} \hat{\Gamma}^\dagger(\tau) e^{-\imath \Omega \tau} \right) \left(\hat{a}^\dagger \hat{\Gamma}(t) e^{\imath \Omega t} + \hat{a} \hat{\Gamma}^\dagger(t) e^{-\imath \Omega t} \right) \end{array} \right\} . \tag{38.20}$$

Let's take a closer look at one of the terms,

$$\begin{aligned} \hat{T} &\equiv -\int_0^t d\tau {\rm Tr}_{\rm res} \left\{ \hat{a}^\dagger \hat{\Gamma}(t) e^{\imath \Omega t} \hat{a} \hat{\Gamma}^\dagger(\tau) e^{-\imath \Omega \tau} \tilde{\rho}(t) \otimes \rho_{\rm res} \right\} \\ &= -\hat{a}^\dagger \hat{a} \tilde{\rho}(t) \int_0^t d\tau \langle \hat{\Gamma}(t) \hat{\Gamma}^\dagger(\tau) \rangle_{\rm res} e^{\imath \Omega t} e^{-\imath \Omega \tau} \ . \end{aligned} \tag{38.21}$$

We will have to evaluate quantities such as

$$ {\rm Tr}_{\rm res} \left(V(t) V(s) \rho_{\rm res} \right) = \hbar^2 \hat{a}^\dagger \hat{a} \langle \hat{\Gamma}(t) \hat{\Gamma}^\dagger(t) \rangle_{\rm res} e^{\imath \Omega (t-s)} + \hbar^2 \hat{a} \hat{a}^\dagger \langle \hat{\Gamma}^\dagger(t) \hat{\Gamma}(t) \rangle_{\rm res} e^{-\imath \Omega (t-s)} \ , \tag{38.22}$$

where $\langle \hat{\Gamma}(t) \hat{\Gamma}^\dagger(t) \rangle_{\rm res} \equiv {\rm Tr}_{\rm res} [\hat{\Gamma}(t) \hat{\Gamma}^\dagger(t) \rho_{\rm res}]$, and for the thermal bath, $\langle \hat{b}_j^\dagger \hat{b}_k \rangle = \delta_{jk} n_k$ and $\langle \hat{b}_j \hat{b}_k^\dagger \rangle = \delta_{jk}(1+n_k)$ and $n_k = (e^{\beta \hbar \omega_k} - 1)^{-1}$. Hence,

$$\begin{aligned} \hat{T} &= -\hat{a}^\dagger \hat{a} \tilde{\rho}(t) \sum_{j,k} g_j g_k \langle b_j b_k^\dagger \rangle_{\rm res} \int_0^t d\tau e^{\imath (\omega_j t - \omega_k \tau)} e^{\imath \Omega (t-\tau)} \\ &\simeq -\hat{a}^\dagger \hat{a} \tilde{\rho}(t) \sum_k g_k^2 n_k \int_0^\infty d\tau e^{\imath (\omega_k - \Omega)(t-\tau)} \ . \end{aligned} \tag{38.23}$$

Then we will have to use the relationship,

$$\int_0^\infty d\tau e^{\pm \imath \varepsilon \tau} = \pi \delta(\varepsilon) \pm \imath PV \ , \tag{38.24}$$

where PV denotes Cauchy part of the principal value. These correspond to a 'Lamb shift' and a 'Stark shift' of the frequency, which are considered to be small in comparison to Ω and should be neglected here,

$$\begin{aligned} \hat{T} &= -\hat{a}^\dagger \hat{a} \tilde{\rho}(t) \sum_k g_k^2 \left(e^{\beta \hbar \omega_k} - 1 \right)^{-1} \int_0^\infty d\tau e^{\imath (\omega_k - \Omega)(t-\tau)} \\ &= -\hat{a}^\dagger \hat{a} \tilde{\rho}(t) \sum_k g_k^2 \left(e^{\beta \hbar \omega_k} - 1 \right)^{-1} \pi \delta(\omega_k - \Omega) \\ &= -\hat{a}^\dagger \hat{a} \tilde{\rho}(t) \sum_k g_k^2 \left(e^{\beta \hbar \Omega} - 1 \right)^{-1} \pi = -\pi \bar{n} \hat{a}^\dagger \hat{a} \tilde{\rho}(t) \sum_k g_k^2 \delta(\omega_k - \Omega) = \bar{n} \hat{a} \hat{a}^\dagger \tilde{\rho}(t) \pi \frac{\gamma}{2} \ . \end{aligned} \tag{38.25}$$

where $\bar{n} \equiv \left(e^{\beta\hbar\Omega} - 1\right)^{-1}$. We define $\frac{\gamma}{2} \equiv \sum_k g_k^2 \delta(\omega_k - \Omega)$. The procedure can be repeated for all terms in the master equation. We then obtain the master equation for a damped harmonic oscillator,

$$\frac{d\tilde{\rho}}{dt} = \tfrac{\gamma}{2}(\bar{n}+1)\left(2\hat{a}\tilde{\rho}\hat{a}^\dagger - \hat{a}^\dagger\hat{a}\tilde{\rho} - \tilde{\rho}\hat{a}^\dagger\hat{a}\right) - \tfrac{\gamma}{2}\bar{n}\left(2\hat{a}^\dagger\tilde{\rho}\hat{a} - \hat{a}\hat{a}^\dagger\tilde{\rho} - \tilde{\rho}\hat{a}\hat{a}^\dagger\right) \ . \tag{38.26}$$

See Excs. 38.1.7.1 and 38.1.7.2.

38.1.6 Deriving the Heisenberg-Langevin from the master equation

The Heisenberg-Langevin equation for the operators $\hat{A}$ of a system subject to dissipation with rates γ_k via the degrees of freedom $\hat{L}_k$ and the *master equation* for the density operator $\hat{\rho}$ are equivalent descriptions for the time-evolution of a system,

$$\boxed{\begin{array}{rclcl} \frac{d\hat{\rho}}{dt} & = & \mathcal{L}\hat{\rho} & = & -\frac{\imath}{\hbar}[\hat{H},\hat{\rho}] + \sum_k \gamma_k \left(\hat{L}_k\hat{\rho}\hat{L}_k^\dagger - \frac{1}{2}\hat{L}_k^\dagger\hat{L}_k\hat{\rho} - \frac{1}{2}\hat{\rho}\hat{L}_k^\dagger\hat{L}_k\right) \\ \frac{d\hat{A}}{dt} & = & \mathcal{L}^\dagger\hat{A} & = & \frac{\imath}{\hbar}[\hat{H},\hat{A}] + \sum_k \gamma_k \left(\hat{L}_k^\dagger\hat{A}\hat{L}_k - \frac{1}{2}\hat{L}_k^\dagger\hat{L}_k\hat{A} - \frac{1}{2}\hat{A}\hat{L}_k^\dagger\hat{L}_k\right) \end{array}} \ , \tag{38.27}$$

as we will show in Exc. 38.1.7.3. The former stresses the Schrödinger picture and the latter the Heisenberg picture. In particular, the dissipative *Lindblad terms* are equivalent. That is, open systems are sufficiently characterized by the system Hamiltonian $\hat{H}$ and a set of the so-called *jump operators* $\hat{L}_k$ with their corresponding rates γ_k.

38.1.7 Exercises

38.1.7.1 Ex: Master equation for cavities

Consider a cavity laser-pumped at a rate η, subject to losses by transmission through the mirrors at a rate κ, and incoherently pumped by thermal photons at a rate $\kappa\bar{n}$, where $\bar{n}$ is the number of thermal photons.
a. Write down the Hamiltonian and the Heisenberg-Liouville equation for an arbitrary operator $\hat{a}$ of the system.
b. Derive the equation of motion for the field annihilation operator $\hat{a}$ and for the photon number operator $\hat{n}$.
c. Solve the equation of motion for the photon number operator for the case of no coherent pumping, $\eta = 0$.
d. Write down the master equation of the system.
e. Derive the equation of motion for the components of the density operator $\rho_{m,n}$.
f. Calculate the photon number evolution from (e).

38.1.7.2 Ex: Photon number distribution in a driven cavity

Simulate the evolution of a light field in a cavity pumped at a rate η and subject to decay κ being initially in a Fock state toward steady-state. Illustrate via representations of the density matrix, the photon number distribution, and the Husimi distribution for the light field

38.1.7.3 Ex: Deriving the Heisenberg-Langevin from the master equation

Derive the Heisenberg-Langevin from the master equation including the dissipative Lindblad terms.

38.2 Dynamics of light fields in empty cavities

The quantization of the electromagnetic field has been introduced in Chp. 40. Nevertheless, we will consider the degree of freedom to be studied in this chapter, that is, the electric field amplitude of a light field developing in a mode of an optical cavity, as a classical entity. Therefore, there is no need to stress quantum mechanics to derive the fundamental equations of motion, and a classical derivation is shown in Sec. 45.1.5. Nevertheless, for reasons of consistency with later discussions, where quantization is required, we will reproduce here the standard procedure, which consists in constructing the Hamiltonian for the relevant degrees of freedom. The degree of freedom under study being a mode of a cavity, we will label it by the field operator $\hat{a}$ normalized to the electric field strength $\vec{\mathcal{E}}_1$ generated by a single photon, such that $|\langle\hat{a}\rangle|^2 = n$ represents the number of photons in the cavity.

In this first section of this chapter we will only consider a bare cavity not containing any matter which could interact with light. The mode of a linear cavity or the two counterpropagating modes of a ring cavity are pumped by incident laser light. We will first set up the equations of motion for the cavity fields and then discuss the main quantities characterizing a cavity, such as free spectral range, mode volume, decay rate, and single-photon field strength. Finally, we will calculate the density of states of cavities.

38.2.1 Master equation

The Hamiltonian of a laser-pumped linear cavity mode $\hat{a}$ coupled to the continuum of a heat bath represented by operators $\hat{a}_\omega$ is ($\hbar = 1$) (see Sec. 38.1.5 and Exc. 38.1.7.1),

$$\boxed{\begin{aligned}
\hat{H} &= \hat{H}_{\text{cavity}} + \hat{H}_{\text{bath}} + \hat{H}_{\text{cavity:bath}} + \hat{H}_{\text{laser:cavity}} \\
\hat{H}_{\text{cavity}} &= \omega_0 \hat{a}^\dagger \hat{a} \\
\hat{H}_{\text{bath}} &= \sum_\omega \omega \hat{a}^\dagger_\omega \hat{a}_\omega \\
\hat{H}_{\text{cavity:bath}} &= \sum_\omega g_{\text{cavity:bath}} \hat{a}^\dagger_\omega \hat{a} + h.c. \\
\hat{H}_{\text{laser:cavity}} &= \imath\eta \hat{a}^\dagger + h.c.
\end{aligned}} \quad , \tag{38.28}$$

with $[\hat{a}_\omega, \hat{a}^\dagger_{\omega'}] = \delta_{\omega,\omega'}$. The part of the Hamiltonian $\hat{H}_{\text{laser:cavity}}$ describes pumping of the cavity with an external light field matched to the cavity mode. The standard procedure consists in setting up the quantum Liouville equation for the total density operator $\hat{\rho}_{\text{total}} = \hat{\rho}_{\text{cavity}} \otimes \hat{\rho}_{\text{bath}}$ and tracing the over the bath's degrees of freedom [340, 190]. From this procedure, as shown in Sec. 38.1.5, we derive a master equation for the reduced density operator $\hat{\rho}_{\text{cavity}}$.

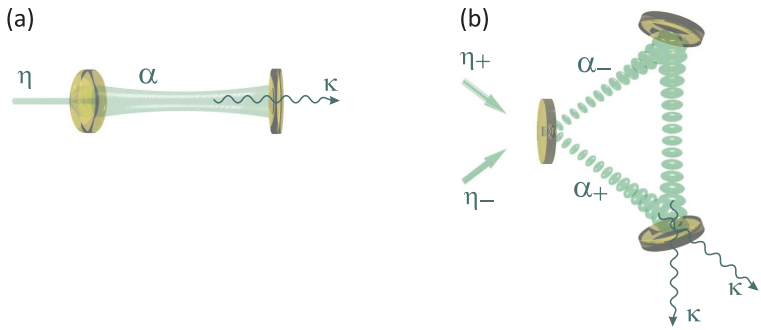

Figure 38.2: Scheme of (a) a linear cavity and (b) a ring cavity with optical modes $\alpha_\pm$ pumped by incident light fields $\eta_\pm$ and decaying into the void with rate κ.

The inevitable coupling of the cavity to the environment, described by $\hat{H}_{\text{cavity:bath}}$, leads to irreversible losses. These losses can be described as spontaneous decay to the continuous vacuum heat bath. The irreversibility of the process is readily understood in terms of the phase space offered by the vacuum being much larger. In fact, whenever discrete states are coupled to a continuum, the equilibrium is very much on the side of the continuum, that is, *discrete states decay.* Since an optical cavity can be considered a *temperature reservoir* T, where,

$$\bar{n} = \frac{1}{1 - e^{-\hbar\omega/k_B T)}} \ , \tag{38.29}$$

is the mean thermal photon number, the *Lindblad operator* is,

$$\begin{aligned}\mathfrak{L}_{\text{bath}}\hat{\rho} = \tfrac{\kappa}{2}(\bar{n}+1)(2\hat{a}\hat{\rho}\hat{a}^\dagger - \hat{a}^\dagger\hat{a}\hat{\rho} - \hat{\rho}\hat{a}^\dagger\hat{a}) + \tfrac{\kappa}{2}\bar{n}(2\hat{a}^\dagger\hat{\rho}\hat{a} - \hat{a}\hat{a}^\dagger\hat{\rho} - \hat{\rho}\hat{a}\hat{a}^\dagger) \\ + \beta(2\bar{n}+1)(2\hat{a}^\dagger\hat{a}\hat{\rho}\hat{a}^\dagger\hat{a} - (\hat{a}^\dagger\hat{a})^2\hat{\rho} - \hat{\rho}(\hat{a}^\dagger\hat{a})^2) \ .\end{aligned} \tag{38.30}$$

We have shown this in Exc. 38.1.7.1. The constants are the *cavity decay rate* κ and the pump rate β. Note that at room temperature in the microwave regime, $\bar{n}$ may be as large as a few hundred photons, whereas in the optical regime we may neglect the thermal excitation,

$$\boxed{\begin{aligned}\dot{\hat{\rho}} &= -\tfrac{\imath}{\hbar}[\hat{H},\hat{\rho}] + \mathfrak{L}_{\text{cavity}} \\ \mathfrak{L}_{\text{cavity}}\hat{\rho}(t) &= -\kappa\{\hat{a}^\dagger\hat{a}\hat{\rho}(t) - 2\hat{a}\rho(t)\hat{a}^\dagger + \hat{\rho}(t)\hat{a}^\dagger\hat{a}\}\end{aligned}} \ . \tag{38.31}$$

The expectation values are given by a *quantum Langevin equation* [190], which in the mean field approximation (neglecting quantum noise)reduces to,

$$\boxed{\dot{\alpha} = \langle\dot{\hat{a}}\rangle = \frac{\imath}{\hbar}\langle[\hat{H},\hat{a}]\rangle - \kappa\langle\hat{a}\rangle = (-\kappa - \imath\Delta_c)\alpha + \eta} \ , \tag{38.32}$$

whose solution is easy to derive,

$$\boxed{\alpha(t) = \left(\alpha(0) - \frac{\eta}{\kappa + \imath\Delta_c}\right) e^{(-\kappa-\imath\Delta_c)t} + \frac{\eta}{\kappa + \imath\Delta_c}} \ , \tag{38.33}$$

or, using the electric field normalized to the amplitude of the field generated by a single photon, $\vec{\mathcal{E}}^{+}_{\rm cav} = \vec{\mathcal{E}}_1 \alpha$,

$$\begin{aligned}\vec{\mathcal{E}}_{\rm cav}(z,t) &= \mathfrak{Re}\left[\vec{\mathcal{E}}_1 e^{\imath(kz-\omega t)}\alpha(t) + \vec{\mathcal{E}}_1 e^{\imath(-kz-\omega t)}\alpha(t)\right] \\ &= 2\vec{\mathcal{E}}_1 \cos kz \mathfrak{Re}\left[e^{-\imath\omega t}\alpha(t)\right] \\ &= 2\vec{\mathcal{E}}_1 \cos kz \mathfrak{Re}\left[\left(\alpha(0) - \frac{\eta}{\kappa+\imath\Delta_{\rm c}}\right) e^{(-\kappa-\imath\omega_c)t} + \frac{\eta}{\kappa+\imath\Delta_{\rm c}} e^{-\imath\omega t}\right] .\end{aligned} \tag{38.34}$$

The stationary solution is simply a Lorentzian,

$$|\alpha(\infty)|^2 = \frac{|\eta|^2}{\kappa^2+\Delta_{\rm c}^2} , \tag{38.35}$$

which represents an approximation of the Airy function(15.253).

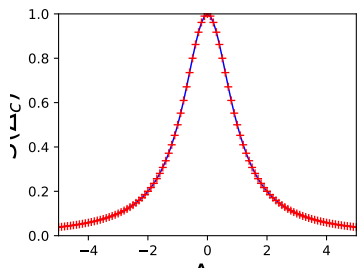

Figure 38.3: (code) Transmission spectrum of a cavity via numerical solution of the master equation (38.33) (solid line) and via the stationary solution (38.35) (crosses).

The result (38.34) shows that, letting $\eta = 0$, we see that the cavity field decays with the time constant κ from the stationary situation. κ also corresponds to the HWHM of the *field intensity*, $|\alpha(|\Delta_{\rm c}| = \kappa)|^2 = \frac{1}{2}|\alpha(0)|^2$. Note, that the intensity decays as 2κ, and the HWHM of the *field amplitude* is $\left|\alpha(|\Delta_{\rm c}| = \sqrt{3}\kappa)\right| = \frac{1}{2}|\alpha(0)|$.

Example 268 (*Evolution of the modes of a linear cavity*): (38.34) also shows that a cavity initially filled with a strong resonant light field $|\alpha(0)| \gg \eta/\kappa$ begins to oscillate at its own frequency ω_c, before the pump dominates and imposes its own frequency ω. This is illustrated in Fig. 38.4. .

Frequently, we are interested in the light reflected from a cavity. The reflective response of the cavity to an incident pump beam $\vec{\mathcal{E}}_{\rm in}$ is,

$$\vec{\mathcal{E}}^{+}_{\rm refl} = r_{\rm in}\vec{\mathcal{E}}^{+}_{\rm in} + t_{\rm in}\vec{\mathcal{E}}^{+}_{\rm cav} . \tag{38.36}$$

Also we may want to consider a temporal variation of the input field, for example of its detuning, $\Delta_{\rm c}(t)$. In such cases, the equation (38.32) can not be integrated easily, and we need to resort to numerical methods. The simplest (and least convergent) method in a Newtonian iteration like,

$$\vec{\mathcal{E}}^{+}_{\rm refl}(t+dt) = \vec{\mathcal{E}}^{+}_{\rm refl}(t) + dt\ t_{\rm in}\left[(-\kappa-\imath\Delta_{\rm c}(t))\vec{\mathcal{E}}^{+}_{\rm cav}(t) + \eta\vec{\mathcal{E}}^{+}_{\rm in}(t)\right] . \tag{38.37}$$

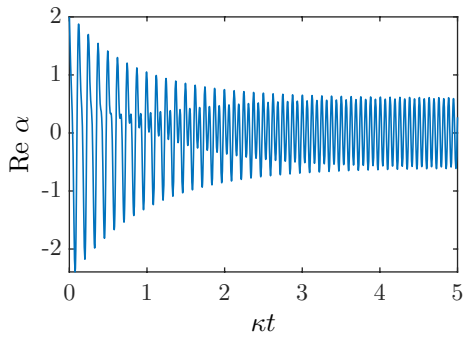

Figure 38.4: (code) Transient oscillations in a cavity pumped out of resonance.

We will study in Exc. 38.2.4.1 how a sudden change of the pump laser detuning may lead to *ringing* with a fixed frequency Δ_c. In Excs. 38.2.4.2 and 38.2.4.3 we will show, how it is possible to empty an optical cavity in times shorter than $1/\kappa$.

38.2.2 Mean field dynamics of an empty ring cavity

Linear cavities are characterized by the fact that they sustain standing light waves. That is, at every point of the mode volume, there are field components pointing into two counterpropagating orientations. In case of a ring cavity, we have two counterpropagating modes $\alpha_\pm$, which may be independently pumped by laser beams $\eta\pm$. Hence, the quantum Langevin equation (38.32) must be generalized to,

$$\boxed{\dot{\alpha}_\pm(t) = (-\kappa - \imath\Delta_c)\alpha_\pm + \eta_\pm} \,, \tag{38.38}$$

and the general solution (38.33) to,

$$\boxed{\alpha_\pm(t) = \left(\alpha_\pm(0) - \frac{\eta_\pm}{\kappa + \imath\Delta_c}\right) e^{(-\kappa-\imath\Delta_c)t} + \frac{\eta_\pm}{\kappa + \imath\Delta_c}} \,. \tag{38.39}$$

The two counterpropagating field modes will, provided they have the same polarization, interfere and form a standing light wave. In contrast to linear cavities, the phase of this standing wave is represents a degree of freedom, as it depends on the phases of the two field modes $\alpha_\pm$, which in turn can be controlled by the incident laser fields $\eta_\pm$. To better understand the behavior of the phase as a function of the pump beams, we analyze the interference of the two modes, which is described by,

$$\begin{aligned}\alpha_+\alpha_-^* = &\left(\alpha_+(0)\alpha_-^*(0) - \frac{\eta_-^*\alpha_+(0)}{\kappa - \imath\Delta_c} - \frac{\eta_+\alpha_-^*(0)}{\kappa + \imath\Delta_c} + \frac{\eta_+\eta_-^*}{\kappa^2 + \Delta_c^2}\right) e^{-2\kappa t} + \frac{\eta_+\eta_-^*}{\kappa^2 + \Delta_c^2} + \\ &+ \left(\alpha_+(0)\frac{\eta_-^*}{\kappa - \imath\Delta_c} - \frac{\eta_+\eta_-^*}{\kappa^2 + \Delta_c^2}\right) e^{(-\kappa-\imath\Delta_c)t} + \left(\alpha_-^*(0)\frac{\eta_+}{\kappa + \imath\Delta_c} - \frac{\eta_+\eta_-^*}{\kappa^2 + \Delta_c^2}\right) e^{(-\kappa+\imath\Delta_c)t} \,.\end{aligned} \tag{38.40}$$

To simplify this expression, we assume a symmetric pump, $\eta_\pm = \eta e^{\pm\imath\phi}$. We are interested in the reaction of the field's phase to a sudden change of ϕ. Now, we define

the initial stationary conditions for $\phi = 0$ to be $\alpha_\pm(0) = \frac{\eta}{\kappa + \imath\Delta_c}$ and obtain,

$$\boxed{\alpha_+\alpha_-^* = \frac{\eta^2}{\kappa^2 + \Delta_c^2}\left[(1-e^{\imath\phi})^2 e^{-2\kappa t} + e^{2\imath\phi} + 2e^{\imath\phi}(1-e^{\imath\phi})e^{-\kappa t}\cos\Delta_c t\right]} \ . \tag{38.41}$$

In resonance, $\Delta_c = 0$, the expression (38.41) simplifies to,

$$\alpha_+\alpha_-^* = \frac{\eta^2}{\kappa^2}\left[(1-e^{-\kappa t})e^{\imath\phi} + e^{-\kappa t}\right]^2 \ . \tag{38.42}$$

This results shows that the cavity phase adjusts itself to the pump field in exponential time κ^{-1}:

$$\tan\theta = \frac{\mathfrak{Im}\,\alpha_+\alpha_-^*}{\mathfrak{Re}\,\alpha_+\alpha_-^*} = \frac{(1-e^{-\kappa t})^2\sin 2\phi + 2(1-e^{-\kappa t})e^{-\kappa t}\sin\phi}{(1-e^{-\kappa t})^2\cos 2\phi + 2(1-e^{-\kappa t})e^{-\kappa t}\cos\phi + e^{-2\kappa t}} \ . \tag{38.43}$$

For small phase slips $\phi \ll \pi$, this reduces to,

$$\theta = 2\phi(1-e^{-\kappa t}) \quad , \quad \dot\theta \simeq \kappa(2\phi - \theta) \quad , \quad \ddot\theta \simeq -\kappa\dot\theta \ . \tag{38.44}$$

Hence, the pump represents a friction force for the phase.

Out of resonance but with negligible decay, $\kappa \simeq 0$, the expression (38.41) simplifies to,

$$\alpha_+\alpha_-^* = \frac{\eta^2}{\Delta_c^2}\left[1 + 2(e^{2\imath\phi} - e^{\imath\phi})(1-\cos\Delta_c t)\right] + \ , \tag{38.45}$$

such that,

$$\tan\theta = \frac{2(\sin 2\phi - \sin\phi)(1-\cos\Delta_c t)}{1 + 2(\cos 2\phi - \cos\phi)(1-\cos\Delta_c t)} \ , \tag{38.46}$$

which, for very small angles ϕ, reduces to,

$$\theta \simeq 4\phi\sin^2\frac{1}{2}\Delta_c t \ . \tag{38.47}$$

38.2.2.1 Transfer function of a ring cavity

Cavities have a finite response time to frequency or amplitude fluctuations of the pump light. To study this, we assume the light pumping a ring cavity to be subject to a phase modulation with frequency Ω and amplitude ϕ_0, that is, the quantum Langevin equation (38.32) is,

$$\boxed{(\partial_t + \kappa + \imath\Delta_c)\alpha_\pm = \eta e^{\pm\imath\phi_0\sin\Omega t}} \ , \tag{38.48}$$

and has the solution,

$$\alpha_\pm(t) = e^{(-\kappa-\imath\Delta_c)t}\left(\alpha_\pm(0) + \eta\int_0^T e^{(\kappa+\imath\Delta_c)\tau \pm \imath\phi_0\sin\Omega\tau}d\tau\right) \ . \tag{38.49}$$

For small amplitude oscillations, we can expand the pump term into a Fourier series of Bessel functions,

$$\begin{aligned}
\alpha_\pm(t) &= e^{(-\kappa-\imath\Delta_c)t}\left(\alpha_\pm(0)+\eta\int_0^T\left(e^{(\kappa+\imath\Delta_c)\tau}\pm\tfrac{\phi_0}{2}e^{(\kappa+\imath\Delta_c)\tau+\imath\Omega\tau}\mp\tfrac{\phi_0}{2}e^{(\kappa+\imath\Delta_c)\tau-\imath\Omega\tau}\right)d\tau\right)\\
&= e^{(-\kappa-\imath\Delta_c)t}\alpha_\pm(0)+\eta\frac{1-e^{(-\kappa-\imath\Delta_c)t}}{\kappa+\imath\Delta_c}\pm\tfrac{\phi_0}{2}\frac{e^{\imath\Omega t}-e^{(-\kappa-\imath\Delta_c)t}}{\kappa+\imath\Delta_c+\imath\Omega}\mp\tfrac{\phi_0}{2}\frac{e^{-\imath\Omega t}-e^{(-\kappa-\imath\Delta_c)t}}{\kappa+\imath\Delta_c-\imath\Omega}\\
&= \frac{\eta}{\kappa+\imath\Delta_c}\pm\tfrac{\phi_0\eta}{2}\frac{e^{\imath\Omega t}-e^{(-\kappa-\imath\Delta_c)t}}{\kappa+\imath\Delta_c+\imath\Omega}\mp\tfrac{\phi_0\eta}{2}\frac{e^{-\imath\Omega t}-e^{(-\kappa-\imath\Delta_c)t}}{\kappa+\imath\Delta_c-\imath\Omega}\\
&= \frac{\eta}{\kappa}\pm\imath\phi_0\eta\frac{\kappa\sin\Omega t-\Omega\cos\Omega t+\Omega e^{-\kappa t}}{\kappa^2+\Omega^2}\ .
\end{aligned}\tag{38.50}$$

In the last two steps, we defined for simplicity, $\alpha_\pm(0)=\frac{\eta}{\kappa+\imath\Delta_c}$ and set $\Delta_c=0$. After some initial transients, when $t\gg\kappa^{-1}$, we can write,

$$\begin{aligned}
\alpha_\pm\alpha_\pm^* &= \frac{\eta^2}{\kappa^2}+\phi_0^2\eta^2\left(\frac{\kappa\sin\Omega t-\Omega\cos\Omega t}{\kappa^2+\Omega^2}\right)^2\\
\alpha_\pm\alpha_\mp^* &= \left(\frac{\eta}{\kappa}\pm\imath\phi_0\eta\frac{\kappa\sin\Omega t-\Omega\cos\Omega t}{\kappa^2+\Omega^2}\right)^2\ ,
\end{aligned}\tag{38.51}$$

giving in analogy to (38.43),

$$\theta=\arctan\frac{2\phi_0(\kappa^2+\Omega^2)\left(\kappa^2\sin\Omega t-\kappa\Omega\cos\Omega t\right)}{(\kappa^2+\Omega^2)^2-\phi_0^2\left(\kappa^2\sin\Omega t-\kappa\Omega\cos\Omega t\right)^2}\simeq 2\phi_0\frac{\kappa^2\sin\Omega t-\kappa\Omega\cos\Omega t}{\kappa^2+\Omega^2}\ .$$

At low frequencies, $\Omega\ll\kappa$, the phase of the cavity field goes as, $\theta(\phi_0)\simeq 2\phi_0\sin\Omega t$, and for high frequencies, $\Omega\gg\kappa$, as, $\theta(\phi_0)\simeq -2\phi_0\frac{\kappa}{\Omega}\cos\Omega t$. Thus, we observe a low-pass behavior of the phase excursions of the cavity field with a cut-off frequency, κ^{-1}:

$$\boxed{\theta_m\simeq\frac{2\phi_0}{1+\Omega/\kappa}}\ .\tag{38.52}$$

38.2.3 Formal solutions of the master equation for a bosonic channel

38.2.3.1 Time dependent solution for decaying cavities

The master equation for a bosonic channel (38.31),

$$\frac{d\hat\rho}{dt}=\mathfrak{L}_{\kappa,\hat a}\hat\rho=\kappa(2\hat a\hat\rho\hat a^\dagger-\hat a^\dagger\hat a\hat\rho-\hat\rho\hat a^\dagger\hat a)\ .\tag{38.53}$$

can be solved formally.

In order to derive the time-dependent solution, we apply the substitution $\tan^2\phi=e^{\kappa t}-1$, with $\phi\in[0,\frac{\pi}{2}]$. This transforms the master equation into,

$$\frac{d\hat\rho}{d\phi}=\frac{\tan\phi}{\kappa}\,\mathfrak{L}_{\kappa,\hat a}\hat\rho\ ,\tag{38.54}$$

which is easy to check. The general solution of this equation [5],

$$\boxed{\hat{\rho}(\phi) = \sum_{n=0}^{\infty} \frac{\sin^{2n}\phi}{n!} \cos^{\hat{a}^\dagger \hat{a}}\phi \, \hat{a}^n \hat{\rho}_0 \hat{a}^{\dagger n} \cos^{\hat{a}^\dagger \hat{a}}\phi} \ , \tag{38.55}$$

as will be shown in Exc. 38.2.4.4.

The solution (38.55) permits to calculate time evolutions of classical or non-classical states of light. For example, we check in Exc. 38.2.4.4 that for Glauber states,

$$\mathrm{Tr}\,\hat{\rho}_{|\alpha\rangle}(t) = 1 = \mathrm{Tr}\,\hat{\rho}^2_{|\alpha\rangle}(t) \quad \text{and} \quad \langle \hat{n}(t)\rangle = \mathrm{Tr}\,\hat{n}\hat{\rho}_{|\alpha\rangle}(t) = |\alpha|^2 e^{-\kappa t} \ . \tag{38.56}$$

That is, Glauber states remain pure during cavity decay. In contrast, for Fock states,

$$\mathrm{Tr}\,\hat{\rho}_{|n_0\rangle}(t) = 1 > \mathrm{Tr}\,\hat{\rho}^2_{|n_0\rangle}(t) \quad \text{and} \quad \langle \hat{n}(t)\rangle = \mathrm{Tr}\,\hat{n}\hat{\rho}_{|n_0\rangle}(t) = n_0 e^{-\kappa t} \ . \tag{38.57}$$

That is, Fock states evolve into mixtures.

The solution (38.55) can easily be numerically simulated in the Fock basis using,

$$\cos^{\hat{a}^\dagger \hat{a}}\phi = e^{\hat{n}\ln\cos\phi} = \sum_{n=0}^{\infty} \cos^n\phi |n\rangle\langle n| \ . \tag{38.58}$$

Fig. 38.5(a) shows the density matrix after some evolution time. It is interesting to note, that cavity decay does not transform an initial Fock state into a Glauber state as, differently from Glauber states, the density matrix in the Fock basis only contains diagonal elements (similarly to thermal states). Panel (b) shows the time evolution of the normalization, the purity, and the photon number in the cavity. Similar results are obtained for squeezed states.

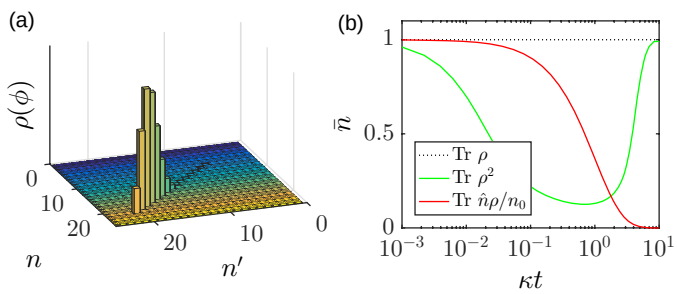

Figure 38.5: (code) (a) Density matrix of an evolved Fock state in a decaying cavity with no pumping. (b) Time evolution of the normalization, the purity, and the photon number in the cavity.

38.2.3.2 Steady state solution for driven cavities

The master equation can also be formally solved for the case that the cavity is driven. Describing the drive by the Hamiltonian,

$$\hat{H} = \eta(\hat{a} + \hat{a}^\dagger) \ , \tag{38.59}$$

the master equation can be transformed by the substitution,

$$\tilde{a} \equiv \hat{a} + \tfrac{\imath\eta}{\kappa}\mathbb{I} \quad \text{and} \quad \tilde{a}^\dagger \equiv \hat{a}^\dagger - \tfrac{\imath\eta}{\kappa}\mathbb{I} \ , \tag{38.60}$$

into,

$$\begin{aligned} \frac{d\hat{\rho}}{dt} &= \imath[\hat{\rho}, \hat{H}] + \mathfrak{L}_{\kappa,\hat{a}}\hat{\rho} \\ &= \imath\eta\left(\hat{\rho}\hat{a} + \hat{\rho}\hat{a}^\dagger - \hat{a}\hat{\rho} - \hat{a}^\dagger\hat{\rho}\right) + \kappa(2\hat{a}\hat{\rho}\hat{a}^\dagger - \hat{a}^\dagger\hat{a}\hat{\rho} - \hat{\rho}\hat{a}^\dagger\hat{a}) \\ &= \kappa\left(2\tilde{a}\hat{\rho}\tilde{a}^\dagger - \tilde{a}^\dagger\tilde{a}\hat{\rho} - \hat{\rho}\tilde{a}^\dagger\tilde{a}\right) \ . \end{aligned} \tag{38.61}$$

The steady state solution is,

$$\boxed{\hat{\rho}(\infty) = C^{-1}\tilde{a}^{-1}\tilde{a}^{\dagger-1} = C^{-1}(\hat{a} + \tfrac{\imath\eta}{\kappa}\mathbb{I})^{-1}(\hat{a}^\dagger - \tfrac{\imath\eta}{\kappa}\mathbb{I})^{-1}} \ , \tag{38.62}$$

where C is a normalization constant obtained from the condition $\mathrm{Tr}\,\rho(\infty) = 1$, (see Exc. 38.2.4.5).

Fig. 38.6(a) shows the steady state photon number calculated from,

$$\langle\hat{n}\rangle = \mathrm{Tr}\,\hat{n}\hat{\rho}(\infty) = C^{-1}\mathrm{Tr}\,\hat{n}\tilde{a}^{-1}\tilde{a}^{\dagger-1} = \frac{\mathrm{Tr}\,\hat{a}^\dagger\hat{a}\,\tilde{a}^{-1}\tilde{a}^{\dagger-1}}{\mathrm{Tr}\,\tilde{a}^{-1}\tilde{a}^{\dagger-1}} \ . \tag{38.63}$$

We see that, for large enough cut-off photon numbers used in the simulation, the intracavity photon number tends toward $\langle\hat{n}\rangle \to (\eta/\kappa)^2$, as expected. Fig. 38.6(b) shows the photon number uncertainty calculated from,

$$\langle\Delta\hat{n}^2\rangle = \mathrm{Tr}\,\hat{n}^2\hat{\rho}(\infty) - [\mathrm{Tr}\,\hat{n}\hat{\rho}(\infty)]^2 \ . \tag{38.64}$$

We see that it tends toward $\langle\Delta\hat{n}^2\rangle \to \langle\hat{n}\rangle$, as expected for a Glauber state, but not for a Fock state, for which we know $\langle\Delta\hat{n}^2\rangle \to 0$ or for a squeezed state (see Exc.37.4.4.5).

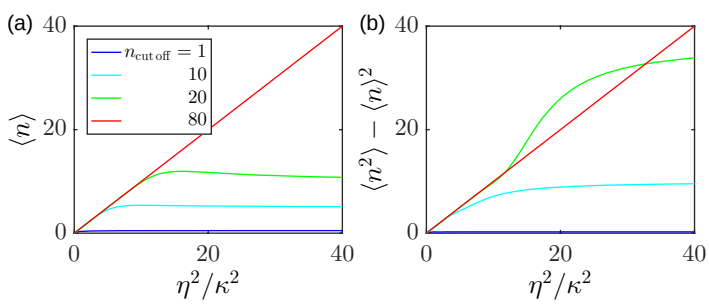

Figure 38.6: (code) Steady state photon number in a driven cavity for various cut-off photon numbers.

38.2.3.3 Time dependent solution for driven cavities

Since $[\tilde{a}, \tilde{a}^\dagger] = 1$ and $\tilde{a}^\dagger\tilde{a}$ is diagonal, the result (38.55) obtained for the purely dissipative cavity hold as well for the driven-dissipative cavity with the substitutions

(38.60). That is, the time dependent solution is,

$$\hat{\rho}(\phi) = \sum_{n=0}^{\infty} \frac{\sin^{2n}\phi}{n!} \cos^{\tilde{a}^\dagger \tilde{a}}\phi \; \tilde{a}^n \hat{\rho}_0 \tilde{a}^{\dagger n} \cos^{\tilde{a}^\dagger \tilde{a}}\phi \;, \tag{38.65}$$

or with $\cos^{\hat{a}^\dagger \hat{a}}\phi = (e^{-\kappa t/2})^{\hat{a}^\dagger \hat{a}}$ and $\sin^2\phi = 1 - e^{-\kappa t}$,

$$\boxed{\hat{\rho}(t) = \sum_{n=0}^{\infty} \frac{(1-e^{-\kappa t})^n}{n!} e^{-\kappa t \tilde{a}^\dagger \tilde{a}/2} \; \tilde{a}^n \hat{\rho}_0 \tilde{a}^{\dagger n} e^{-\kappa t \tilde{a}^\dagger \tilde{a}/2}} \;. \tag{38.66}$$

The simulation shown in Fig. 38.7 reveals that any initial state, be it a Glauber, Fock, or squeezed state, is transformed into a pure Glauber state after some time. The photon number uncertainty increases.

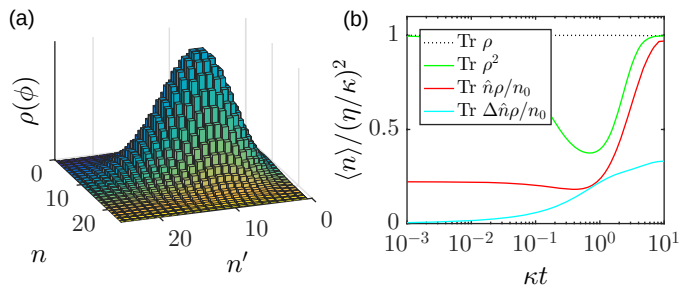

Figure 38.7: (code) (a) Density matrix of an evolved Fock state in a driven cavity with $\eta^2/\kappa^2 = 3$. (b) Time evolution of the normalization, the purity, the photon number and its variance in the cavity starting from an initial photon number of $\langle \hat{n}_0 \rangle = 2 \approx 0.22\eta^2/\kappa^2$.

38.2.4 Exercises

38.2.4.1 Ex: Ringing of an optical cavity

Consider a linear cavity with resonant frequency ω_c and the decay rate κ pumped by a laser beam whose frequency is swept linearly over a range $\omega \in [-10\kappa, 10\kappa]$. Prepare a numerical simulation varying the time Δt of the sweep.

38.2.4.2 Ex: Quick ullage of an optical cavity

Consider a linear cavity resonantly pumped by a laser beam until a stationary state is reached. Suddenly, the phase of the incident light is changed by 180°. Based on equation (38.33), analyze the evolution of the light field inside the cavity [788].

38.2.4.3 Ex: Photon number distribution in a driven cavity

In Exc. 39.4.4.15 we have seen that atoms can be deexcited faster than Γ using an adequate driving laser switch-off time and in Exc. 38.2.4.1 that optical cavities can be emptied faster than κ by injecting light having an inverted phase. Study and discuss the possibility of reducing the ullage rate by just adapting the driving laser switch-off time.

38.2.4.4 Ex: Formal solution of the master equation

a. Check that the expression (38.55) solved the master equation (38.54).
b. Evaluate the expression (38.55) for an initial Fock state, $\hat{\rho}_0 \equiv |n_0\rangle\langle n_0|$.
c. Evaluate the expression (38.55) for an initial Glauber state, $\hat{\rho} = |\alpha\rangle\langle\alpha|$. For (b) and (c) check normalization and purity during evolution.

38.2.4.5 Ex: Steady state photon number in a driven cavity

a. Expand the steady state solution (38.62) in power series of $\hat{a}$ respectively $\hat{a}^{\dagger-1}$, and determine the normalization constant.
b. Calculate the steady state photon number and its variance.

38.3 Mode structure and density-of-states of cavities

38.3.1 Characterization of the bare cavity

We first consider a linear cavity of length L pumped by a laser without any scatterer located inside the cavity. The cavity spectrum is an equidistant comb of eigenfrequencies separated by,

$$\delta_{\text{fsr}} \equiv \tau_{\text{rt}}^{-1} = \frac{c}{2L} \,. \tag{38.67}$$

The *free spectral range* δ_{fsr} is given in units of a real frequency. τ_{rt}^{-1} is the time for a photon to make a round trip in the cavity. The amplitude *decay rate of the cavity*,

$$\boxed{\kappa = \tau_{\kappa}^{-1} = \frac{\pi\delta_{\text{fsr}}}{F}} \,. \tag{38.68}$$

The intensity decay rate of the cavity, measured by 'cavity ring-down' is $\kappa_{\text{int}} = 2\kappa$. Note, that κ_{int} is also the FWHM width of the intensity transmission spectrum (see Exc. 15.3.7.18), such that the finesse

$$F = \frac{\delta_{\text{fsr}}}{\kappa_{\text{int}}/2\pi} \tag{38.69}$$

is simply the ratio between the free spectral range and the FWHM of the cavity intensity transmission curve, both measured in Hertz.

Example 269 (*Finesse of a cavity*): For example, for a cavity of length $L = 10\,\text{cm}$ an intensity decay time of $\tau_{\text{int}} = 20\,\mu\text{s}$ is measured, and we want to evaluate the finesse. We begin calculating the free spectral range $\delta_{\text{fsr}} = c/2L \approx 1.5\,\text{GHz}$. Since the cavity field decays like $\mathcal{E}(t) = \mathcal{E}_0 e^{-\kappa t}$ and the intensity like $I(t) = \mathcal{E}_0^2 e^{-2\kappa t}$, we get $\kappa = 1/\tau_\kappa = 1/2\tau_{\text{int}} \approx (2\pi)\,4\,\text{kHz}$. Finally, the finesse is $F = \pi\delta_{\text{fsr}}/\kappa \approx 189000$.

For a cavity with a given geometry filled with a Gaussian mode of light with power P, the intensity is determined by Gaussian optics (see Sec. ?? and Exc. 15.3.7.18),

$$I(\mathbf{r}) = \frac{2P}{\pi w^2(z)} e^{-2\rho^2/w^2(z)} \qquad \text{and} \qquad w(z) = w_0\sqrt{1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2} \,. \tag{38.70}$$

Defining the *mode volume* via $I(0)V_{\rm m} \equiv \int I(\mathbf{r})dV$ and evaluating the spatial integral over the Gaussian mode along the cavity, we obtain,

$$\boxed{V_{\rm m} = \frac{1}{I(0)}\int_0^L \int_0^\infty \int_0^{2\pi} \frac{2P}{\pi w^2(z)} e^{-2\rho^2/w^2(z)} d\phi\rho d\rho dz = \tfrac{\pi}{2} L w_0^2} \ . \tag{38.71}$$

Defining the amplitude of the electric field generated by a *single photon* via,

$$I(\mathbf{r}) = n\varepsilon_0 c \mathcal{E}_1^2(\mathbf{r}) \ , \tag{38.72}$$

where n is the number of photons in the cavity, we calculate for the energy stored in the cavity,

$$\frac{\hbar\omega}{2} = \int u_1(\mathbf{r})dV = \frac{1}{c}\int I_1(\mathbf{r})dV = \frac{1}{c} I_1(0) V_{\rm m} \ . \tag{38.73}$$

Hence,

$$\boxed{|\vec{\mathcal{E}}_1(0)| = \sqrt{\frac{I_1(0)}{\varepsilon_0 c}} = \sqrt{\frac{\hbar\omega}{2\varepsilon_0 V_{\rm m}}}} \ . \tag{38.74}$$

See Exc. 15.4.4.2.

The light power in the linear cavity can now be expressed using its free spectral range (38.67),

$$P = \frac{\pi w_0^2}{2} I(0) = \frac{2V_{\rm m}}{L} n\varepsilon_0 c |\vec{\mathcal{E}}_1^2(0)| = 2V_{\rm m}\delta_{\rm fsr} n\varepsilon_0 \frac{\hbar\omega}{2\varepsilon_0 V_{\rm m}} = \delta_{\rm fsr} n\hbar\omega \ . \tag{38.75}$$

We assume that the cavity is pumped by a laser beam. To estimate the pump rate, we assume that the power $P_{\rm input}$ be measured in transmission. The coefficient η for resonant pumping is related to the number n of photons inside the cavity,

$$n = |\alpha|^2 = \frac{\eta^2}{\kappa^2} \ . \tag{38.76}$$

The intracavity field is resonantly amplified by the finesse,

$$\boxed{\alpha = \sqrt{\frac{F}{\pi}}\alpha_{\rm input} = \sqrt{\frac{\delta_{\rm fsr}}{\kappa}}\alpha_{\rm input}} \ . \tag{38.77}$$

This gives,

$$\eta = \kappa\alpha = \kappa\sqrt{\frac{I}{c\hbar\omega}V_{\rm m}} = \sqrt{\kappa\delta_{\rm fsr}}\alpha_{\rm input} = \sqrt{\kappa\delta_{\rm fsr}}\sqrt{\frac{I_{\rm input}}{c\hbar\omega}V_{\rm m}} \ . \tag{38.78}$$

In practice, the pump rate will depend on the quality of the phase matching of the Gaussian beams and the impedance matching (in case of partially absorbing mirrors).

We will pursue the characterization of ring cavities including their interaction with scattering atoms in Sec. 45.1.2.

38.3.1.1 The Schawlow-Townes limit

The *Schawlow-Townes limit* results from phase fluctuation of the standing light wave in the cavity demand $\Delta\phi = \frac{1}{n}$. Using the relationships (38.75) and (38.77), we find [978],

$$\Delta\omega_{\text{laser}} = \frac{\kappa}{|\alpha|^2} = \kappa\frac{\delta_{\text{fsr}}\hbar\omega_{\text{laser}}}{P_{\text{cav}}} = \kappa\frac{\delta_{\text{fsr}}\hbar\omega_{\text{laser}}}{\frac{\delta_{\text{fsr}}}{\kappa}P_{\text{out}}} = \kappa^2\frac{\hbar\omega_{\text{laser}}}{P_{\text{out}}} \ . \tag{38.79}$$

Example 270 (*Schawlow-Townes limit of a HeNe laser*): For a typical HeNe laser, $F = 100$, $P_{\text{out}} = 1\,\text{mW}$, $L = 20\,\text{cm}$, we estimate,

$$\Delta\omega_{\text{laser}} = \left(\frac{\pi\delta_{\text{fsr}}}{F}\right)^2\frac{h\nu_{\text{laser}}}{P_{\text{out}}} = \left(\frac{\pi c}{2LF}\right)^2\frac{h\nu_{\text{laser}}}{P_{\text{out}}} \approx (2\pi)30\,\text{mHz} \ .$$

38.3.2 Calculation of the density of states

The density of states $\rho(\omega, \mathbf{k})$ of an optical cavity is defined by,

$$\int_{\mathcal{R}} \rho(\omega, \mathbf{k}) d\omega d\Omega = \frac{1}{(2\pi)^3}\int d^3x d^3k \ , \tag{38.80}$$

where $\mathcal{R}$ denotes the boundary imposed by the cavity. For free space photons we calculate (see Eq. (39.22)),

$$4\pi\int \rho_{\text{free}}(\omega, \mathbf{k}) d\omega = \frac{V}{(2\pi)^3}\int k^2 \sin\theta d\theta d\phi dk = \frac{Vk^3}{6\pi^2} = \frac{V\omega^3}{6\pi^2 c^3} \ , \tag{38.81}$$

such that,

$$\rho_{\text{free}}(\omega, \mathbf{k}) = \rho_{\text{free}}(\omega) = \frac{V\omega^2}{(2\pi c)^3} \ , \tag{38.82}$$

is isotropic.

For light in a cavity, the density of states is modified with respect to free space, because it becomes frequency-dependent and anisotropic. The frequency dependence is expressed by the Airy formula,

$$\mathfrak{L}(\omega) \equiv \frac{I_{\text{cav}}}{I_{\text{in}}} = \frac{\sqrt{1 + (2F/\pi)^2}}{1 + (2F/\pi)^2 \sin^2 kL} \ , \tag{38.83}$$

which will be derived in Excs. 38.3.4.1, 38.3.4.2, and 38.3.4.3, and the anisotropy by,

$$\mathcal{R}(\hat{\mathbf{e}}_k) = 1 \qquad \forall \qquad \hat{\mathbf{e}}_k \in \Omega_{\text{cav}} \ , \tag{38.84}$$

where Ω_{cav} is the solid angle covered by the cavity mode. The formula,

$$\boxed{\rho_{\text{cav}}(\omega, \mathbf{k}) = \rho_{\text{free}}(\omega)[1 - \mathcal{R}(\hat{\mathbf{e}}_k)] + \rho_{\text{free}}(\omega)\mathfrak{L}(\omega)\mathcal{R}(\hat{\mathbf{e}}_k)} \tag{38.85}$$

expresses that the density of states is nothing more than the *structure factor* of the cavity.

38.3.2.1 Confocal cavities

For a confocal cavity the solid angle is easy to calculate [422, 423]. Denoting by b is the clear aperture of the cavity mirrors, we get,

$$\Omega_{\rm cav,con} = 2\int_0^{2\pi}\int_0^{\arcsin(2b/L)} \sin\theta d\theta d\phi = 4\pi\left(1-\sqrt{1-4\frac{b^2}{L^2}}\right) . \tag{38.86}$$

Expanding the root for small $b \ll L$, we get,

$$\boxed{\Omega_{\rm cav,con} \simeq \frac{8\pi b^2}{L^2}} . \tag{38.87}$$

For non-degenerate geometries the functions $\mathfrak{L}$ and $\mathcal{R}$ depend on the order mn of the transverse Gaussian modes:

$$\mathfrak{L}_{mn}(\omega) = \frac{\sqrt{1+(2F/\pi)^2}}{1+(2F/\pi)^2\sin^2(kL+\varphi_{mn})} \qquad \text{and} \qquad \mathcal{R}_{mn}(\hat{\mathbf{e}}_k) = 1 \quad \forall \quad \hat{\mathbf{e}}_k \in \Omega_{mn} ,$$

where φ_{mn} is the frequency shift of the transverse modes.

38.3.2.2 Expansion into Hermite-Gaussian modes

More correctly, $\hat{\mathbf{e}}_k \in \Omega_{mn}$ means that we must weigh the density of states by the structure factor of the mode volume, which is nothing more than the Fourier transform of the cavity mode function,

$$\boxed{\mathcal{R}_{mn}(\hat{\mathbf{e}}_k) = \int_{\hat{\mathbf{e}}_k\in\Omega_{mn}} d^2k = \int_{\mathbb{R}^2} \mathcal{F}\left[\frac{u_{mn}(\mathbf{r})}{\hbar\omega}\right] d^2k} . \tag{38.88}$$

For a Hermite-Gaussian mode with waist $w(z)$ [see (15.290)],

$$u_{mn}(\mathbf{r}) = \hbar\omega\frac{w_0}{w}e^{-2(x^2+y^2)/w^2}H_m(\sqrt{2}x/w)^2H_n(\sqrt{2}y/w)^2 . \tag{38.89}$$

The Hermite polynomials are the eigenfunctions of the Fourier transform,

$$\mathcal{F}[e^{-x^2/2}H_n(x)] = (-\imath)^n e^{-k^2/2}H_n(k) . \tag{38.90}$$

Hence,

$$\begin{aligned}\mathcal{F}\left[\tfrac{1}{\hbar\omega}u_{mn}(\mathbf{r})\right] &= \frac{1}{\hbar\omega}\frac{w_0}{w}\mathcal{F}\left[e^{-2(x^2+y^2)/w^2}H_m(\sqrt{2}x/w)^2H_n(\sqrt{2}y/w)^2\right] \\ &= \frac{1}{\hbar\omega}\frac{w_0}{w}\mathcal{F}\left[e^{-2x^2/w^2}H_m(\sqrt{2}x/w)^2\right]\mathcal{F}\left[e^{-2y^2/w^2}H_n(\sqrt{2}y/w)^2\right] \\ &= \frac{1}{\hbar\omega}\frac{w_0}{w}e^{-2k_x^2w^2}H_m(\sqrt{2}k_xw)^2e^{-2k_y^2w^2}H_n(\sqrt{2}k_yw)^2 \overset{m,n=0}{\longrightarrow} \frac{1}{\hbar\omega}\frac{w_0}{w}e^{-2\left(k_x^2+k_y^2\right)w^2} .\end{aligned} \tag{38.91}$$

Finally,

$$\begin{aligned}\mathcal{R}_{mn}(\hat{\mathbf{e}}_k) &= \int \mathcal{F}\left[\frac{u_{mn}(\mathbf{r})}{\hbar\omega}\right] d\left(\tfrac{k_x}{k}\right) d\left(\tfrac{k_y}{k}\right) \\ &= \frac{1}{\hbar\omega}\frac{w_0}{w}\int e^{-2k_x^2w^2}H_m(\sqrt{2}k_xw)^2 d\left(\tfrac{k_x}{k}\right)\int e^{-2k_y^2w^2}H_n(\sqrt{2}k_yw)^2 d\left(\tfrac{k_y}{k}\right) .\end{aligned} \tag{38.92}$$

For the TEM_{00} mode, we get,

$$\mathcal{R}_{00}(\hat{\mathbf{e}}_k) = \frac{\pi}{2k^2w^2} \ , \tag{38.93}$$

using $P = \int I_{mn}(\mathbf{r})dxdy = \frac{1}{2}\pi w^2 I_0$. This coincides with the intuition, that for the TEM_{00}, the aperture is simply the divergence angle of the Gaussian mode.

The solid angle of a Gaussian mode in a non-degenerate cavity is calculated via,

$$\Omega_{\mathrm{cav}} = 2 \cdot \frac{\pi w(z)^2}{z^2} = 2 \cdot \frac{\pi w_0^2}{z^2}\left(1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2\right) \ . \tag{38.94}$$

In the far field, we get,

$$\boxed{\Omega_{\mathrm{cav}} \overset{z\to\infty}{\longrightarrow} \frac{8\pi}{k^2w_0^2}} \ . \tag{38.95}$$

Example 271 (*Solid angle for Hermite-Gaussian modes in a confocal cavity*): For confocal cavities, we must add $\sum_{mn}\mathcal{F}\left[\frac{1}{\hbar\omega}u_{mn}(\mathbf{r})\right]$ up to a limit, where the maximum $H_m(\sqrt{2}kw)$ is cut by the finite aperture of the mirrors of the cavity. Empirically, we find that $H_n(\xi)^2e^{-\xi^2}$ has its maximum at $\xi_{\max} = 13.7 \cdot n^{1/2}$. From the condition $u_{mn}(x, y, L) = 0$ for $xy > a^2$, we obtain,

$$\begin{aligned} x_{\max}y_{\max} &< a^2 \\ \left(13.7 \cdot n^{1/2}\right)^2 &= \frac{\sqrt{2}x_{\max}}{w(L)}\frac{\sqrt{2}y_{\max}}{w(L)} < \frac{2a^2}{w(L)^2} \to \frac{a^2k^2w_0^2}{2L^2} \ , \end{aligned}$$

using $w(L) = w_0\sqrt{1 + \left(\frac{\lambda L}{\pi w_0^2}\right)^2} \to \frac{\lambda L}{\pi w_0}$. Finally,

$$\sum_{mn}\mathcal{F}\left[\frac{1}{\hbar\omega}u_{mn}(\mathbf{r})\right] = \frac{\pi}{2k^2w^2}\sum_{13.7^2 m,n<a^2k^2w_0^2/2L^2} = \frac{\pi}{2k^2w^2}\frac{1}{13.7^2}\frac{a^2k^2w_0^2}{2L^2} = \frac{1}{13.7^2}\frac{\pi a^2}{4L^2} \ .$$

38.3.3 Cumulant expansion of correlation functions and power spectra

38.3.3.1 Correlation functions

The evolution of the two-time correlation function of two operators $\hat{A}$ and $\hat{B}$ given by,

$$R(t,\tau) \equiv \langle \hat{A}(t+\tau)\hat{B}(t)\rangle \quad , \quad R(\tau) = \lim_{t\to\infty}\langle \hat{A}(t+\tau)\hat{B}(t)\rangle \ , \tag{38.96}$$

with respect to the time delay τ is determined by,

$$\frac{d}{d\tau}R(t,\tau) = \langle[\partial_\tau\hat{A}(t+\tau)]\hat{B}(t)\rangle \ . \tag{38.97}$$

Hence, the set of equations required to compute the correlation function can be derived from the equation of motion for the operator $\hat{A}$. The cumulant expansion of the correlation function then follows the same procedure as for a standard time evolution: the set of equations is expanded to a certain order and completed. Solve Exc. 38.3.4.4.

38.3.3.2 Steady state

If the original system is evolved up to a time t such that it is in steady state, i.e. expectation values no longer change after that time, the set of equations determining the correlation function has a special property. specifically, after the cumulant expansion has been performed, there can only be a single term in each product on the right-hand-side of the set of equations that depends on τ. All other terms depend on t alone, meaning that they are constant since they no longer change after the time t. Therefore, the system of equations from which the correlation function is computed is linear, in the sense that it can be written as,

$$\frac{d}{d\tau}\mathbf{y}(\tau) = \mathbf{M}\mathbf{y}(\tau) + \mathbf{d} \ , \tag{38.98}$$

where $\mathbf{y}(\tau)$ is the vector of τ-dependent variables. The elements of the matrix $\mathbf{M}$ as well as the vector $\mathbf{d}$ are given by steady-state expectation values and parameters, i.e. they are independent of τ.

38.3.3.3 Power spectra

According to the Wiener-Khinchin theorem. the spectral density associated with a correlation function is given by its Fourier transform,

$$S(t,\omega) = 2\mathfrak{Re} \int e^{-\imath\omega\tau} R(t,\tau) d\tau \ . \tag{38.99}$$

In order to compute this, we can solve the system of equations determining $R(t,\tau)$, subsequently taking the Fourier transform. However, if we are not interested in the temporal behavior of the correlation function, and if the system of which we want to compute the spectrum is in steady state, we can directly compute the spectrum from Eq. (38.98). To this end, we define

$$\mathbf{x}(s) = \mathfrak{L}[y(\tau)] \ , \tag{38.100}$$

where $\mathfrak{L}$ denotes the Laplace transform with respect to τ. Taking the Laplace transform of Eq. (38.98), we have,

$$(s\mathbb{I} - \mathbf{M})\mathbf{x}(s) = \mathbf{y}(0) + \frac{\mathbf{d}}{s} \ . \tag{38.101}$$

Note that the Laplace transform is equivalent to the Fourier transform at the point where $s = \imath\omega$, i.e. $S(\omega) = 2\mathfrak{Re}\,\mathbf{x}_1(\imath\omega)\}$. Hence, instead of computing the time evolution of the correlation function we can directly compute the spectrum by solving the linear equation,

$$\mathbf{x} = (\imath\omega\mathbb{I} - \mathbf{M})^{-1}[\mathbf{y}(0) + \tfrac{1}{\imath\omega}\mathbf{d}] \ . \tag{38.102}$$

For larger systems, the method using a Laplace transform is usually faster than integrating a system of equations of the same size. Additionally, it avoids numerical errors of the integration and the subsequent discrete Fourier transform.

38.3.4 Exercises

38.3.4.1 Ex: Derivation of the Airy formula

Derive the Airy formula (38.83).

38.3.4.2 Ex: Airy formula for ring cavities

Derive the Airy formulas for a ring cavity laser-pumped through an incoupling mirror with reflectivity r_{ic} and comprising two more high-reflecting mirrors with reflectivity r_{hr}. Calculate (a) the intracavity intensity, (b) the intensity of the light reflected from the incoupler, and (c) the intensity of the light transmitted through the first encountered high reflector. For each for intensity study the cases that (i) the ring cavity is resonant and (ii) off-resonance. Also study the limit $r_{\mathrm{hr}} \to 1$. Disregard absorption losses.

38.3.4.3 Ex: Filling rate for long cavities

Using the solution (38.33) try to calculate the transmission of a 15 km long cavity of finesse $F = 1000$ as a function of time, when it is pumped by a suddenly switched on laser. Analyze the results in the light of local causality.

38.3.4.4 Ex: Fluorescence spectrum of an empty cavity

a. Calculate the fluorescence spectrum of an empty cavity pumped at a rate η classically via the autocorrelation function $\langle \alpha^*(t+\tau)\alpha(t)\rangle$.
b. Calculate the time evolution of the cumulants $\langle \hat{a}\rangle$, $\langle \hat{a}^\dagger \hat{a}\rangle$, $\langle \hat{a}^\dagger \hat{a}^\dagger \hat{a}\rangle$, $\langle \hat{a}\hat{a}^\dagger \hat{a}\rangle$, and $\langle \hat{a}^\dagger \hat{a}\hat{a}^\dagger \hat{a}\rangle$ expanding up to forth order.
c. Based on the results obtained in (b) and applying the quantum regression theorem derive a set of linear differential equations for the autocorrelation functions $\langle \hat{a}(\tau)\rangle$, $\langle \hat{a}^\dagger(t+\tau)\hat{a}(t)\rangle$, $\langle \hat{a}^\dagger(t+\tau)\hat{a}^\dagger(t)\hat{a}(t)\rangle$, $\langle \hat{a}(t+\tau)\hat{a}^\dagger(t)\hat{a}(t)\rangle$, and $\langle \hat{a}^\dagger(t+\tau)\hat{a}(t+\tau)\hat{a}^\dagger(t)\hat{a}(t)\rangle$. Express them in matrix notation.
d. Calculate $g^{(1)}(\tau)$, the fluorescence spectrum, and $g^{(2)}(\tau)$ for the case $\eta = 0$.
e. Repeat the calculations in (c) to the case $\eta \neq 0$.

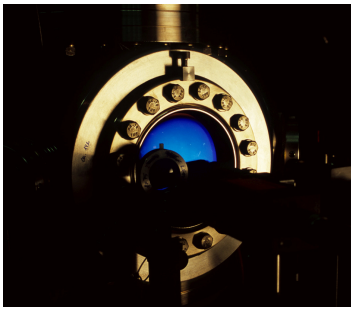
Part VIII

Light-Matter Interaction

Preface to the part *Light-Matter Interaction*



We have seen in previous lectures, how to describe light in quantum mechanics and how to unravel the atomic structure. The topic of this part of the lecture is the description of how both interact with special emphasis on non-classical features.

Chapter 39

Semiclassical theory of light-atom interaction

In Part VI of this script we solved the problem of a *stationary* atom using the formalism of quantum mechanics developed in Part IV. We now come back to Bohr's original idea that *transitions* between atomic states be induced by absorption and emission of electromagnetic radiation and develop a semi-classical theory of light-atom interaction. That is, the atom will be treated as a quantum object, while the radiation is assumed to obey the rules of classical electrodynamics. The main objective of this chapter will be to derive an equation describing the temporal evolution of atoms interacting with a radiation field.

We begin with a perturbative approach to the excitation of atomic transitions in Sec. 39.1. In quantum mechanics we learned (see in Sec. 27.4) how time-dependent perturbations, such as suddenly applied force fields or periodic oscillations, can induce transitions between eigenstates. We will not repeat the concepts here. Rather we will focus on the calculation of transitions rates employing Fermi's Golden rule derived in Eq. (27.111). In Secs. 23.2 we introduced the Einstein coefficients A and B, which we associated with Planck's spectral distribution of black-body radiation. This procedure allowed us to connect the coefficients for spontaneous and stimulated transitions, but did not provide any method to calculate them from the intrinsic properties of the atoms. The purpose of Sec. 39.2 is to find expressions for the matrix elements coupling different atomic states using quantum mechanics and relate them to the Einstein coefficients in order to calculate the rates of absorption and emission of atomic radiation. In particular, we will dedicate some space to the dipolar approximation and to the derivation of selection rules allowing to quantify transition probabilities as a function of the quantum numbers characterizing the atomic states coupled by radiation.

Perturbation theory can describe the light-atom dynamics only at interaction times short enough, that the initially occupied atomic states is not noticeably depleted. An exception is the two-level atom, for which perturbation theory reproduces the exact results obtained by solving the time-dependent Schrödinger equation. This, however, only holds as long as spontaneous processes can be neglected. To portray systems that contain excitation and relaxation processes occurring simultaneously, a theory based on Schrödinger's equation is no longer sufficient, because it is only capable of explaining stimulated processes, such as the absorption of a monochromatic wave. Dissipative processes, such as spontaneous emission, require a more general approach

to describe the evolution of a system. A single wavefunction is, in general, not enough to represent such a system nor to quantify the probabilities associated with each of its states, but we rather need an ensemble of wavefunctions, which requires the description of the atom in terms of a density operator. This has been done in Sec. 37.2.

The equations of motion ruling the time evolution of the density operator are the so-called Bloch equations. They will be derived and studied in Sec. 39.3, and in Sec. 39.4 we will phenomenologically include spontaneous emission. In Sec. 39.5 we will discuss line broadening mechanisms and in Sec. 39.6 generalize the Bloch equation formalism to multilevel systems.

39.1 Perturbative approach to atomic excitation

In a model of an isolated atom, the atomic energy levels are eigenstates of the Hamiltonian and describe the system completely, i.e. they do not undergo any evolution. Transitions between atomic energy levels may, however, be induced by oscillatory perturbations, such as electromagnetic radiation accelerating bound electrons.

39.1.1 Time-dependent perturbation by a plane wave

Looking at the Hamiltonian (33.11) describing the interaction of a charged particle with an electromagnetic field, we find that the term $\mathbf{A}\cdot\nabla \propto e^{\imath\omega t}$ oscillates with frequency ω, while the term $\mathbf{A}^2 \propto e^{2\imath\omega t}$ oscillates with twice that frequency. We will only consider the interaction term (33.12), which is linear in $\mathbf{A}$, and we will treat this term as first-order perturbation by *time-dependent perturbation theory* (TPDT).

With this scope we separate the Hamiltonian in a stationary part and a time-dependent part [1],

$$\hat{H}(t) = \hat{H}^{(0)} + \hat{H}_{\text{int}}(t) \qquad \text{with} \qquad \hat{H}_{\text{int}} = \tfrac{e}{m}\mathbf{A}(\mathbf{r},t)\cdot\hat{\mathbf{p}}\ , \tag{39.1}$$

where $\hat{H}^{(0)}$ contains the kinetic energy and the Colombian potential of Eq. (33.11). In Sec. 27.4.4, inserting the expansion,

$$|\psi\rangle = \sum_k a_k(t)|k\rangle e^{-\imath E_k t/\hbar}\ , \tag{39.2}$$

along with the Hamiltonian (39.1) in the Schrödinger equation, we obtained the first order perturbative approximation (27.72). Setting the initial condition to $c_k(t\leq 0) = \delta_{ki}$ and supposing that the probability of finding the atom initially in the ground state $|i\rangle$ for short times is 1, we got,

$$\boxed{a_f^{(1)}(t) \simeq \frac{1}{\imath\hbar}\int_0^t \langle f|\hat{H}_{\text{int}}|i\rangle e^{\imath\omega_{fi}t'}\,dt'}\ . \tag{39.3}$$

We now consider a perturbation by an electromagnetic plane wave within the Coulomb gauge,

$$\Phi = 0 \qquad \text{and} \qquad \nabla\cdot\mathbf{A} = 0\ . \tag{39.4}$$

[1] The energy of the light field is not considered in the Hamiltonian, because it is treated as classical, that is, its energy commutes with the other observables of the system.

The solution of the wave equation can be written,

$$\mathbf{A}(\mathbf{r},t) = \mathbf{A}_0^*(\mathbf{r})e^{\imath\omega t} + \mathbf{A}_0(\mathbf{r})e^{-\imath\omega t} \ . \tag{39.5}$$

For plane waves,

$$\mathbf{A}_0(\mathbf{r}) = \mathbf{A}_0 e^{\imath\mathbf{k}\cdot\mathbf{r}} \tag{39.6}$$

and $k = \omega/c$ and $\mathbf{k}\cdot\mathbf{A}_0 = 0$. With this, it is possible to show (see Exc. 39.1.4.1), that the energy density is,

$$u(\omega) = \tfrac{\varepsilon_0}{2}\vec{\mathcal{E}}^2 + \tfrac{1}{2\mu_0}\vec{\mathcal{B}}^2 = 2\varepsilon_0\omega^2 A_0^2 \ . \tag{39.7}$$

On the other hand, the energy density is proportional to the number of photons $N(\omega)$ inside the volume V,

$$u(\omega) = \frac{N(\omega)\hbar\omega}{V} \ . \tag{39.8}$$

The intensity corresponds to a flow of energy,

$$I(\omega) = u(\omega)c \ . \tag{39.9}$$

Separating the polarization $\hat{\epsilon}$ from the amplitude A_0,

$$\mathbf{A} = \hat{\epsilon}A_0 e^{\imath\mathbf{k}\cdot\mathbf{r}}e^{-\imath\omega t} + c.c. \ , \tag{39.10}$$

and inserting the perturbation (39.1) into the approximation (39.3),

$$\begin{aligned} a_f^{(1)}(t) &= -\tfrac{e}{m}\int_0^t dt'\langle f|\mathbf{A}\cdot\nabla|i\rangle e^{\imath\omega_{fi}t'}dt' \qquad (39.11)\\ &= -\tfrac{eA_0}{m}\langle f|e^{\imath\mathbf{k}\cdot\mathbf{r}}\hat{\epsilon}\cdot\nabla|i\rangle\int_0^t dt' e^{\imath(\omega_{fi}-\omega)t'}dt' - \tfrac{eA_0}{m}\langle f|e^{-\imath\mathbf{k}\cdot\mathbf{r}}\hat{\epsilon}\cdot\nabla|i\rangle\int_0^t dt' e^{\imath(\omega_{fi}+\omega)t'}dt' \ . \end{aligned}$$

Which one of the two processes described by Eq. (39.11) takes place, depends on the initial and final energies. For $E_f = E_i + \hbar\omega$ the first term describing the process of *absorption* will dominate, for $E_f = E_i - \hbar\omega$ the second term describing *emission* prevails.

39.1.2 Absorption and stimulated emission

39.1.2.1 Absorption

We define the *matrix element*,

$$M_{fi} \equiv \langle f|e^{\imath\mathbf{k}\cdot\mathbf{r}}\hat{\epsilon}\cdot\nabla|i\rangle \ , \tag{39.12}$$

and concentrate on the absorption process. Defining the detuning by $\Delta \equiv \omega - \omega_{fi}$ and evaluating the integral,

$$\left|\int_0^t e^{-\imath\Delta t'}dt'\right|^2 = \left|\frac{e^{-\imath\Delta t}-1}{-\imath\Delta}\right|^2 = 4\frac{\sin^2\frac{\Delta t}{2}}{\Delta^2} \simeq 2\pi t\delta(\Delta) \ , \tag{39.13}$$

at short times (see the formula (27.76)), the absorption probability becomes,

$$|a_f^{(1)}(t)|^2 = \tfrac{e^2}{m^2} A_0(\omega)^2 |M_{fi}|^2 \left| \int_0^t dt' e^{\imath(\omega_{fi}-\omega)t'} dt' \right|^2 = \tfrac{e^2}{m^2} A_0(\omega)^2 |M_{fi}|^2 2\pi t \delta(\Delta) \ . \tag{39.14}$$

The $\delta(\Delta = 0)$ function simply represents conservation of energy. Of course this is only an approximation not taking into account the finite width of the transition line.

Expressing the field by the intensity (39.10), we obtain the transition rate for absorption,

$$\boxed{W_{fi}^{(\mathrm{ab})} = \frac{d}{dt}|a_f^{(1)}(t)|^2 = 2\pi \left(\frac{eA_0}{m}\right)^2 |M_{fi}|^2 \delta(\omega - \omega_{fi}) = \frac{\pi e^2}{\varepsilon_0 m^2 c} \frac{I(\omega)}{\omega^2} |M_{fi}|^2 \delta(\omega - \omega_{fi})} \ . \tag{39.15}$$

We note that the absorption rate is proportional to the intensity of the radiation, which characterizes a typically linear effect.

If we want to express the rate of absorption by atoms in terms of energy, we simply multiply W_{fi} by $\hbar\omega$ and, hence, we can define the cross section for the absorption of radiative energy as,

$$\sigma_{i\to f} \equiv \frac{\text{absorption rate}}{\text{incident intensity}} = \frac{\hbar\omega W_{fi}}{I(\omega)} = \frac{\pi e^2}{\varepsilon_0 m^2 c} \frac{\hbar}{\omega} |M_{fi}(\omega_{fi})|^2 \delta(\omega - \omega_{fi}) \ . \tag{39.16}$$

39.1.2.2 Stimulated emission

For $E_f = E_i - \hbar\omega$ the equation describes the process of *stimulated emission*. Analogously to the calculation of the absorption, we obtain,

$$\boxed{W_{if}^{(\mathrm{st})} = \frac{\pi e^2}{\varepsilon_0 m^2 c} \frac{I(\omega)}{\omega^2} |M_{if}^*|^2 \delta(\omega + \omega_{fi})} \ , \tag{39.17}$$

with $M_{fi}^* = \langle f | e^{-\imath \mathbf{k}\cdot\mathbf{r}} \hat{\epsilon} \cdot \nabla | i \rangle$. Of course,

$$W_{if}^{(\mathrm{st})} = W_{fi}^{(\mathrm{ab})} \ . \tag{39.18}$$

The fact that, in a coupled atom-radiation system in equilibrium, the radiation field excites the same number of transitions in absorption $i \to f$ as in stimulated emission $f \to i$ is called the principle of *detailed balance*.

Obviously, the situation is different, if instead of two states we have several states that can be excited by radiation or decay.

39.1.3 Spontaneous emission

Absorption and stimulated emission are due to the interaction of an atom with a radiation field. However, even in the absence of radiation the atom couples to the field of the electromagnetic vacuum, and an accurate description of the atom must account for this fact. The total system has different eigenstates and their projection on the unperturbed eigenstates changes over time, as any excited atomic state has a constant probability, depending on the coupling to the electromagnetic field, to decay

to another state. The probability of measuring a specific lifetime thus follows a Poisson distribution. The decay process caused by atomic interaction with fluctuations of the electromagnetic vacuum is called *spontaneous emission*. It is understood in the framework of *quantum electrodynamics*, and a thorough discussion is postponed to Sec. 40.4. Here, we will adopt a preliminary heuristic treatment.

Replacing in Eq. (39.17) the intensity by the number of photons (39.8), we obtain,

$$W_{if}^{(\mathrm{st})} = \frac{\pi\hbar e^2 N(\omega)}{\varepsilon_0 m^2 \omega V} |M_{fi}|^2 \delta(\omega - \omega_{fi}) \ . \tag{39.19}$$

In fact, the introduction of the concept of photons already implies the quantization of the electromagnetic field. Adding to the number of photons a photon representing the vacuum fluctuations, $N(\omega) \longrightarrow N(\omega) + 1$, we are able to include spontaneous emission,

$$\boxed{W_{if}^{(\mathrm{st})} + W_{if}^{(\mathrm{sp})} = \frac{\pi\hbar e^2 [N(\omega) + 1]}{\varepsilon_0 m^2 \omega V} |M_{fi}|^2 \delta(\omega + \omega_{fi})} \ . \tag{39.20}$$

This means that even in the absence of a classical radiation field, $N(\omega) = 0$, there is an emission probability. We note that $W_{if}^{(\mathrm{sp})}$ depends on the volume confining the atom, that is, the cavity, since it describes the transfer of energy to this volume. Here, it is clear that an argument is still missing, because the transfer rate must depend in some way on the number of states available to accommodate the emitted photon, that is, on the *density of states* within the cavity. The calculation of this density of states should allow us to evaluate the quantization volume V.

39.1.3.1 Density of states

In Sec. 23.2.2 we calculated the isotropic spectral *density of modes* per volume (23.53),

$$\varrho(\omega) = \frac{\omega^2}{\pi^2 c^3} \ . \tag{39.21}$$

The density of modes in a specific direction of free space (i.e. no boundary conditions imposed e.g. by dielectric surfaces) regardless of the mode volume is then given by [2],

$$\int_{4\pi} \rho_{free}(\omega) d\Omega = V \varrho(\omega) \ , \tag{39.22}$$

that is,

$$\rho_{free}(\omega) = \frac{V}{(2\pi)^3} \frac{\omega^2}{c^3} \ . \tag{39.23}$$

Thus, the spontaneous emission rate of photons into the solid angle $d\Omega$ is,

$$\begin{aligned} \mathcal{W}_{if}^{(\mathrm{sp})} \ d\Omega &= \left(\int_\omega W_{if}^{(\mathrm{sp})} \rho_{free}(\omega) d\omega \right) \ d\Omega \\ &= \int_\omega \frac{\pi\hbar e^2}{\varepsilon_0 m^2 \omega V} |M_{fi}|^2 \delta(\omega + \omega_{fi}) \frac{V}{(2\pi)^3} \frac{\omega^2}{c^3} d\omega \ d\Omega = \frac{\hbar e^2}{8\pi^2 \varepsilon_0 m^2 c^3} |M_{fi}|^2 \omega_{fi} \ d\Omega \ , \end{aligned} \tag{39.24}$$

[2] See also (38.81) and (45.10) in Sec. 45.1.1.

This simplified treatment with only two atomic states considers light as a scalar field. In fact, light is a vector field and can have two independent orthogonal polarizations. The transition matrix may depend on polarization, such that,

$$\mathcal{W}_{if}^{(\mathrm{sp})} = \frac{\hbar e^2}{8\pi^2 \varepsilon_0 m^2 c^3} \int \sum_{\lambda=1,2} |M_{fi}^{\lambda}|^2 \omega_{fi} \, d\Omega \ . \tag{39.25}$$

Example 272 (*Natural linewidth of a transition*): Be $\Gamma \equiv \sum_f W_{if}^{(\mathrm{sp})}$ the spontaneous decay rate of a state $|i\rangle$. This means that its population is decreasing,

$$\dot{N}_i = -\Gamma N_i \ . \tag{39.26}$$

Since $N_i = \langle\psi_i|\psi_i\rangle$, we have $|\psi_i(t)\rangle = |\psi_i(0)\rangle e^{\imath\omega_{if}t - \Gamma t/2}$. The Fourier transform is,

$$\begin{aligned} |\xi(\omega)\rangle &= \frac{1}{\sqrt{2\pi}} \int_0^\infty |\psi_i(t)\rangle e^{-\imath\omega t} dt = \frac{1}{\sqrt{2\pi}} \int_0^\infty e^{\imath\omega_{if}t - \imath\omega t - \Gamma t/2} dt |\psi_i(0)\rangle \\ &= \frac{1}{\sqrt{2\pi}} \lim_{t\to\infty} \frac{e^{\imath(\omega_{if}-\omega)t - \Gamma t/2} - 1}{\imath(\omega_{if} - \omega) - \Gamma/2} |\psi_i(0)\rangle = \frac{1}{\sqrt{2\pi}} \frac{1}{\imath(\omega - \omega_{if}) + \Gamma/2} |\psi_i(0)\rangle \ . \end{aligned} \tag{39.27}$$

The spectrum,

$$|\xi(\omega)|^2 = \frac{1}{2\pi} \frac{1}{(\omega - \omega_{if})^2 + \Gamma^2/4} \ , \tag{39.28}$$

is a *Lorentz distribution*. Note, that the natural linewidth can be blurred by line broadening effects, such as the Doppler broadening or collisions between atoms. These effects will be discussed in the Sec. 39.5.

Excited states can sometimes decay into various states of lower energy. In this case the linewidth is simply given by the sum of the partial decay rates, since the convolution of Lorentz distributions $\mathfrak{L}_{\Gamma_k}$ with widths Γ_k is again a Lorentzian with the total width $\Gamma = \sum_k \Gamma_k$.

39.1.4 Exercises

39.1.4.1 Ex: Energy density of plane waves

Derive the result (39.7) for the temporal averages of the squares of the fields $\overline{\vec{\mathcal{E}}(\mathbf{r},t)^2} = \overline{[-\partial_t \mathbf{A}(\mathbf{r},t)]^2}$ and $\overline{\vec{\mathcal{B}}(\mathbf{r},t)^2} = \overline{[\nabla \times \mathbf{A}(\mathbf{r},t)]^2}$.

39.2 The dipolar approximation and beyond

39.2.1 Dipolar transitions

So far, we have used the matrix element $M_{fi}^{\lambda}(\omega_{fi})$ without saying how it can be calculated, nor when it is significant. In many cases of interest the calculation of this matrix element is considerably simplified by an expansion of the term $e^{-\imath\mathbf{k}\cdot\mathbf{r}}$, which is part of the matrix element (39.12) [3],

$$e^{-\imath\mathbf{k}\cdot\mathbf{r}} = 1 - \imath\mathbf{k}\cdot\mathbf{r} - \tfrac{1}{2!}(\mathbf{k}\cdot\mathbf{r})^2 + \ldots \ . \tag{39.29}$$

[3] Note however, that doing the dipole approximation via $e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}} \simeq 1$ also deactivates the operator function of the recoil operator dipole, $e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}} = |\mathbf{p} + \hbar\mathbf{k}\rangle\langle\mathbf{k}|$. For discussions of photonic recoil the operator character must be maintained even in the dipole approximation, which can be done by reinserting the recoil operator in the Hamiltonian after the dipole approximation has been applied.

This expansion is justified by the fact that the wavelength ($\sim 600\,\mathrm{nm}$ in the visible spectrum) is much larger than the size of the scattering atom, $ka_{\mathrm{B}} \ll 1$. The *dipolar approximation* supposes,

$$e^{-\imath \mathbf{k}\cdot\mathbf{r}} \simeq 1 \ , \tag{39.30}$$

such that we can remove the spatial dependence. In this approximation there is only an interaction of the *electric field* of the radiation with the atom via an electric dipole term $\mathbf{d}\cdot\vec{\mathcal{E}}$. Thus,

$$M^{\lambda}_{fi}(\omega_{fi}) = \langle f|e^{-\imath \mathbf{k}\cdot\mathbf{r}}\hat{\epsilon}\cdot\nabla|i\rangle \simeq \hat{\epsilon}\tfrac{\imath}{\hbar}\langle f|\hat{\mathbf{p}}|i\rangle = \hat{\epsilon}\tfrac{\imath m}{\hbar}\langle f|\dot{\hat{\mathbf{r}}}|i\rangle \ . \tag{39.31}$$

We can calculate the expectation value of the velocity of the moving charge by the Heisenberg equation using the unperturbed Hamiltonian,

$$M^{\lambda}_{fi}(\omega_{fi}) \simeq \hat{\epsilon}\tfrac{\imath m}{\hbar}\langle f|\tfrac{1}{\imath\hbar}[\hat{\mathbf{r}},\hat{H}_0|i\rangle = \hat{\epsilon}\tfrac{m}{\hbar^2}\langle f|\hat{\mathbf{r}}\hat{H}_0 - \hat{H}_0\hat{\mathbf{r}}|i\rangle = \hat{\epsilon}\tfrac{m}{\hbar^2}(E_i - E_f)\langle f|\hat{\mathbf{r}}|i\rangle \ . \tag{39.32}$$

The interpretation of the last equation is, that the states $|i\rangle$ and $|f\rangle$ are connected through a displacement of the electronic cloud which, therefore, represents the induction of an electric dipole during the electronic transition. It is convenient to introduce the *electric dipole moment* [4].

$$\mathbf{d}_{fi} \equiv -e\langle f|\hat{\mathbf{r}}|i\rangle \ . \tag{39.33}$$

As a result, the matrix element becomes,

$$\boxed{M^{\lambda}_{fi}(\omega_{fi}) \simeq \tfrac{m\omega_{fi}}{e\hbar}\hat{\epsilon}\cdot\mathbf{d}_{fi}} \tag{39.34}$$

and the absorption rate (39.15) is then, in the dipolar approximation,

$$\begin{aligned} W^{(\mathrm{dp})}_{fi} &= \frac{\pi e^2}{\varepsilon_0 m^2 c}\frac{I(\omega_{fi})}{\omega^2_{fi}}|M_{fi}|^2\delta(\omega-\omega_{fi}) \\ &= \frac{\pi}{\varepsilon_0\hbar^2 c}I(\omega_{fi})|\hat{\epsilon}\cdot\mathbf{d}_{fi}|^2\delta(\omega-\omega_{fi}) = \frac{4\pi^2\alpha}{\hbar}I(\omega_{fi})|\hat{\epsilon}\cdot\mathbf{r}_{fi}|^2\delta(\omega-\omega_{fi}) \ . \end{aligned} \tag{39.35}$$

using the definition of the fine structure constant $\alpha = e^2/4\pi\varepsilon_0\hbar c$.

39.2.1.1 Polarization dependence

Following Eq. (39.34) the absorption rate depends on the orientation of the dipole moment with respect to the polarization of light, which therefore plays an important role in this transition. When $\mathbf{d}_{fi}$ between two states is zero, the transition via electric dipole radiation is prohibited. This is not to say that there is no transition, since other terms of the expansion (39.29) are not necessarily zero, and there may be transitions of higher multipolar orders. Even the matrix element $M^{\lambda}_{fi}(\omega_{fi})$ being zero for transitions involving one photon, there is still the possibility of two-photon transitions.

Setting θ as the angle between $\hat{\epsilon}$ and $\mathbf{d}_{fi}$ we obtain,

$$W^{(\mathrm{dp})}_{fi} = \frac{\pi}{\varepsilon_0\hbar^2 c}I(\omega_{fi})|\mathbf{d}_{fi}|^2\cos^2\theta\ \delta(\omega-\omega_{fi}) \ . \tag{39.36}$$

[4] In the presence of several atoms $\mathbf{d} = -e\sum_j \mathbf{r}_j$, where the $\mathbf{r}_j$ are the radii of the orbits of the various electrons of the atom.

In case of unpolarized (or randomly polarized) radiation we can replace the angular distribution $\cos^2\theta$ by its average value,

$$\overline{\cos^2\theta} = \frac{1}{4\pi}\int_0^{2\pi}\int_0^{\pi}\cos^2\theta\sin\theta d\theta d\phi = \tfrac{1}{3}\ , \tag{39.37}$$

such that,

$$\boxed{W_{fi}^{(\text{dp,no-pol})} = \frac{\pi}{3\varepsilon_0\hbar^2 c}I(\omega_{fi})|\mathbf{d}_{fi}|^2\delta(\omega-\omega_{fi})}\ . \tag{39.38}$$

This expression also represents the stimulated emission rate in the electric dipole approximation.

The total spontaneous emission rate can be obtained from Eq. (39.25) integrating over all possible orientations,

$$\begin{aligned}\mathcal{W}_{fi}^{(\text{sp})} &= \frac{\hbar e^2}{8\pi^2\varepsilon_0 m^2c^3}\int\sum_{\lambda=1,2}|M_{fi}^{\lambda}|^2\omega_{fi}d\Omega \\ &= 2\frac{\hbar e^2}{8\pi^2\varepsilon_0 m^2c^3}\int_0^{2\pi}\int_0^{\pi}\left|\frac{m\omega_{fi}}{e\hbar}\hat{\epsilon}\cdot\mathbf{d}_{fi}\right|^2\omega_{fi}\sin\theta d\theta d\phi \\ &= \frac{e^2}{4\pi^2\varepsilon_0\hbar c^3}\omega_{fi}^3|\mathbf{r}_{fi}|^2\int_0^{2\pi}\int_0^{\pi}\cos^2\theta\sin\theta d\theta d\phi = \frac{e^2}{3\pi\varepsilon_0\hbar c^3}\omega_{fi}^3|\mathbf{r}_{fi}|^2\ ,\end{aligned} \tag{39.39}$$

such that, for non-polarized light,

$$\boxed{\mathcal{W}_{fi}^{(\text{sp})} = \frac{4\alpha}{3c^2}\omega_{fi}^3|\mathbf{r}_{fi}|^2 = \frac{4\alpha}{3c^2}\omega_{fi}^3|\mathbf{r}_{fi}|^2 = \Gamma}\ . \tag{39.40}$$

This is the rate of spontaneous decay of an excited atomic state. It can be measured experimentally which, in turn, allows the calculation of the *induced dipole moment*,

$$d_{fi} = \sqrt{\frac{3\pi\varepsilon_0\hbar\Gamma}{k^3}}\ . \tag{39.41}$$

In Exc. 39.2.6.1 we calculate the Rabi frequency from the dipole moment of an atomic transition and the electric field of a radiation field.

39.2.2 Einstein transition rates

Considering the problem of the transfer of energy between the electromagnetic field and a sample of atoms in thermal equilibrium, Einstein realized that the processes of absorption and stimulated emission are not sufficient to understand the radiative coupling between two energy levels, that is, the coupling is not correctly described by Fermi's Golden rule, and we need to introduce the notion of spontaneous emission. Differently from the derivation of the preceding section, Einstein considered atoms whose populations of energy states are in thermal equilibrium with the electromagnetic field of a *black-body*. With this picture he came to the same result for the spontaneous emission rate (39.38), as we will show in the following.

The famous *Einstein coefficients* A_{fi} and B_{fi} are given by (23.70),

$$A_{fi}N_f = W_{fi}^{(\mathrm{sp})} \qquad \text{and} \qquad \frac{A_{fi}}{B_{fi}} = \frac{\hbar\omega_{fi}^3}{\pi^2 c^3} \ , \tag{39.42}$$

where N_f is the population of the excited state. This shows that, in fact, spontaneous emission is a necessary consequence of the interaction of an atom with a *thermal bath* (also called *reservoir*).

We now consider the problem of energy transfer between an electromagnetic field and a sample of atoms. The rate of *absorption* of a light field is,

$$R_{i\to f} \equiv \tfrac{1}{3}\dot{P}_{i\to f} = \frac{\pi}{6\hbar^2}\mathcal{E}_0^2|d_{fi}|^2\varrho(\omega_{fi}) \ , \tag{39.43}$$

with $W_0 = \mathcal{E}_0 d_{fi}$ and d_{fi} being the transition matrix element between atomic states. The factor $\frac{1}{3}$ comes from the fact that the vector $\vec{\mathcal{E}}$ of the electric field can have any polarization, but only polarizations along the direction of the oscillation of the dipole moment contribute.

For a single atom, the result (39.43) is symmetric with respect to an exchange of the initial and final states, that is, the rates for absorption and *induced emission* of light are the same. For a sample of atoms being in *thermal equilibrium*, the populations N_i of the ground state and N_f of the excited state are unequal according to Boltzmann's law. Therefore, as we have shown in Sec. 23.2.5,

$$N_f R_{f\to i} \neq N_i R_{i\to f} \ . \tag{39.44}$$

Thus, Einstein came to the conclusion that Fermi's golden rule correctly describes absorption, but does not contain all contributions of emission. The rates being related to the Einstein coefficients by the equation (23.65), we find,

$$R_{f\to i} = B_{fi}N_f u(\omega_{fi}) \tag{39.45}$$

and

$$\mathcal{S}_{f\to i} = A_{fi}N_f = \frac{\hbar\omega_{fi}^3}{\pi^2c^3}B_{if}N_f = \frac{\hbar\omega_{fi}^3}{\pi^2c^3}\frac{R_{i\to f}}{u(\omega_{fi})} = \frac{\omega_{fi}^3}{3\pi\epsilon_0\hbar c^3}|d_{fi}|^2 \ , \tag{39.46}$$

exploiting the relation (23.70).

Example 273 (*Line and oscillator strength*): Several disciplines such as spectrometry, spectroscopy and astrophysics have developed their own terminologies to describe absorption and emission of light by matter. We will explain how the most frequently used parameters are interrelated by placing particular emphasis on the simplest system, which is the two-level atom with no degeneracy and no spin.

In addition to the Einstein coefficients A_{21}, B_{21}, and B_{12}, the amplitude of the transition dipole moments d_{12} and the absorption cross-section $\sigma_{0a}(\omega)$, three other quantities are sometimes used to characterize atomic transitions: the oscillator strength f, the line strength S, and the spectral absorption cross section σ_ω. In the following sections, we will connect these different concepts.

The line strength S is defined as the square of the transition dipole moment summed over all degeneracies of the ground and excited states,

$$S_{12} = S_{21} = \sum_{m_1,m_2} |\langle\psi_{1,m_1}|d|\psi_{2,m_2}\rangle|^2 \ . \tag{39.47}$$

The notion of the line strength becomes significant when working with real atoms characterized by degenerate ground and excited states. In such cases we need to extend the meaning of d_{12} and consider transitions between each of the degenerate sublevels. For a non-degenerate two-level atom, the quantities d_{12} and A_{21} are simply related by,

$$A_{21} = \frac{\omega_0^3}{3\pi\epsilon_0\hbar c^3} d_{12}^2 \ . \tag{39.48}$$

If the lower level would be degenerate, the spontaneous emission rate coefficient would be given by the sum of all possible deexcitation rates. In this case, d_{12}^2 is defined as the sum of the elements of the transition matrix coupling the excited and the lower states,

$$d_{12}^2 = \sum_{m_1} |\langle\psi_{1,m_1}|d|\psi_2\rangle|^2 \ . \tag{39.49}$$

Now, it can be shown that the spontaneous emission rate from any sublevel of a degenerate excited state toward a lower level (that is, the sum over all lower sublevels) is the same for all excited sublevels [5] This statement reflects the intuitively plausible idea that spontaneous emission must be isotropic and unpolarized, if the sublevels of an excited state are uniformly populated. Therefore, the insertion of Eq. (39.49) into (39.48) should produce correct results, even when the excited state is degenerate. Comparing the sum over all upper and lower degeneracies with the line strength S,

$$S_{12} = \sum_{m_1,m_2} |\langle\psi_{1,m_1}|d|\psi_{2,m_2}\rangle|^2 = g_2 d_{12}^2 \ . \tag{39.50}$$

Therefore, the insertion of Eq. (39.50) into (39.48) must be accompanied by a factor of $1/g_2$ to correct for the fact that all excited sub-levels radiate at the same rate. Therefore, using the S_{12} of Eq. (39.50) the correct expression relating the transition dipole between degenerate levels to the spontaneous emission rate is,

$$S_{12} = g_2 \frac{3\pi\epsilon_0\hbar c^3}{\omega_0^3} A_{21} \ , \tag{39.51}$$

meaning that the line strength is proportional to the sum of the spontaneous emission rates A_{21} from each one of the g_2 excited levels toward all fundamental levels.

For an atom with two levels separated by an energy $\hbar\omega_0$ the *oscillator strength for emission* is defined as a measure for the radiative decay rate A_{21} as compared to the radiative decay rate γ_e of a classical electronic oscillator with frequency ω_0:

$$f_{21} = -\frac{1}{3}\frac{A_{21}}{\gamma_e} \ . \tag{39.52}$$

[5] This applies to Zeeman sublevels (summing up $(3j)$-coefficients). Check for other degeneracy (also summing up $\{6j\}$-coefficients)!

In case of degeneracy the *oscillator strength for absorption* is consequently defined by,

$$f_{12} = -\frac{g_2}{g_1} f_{21} = \frac{g_2}{3g_1} \frac{A_{21}}{\gamma_e} \ . \tag{39.53}$$

The transitions $S \leftrightarrow P$ in real atoms behave roughly as classical oscillators, that is, $A_{21} \simeq \gamma_e$. The factor $\frac{1}{3}$ in the definition compensates for the triple degeneracy of the P levels. So, a transition $S \leftrightarrow P$ which behaves exactly as a classical oscillator would be characterized by an oscillator strength for emission of $f_{21} = -\frac{1}{3}$ and an oscillator strength for absorption of $f_{12} = 1$. The classical expression for γ_e derived from the *Lorentz model* is [388],

$$\gamma_e = \frac{e^2 \omega_0^2}{6\pi\epsilon_0 m_e c^3} \ . \tag{39.54}$$

Therefore, in terms of the A_{21} coefficient and of fundamental constants, the oscillator strength for absorption is given by,

$$f_{12} = A_{21} \frac{2\pi\epsilon_0 m_e c^3}{e^2 \omega_0^2} \ . \tag{39.55}$$

Oscillator strengths obey certain sum rules that are useful for analyzing the relative intensities of atomic spectral lines. For example, atoms with single valence electrons (which are closer to the classical situation) obey the following sum rule,

$$\sum_k f_{ik} = 1 \ , \tag{39.56}$$

where the sum goes over all the excited states reached from the ground state. Alkaline atoms are approximately one-electron systems, and the oscillator strength of the first transition $S \longrightarrow P$ is typically of the order of $f_{12} = 0.7 - 0.95$. The sum rule tells us that most of the total transition probability for the excitation of the valence electron is concentrated in the first transition $S \to P$, and that transitions to higher states will be comparatively weaker. Another sum rule exists for the excitation and spontaneous emission from excited intermediate states j:

$$\sum_{i<j} f_{ji} + \sum_{k>j} f_{jk} = Z \ , \tag{39.57}$$

which is called the *Thomas-Reiche-Kuhn sum rule*. In the form of many electrons [Eq. (39.57)] this rule is very useful, when Z is the number of equivalent electrons, that is, electrons with the same quantum numbers n, l. Note also, that the numbers are intrinsically negative. Oscillator strengths are often used in astrophysics and plasma spectroscopy [6]. They are sometimes tabulated as $\log gf$, where,

$$g_1 f_{12} = -g_2 f_{21} \equiv gf \ . \tag{39.58}$$

39.2.3 Selection rules and electronic transitions

The selection rules that determine which transitions between two sets of quantum numbers $i \to f$ are allowed, reflect the symmetry properties of the system, e.g. the

[6] To find information about the atomic transition lines see 'http://www.nist.gov/pml/data/asd.cfm'.

conservation of angular momentum (including the spin of the photon) or the change of parity, which can be understood by the fact that the emission of a photon in a particular direction must in some way alter the spatial isotropy of the atom. Note that radially symmetric oscillations of the shape of the charge distribution *do not radiate*.

Since the electronic transitions via electric dipole radiation are described by $|\hat{\epsilon}\cdot\mathbf{r}_{fi}|$, we expect a strong dependence of the transition rate on the orientation of the polarization state of the light with respect to the electronic displacement $\mathbf{r}_{fi}$. Let us express $\hat{\epsilon}$ and $\mathbf{r}_{fi}$ in spherical coordinates, which are more adapted to the problem [7]. For an arbitrary vector $\mathbf{r}$ we have,

$$x = \mathbf{r}\cdot\hat{\mathbf{e}}_x = r\sin\vartheta\cos\varphi \quad , \quad y = \mathbf{r}\cdot\hat{\mathbf{e}}_y = r\sin\vartheta\sin\varphi \quad , \quad z = \mathbf{r}\cdot\hat{\mathbf{e}}_z = r\cos\vartheta \ . \tag{39.59}$$

Defining,

$$\hat{\mathbf{e}}_{\pm1} \equiv \tfrac{1}{\sqrt{2}}(\mp\hat{\mathbf{e}}_x - \imath\hat{\mathbf{e}}_y) \qquad , \qquad \hat{\mathbf{e}}_0 \equiv \hat{\mathbf{e}}_z \ . \tag{39.60}$$

we obtain

$$\begin{aligned} r_{\pm1} &\equiv \mathbf{r}\cdot\hat{\mathbf{e}}_\pm = \mathbf{r}\cdot\tfrac{1}{\sqrt{2}}(\mp\hat{\mathbf{e}}_x - \imath\hat{\mathbf{e}}_y) = \tfrac{1}{\sqrt{2}}(\mp x - \imath y) = \mp\tfrac{1}{\sqrt{2}}r\sin\vartheta e^{\pm\imath\varphi} = r\sqrt{\tfrac{4\pi}{3}}Y_{1,\pm1}(\vartheta,\varphi) \\ r_0 &\equiv \mathbf{r}\cdot\hat{\mathbf{e}}_0 = \mathbf{r}\cdot\hat{\mathbf{e}}_z = z = r\cos\vartheta = r\sqrt{\tfrac{4\pi}{3}}Y_{1,0}(\vartheta,\varphi) \ . \end{aligned} \tag{39.61}$$

Now, applying the expansion into spherical coordinates to the polarization, we get,

$$\epsilon_{\pm1} \equiv \hat{\epsilon}\cdot\hat{\mathbf{e}}_\pm \qquad , \qquad \epsilon_0 \equiv \hat{\epsilon}\cdot\hat{\mathbf{e}}_0 \ . \tag{39.62}$$

and applying the expansion to the matrix element $\mathbf{r}_{fi} = \langle f|\mathbf{r}|i\rangle$ with $\hat{\mathbf{e}}_q\cdot\hat{\mathbf{e}}_{q'} = \delta_{qq'}$, it is easy to check,

$$\hat{\epsilon}\cdot\mathbf{r}_{fi} = \sum_{q=0,\pm1}(\hat{\epsilon}\cdot\hat{\mathbf{e}}_q)\hat{\mathbf{e}}_q\cdot\sum_{q=0,\pm1}(\mathbf{r}_{fi}\cdot\hat{\mathbf{e}}_q)\hat{\mathbf{e}}_q = \sum_{q=0,\pm1}\epsilon_q\langle f|r_q|i\rangle = \sqrt{\tfrac{4\pi}{3}}\sum_{q=0,\pm1}\epsilon_q\langle f|rY_{1,q}|i\rangle \ . \tag{39.63}$$

The matrix elements are evaluated inserting the ansatz (25.18) separating the radial from the angular part of the wavefunction, where the angular part is solved by (25.32),

$$\begin{aligned} \langle f|r_q|i\rangle &= \sqrt{\tfrac{4\pi}{3}}\langle n_f\ell_f m_f|rY_{1,q}|n_i\ell_i m_i\rangle \\ &= \int_0^\infty r^3 R_{n_f,\ell_f}R_{n_i,\ell_i}dr\ \sqrt{\tfrac{4\pi}{3}}\int Y^*_{\ell_f,m_f}Y_{1,q}Y_{\ell_i,m_i}d\Omega \ . \end{aligned} \tag{39.64}$$

The angular integral,

$$\int Y^*_{\ell_f,m_f}Y_{\kappa,q}Y_{\ell_i,m_i}d\Omega = \sqrt{\tfrac{(2\ell_i+1)(2\ell_f+1)}{4\pi(2\kappa+1)}}\begin{pmatrix}\ell_i & \kappa & \ell_f\\ 0 & 0 & 0\end{pmatrix}\begin{pmatrix}\ell_i & \kappa & \ell_f\\ m_i & q & m_f\end{pmatrix} \ , \tag{39.65}$$

[7] In the presence of a magnetic field it is often useful to choose the quantization axis along the field direction, because this simplifies the interpretation of π and $\sigma_\pm$ transitions in terms of light polarizations (see also Secs. 39.6.4 and 39.7.2).

here with $\kappa = 1$, is only non-zero, if the values of ℓ_i, m_i, ℓ_f, m_f and q satisfy certain conditions called *selection rules* [8].

The radial integral, together with the coefficients of (39.65) which do not depend on the magnetic quantum numbers, is called *reduced matrix element* or *irreducible matrix element* with the notation,

$$\langle n_f \ell_f || r || n_i \ell_i \rangle \equiv \int_0^\infty r^3 R_{n_f,\ell_f} R_{n_i,\ell_i} dr \sqrt{\tfrac{(2\ell_i+1)(2\ell_f+1)}{3(2\kappa+1)}} \left(\begin{array}{cc|c} \ell_i & \kappa & \ell_f \\ 0 & 0 & 0 \end{array}\right) . \tag{39.66}$$

Defining the electric dipole tensor operator,

$$Q_1^q(\mathbf{r}) = e r_q(\mathbf{r}) = \sqrt{\tfrac{4\pi}{3}} Y_{1,q}(\vartheta, \varphi) e r \ , \tag{39.67}$$

we can finally write,

$$\boxed{\langle n_f \ell_f m_f | Q_1^q(\mathbf{r}) | n_i \ell_i m_i \rangle = \langle n_f \ell_f || e r || n_i \ell_i \rangle \left(\begin{array}{cc|c} \ell_i & 1 & \ell_f \\ m_i & q & m_f \end{array}\right)} . \tag{39.68}$$

This is the *Wigner-Eckart theorem*. The electric dipole operator is a simpler example of a tensor operator $Q_\kappa^q(\mathbf{r})$ characterizing the transition between atomic states. In Excs. 39.2.6.2 and 39.2.6.3 we explicitly calculate, for a hydrogen atom subjected to a magnetic field, components of the electric dipole operator. Resolve Exc. 39.2.6.4.

Selection rules may be violated in higher orders, e.g. by multipolar radiation, as in the cases of *magnetic dipole transitions* or *electric quadrupole transitions*. This also is the case of the phenomenon of *phosphorescence*, which is a type of fluorescence emitted by metastable states.

39.2.3.1 Parity

The *parity* of a state has been defined as,

$$\mathcal{P}\psi_{n\ell m}(\mathbf{r}) = \psi_{n\ell m}(-\mathbf{r}) = (-1)^\ell \psi_{n\ell m}(\mathbf{r}) \ , \tag{39.69}$$

as shown above. That is, states with ℓ pair (impair) have even (odd) parity. Now the integral (39.67) only does not vanish, when $\ell_i + \ell_f + 1 = even$. Therefore, *dipole transitions must change the parity of the states*. F.ex. transitions $S \to P$ would be possible, while $S \to S$ would be prohibited.

39.2.3.2 Angular momentum

The irreducible matrix element (39.66) with $\kappa = 1$ is only non-zero, when $|\ell_f - \ell_i| \leq 1 \leq \ell_f + \ell_i$. That is, *dipole transitions can not change the angular momentum by more than one unit.*

[8] Frequently used are the $(3j)$-symbols connected to the Clebsch-Gordan coefficients by,

$$\langle j_i m_i, j_f m_f | J, M \rangle = (-1)^{j_i - j_f + M} \sqrt{2J+1} \begin{pmatrix} j_i & j_f & J \\ m_i & m_f & -M \end{pmatrix} .$$

39.2.3.3 Magnetic quantum number

In the decomposition (39.68) the Clebsch-Gordan coefficient is only non-zero, when $|q| \leq 1$. That is, *dipole transitions can not change the magnetic quantum number by more than one unit.* This can also be seen from,

$$\int Y^*_{\ell_f,m_f} Y_{\kappa,q} Y_{\ell_i,m_i} d\Omega \propto \int e^{\imath(m_i+q-m_f)} d\Omega \propto \delta_{m_i+q,m_f} \ . \tag{39.70}$$

39.2.3.4 Selection rules for emission in certain directions

As shown in Eq. (39.63), the excitation rate induced by a light field depends on the relative orientation of the laser polarization $\hat{\epsilon}$ and the atomic quantization axis (which may be set by the orientation of an applied magnetic field $\vec{\mathcal{B}}$). To take this dependence into account, we decompose the polarization vector (which can be linear or elliptical) on a coordinate basis, as shown in Eq. (39.62). Thus, the relative amplitude of the transitions $\Delta m_J = 0$ is proportional to the projection of the polarization vector onto the quantization axis, $\epsilon_0 \equiv \hat{\epsilon} \cdot \hat{\mathbf{e}}_0$. To estimate the amplitude of the transitions $\Delta m_J = \pm 1$, we must project onto the coordinates $\epsilon_{\pm 1} \equiv \hat{\epsilon} \cdot \hat{\mathbf{e}}_\pm$. Note that the direction of incidence of the beam, given by the wavevector $\mathbf{k}$, does not influence the transition probability directly (after all, the spatial dependence $e^{\imath \mathbf{k}\cdot\mathbf{r}}$ was removed by the dipolar approximation (39.29)); only through the fact, that the polarization is perpendicular to the propagation vector, $\hat{\epsilon} \perp \mathbf{k}$.

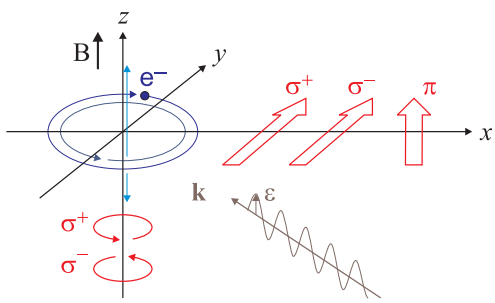


Figure 39.1: Selection rules due to polarization $\hat{\epsilon}$ of the incident light. The projection of this vector onto the axes $\pi = \hat{\epsilon} \cdot \hat{\mathbf{e}}_0$ and $\sigma_\pm = \hat{\epsilon} \cdot \hat{\mathbf{e}}_\pm$ is proportional to the excitation probability (and, obviously, also to the emission probability).

39.2.4 Reduction of the fine and hyperfine structure

In Sec. 39.2.3 we developed the Wigner-Eckart theorem for arbitrary angular momenta ℓ_i and ℓ_f. We will now be more specific identifying them with orbital angular momenta, $(\ell_i, \ell_f) = (\mathbf{L}, \mathbf{L}')$, total angular momenta of the electron shell, $(\ell_i, \ell_f) = (\mathbf{J}, \mathbf{J}')$, or total angular momenta including hyperfine structure, $(\ell_i, \ell_f) = (\mathbf{F}, \mathbf{F}')$.

39.2.4.1 Summary of selection rules including fine structure

The fine structure is due to a coupling of the type $\mathbf{L}+\mathbf{S}=\mathbf{J}$. The reduced matrix element (39.66) can then be recoupled as follows,

$$\boxed{\begin{aligned}\langle J', m'_J|\hat{\mathbf{d}}|J, m_J\rangle &= \langle J'||\hat{\mathbf{d}}||J\rangle \left(\begin{array}{cc|c} J & \kappa & J' \\ m_J & q & m'_J \end{array}\right) \quad \text{with} \\ \langle (L',S')J'||\hat{\mathbf{d}}||(L,S)J\rangle &= (-1)^{J+L'+1+S}\sqrt{(2J+1)(2L'+1)}\begin{Bmatrix} L' & L & 1 \\ J & J' & S \end{Bmatrix}\langle L'||\hat{\mathbf{d}}||L\rangle \end{aligned}} , \tag{39.71}$$

where the matrix in the second line represents a so-called *{6j}-symbol*, and the first line rewrites the Wigner-Eckart theorem (39.68) for total angular momenta. In this case,

$$\begin{aligned}\langle (L,S)Jm_J|er|(L',S')J'm'_J\rangle &= (-1)^{J+L'+1+S}\sqrt{2J+1}\sqrt{2L'+1}\ \times \\ &\times \delta_{S'S}\begin{Bmatrix} L & L' & 1 \\ J' & J & S \end{Bmatrix}\begin{pmatrix} J' & 1 & J \\ m'_J & q & -m_J \end{pmatrix}\langle n'L'||er||nL\rangle \\ &\propto \delta_{S'S}\begin{Bmatrix} L & L' & 1 \\ J' & J & S \end{Bmatrix}\begin{pmatrix} J' & 1 & J \\ m'_J & q & -m_J \end{pmatrix}\begin{pmatrix} L' & 1 & L \\ 0 & 0 & 0 \end{pmatrix} ,\end{aligned} \tag{39.72}$$

Electric dipolar transitions are excited by Stark-like perturbations,

$$\hat{V}_{\text{Stark}} = -e\mathbf{d}\cdot\mathcal{E} , \tag{39.73}$$

where $\mathcal{E}=\mathcal{E}_0\cos(\mathbf{k}\cdot\mathbf{r}-\omega t)$ is the electric field of an electromagnetic oscillating wave with polarization $\mathcal{E}_0$. With $\mathbf{d}=ez\hat{\mathbf{e}}_z$, in order to determine which dipole transitions are possible, we must look at the matrix $\langle J'm'_J|\hat{z}|Jm_J\rangle$. Applying the Wigner-Eckart theorem (33.72), it is already possible to determine, between which magnetic quantum numbers m_J and m'_J transitions may occur.

We can compare the amplitudes of the various transitions between states $|m_J\rangle$ and $|m'_J\rangle$ via the Clebsch-Gordan coefficients (see Exc. 33.3.2.1). Again, transitions are only possible between states for which the corresponding Clebsch-Gordan coefficient does not zero. Looking at the equations (33.74), we find for dipolar transitions the following selection rules,

$$\begin{aligned}&\Delta J = 0, \pm 1 \ \text{ but } \ (J=0)\to(J'=0) \ \text{ is prohibited} \\ &\Delta m_J = 0, \pm 1 \ \text{ but } \ (m_J=0)\to(m'_J=0) \ \text{ is prohibited when } \ \Delta J = 0 .\end{aligned} \tag{39.74}$$

In addition, we have for the $\mathbf{L}\cdot\mathbf{S}$ coupling,

$$\Delta S = 0, \Delta L = \pm 1 \ \text{ and for the electron undergoing the transition } \ \Delta\ell = \pm 1 . \tag{39.75}$$

In the presence of a strong magnetic field (Paschen-Back regime) breaking up the $\mathbf{L}\cdot\mathbf{S}$-coupling the selection rules are,

$$\Delta m_S = 0, \Delta m_L = 0, \pm 1 . \tag{39.76}$$

For $\mathbf{j}\cdot\mathbf{j}$-coupling,

$$\Delta j = 0, \pm 1 \ \text{ for one electron and } \ \Delta j = 0 \ \text{ for all others} . \tag{39.77}$$

For all dipole transitions the parity must change between even and odd.

Table 39.1: Allowed transitions: (1-3) rigorous rules, (4-5) LS-coupling, and (6) intermediate coupling (https://en.wikipedia.org/wiki/Selection_rule).

	(E1)	(M1)	(E2)	(M2)	(E3)	(M3)
(1)	$\Delta J = 0, \pm 1$ ($\Delta J = 0 \nleftrightarrow 0$)		$\Delta J = 0, \pm 1, \pm 2$ ($\Delta J = 0 \nleftrightarrow 0, 1; \frac{1}{2} \nleftrightarrow \frac{1}{2}$)		$\Delta J = 0, \pm 1, \pm 2, \pm 3$ ($0 \nleftrightarrow 0, 1, 2; \frac{1}{2} \nleftrightarrow \frac{1}{2}, \frac{3}{2}; 1 \nleftrightarrow 1$)	
(2)	$\Delta M_J = 0, \pm 1$		$\Delta M_J = 0, \pm 1, \pm 2$		$\Delta M_J = 0, \pm 1, \pm 2, \pm 3$	
(3)	$\mathcal{P}_f = -\mathcal{P}_i$	$\mathcal{P}_f = \mathcal{P}_i$		$\mathcal{P}_f = -\mathcal{P}_i$		$\mathcal{P}_f = \mathcal{P}_i$
(4)	one e^- jump $\Delta L = \pm 1$	no e^- jump $\Delta L = 0; \Delta n \neq 0$	none or one e^- jump $\Delta L = 0, \pm 2$	one e^- jump $\Delta L = \pm 1$	one e^- jump $\Delta L = \pm 1, \pm 3$	one e^- jump $\Delta L = 0, \pm 2$
(5)	if $\Delta S = 0$ $\Delta L = 0, \pm 1$ ($L = 0 \nleftrightarrow 0$)	if $\Delta S = 0$ $\Delta L = 0$	if $\Delta S = 0$ $\Delta L = 0, \pm 1, \pm 2$ ($L = 0 \nleftrightarrow 0, 1$)		if $\Delta S = 0$ $\Delta L = 0, \pm 1, \pm 2, \pm 3$ ($L = 0 \nleftrightarrow 0, 1, 2; 1 \nleftrightarrow 1$)	
(6)	if $\Delta S = \pm 1$ $\Delta L = 0, \pm 1, \pm 2$		if $\Delta S = \pm 1$ $\Delta L = 0, \pm 1, \pm 2, \pm 3$ ($L = 0 \nleftrightarrow 0$)	if $\Delta S = \pm 1$ $\Delta L = 0, \pm 1$ ($L = 0 \nleftrightarrow 0$)	if $\Delta S = \pm 1$ $\Delta L = 0, \pm 1, \pm 2, \pm 3, \pm 4$ ($L = 0 \nleftrightarrow 0, 1$)	if $\Delta S = \pm 1$ $\Delta L = 0, \pm 1, \pm 2$ ($L = 0 \nleftrightarrow 0$)

Example 274 (*Transitions allowed and prohibited in the dipolar approximation*): Examples of allowed transitions are ${}^2S_{1/2} \leftrightarrow {}^2P_{1/2}$, ${}^1S_0 \leftrightarrow {}^1P_0$. Prohibited transitions are ${}^1S_0 \nleftrightarrow {}^3P_1$, ${}^2S_{1/2} \nleftrightarrow {}^2D_{3/2}$, $(5s)^2\,{}^3P_0 \nleftrightarrow (5s6s)\,{}^3P_0$.

39.2.4.2 Summary of selection rules including hyperfine structure

The fine structure is due to a coupling of the type $\mathbf{J} + \mathbf{I} = \mathbf{F}$. The reduced matrix element (39.66) can then be recoupled in a similar way as for the fine structure. Applying the Wigner-Eckart theorem (25.107) to the *hyperfine structure* [966],

$$\boxed{\begin{aligned}
\langle F', m'_F|\hat{\mathbf{d}}|F, m_F\rangle &= \langle F'||\hat{\mathbf{d}}||F\rangle \left(\begin{array}{cc|c} F & \kappa & F' \\ m_F & q & m'_F \end{array}\right) \qquad \text{with} \\
\langle (J', I')F'||\hat{\mathbf{d}}||(J, I)F\rangle &= (-1)^{F+J'+1+I}\sqrt{(2F+1)(2J'+1)} \begin{Bmatrix} J' & J & 1 \\ F & F' & I \end{Bmatrix} \langle J'||\hat{\mathbf{d}}||J\rangle \\
\langle (L', S')J'||\hat{\mathbf{d}}||(L, S)J\rangle &= (-1)^{J+L'+1+S}\sqrt{(2J+1)(2L'+1)} \begin{Bmatrix} L' & L & 1 \\ J & J' & S \end{Bmatrix} \langle L'||\hat{\mathbf{d}}||L\rangle
\end{aligned}} \; . \tag{39.78}$$

39.2.5 Irreducible tensor operators

Irreducible tensor operators are defined by their commutation relation with the angular momentum $\mathbf{J}$,

$$[\mathbf{J}, \mathbb{T}^{(k)}_q] = \sum_{q'} \langle kq|\mathbf{J}|kq'\rangle T^{(k)}_{q'} \; . \tag{39.79}$$

Using the spherical unit vectors $\hat{\mathbf{e}}_{\pm 1} = \frac{1}{\sqrt{2}}(\mp\hat{\mathbf{e}}_x - \imath\hat{\mathbf{e}}_y)$ and $\hat{\mathbf{e}}_0 = \hat{\mathbf{e}}_z$, we can reduce Cartesian vector operators to first-order tensor operators:

$$\vec{T} = \sum_q T^{(1)}_q \hat{\mathbf{e}}_q \qquad \text{resp.} \qquad T^{(1)}_q = \vec{T} \cdot \hat{\mathbf{e}}_q \; . \tag{39.80}$$

Examples for tensor operators are $\mathbb{I}_0^{(0)}$, $\hat{\mathbf{e}}_q^{(1)}$, $\mathbf{J}_q^{(1)}$, and $Y_q^{(k)}$. The most general tensor product is defined by:

$$(\mathbb{T}^{(k)} \times \mathbb{U}^{(k')})_m^{(j)} \equiv \sum_{q,q'} \begin{pmatrix} k & k' & j \\ q & q' & -m \end{pmatrix} \mathbb{T}_q^{(k)} \mathbb{U}_{q'}^{(k')} \ . \tag{39.81}$$

With this product it is possible to represent scalar, vector or tensor products of higher ranks,

$$\begin{aligned}
(\mathbb{T}^{(1)} \times \mathbb{U}^{(1)})_0^{(0)} &= \tfrac{1}{\sqrt{3}} \vec{\mathbb{T}} \cdot \vec{\mathbb{U}} \\
(\mathbb{T}^{(1)} \times \mathbb{U}^{(1)})_m^{(1)} &= \tfrac{1}{\sqrt{2}} (\vec{\mathbb{T}} \times \vec{\mathbb{U}}) \cdot \hat{\mathbf{e}}_m \\
(\mathbb{T}^{(1)} \times \mathbb{U}^{(1)})_0^{(2)} &= -\tfrac{1}{\sqrt{6}} (3\mathbb{T}_z \mathbb{U}_z - \vec{\mathbb{T}} \cdot \vec{\mathbb{U}}) \\
(\mathbb{T}^{(1)} \times \mathbb{U}^{(1)})_{\pm 1}^{(2)} &= \pm \tfrac{1}{2} [(\mathbb{T}_x \mathbb{U}_z + \mathbb{T}_z \mathbb{U}_x) \pm \imath (\mathbb{T}_y \mathbb{U}_z + \mathbb{T}_z \mathbb{U}_y)] \\
(\mathbb{T}^{(1)} \times \mathbb{U}^{(1)})_{\pm 2}^{(2)} &= -\tfrac{1}{2} [(\mathbb{T}_x \mathbb{U}_x - \mathbb{T}_y \mathbb{U}_y) \pm \imath (\mathbb{T}_x \mathbb{U}_y + \mathbb{T}_y \mathbb{U}_x)] \ .
\end{aligned} \tag{39.82}$$

39.2.5.1 The Wigner-Eckart theorem

Be $\mathbb{T}_q^{(k)}$ an irreducible tensor of rank k. Then, there exists then an irreducible matrix element $\langle j || \mathbb{T}^{(k)} || j' \rangle$, which does not depend on the Zeeman sublevels:

$$\langle jm | \mathbb{T}_q^{(k)} | j'm' \rangle = \begin{pmatrix} j' & k & j \\ m' & q & -m \end{pmatrix} \frac{1}{\sqrt{2j+1}} \langle j || \mathbb{T}^{(k)} || j' \rangle \ . \tag{39.83}$$

From the possible values for the Clebsch-Gordan coefficients follow directly the selection rules for multipolar radiation:

$$\begin{aligned}
\langle jm | \mathbb{T}_q^{(k)} | j'm' \rangle = 0 \qquad \text{else} \qquad & E' - E = \hbar\omega \\
& |j' - j| \le k \le j' + j \\
& m' - m = q \\
& \tau' \tau = T \ .
\end{aligned} \tag{39.84}$$

For tensor products the reduced matrix element can be reduced:

$$\langle j || (\mathbb{T}^{(k)} \times \mathbb{U}^{(k')})^{(l)} || j' \rangle = (-)^{j+\ell+j'} \sqrt{2\ell+1} \sum_q \begin{Bmatrix} k & k' & \ell \\ j' & j & q \end{Bmatrix} \langle j || \mathbb{T}^{(k)} || q \rangle \langle q || \mathbb{U}^{(k')} || \mathrm{j}' \rangle \ . \tag{39.85}$$

In particular, it is possible to show,

$$\begin{aligned}
\langle j || \mathbb{I}^{(0)} || j' \rangle &= \sqrt{2j+1} \delta_{jj'} \\
\langle j || \mathbb{J}^{(1)} || j' \rangle &= \sqrt{2j+1} \sqrt{j(j+1)} \delta_{jj'} \\
\langle j || \mathbb{Y}^{(k)} || j' \rangle &= \imath^{j+k+j'} \frac{\sqrt{2j+1}\sqrt{2k+1}\sqrt{2j'+1}}{4\pi} \begin{pmatrix} j & k & j' \\ 0 & 0 & 0 \end{pmatrix} \ .
\end{aligned} \tag{39.86}$$

39.2.5.2 Matrix element for angular momentum coupling

We consider states $|(l,s)j\rangle$. If the factors $\mathbb{T}$ and $\mathbb{U}$ of the tensor product act on different angular momenta, it can be reduced as follows:

$$\langle (l,s)j||(\mathbb{T}^{(k)}\times\mathbb{U}^{(k')})^{(l)}||(l',s')j'\rangle = \sqrt{2l+1}\sqrt{2j+1}\sqrt{2j'+1}\begin{Bmatrix} l' & s' & j' \\ k & k' & l \\ l & s & j \end{Bmatrix}\langle l||\mathbb{T}^{(k)}||l'\rangle\langle s||\mathbb{U}^{(k')}||s'\rangle \ . \tag{39.87}$$

Assuming, in particular, $\mathbb{U}^{(k')} \equiv \mathbb{I}^{(0)}$, we get, with $\mathbb{T}^{(k)} = \left(\mathbb{T}^{(k)} \times \mathbb{I}^{(0)}\right)^{(k)}$,

$$\langle (l,s)j||\mathbb{T}^{(k)}||(l',s')j'\rangle = (-)^{l+s+j'+k}\delta_{ss'}\sqrt{2j+1}\sqrt{2j'+1}\begin{Bmatrix} l & l' & k \\ j' & j & s \end{Bmatrix}\langle l||\mathbb{T}^{(k)}||l'\rangle \ . \tag{39.88}$$

The last equation therefore applies when $\mathbb{T}^{(k)}$ only acts on the angular momentum component ℓ. If on the other hand, $\mathbb{T}^{(k)}$ only acts on j, then we obviously have,

$$\langle (l,s)j||\mathbb{T}^{(k)}||(l',s')j'\rangle = \langle j||\mathbb{T}^{(k)}||j'\rangle \ . \tag{39.89}$$

39.2.6 Exercises

39.2.6.1 Ex: Rabi frequency

From the expression for the dipole moment d and the relationship between the intensity I and the electric field derive the Rabi frequency Ω produced by a laser beam of intensity I by exciting an atomic dipole transition with the wavelength λ and decay width Γ.

39.2.6.2 Ex: Non-stationary state

Construct a non-stationary hydrogen wavefunction with equal contributions of $(n = 1, \ell = 0, m = 0)$ and $(n = 2, \ell = 1, m = 1)$. Calculate the expectation values $\langle|\mathbf{r}|\rangle$ and $\langle\mathbf{r}\rangle$ as a function of time.

39.2.6.3 Ex: Transitions between Zeeman substates

Consider a hydrogen atom immersed in a uniform magnetic field, described by the Hamiltonian $\hat{H} = \hat{H}^{(0)} + \hat{H}^{(1)}$, being $\hat{H}^{(0)} = \hat{\mathbf{p}}^2/2m + V(r)$ and $H^{(1)} = -(\mu_{\rm B}/\hbar)\hat{\mathbf{L}}\cdot\vec{\mathcal{B}}$ despising the spin [9].

a. Given the initial function, $|\psi_m(0)\rangle = \cos\alpha|\phi_{000}\rangle + \sin\alpha|\phi_{21m}\rangle$, determine its shape at time t.

b. Calculate the mean value $\langle\mathbf{d}\rangle_m(t) = \langle\psi_m(t)|\mathbf{d}|\psi_m(t)\rangle$ of the electric dipole operator of the atom $\mathbf{d} = q\mathbf{R}$.

c. Analyze the frequencies and polarizations of the emitted radiation by the transition of the excited states $|\phi_{21m}\rangle$ to the ground state.

[9] See Cohen-Tannoudji, Complemento D_VII

39.2.6.4 Ex: Derivation of selection rules

a. Prove $[L_k, r_m] = \imath\hbar r_n \epsilon_{kmn}$ for an *orbital angular momentum.*
b. Using the commutator derived in (a) derive the selection rules for transitions $\langle \alpha' L' m' | \vec{\varepsilon} \cdot \hat{\mathbf{r}} | \alpha L m \rangle$, where $\vec{\varepsilon}$ is the polarization vector of the radiation field chosen to be $\hat{\mathbf{e}}_0$ or $\hat{\mathbf{e}}_\pm$.
c. Prove $[\hat{L}^2, [\hat{L}^2, \hat{\mathbf{r}}]] = 2\hbar^2(\hat{\mathbf{r}}\hat{L}^2 + \hat{L}^2\hat{\mathbf{r}})$ for an orbital angular momentum $\hat{\mathbf{L}}$.
d. Using the commutator derived in (b) derive the selection rule for $\hat{L}^2$.

39.3 Bloch equations for two-level atoms

In this section we will begin to apply the ideas and tools developed in the previous sections. Let us first make use of the density matrix to describe a two-level atom coupled to a single-mode light field without spontaneous emission. We will then introduce the atomic Bloch vector as a convenient and suggestive method to describe the time evolution of a coupled two-level atom.

The internal structure of atoms is analyzed in atomic physics, where we find that the energy levels are discrete (Bohr's axiom). The center of mass motion of the atoms and collisions with other atoms are ignored, and concerning the interaction of the atoms with light, we are only interested in the aspect, that the interaction can induce transitions between internal states via absorption or emission of photons. It is the duty of atomic physics to calculate the frequencies and strengths of transitions (by Hartree-Fock or similar methods), as well as their behavior in external electric and magnetic fields. The results of these calculations are visualized in energy level schemes called *Grotrian diagrams*. In quantum optics we do not care, how the energies of the levels were calculated, but accept them as given. That is, we assume the Hamiltonian of the unperturbed atom to be diagonalized, so that its internal structure can be written as,

$$\hat{H}_{\text{atom}} = \sum_j \hbar\omega_j |j\rangle\langle j| \ . \tag{39.90}$$

39.3.1 Liouville equation

As long as we are only interested in stimulated processes, such as the absorption of a monochromatic wave, the Schrödinger equation suffices to describe the light-atom interaction. A problem arises when we want to describe relaxation processes at the same time as excitation processes. Spontaneous emission (and any other dissipative process) must therefore be included in the physical description of the temporal evolution of our light-atom system. In this case, however, our system is no longer restricted to a single mode of the light field and the two atomic states of excitation. Spontaneous emission populates a statistical distribution of states of the light field and leaves the atom in a superposition of many momentum states. This situation can not be described by a single wavefunction, but only by a distribution of wavefunctions, and we can only expect to calculate the probability of finding the system within this distribution. The Schrödinger equation, therefore, no longer applies, and we need to trace the time evolution of a system characterized by a density operator describing a statistical mixture of quantum states. The equations which describe the

time evolution of the matrix elements of this density operator are the optical Bloch equations, and we must use them instead of the Schrödinger equation. In order to appreciate the origin and the physical content of the optical Bloch equations we begin by reviewing the rudiments of the density matrix theory.

39.3.1.1 Transformation to the interaction picture

For a two-level system perturbatively interacting with a light field, the Hamiltonian can be decomposed as in (23.252) into a stationary part and a time-dependent part,

$$\hat{H} = \hat{H}_{\text{atom}} + \hat{H}_{\text{atom:field}}(t) \ , \tag{39.91}$$

where $\hat{H}_{\text{atom}}$ is the part of the Hamiltonian describing the atomic structure and $\hat{H}_{\text{atom:field}}(t)$ the interaction of the dipole transition with the classical oscillating electric field. The interaction picture is the natural choice for this type of problem. In this case, we can transform the density operator into the interaction picture defined by (23.253),

$$\tilde{\rho}(t) = e^{\imath \hat{H}_{\text{atom}}(t-t_0)/\hbar} \hat{\rho}(t_0) e^{-\imath \hat{H}_{\text{atom}}(t-t_0)/\hbar} \ , \tag{39.92}$$

where the 'tilde' decoration (replacing the 'hat') emphasizes, that we are now in the *interaction picture*. We look for the time evolution rate of $\tilde{\rho}(t)$ analogously to the Liouville equation. Calculating the time derivatives on both sides of (39.92) and substituting Eq. (38.6) for $\frac{d\hat{\rho}}{dt}$ results in,

$$\boxed{\frac{d\tilde{\rho}(t)}{dt} = \frac{\imath}{\hbar}[\tilde{\rho}(t), \hat{H}_{\text{atom:field}}(t)]} \ . \tag{39.93}$$

This equation shows that the time evolution of the density operator in the interaction picture depends only on the time-dependent part of the total Hamiltonian.

In the following we will derive a ready-to-use form of the Hamiltonian governing the interaction of a weak single-mode light field with a two-level atom in the dipolar approximation.

39.3.1.2 Semi-classical two-level atom in the dipolar approximation

According to (39.91) the semi-classical light-atom interaction Hamiltonian comprises two terms which, in the dipolar approximation, can be written,

$$\hat{H} = \begin{pmatrix} 0 & 0 \\ 0 & \hbar\omega_0 \end{pmatrix} - \hat{\mathbf{d}} \cdot \vec{\mathcal{E}}(\mathbf{r}, t) \quad \text{where} \quad \hat{\mathbf{d}} = -e\hat{\mathbf{r}} = \begin{pmatrix} 0 & \langle 1|\mathbf{d}|2\rangle \\ \langle 2|\mathbf{d}|1\rangle & 0 \end{pmatrix} \tag{39.94}$$

is the dipole operator and

$$\vec{\mathcal{E}}(\mathbf{r}, t) = \frac{\vec{\epsilon}}{2} \left[\mathcal{E}_0(\mathbf{r}) e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega t)} + \mathcal{E}_0^*(\mathbf{r}) e^{-\imath(\mathbf{k}\cdot\mathbf{r} - \omega t)} \right] \tag{39.95}$$

the electric field. Note that via $\mathcal{E}_0(\mathbf{r}) \to \imath\sqrt{\frac{\hbar\omega}{2\varepsilon_0 V}}\hat{a}$, we can quantize the radiation mode, as will be shown in Sec. 40.1.1. Introducing the Rabi frequencies

$$\hbar\Omega(\mathbf{r}) \equiv -\mathcal{E}_0(\mathbf{r})\vec{\epsilon} \cdot \langle 2|\mathbf{d}|1\rangle \qquad \text{and} \qquad \hbar\Theta(\mathbf{r}) \equiv -\mathcal{E}_0(\mathbf{r})\vec{\epsilon} \cdot \langle 1|\mathbf{d}|2\rangle \tag{39.96}$$

as an abbreviation, we can write the Hamiltonian,

$$\hat{H} = \hbar \begin{pmatrix} 0 & \frac{\Theta(\mathbf{r})}{2} e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)} + \frac{\Omega^*(\mathbf{r})}{2} e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)} \\ \frac{\Omega(\mathbf{r})}{2} e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)} + \frac{\Theta^*(\mathbf{r})}{2} e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega t)} & \hbar\omega_0 \end{pmatrix} . \tag{39.97}$$

As shown in Sec. 23.6.5 the transformation from the Schrödinger to Dirac's interaction picture, is done via,

$$\hat{H}_{\text{atom:field}} \equiv \mathcal{U}^\dagger \hat{H} \mathcal{U} + \hbar \dot{\mathcal{U}}^\dagger \mathcal{U} \qquad \text{with} \qquad \mathcal{U} = e^{-\imath \hat{H}_{\text{atom}} t/\hbar} . \tag{39.98}$$

Introducing the abbreviation $\Delta = \omega - \omega_0$ we obtain,

$$\begin{aligned} \hat{H}_{\text{atom:field}} &= \begin{pmatrix} 0 & \frac{\hbar}{2}\Omega^*(\mathbf{r}) e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\Delta t)} \\ \frac{\hbar}{2}\Omega(\mathbf{r}) e^{\imath(\mathbf{k}\cdot\mathbf{r}-\Delta t)} & 0 \end{pmatrix} \\ &+ \begin{pmatrix} 0 & \frac{\hbar}{2}\Theta(\mathbf{r}) e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t-\omega_0 t)} \\ \frac{\hbar}{2}\Theta^*(\mathbf{r}) e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega t-\omega_0 t)} & 0 \end{pmatrix} \equiv \hat{H}^{(\text{slow})}_{\text{atom:field}} + \hat{H}^{(\text{fast})}_{\text{atom:field}} . \end{aligned} \tag{39.99}$$

39.3.1.3 The rotating wave approximation

The transition amplitude in first-order time-dependent perturbation theory is according to (27.71),

$$\begin{aligned} a_{i\to f}(t) &= \frac{1}{\imath\hbar} \int_0^t \langle 2|\hat{H}_{\text{atom:field}}(\tau)|1\rangle d\tau = \frac{\hbar}{2}\frac{1}{\imath\hbar} \int_0^t \left[\Omega(\mathbf{r}) e^{\imath(\mathbf{k}\cdot\mathbf{r}-\Delta t)} + \Theta^*(\mathbf{r}) e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega t-\omega_0 t)}\right] d\tau \\ &= \frac{\Omega(\mathbf{r}) e^{\imath\mathbf{k}\cdot\mathbf{r}}}{2\Delta}(e^{-\imath\Delta t} - 1) + \frac{\Theta^*(\mathbf{r}) e^{-\imath\mathbf{k}\cdot\mathbf{r}}}{2(\omega+\omega_0)}\left(e^{-\imath(\omega+\omega_0)\Delta t} - 1\right) \\ &\simeq \frac{\Omega(\mathbf{r}) e^{\imath\mathbf{k}\cdot\mathbf{r}}}{2\Delta}(e^{-\imath\Delta t} - 1) , \end{aligned} \tag{39.100}$$

where the last step corresponds to the *rotating wave approximation*. This allows us to neglect $\hat{H}^{(\text{fast})}_{\text{atom:field}}$.

39.3.1.4 Transformation into the rotating frame

Now, we further transform into rotating frame using,

$$\tilde{H}_{\text{atom:field}} = \mathcal{U}^\dagger \hat{H}_{\text{atom:field}} \mathcal{U} + \imath\hbar \dot{\mathcal{U}}^\dagger \mathcal{U} \qquad \text{with} \qquad \mathcal{U} = \begin{pmatrix} 1 & 0 \\ 0 & e^{-\imath\Delta t} \end{pmatrix} . \tag{39.101}$$

This yields,

$$\tilde{H}_{\text{atom:field}} = \begin{pmatrix} 0 & \frac{\hbar}{2}\Omega^*(\mathbf{r}) e^{-\imath\mathbf{k}\cdot\mathbf{r}} \\ \frac{\hbar}{2}\Omega(\mathbf{r}) e^{\imath\mathbf{k}\cdot\mathbf{r}} & -\hbar\Delta \end{pmatrix} . \tag{39.102}$$

We always can write the Rabi frequency as $\Omega = |\Omega| e^{\imath\phi}$ and attribute the phase to the atomic position if necessary. Locating the atom in the center of the coordinate system, we finally get,

$$\tilde{H}_{\text{atom:field}} = \begin{pmatrix} 0 & \frac{\hbar}{2}\Omega^* \\ \frac{\hbar}{2}\Omega & -\hbar\Delta \end{pmatrix} , \tag{39.103}$$

yielding the new Liouville equation,

$$\boxed{\frac{d\rho(t)}{dt} = \frac{\imath}{\hbar}[\rho(t), \tilde{H}_{\text{atom:field}}]} \ . \tag{39.104}$$

The matrix representation of the Hamiltonian given in this section are given in the basis of the unperturbed states, but we still need to derive the matrix form of the Liouville equations (38.6), (39.93), and (39.93) in the various pictures. This will be the topic of the next section.

39.3.2 The matrix elements of the density operator

Since the optical Bloch equations are coupled differential equations relating the elements of the density operator matrix, we must examine the temporal dependence of these matrix elements, based on our knowledge of the operator's properties. This can be done in the Schrödinger picture using Eq. (38.6), in the interaction picture using Eq. (39.93), or directly in the co-rotating frame using Eq. (39.102). For didactic reason we will begin with the Schrödinger picture and then derive the interaction picture once again.

So, let us begin with the Liouville equation (38.6) and evaluate the elements of the matrix,

$$\begin{aligned}\langle m|\frac{d\hat{\rho}(t)}{dt}|n\rangle &= \tfrac{\imath}{\hbar}\langle m|[\hat{\rho}(t), \hat{H}]|n\rangle = \tfrac{\imath}{\hbar}\langle m|[\hat{\rho}(t), \hat{H}_{\text{atom}} + \hat{H}_{\text{atom:field}}(t)]|n\rangle \\ &= \tfrac{\imath}{\hbar}(E_n - E_m)\langle m|\hat{\rho}(t)|n\rangle + \tfrac{\imath}{\hbar}\langle m|[\hat{\rho}(t), \hat{H}_{\text{atom:field}}(t)]|n\rangle \ ,\end{aligned} \tag{39.105}$$

where $|m\rangle$ and $|n\rangle$ are members of a complete set of vectors of a basis $\{|k\rangle\}$ which are also eigen-kets of $\hat{H}_{\text{atom}}$ and span the space of $\hat{H}$. Now, we insert the closing expression $\sum_k |k\rangle\langle k| = \mathbb{I}$ in the commutator on the right-hand side of Eq. (39.105):

$$\begin{aligned}&\langle m|[\hat{\rho}(t), \hat{H}_{\text{atom:field}}(t)]|n\rangle \\ &= \sum_k [\langle m|\hat{\rho}(t)|k\rangle\langle k|\hat{H}_{\text{atom:field}}|n\rangle - \langle m|\hat{H}_{\text{atom:field}}|k\rangle\langle k|\hat{\rho}(t)|n\rangle] \ .\end{aligned} \tag{39.106}$$

For our two-level atom the complete set only includes two states: $|1(t)\rangle = |1\rangle$ and $|2(t)\rangle = e^{-\imath\omega_0 t}|2\rangle$. In addition, the matrix elements of the dipole coupling operator $\hat{H}_{\text{atom:field}}$ are only non-diagonal,

$$V \equiv \langle 1|\hat{H}_{\text{atom:field}}|2\rangle = \overline{\langle 2|\hat{H}_{\text{atom:field}}|1\rangle} = V^* \ . \tag{39.107}$$

Hence, Eq. (39.105) adopts the form,

$$\boxed{\begin{aligned}\frac{d\hat{\rho}_{11}}{dt} &= \tfrac{\imath}{\hbar}[\hat{\rho}_{12}V^* - \hat{\rho}_{21}V] \\ \frac{d\hat{\rho}_{22}}{dt} &= \tfrac{\imath}{\hbar}[\hat{\rho}_{21}V - \hat{\rho}_{12}V^*] = -\frac{d\hat{\rho}_{11}}{dt} \\ \frac{d\hat{\rho}_{12}}{dt} &= \imath\omega_0\hat{\rho}_{12} + \tfrac{\imath}{\hbar}[V(\hat{\rho}_{11} - \hat{\rho}_{22})] \\ \frac{d\hat{\rho}_{21}}{dt} &= -\imath\omega_0\hat{\rho}_{21} + \tfrac{\imath}{\hbar}[V^*(\hat{\rho}_{22} - \hat{\rho}_{11})] = \frac{d\hat{\rho}_{12}^*}{dt}\end{aligned}} \ , \tag{39.108}$$

remembering that the dash of the diagonal terms, called *populations*, must be unitary, and that the non-diagonal terms, called *coherences*, must be complex,

$$\hat{\rho}_{11} + \hat{\rho}_{22} = 1 \quad , \quad \hat{\rho}_{21} = \hat{\rho}_{12}^* \ . \tag{39.109}$$

The above set of equations constitutes the *optical Bloch equations* in the *Schrödinger picture*. We transform the Bloch equations to the *interaction picture* by replacing the Liouville equation (38.6) by (39.93), and calculating the matrix elements. We obtain,

$$\frac{d\tilde{\rho}_{22}}{dt} = \frac{\imath}{\hbar}(V\tilde{\rho}_{21} - V^*\tilde{\rho}_{12}) \quad \text{and} \quad \frac{d\tilde{\rho}_{12}}{dt} = \frac{\imath}{\hbar}V(\tilde{\rho}_{11} - \tilde{\rho}_{22}) \ . \tag{39.110}$$

We would also have obtained this expression via the substitution $\hat{\rho}_{12} = \tilde{\rho}_{12}e^{\imath\omega_0 t}$ in the equations (39.108). The interaction picture simplifies the expressions for the temporal dependence of the coherences by eliminating the first term on the right-hand side. Transforming to the interaction picture removes the temporal dependence of the basis vectors spanning the Hilbert space of the two-level atom.

We have derived the optical Bloch equations from the Liouville equation, which is the fundamental equation of motion of the density operator, and we have seen how a unitary transformation can be used to *represent* these equations in the Schrödinger, Heisenberg or interaction picture. So far, the Bloch equations do not include the possibility of spontaneous emission. We will learn later, how to include this phenomenon.

39.3.2.1 Rotating wave approximation

In the following, we will only consider exponentials rotating with the frequency $\Delta \equiv \omega - \omega_0$, and we will neglect terms rotating like $\Delta \equiv \omega + \omega_0$ in the time dependence of the coupling operator,

$$V(t) = \hbar\Omega\cos\omega t \to \tfrac{\hbar}{2}\Omega e^{-\imath\omega t} \ , \tag{39.111}$$

neglecting the part $\frac{1}{2}\hbar\Omega e^{\imath\omega t}$. The amplitude Ω is called *Rabi frequency*. This approximation, called *rotating wave approximation* (RWA) is good, when the Rabi frequency is sufficiently small, $\Omega \ll \omega$. Otherwise, we observe an energy correction of the levels called *Bloch-Siegert shift*.

Once the RWA made, we can transform to the rotating system by the prescription,

$$\rho_{12} \equiv \hat{\rho}_{12}e^{-\imath\omega t} \quad , \quad \rho_{22} \equiv \hat{\rho}_{22} \ , \tag{39.112}$$

which, applied to the Bloch equations in the *Schrödinger picture* Eq. (39.108), yields,

$$\frac{d\rho_{22}}{dt} = \frac{\imath\Omega}{2}\rho_{21} - \frac{\imath\Omega^*}{2}\rho_{12} \quad , \quad \frac{d\rho_{12}}{dt} = -\imath\Delta\rho_{12} + \frac{\imath\Omega}{2}(\rho_{11} - \rho_{22}) \ . \tag{39.113}$$

In Exc. 39.3.7.1 we derive the Bloch equations from the equations of motion for the population amplitudes a_1 and a_2.

39.3.3 Solution of the optical Bloch equations

For arbitrary starting conditions, the solution of these equations is not simple. To solve the problem we write the equations in a matrix form,

$$\boxed{\vec{\rho} \equiv \begin{pmatrix} \rho_{11} \\ \rho_{22} \\ \rho_{12} \\ \rho_{21} \end{pmatrix} \quad , \quad \mathcal{M} \equiv \begin{pmatrix} 0 & 0 & \frac{\imath}{2}\Omega^* & -\frac{\imath}{2}\Omega \\ 0 & 0 & -\frac{\imath}{2}\Omega^* & \frac{\imath}{2}\Omega \\ \frac{\imath}{2}\Omega & -\frac{\imath}{2}\Omega & -\imath\Delta & 0 \\ -\frac{\imath}{2}\Omega^* & \frac{\imath}{2}\Omega^* & 0 & \imath\Delta \end{pmatrix} \quad , \quad \dot{\vec{\rho}} = \mathcal{M}\vec{\rho} \ .} \tag{39.114}$$

To solve this system of differential equations, we calculate the eigenvalues of the matrix,

$$\begin{aligned} \det(\mathcal{M} - \lambda \mathbb{I}_4) &= \lambda^2(\Delta^2 + |\Omega|^2) + \lambda^4 = 0 \\ \lambda &= 0, \pm\imath G \ , \end{aligned} \tag{39.115}$$

with the so-called *generalized Rabi frequency* $G \equiv \sqrt{\Delta^2 + |\Omega|^2}$. Therefore, the general solution is,

$$\begin{aligned} \rho_{22}(t) &= \rho_{22}^{(1)} + \rho_{22}^{(2)} e^{\imath G t} + \rho_{22}^{(3)} e^{-\imath G t} \\ \rho_{12}(t) &= \rho_{12}^{(1)} + \rho_{12}^{(2)} e^{\imath G t} + \rho_{12}^{(3)} e^{-\imath G t} \ . \end{aligned} \tag{39.116}$$

The coefficients follow from the Bloch equations with particular starting conditions. With a little algebra we get

$$\begin{aligned} \rho_{22}^{(1)} &= \rho_{22}(0) + \tfrac{1}{2G^2}\left[|\Omega|^2\left(1 - 2\rho_{22}(0)\right) - \Delta\left(\Omega\rho_{12}^*(0) + \Omega^*\rho_{12}(0)\right)\right] \\ \rho_{22}^{(2)} &= \tfrac{1}{4G^2}\left[-|\Omega|^2(1 - 2\rho_{22}(0)) + (\Delta + G)\Omega\rho_{12}^*(0) + (\Delta - G)\Omega^*\rho_{12}(0)\right] \\ \rho_{22}^{(3)} &= \tfrac{1}{4G^2}\left[-|\Omega|^2(1 - 2\rho_{22}(0)) + (\Delta - G)\Omega\rho_{12}^*(0) + (\Delta + G)\Omega^*\rho_{12}(0)\right] \\ \rho_{12}^{(1)} &= \tfrac{1}{2G^2}\left[\Delta\Omega(1 - 2\rho_{22}(0)) + \Omega\left(\Omega\rho_{12}^*(0) + \Omega^*\rho_{12}(0)\right)\right] \\ \rho_{12}^{(2)} &= \tfrac{\Delta - G}{4G^2}\left[-\Omega(1 - 2\rho_{22}(0)) + (\Delta + G)\tfrac{\Omega}{\Omega^*}\rho_{12}^*(0) + (\Delta - G)\rho_{12}(0)\right] \\ \rho_{12}^{(3)} &= \tfrac{\Delta + G}{4G^2}\left[-\Omega(1 - 2\rho_{22}(0)) + (\Delta - G)\tfrac{\Omega}{\Omega^*}\rho_{12}^*(0) + (\Delta + G)\rho_{12}(0)\right] \ . \end{aligned} \tag{39.117}$$

We derive this solution in Exc. 39.3.7.2.

To begin the discussion of this solution, let us consider a sample of atoms initially in the ground state when the light field is switched on at time $t = 0$,

$$\rho_{11}(0) = 1 = 1 - \rho_{22}(0) \quad , \quad \rho_{12}(0) = 0 = \rho_{21}(0) \ . \tag{39.118}$$

In this case, the conditions (39.117) simplify to,

$$\begin{aligned} \rho_{22}^{(1)} &= \tfrac{|\Omega|^2}{2G^2} \quad , \quad \rho_{12}^{(1)} = \tfrac{1}{2G^2}\Delta\Omega \\ \rho_{22}^{(2)} &= \tfrac{-|\Omega|^2}{4G^2} \quad , \quad \rho_{12}^{(2)} = \tfrac{G - \Delta}{4G^2}\Omega \\ \rho_{22}^{(3)} &= \tfrac{-|\Omega|^2}{4G^2} \quad , \quad \rho_{12}^{(3)} = \tfrac{-G - \Delta}{4G^2}\Omega \ , \end{aligned} \tag{39.119}$$

such that,

$$\rho_{22} = \rho_{22}^{(1)} + \rho_{22}^{(2)} e^{\imath Gt} + \rho_{22}^{(3)} e^{-\imath Gt} = \frac{|\Omega|^2}{4G^2}(2 - e^{\imath Gt} - e^{-\imath Gt}) \tag{39.120}$$
$$\rho_{12} = \rho_{12}^{(1)} + \rho_{12}^{(2)} e^{\imath Gt} + \rho_{12}^{(3)} e^{-\imath Gt} = \frac{\Delta\Omega}{2G^2} - \frac{\Delta - G}{4G^2}\Omega e^{\imath Gt} - \frac{\Delta + G}{4G^2}\Omega e^{-\imath Gt}$$
$$= \frac{2\Omega}{4G^2}(\Delta - \Delta\cos Gt + \imath G \sin Gt) \ .$$

Using $\cos x = 1 - 2\sin^2\frac{x}{2}$ and $\sin x = 2\sin\frac{x}{2}\cos\frac{x}{2}$, we finally obtain,

$$\boxed{\rho_{22} = \frac{|\Omega|^2}{G^2}\sin^2\frac{Gt}{2} \quad , \quad \rho_{12} = \frac{\Omega}{G^2}\sin\frac{Gt}{2}\left(\Delta\sin\frac{Gt}{2} + \imath G\cos\frac{Gt}{2}\right)} \ . \tag{39.121}$$

And comparing with the solutions of the Schrödinger equation for a coupled two-level atom obtained in Exc. 23.6.7.1 and (27.93), we verify,

$$\rho_{22} = \left|\tfrac{\imath\Omega}{G} e^{-\imath t\Delta/2}\sin\tfrac{Gt}{2}\right|^2 = |a_2|^2 \tag{39.122}$$
$$\rho_{12} = -e^{-\imath t\Delta/2}\left[\cos\tfrac{Gt}{2} - \imath\tfrac{\Delta}{G}\sin\tfrac{Gt}{2}\right]\ \tfrac{-\imath\Omega}{G} e^{\imath t\Delta/2}\sin\tfrac{Gt}{2} = a_1^* a_2 \ .$$

39.3.4 Pauli matrices and the atomic Bloch vector

Let us come back to the unperturbed atomic Hamiltonian (39.90). The electronic states are orthonormal $\langle i|j\rangle = \delta_{ij}$, and we define the transition operators by

$$\hat\sigma_{ij}|k\rangle = \delta_{jk}|i\rangle \ , \tag{39.123}$$

and $\hat\sigma_{ij}^\dagger = \hat\sigma_{ji}$ satisfying the commutation relation,

$$[\hat\sigma_{ij}, \hat\sigma_{lk}] = \delta_{jl}\hat\sigma_{ik} - \delta_{ik}\hat\sigma_{lj} \ . \tag{39.124}$$

Many times we will restrict ourselves to atoms of two or three levels. For a two-level system we obtain the *Pauli spin matrix* defined in (23.152). Every 2×2 matrix can be expanded on a Pauli matrix basis (see Exc. 39.3.7.3),

$$\begin{pmatrix}\rho_{11} & \rho_{12}\\ \rho_{21} & \rho_{22}\end{pmatrix} = |1\rangle\rho_{11}\langle 1| + |1\rangle\rho_{12}\langle 2| + |2\rangle\rho_{21}\langle 1| + |2\rangle\rho_{22}\langle 2| \tag{39.125}$$
$$= \rho_{11}(\tfrac12 + \tfrac12\hat\sigma_z) + \rho_{12}\hat\sigma^- + \rho_{21}\hat\sigma^+ + \rho_{22}(\tfrac12 - \tfrac12\hat\sigma_z)$$
$$= \rho_{11}\hat\sigma^-\hat\sigma^+ + \rho_{12}\hat\sigma^- + \rho_{21}\hat\sigma^+ + \rho_{22}\hat\sigma^+\hat\sigma^- = \begin{pmatrix}\langle\hat\sigma^-\hat\sigma^+\rangle & \langle\hat\sigma^-\rangle\\ \langle\hat\sigma^+\rangle & \langle\hat\sigma^+\hat\sigma^-\rangle\end{pmatrix} \ .$$

For the two-level case it is useful to introduce an alternative notation based on the *Bloch vector* defined in (23.159),

$$\vec\varrho \equiv \langle\hat{\vec\sigma}\rangle \equiv \begin{pmatrix}2\,\mathfrak{Re}\,\rho_{12}\\ 2\,\mathfrak{Im}\,\rho_{12}\\ \rho_{22} - \rho_{11}\end{pmatrix} = \begin{pmatrix}\langle\hat\sigma^+\rangle + \langle\hat\sigma^-\rangle\\ \imath(\langle\hat\sigma^+\rangle - \langle\hat\sigma^-\rangle)\\ \langle\hat\sigma^+\hat\sigma^-\rangle - \langle\hat\sigma^-\hat\sigma^+\rangle\end{pmatrix} = \begin{pmatrix}\langle\hat\sigma_x\rangle\\ \langle\hat\sigma_y\rangle\\ \langle\hat\sigma_z\rangle\end{pmatrix} \ . \tag{39.126}$$

We also define the torque vector,

$$\boxed{\mathbf{G} \equiv \begin{pmatrix} \mathfrak{Re}\,\Omega \\ \mathfrak{Im}\,\Omega \\ -\Delta \end{pmatrix} \qquad \text{with} \qquad \|\mathbf{G}\| = G = \sqrt{|\Omega|^2 + \Delta^2}} \ , \tag{39.127}$$

the length of which is simply the generalized Rabi frequency. Note that here we allow for the possibility of complex Rabi frequency.

Now, using $\hat{\sigma}_z = [\hat{\sigma}^+, \hat{\sigma}^-]$, we may write the Hamiltonian of an unperturbed two-level system,

$$\hat{H}_0 = -\hbar\Delta\hat{\sigma}^+\hat{\sigma}^- = -\tfrac{\hbar}{2}\Delta(\hat{\sigma}_z + \mathbb{I}_2) = -\tfrac{\hbar}{2}\Delta\hat{\sigma}_z + \text{offset} \ . \tag{39.128}$$

For the perturbed system,

$$\hat{H} = \hat{\mathbf{s}} \cdot \mathbf{G} = \tfrac{\hbar}{2}\mathbf{G} \cdot \hat{\vec{\sigma}} = -\tfrac{\hbar}{2}\hat{\sigma}_z\Delta + \tfrac{\hbar}{2}\hat{\sigma}_x\mathfrak{Re}\,\Omega + \tfrac{\hbar}{2}\hat{\sigma}_y\mathfrak{Im}\,\Omega = \begin{pmatrix} \frac{\hbar}{2}\Delta & \frac{\hbar}{2}\Omega^* \\ \frac{\hbar}{2}\Omega & -\frac{\hbar}{2}\Delta \end{pmatrix} \ . \tag{39.129}$$

The Bloch equations (39.128) then follow as the Heisenberg equation with the Hamiltonian (39.130) using $[\hat{\sigma}_k, \hat{\sigma}_m] = 2\imath\epsilon_{klm}\hat{\sigma}_m$,

$$\begin{aligned} \frac{d\hat{\vec{\sigma}}}{dt} &= \tfrac{\imath}{\hbar}[\hat{H}, \hat{\vec{\sigma}}] = \tfrac{\imath}{2}[\mathbf{G} \cdot \hat{\vec{\sigma}}, \hat{\vec{\sigma}}] \\ &= \tfrac{\imath G_x}{2}[\hat{\sigma}_x, \hat{\vec{\sigma}}] + \tfrac{\imath G_y}{2}[\hat{\sigma}_y, \hat{\vec{\sigma}}] + \tfrac{\imath G_z}{2}[\hat{\sigma}_z, \hat{\vec{\sigma}}] = \begin{pmatrix} G_y\hat{\sigma}_z - G_z\hat{\sigma}_y \\ G_z\hat{\sigma}_x - G_x\hat{\sigma}_z \\ G_x\hat{\sigma}_y - G_y\hat{\sigma}_x \end{pmatrix} = \mathbf{G} \times \hat{\vec{\sigma}} \ . \end{aligned} \tag{39.130}$$

The expectation values yield,

$$\boxed{\frac{d\vec{\varrho}}{dt} = \mathbf{G} \times \vec{\varrho}} \ . \tag{39.131}$$

As will be shown in Exc. 39.3.7.4, these equations are identical to the Liouville equations (39.114). ρ_{12} describes the polarization and $\rho_{22} - \rho_{11}$ the *population inversion* of the atom. The equation is analogous to the equation of motion for a *rigid rotor* or *spinning top* (for example, a dipole in a homogeneous field). It displays phenomena such as *precession* and *nutation*. The physical content and usefulness of the Bloch vector will become clearer when we use the formalism to analyze electric and magnetic couplings. In Exc. 39.3.7.5 we verify that the Bloch vector is normalized (as long as spontaneous emission is not considered).

39.3.5 State manipulations by sequences of radiation pulses

The temporal dependence of the three components of the atomic Bloch vector provides a useful illustration of the atom-field interaction. Resonant coupling, $\Delta = 0$ and $G = \Omega$, puts the solutions (39.121) into the form,

$$\rho_{22}(t) = \tfrac{1}{2}(1 - \cos\Omega t) \qquad , \qquad \rho_{12}(t) = \tfrac{\imath}{2}\sin\Omega t \ , \tag{39.132}$$

that is,

$$\vec{\varrho}(t) = \begin{pmatrix} 0 \\ \sin \Omega t \\ -\cos \Omega t \end{pmatrix} . \tag{39.133}$$

That is, a resonant pulse rotates a Bloch vector initially pointing in the direction $-z$ within the plane z-y, until it arrives, at time $t = \frac{\pi}{2\Omega}$, at the $+y$ direction and at time $t = \frac{\pi}{\Omega}$ at the $+z$ direction. This means that the entire population has been transferred to the excited state. The Bloch vector continues to rotate (the movement is called *nutation*) around the torque vector $\mathbf{G}$ which, as can be seen from Eq. (39.128), points at the $+x$ direction when $\Delta = 0$. The nutation frequency is proportional to the force Ω of the atom-field interaction. With the Eq. (39.121) we see that the population oscillates between the ground and excited state with the frequency Ω. This means that the energy $\hbar\omega$ is periodically exchanged between the atom and the field. A pulse of resonant light of duration such that $\tau = \pi/2\Omega$ is called a $\pi/2$-pulse. The nutation is illustrated in Fig. 39.2(a).

Once the coherence has been excited by a detuned radiation, $\Delta \neq 0$, the Bloch vector does not stand still, even after the radiation has been switched off. To see this, we consider again the general solution (39.117) now entering $\Omega = 0$. If the Bloch vector is initially at a point in the unitary circle of the plane z-y, it will rotate according to the formula,

$$\rho_{22}(t) = \rho_{22}(0) \quad , \quad \rho_{12}(t) = \rho_{12}(0)e^{-\imath\Delta t} , \tag{39.134}$$

that is,

$$\vec{\varrho}(t) = \begin{pmatrix} \rho_{12}(0) \sin \Delta t \\ \rho_{12}(0) \cos \Delta t \\ 2\rho_{22}(0) - 1 \end{pmatrix} . \tag{39.135}$$

That is, the Bloch vector performs a motion of *precession* around the symmetry axis. The precession is illustrated in Fig. 39.2(b).

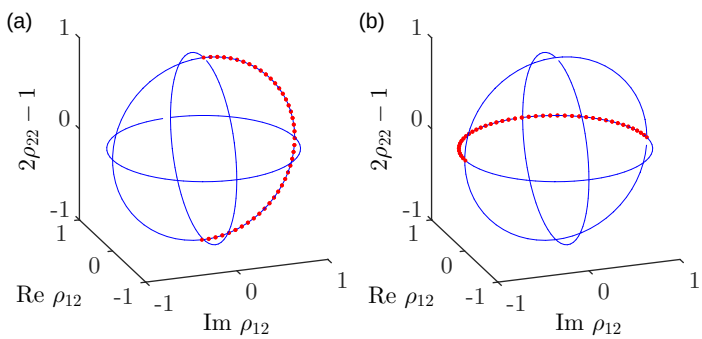

Figure 39.2: (code) (a) Nutation of the Bloch vector. The red circles show the evolution of the Bloch vector on the Bloch sphere for a resonant π-pulse. (b) Precession of the Bloch vector.

The evolution of the Bloch vector on the surface of the Bloch sphere under the influence of radiation fields can be considered a coherent trajectory of the wavefunction

of the atomic state, which is therefore subject to interference phenomena [459]. Interferometers can be realized by sequences of consecutive pulses splitting populations, exciting coherences, and remixing populations.

Sensors based on interferometry of atomic excitation are nowadays among the most accurate and most sensitive. We will discuss the method of radiation pulse sequences in several exercises: In the Excs. 39.3.7.6, 39.3.7.7, and 39.3.7.8 the *Ramsey method*.

39.3.5.1 Atomic ensembles

While it is technically challenging to observe the dynamics of single atoms, it is relatively easy monitor the dynamics of ensembles of atoms, provided that they react synchronously to incident radiation. The concentration of a sufficient number of atoms in a small volume can, however, introduce additional (desirable or undesirable) effects. Collisions, for instance, induce (irreversible) decoherence. On the other hand, if the ensemble is sufficiently dense that the mean distance between atoms is less than a resonant wavelength, then the transition dipoles of the individual atoms will couple to produce a collective dipole moment and generate effects known as superradiance.

Thermal motion of the atoms is another undesired effect, because every atom will interact with the radiation on a different Doppler-shifted frequency. This leads to diffusion of the individual atomic Bloch vectors in the x-y-plane, which in turn limits the resolution of interferometric applications. We will discuss in Exc. 39.3.7.9 the *photon echo method*, which allows to circumvent this problem.

39.3.6 Nuclear magnetic resonance

Nuclear magnetic resonance (NMR) is a physical phenomenon in which nuclei in a strong constant magnetic field (up to 20 T) are perturbed by a weak oscillating magnetic field (in the near field) and respond by producing an electromagnetic signal with a frequency characteristic of the magnetic field at the nucleus. This process occurs near resonance, when the oscillation frequency (typically 60..1000 MHz) matches the intrinsic frequency of the nuclei, which depends on the strength of the static magnetic field, the chemical environment, and the magnetic properties of the isotope involved. NMR spectroscopy is widely used to determine the structure of organic molecules in solution and in advanced medical imaging techniques, such as in magnetic resonance imaging (MRI). The most commonly used nuclei are ^{1}H and ^{13}C.

NMR transitions can be excited, when the electron spins do not participate in the interaction, e.g. because they are paired (see Eq. (33.41)), and when the nucleus has an intrinsic nuclear magnetic moment $\hat{\vec{\mu}}_I$ and hence an angular momentum $\hat{\mathbf{I}}$. This is the case for an odd number of protons and/or neutrons. Nuclides with even numbers of both have a total spin of zero and are therefore NMR-inactive.

The principle of NMR usually involves three sequential steps: (i) The alignment of the magnetic nuclear spins in an applied, constant magnetic field $\vec{\mathcal{B}}_0$. (ii) The perturbation of this alignment of the nuclear spins by a weak oscillating magnetic field $\vec{\mathcal{B}}_1(t)$ called rf-pulse. (iii) The detection of the NMR signal during or after the rf-pulse via the voltage induced in a detection coil due to the precession of the nuclear spins around $\vec{\mathcal{B}}_0$. After an rf-pulse, the nuclear dipole moment precesses at

the nuclei's intrinsic Larmor frequency without involving transitions between spin states. Choosing the two magnetic fields perpendicular to each other, one maximizes the NMR signal strength,

$$\vec{\mathcal{B}}(t) = \mathcal{B}_{\rm rf}(t)\hat{\mathbf{e}}_x + \mathcal{B}_0\hat{\mathbf{e}}_z \ , \tag{39.136}$$

where, because of $|\mathcal{B}_{\rm rf}(t)| \ll \mathcal{B}_0$, we choose the z-axis as the quantization axis and the rf-field as a perturbation along the x-axis.

The energy of a nuclear magnetic dipole moment placed in a magnetic field is [258],

$$\boxed{\hat{H} = -\hat{\vec{\mu}}\cdot\vec{\mathcal{B}} = -\gamma_I\hat{\mathbf{I}}\cdot\vec{\mathcal{B}}} \ , \tag{39.137}$$

where γ_I is the *gyromagnetic ratio* of the specific nucleus and $\hat{\mathbf{I}}$ the nuclear spin satisfying the usual commutation relation $[\hat{I}_m, \hat{I}_n] = \imath\hbar\epsilon_{kmn}\hat{I}_k$. Hence, as shown in Exc. 39.3.7.10, we can derive from the Heisenberg equation,

$$\imath\hbar\frac{d\hat{\vec{\mu}}}{dt} = [\hat{\vec{\mu}}, \hat{H}] \ , \tag{39.138}$$

the Bloch equations,

$$\boxed{\frac{d\hat{\vec{\mu}}}{dt} = \gamma_I\hat{\vec{\mu}}\times\vec{\mathcal{B}}} \ . \tag{39.139}$$

Now, let us restrict to a two-level system, $I = \frac{1}{2}$ such that $\hat{I}_z = \frac{\hbar}{2}\hat{\sigma}_z$. In thermal equilibrium, without time-dependent perturbation,

$$\hat{H}_0 = -\hat{\vec{\mu}}\cdot\vec{\mathcal{B}}_0 = -\hat{\mu}_z\mathcal{B}_0 = -\gamma_I\hat{I}_z\mathcal{B}_0 \equiv -\omega_{\rm L}\hat{I}_z \ . \tag{39.140}$$

where we introduced the *Larmor frequency* $\omega_{\rm L}$. We expect energy levels,

$$E = -\hbar\gamma_I m\mathcal{B}_0 \ , \tag{39.141}$$

with $m = \pm\frac{1}{2}$. The energy difference between the two states, $\Delta E = \gamma_I\hbar\mathcal{B}_0$, results in a small population bias favoring the lower energy state in thermal equilibrium and, hence, in a net spin magnetization $\vec{\mathcal{M}} = \frac{1}{V}\sum_i\langle\vec{\mu}_i\rangle$ along the magnetic field $\vec{\mathcal{B}}_0$. For a thermal statistical mixture, as shown in (37.39), we write the density operator [10],

$$\boxed{\hat{\rho} = \frac{e^{-\hat{H}_0/k_{\rm B}T}}{Z} = \frac{e^{-\frac{1}{2}\beta\hbar\omega_{\rm L}\hat{\sigma}_z}}{Z} = \sum_{m=\pm1/2}|I,m\rangle\frac{e^{-\beta\hbar\omega_{\rm L}m}}{Z}\langle I,m|} \ , \tag{39.142}$$

with the partition function,

$$Z \equiv {\rm Tr}\, e^{-\hat{H}_0/k_{\rm B}T} = \sum_{m=\pm1/2} e^{-\beta\hbar\omega_{\rm L}m} \ . \tag{39.143}$$

[10] Note that at high temperatures we get, $Z \simeq 1$ and may approximate,

$$\hat{\rho} - 1 \simeq \beta\hbar\omega_{\rm L}\hat{I}_z \ .$$

Now, as shown in (39.92), we can express the time-evolution of the density operator as,

$$\hat{\rho}(t) = e^{-\imath \hat{H}_0 t}\hat{\rho}(0)e^{\imath \hat{H}_0 t} = e^{-\imath\beta\hbar\omega_{\rm L}\hat{I}_z t}\hat{\rho}(0)e^{\imath\beta\hbar\omega_{\rm L}\hat{I}_z t} \ . \tag{39.144}$$

Then, as shown in Exc. 39.3.7.11,

$$\langle\hat{\mathbf{I}}(t)\rangle = \begin{pmatrix} \cos\omega_{\rm L}t & -\sin\omega_{\rm L}t & 0 \\ \sin\omega_{\rm L}t & \cos\omega_{\rm L}t & 0 \\ 0 & 0 & 1 \end{pmatrix} \langle\hat{\mathbf{I}}(0)\rangle \ , \tag{39.145}$$

which corroborates the result (39.139). Apparently, the nuclear magnetic dipole moment (and hence the spin magnetization) precesses around the magnetic field with the Larmor frequency leaving the populations of the energy levels unaffected.

A perturbation of nuclear spin orientations from equilibrium will occur when an oscillating magnetic field is applied whose frequency $\omega_{\rm rf}$ sufficiently closely matches the Larmor precession frequency $\omega_{\rm L}$. The populations of the spin-up and -down energy levels then undergo Rabi oscillations. The stronger the oscillating field, the faster the Rabi oscillations or the precession around the effective field in the rotating frame. After a certain time (typically on the order of 2..1000 μs), a resonant rf-$\pi/2$-pulse flips the spin magnetization to the transverse plane, while after a twice longer time, the initial magnetization is inverted (π-pulse). It is the transverse magnetization generated by a resonant oscillating field which is usually detected in NMR.

The most important perturbation of the NMR frequency for applications of NMR is the 'shielding' effect of the surrounding shells of electrons. Electrons, similar to the nucleus, are also charged and rotate with a spin to produce a magnetic field opposite to the applied magnetic field. In general, this electronic shielding reduces the magnetic field at the nucleus. The corresponding shift in the NMR frequency due to the electronic molecular orbital coupling to the external magnetic field is called chemical shift, and it explains why NMR is able to probe the chemical structure of molecules, which depends on the electron density distribution in the corresponding molecular orbitals.

After perturbation the nuclear spins return to thermodynamic equilibrium due to relaxation processes. These are phenomenological included in the Bloch equations via decay time constants T_i,

$$\frac{d\hat{\vec{\mu}}}{dt} = \gamma_I \hat{\vec{\mu}} \times \vec{\mathcal{B}} - \frac{\hat{\mu}_z}{T_1}\hat{\mathbf{e}}_z - \frac{\hat{\mu}_x}{T_2}\hat{\mathbf{e}}_x \ . \tag{39.146}$$

$T_1 = \Gamma^{-1}$ is the time constant for 'longitudinal magnetic' relaxation and refers to the mean time for an individual nucleus to return to its thermal equilibrium state of the spins. The precessing nuclei can also fall out of alignment with each other and gradually stop producing a signal. This is called T_2 or transverse relaxation, where $T_2 = 2\gamma^{-1}$. Because of the difference in the actual relaxation mechanisms involved (for example, intermolecular versus intramolecular magnetic dipole-dipole interactions), T_1 is usually longer than T_2, which, in practice, also depends on significant static magnetic field inhomogeneities.

39.3.7 Exercises

39.3.7.1 Ex: Derivation of Bloch equations

Derive the Bloch equations explicitly based on the temporal evolutions of the coefficients $a_{1,2}$ (27.63) knowing that $\rho_{ij} = a_i^* a_j$.

39.3.7.2 Ex: General solution of Bloch equations

Derive the solution (39.117) of the Bloch equations (39.114).

39.3.7.3 Ex: Expansion in Pauli matrices

Show explicitly $\mathrm{Tr}\, \hat{\rho}\hat{\sigma}^- \hat{\sigma}^+ = \rho_{11}$.

39.3.7.4 Ex: Bloch vector and Bloch equations

Show that Eq. (39.131) is equivalent to the Bloch equations (39.114).

39.3.7.5 Ex: Normalization of the Bloch vector

Verify $\|\vec{\rho}\| = 1$.

39.3.7.6 Ex: Sequence of Ramsey pulses

Many atomic clocks work according to the Ramsey spectroscopy method: The two-level atom is resonantly excited by a microwave $\pi/2$-pulse. Then, the phase of atomic coherence precesses freely over a period of time T accumulating an angle ϕ. Finally, a second $\pi/2$-pulse is applied and the population of the upper-level is measured. Calculate this population as a function of the angle ϕ. Neglect spontaneous emission.

39.3.7.7 Ex: Analytical treatment of the Ramsey experiment

Derive the analytic formula for the final population ρ_{22} for the Rabi and Ramsey experiments. Derive and compare the line widths of the 'interference fringes' in these two experiments.

39.3.7.8 Ex: Atomic clocks by the Ramsey method with spontaneous emission

In this exercise we study the Ramsey method used in atomic clocks. For this, we will consider a two-level system $|1\rangle$ and $|2\rangle$ excited by a microwave radiation field characterized by the Rabi frequency Ω_{12}, and we will compare two cases: without and with spontaneous emission:
a. Write down the Hamiltonian of the system, propose a sequence of pulses allowing the observation of the Ramsey fringes, do a numerical simulation of the Schrödinger equation (based on the prescription (39.246)), and prepare a graph of the type Fig. 39.2 illustrating the temporal evolution of the Bloch vector during the sequence.

b. Calculate numerically from the Schrödinger equation the population ρ_{22} immediately after the pulse sequence as a function of the detuning Δ_{12} of the radiation field, and prepare a graph of the spectrum. Also, assuming a decay rate of $\Gamma_{12} = 0.1\Omega_{12}$, calculate the population ρ_{22} as a function of detuning Δ_{12} from the Bloch equations (making sequences of type (39.246)), prepare a new graph, and compare it with the previous graph obtained by the Schrödinger equation.
c. What happens to the width of the fringes, when the free precession time τ between the Ramsey pulses is increased? Prepare a graph of the inversion $2\rho_{22}-1$ as a function of Δ_{12} and τ and interprete the results.

39.3.7.9 Ex: Photon echo

'Photon echo' is a powerful spectroscopic technique that allows circumvention of certain dephasing processes, for example, the Doppler shift due to the atomic motion in a thermal sample of atoms. The technique resembles the Ramsey method with the difference, that between the two Ramsey $\pi/2$-pulses, that is, during the free precession time, we apply an additional π-pulse, which inverts the imaginary part of the coherence. We will study this method by numerical simulation of the Schrödinger equation and the Bloch equations for a two-level system with and without spontaneous emission:
a. Write down the Hamiltonian of the system and do a numerical simulation of the Schrödinger equation (concatenating the pulses as explained in Eq. (39.246)) for the following temporal pulse sequence:
(i) resonant $\pi/2$-pulse ($\Delta_{12} = 0$) choosing $\Omega_{12} = 2$,
(ii) evolution for a time T without radiation ($\Omega_{12} = 0$),
(ii) resonant π-pulse using the same parameters as in (i),
(iv) evolution for a time T without radiation, and
(v) resonant $\pi/2$-pulse identical to the first pulse.
Prepare a graph of type Fig. 39.2 illustrating the temporal evolution of the Bloch vector during the sequence. Now, repeat the sequence taking into account a possible Doppler shift leading to $\Delta_{12} \neq 0$.
b. Repeat the calculation of (a), now numerically solving the Bloch equations, which allow the occurrence of spontaneous emission ($\Gamma_{12} = 0.03\Omega_{12}$). Interpret the results.

39.3.7.10 Ex: Time-evolution of NMR spin components

Derive the coherent part of the Bloch equations (39.138) from the Heisenberg equation (39.137).

39.3.7.11 Ex: Precession of the nuclear spin in a magnetic field

Show for $\hat{H}_0 = -\frac{\hbar\omega_{\rm L}}{2}\hat{\sigma}_z$ that,

$$\langle\hat{\vec{\sigma}}(t)\rangle = \begin{pmatrix} \cos\omega_{\rm L}t & -\sin\omega_{\rm L}t & 0 \\ \sin\omega_{\rm L}t & \cos\omega_{\rm L}t & 0 \\ 0 & 0 & 1 \end{pmatrix} \langle\hat{\vec{\sigma}}(0)\rangle \ .$$

39.4 Bloch equations with spontaneous emission

In this section we will introduce spontaneous emission and the important concepts of polarization and susceptibility emanating from an excited sample of oscillating dipoles. Optical Bloch equations including spontaneous emission will be given and their stationary solutions will be discussed. Dissipative processes always broaden transition lines, and thus we will discuss various broadening mechanisms.

39.4.1 Phenomenological inclusion of spontaneous emission

To find the Bloch equations including spontaneous emission, we proceed similarly for Eq. (39.26) and insert the phenomenological decay term $-\imath\gamma a_2$ into the Eqs. (27.63),

$$\Omega^* \cos\omega t e^{\imath\omega_0 t} a_1 - \imath\gamma a_2 = \imath \frac{da_2}{dt} \ , \tag{39.147}$$

that is, the equations of motion can be corrected by simply replacing,

$$\frac{da_2}{dt} \curvearrowright \left(\frac{d}{dt} + \gamma\right) a_2 \ . \tag{39.148}$$

Knowing $\rho_{mn} = a_m^* a_n$, it is easy to check,

$$\frac{d\rho_{22}}{dt} \curvearrowright \left(\frac{d}{dt} + \Gamma\right) \rho_{22} \qquad \text{and} \qquad \frac{d\rho_{12}}{dt} \curvearrowright \left(\frac{d}{dt} + \gamma\right) \rho_{12} \ , \tag{39.149}$$

with $\gamma = \Gamma/2$, such that the Bloch equations become,

$$\boxed{\frac{d}{dt}\begin{pmatrix}\rho_{11}\\ \rho_{22}\\ \rho_{12}\\ \rho_{21}\end{pmatrix} = \begin{pmatrix} 0 & \Gamma & \frac{\imath}{2}\Omega & -\frac{\imath}{2}\Omega \\ 0 & -\Gamma & -\frac{\imath}{2}\Omega & \frac{\imath}{2}\Omega \\ \frac{\imath}{2}\Omega & -\frac{\imath}{2}\Omega & -\imath\Delta - \gamma & 0 \\ -\frac{\imath}{2}\Omega & \frac{\imath}{2}\Omega & 0 & \imath\Delta - \gamma \end{pmatrix}\begin{pmatrix}\rho_{11}\\ \rho_{22}\\ \rho_{12}\\ \rho_{21}\end{pmatrix}} \ . \tag{39.150}$$

Example 275 (*Langevin equation*): The *Heisenberg equation* for the evolution of the internal degrees of freedom, including the phenomenologically introduced decay, is also called *Langevin equation*. It can be written as,

$$\imath \frac{d\hat{\sigma}^-}{dt} = \tfrac{1}{\hbar}[\hat{\sigma}^-, \hat{H}] - \tfrac{\imath}{2}\Gamma\hat{\sigma}^- \ ,$$

and analogously for $\hat{\sigma}_z$. With the Hamiltonian $\hat{H} = \hbar\Delta\hat{\sigma}^+\hat{\sigma}^- + \frac{1}{2}\hbar\Omega(e^{\imath\omega t}\hat{\sigma}^- + h.c.)$ we obtain, using the Pauli spin matrices, exactly the Bloch equations,

$$\begin{aligned}
\imath\dot{\hat{\sigma}}^- &= \Delta[\hat{\sigma}^-, \hat{\sigma}^+\hat{\sigma}^-] + \tfrac{1}{2}\Omega e^{-\imath\omega t}[\hat{\sigma}^-, \hat{\sigma}^+] - \tfrac{\imath}{2}\Gamma\hat{\sigma}^- = \Delta\hat{\sigma}^- - \tfrac{1}{2}\Omega e^{-\imath\omega t}\hat{\sigma}_z - \tfrac{\imath}{2}\Gamma\hat{\sigma}^- \\
\imath\dot{\hat{\sigma}}_z &= \Delta[\hat{\sigma}_z, \hat{\sigma}^+\hat{\sigma}^-] + \tfrac{1}{2}\Omega e^{-\imath\omega t}[\hat{\sigma}_z, \hat{\sigma}^+] + \tfrac{1}{2}\Omega e^{\imath\omega t}[\hat{\sigma}_z, \hat{\sigma}^-] - \tfrac{\imath}{2}\Gamma\hat{\sigma}_z = \Omega(\hat{\sigma}^- - \hat{\sigma}^+) - \tfrac{\imath}{2}\Gamma\hat{\sigma}_z \ .
\end{aligned}$$

39.4.1.1 Stationary solution of the Bloch equations

The dissipation introduced by the spontaneous emission allows the system to reach a steady state. Letting the time derivatives be 0, we obtain the stationary solutions,

$$\boxed{\rho_{22}(\infty) = \frac{\frac{1}{4}|\Omega|^2}{\Delta^2 + \frac{1}{2}|\Omega|^2 + \frac{1}{4}\Gamma^2} \qquad \text{and} \qquad \rho_{12}(\infty) = e^{\imath\Delta t}\frac{\frac{1}{2}\Omega(\Delta - \frac{\imath}{2}\Gamma)}{\Delta^2 + \frac{1}{2}|\Omega|^2 + \frac{1}{4}\Gamma^2}} \ . \tag{39.151}$$

This will be shown in Exc. 39.4.4.1. We see that the populations and coherences both have a Lorentzian frequency dependence, which is similar to the one of the absorption cross section σ derived in (23.72). However, the denominators have an extra term $\frac{1}{2}\Omega^2$ contributing to an *effective* widths of ρ_{22} and ρ_{12},

$$\Gamma_{\text{eff}} = \sqrt{2|\Omega|^2 + \Gamma^2} \ . \tag{39.152}$$

This effect, called *power broadening* or *saturation broadening*, has already been discussed in (23.102). The phase factor $e^{\imath\Delta t}$ describes the optical precession of the Bloch vector.

By introducing the *saturation parameter*,

$$s \equiv \frac{2|\Omega|^2}{4\Delta^2 + \Gamma^2} \ , \tag{39.153}$$

we can rewrite the stationary dipole moment and the excited state population (39.151) as,

$$\boxed{\rho_{22}(\infty) = \frac{s/2}{1+s} \qquad , \qquad \rho_{12}(\infty) = e^{\imath\Delta t}\frac{\Delta - \imath\Gamma/2}{\Omega}\frac{s}{1+s} \ .} \tag{39.154}$$

and

$$|\rho_{12}(\infty)|^2 = \frac{s/2}{(1+s)^2} \ . \tag{39.155}$$

Fig. 39.3(a) shows the Rabi oscillations damped by spontaneous emission. For long times the population of the excited state ρ_{22} converges to the asymptote (39.154). Fig. 39.3(b) shows the temporal evolution of the Bloch vector subject to spontaneous emission. In Exc. 39.4.4.2 we the behavior of the phase of the dipole moment ρ_{12} with respect to the driving field. In Exc. 39.4.4.3 and 39.4.4.4 we calculate the impact of the spontaneous emission on the determinant of the density operator. Solve the Excs. 39.4.4.5, 39.4.4.6, 39.4.4.7, and 39.4.4.8.

Example 276 (*Resonant excitation and weak excitation*): A case where the Bloch equations can be analytically treated is under resonant excitation, $\Delta = 0$. In this case, for the initial conditions, $\rho_{12}(0) = \rho_{22}(0) = 0$, the solution including decay is,

$$\rho_{22}(t) = \frac{\Omega^2}{2|\Omega|^2 + \Gamma^2}\left[1 - e^{-3\Gamma t/4}\left(\cos\lambda t + \frac{3\Gamma}{4\lambda}\sin\lambda t\right)\right] \qquad \text{and} \qquad \rho_{12}(t) = 0 \ , \tag{39.156}$$

where $\lambda \equiv \sqrt{\Omega^2 - \Gamma^2}$. This solution (which will be derived in Exc. 39.4.4.9), describes the optical nutation of the Bloch vector along the ρ_z axis. We note here that, due to spontaneous emission, the norm of the Bloch vector is NOT

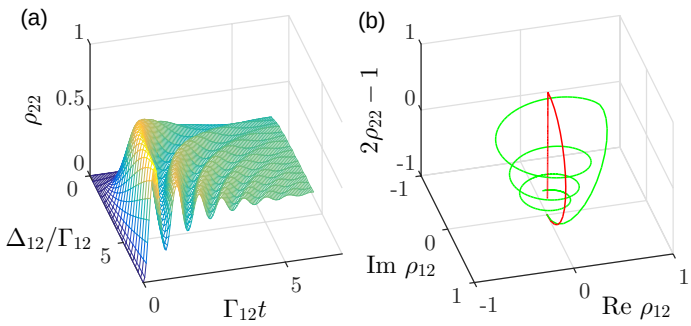

Figure 39.3: (code) (a) Rabi oscillations damped by spontaneous emission for Rabi frequencies between $\Omega/\Gamma = 0.2, .., 5$. (b) Evolution of the Bloch vector subject to spontaneous emission ($\Gamma_{12} = 0.05\Omega_{12}$) after application of a resonant π-pulse (red) and after a π-pulse with detuning $\Delta_{12} = \Omega_{12}/2$ (green).

conserved, i.e. the Bloch vector evolves to the interior of the Bloch sphere.
Another case that can be solved analytically is the weakly excited atom, $|\Omega| \ll \Gamma$,

$$\rho_{22} \simeq \frac{\Omega^2}{4G^2}\left(1 + e^{-2\Gamma t} - 2\cos\Delta t\right) \tag{39.157}$$

$$\text{and} \qquad \rho_{12}(t) \simeq \frac{-\imath\Omega}{2\imath\Delta + 2\Gamma}\left(e^{-(\imath\Delta+\Gamma)t} - 1\right) + \rho_{12}(0)e^{-(\imath\Delta+\Gamma)t} \ .$$

39.4.1.2 Nonlinearity of the Bloch equations

Because the Bloch equation go beyond perturbation theory they contain nonlinear optics. We can see this by the simple fact that strong radiation field can saturate atomic transitions. For example, expanding the population and coherence (39.151) by the incident electric field amplitude $\mathcal{E} \propto \Omega$,

$$\rho_{22}(\infty) \simeq \frac{1}{4\Delta^2 + \Gamma^2}\Omega^2 - \frac{2}{(4\Delta^2 + \Gamma^2)^2}\Omega^4 + ... \tag{39.158}$$

$$\rho_{12}(\infty) \simeq e^{\imath\Delta t}\frac{2\Delta - \imath\Gamma}{4\Delta^2 + \Gamma^2}\Omega - 2e^{\imath\Delta t}\frac{2\Delta - \imath\Gamma}{(4\Delta^2 + \Gamma^2)^2}\Omega^3 + ... \ .$$

The theory of nonlinear optics will be developed in Sec. 40.5.2 and Chp. 42.

Example 277 (*Complex susceptibility and absorption coefficient*): The objective of this section is to obtain an expression for the susceptibility in the presence of spontaneous emission. For the present discussion we are only concerned with the temporal dependence of the actual light wave, which we write as,

$$\vec{\mathcal{E}}(t) = \vec{\mathcal{E}}_0 \cos\omega t = \tfrac{1}{2}[e^{\imath\omega t} + e^{-\imath\omega t}] \ . \tag{39.159}$$

Then we consider how to write the polarization in terms of a susceptibility when the field contains two conjugate frequencies, $\pm\omega$. Substituting into the polarization Eq. (11.20), we get,

$$\vec{\mathcal{P}}(t) = \varepsilon_0\chi_e\vec{\mathcal{E}} = \tfrac{1}{2}\varepsilon_0\vec{\mathcal{E}}_0[\chi_e(\omega)e^{\imath\omega t} + \chi_e(-\omega)e^{-\imath\omega t}] \ . \tag{39.160}$$

The polarization can also be expressed in terms of the density of the transition dipoles in a gas of two-level atoms,

$$\vec{\mathcal{P}}(t) = \frac{N}{V}\mathbf{d}_{12}(t) \longrightarrow \frac{N}{V}\langle \mathbf{d}_{12}(t)\rangle \ . \tag{39.161}$$

where $\mathbf{d}$ is the transition dipole of only one atom, N/V is the atomic density, and the quantum expectation value for the transition dipole moment is,

$$\langle \mathbf{d}_{12}\rangle = -e\int \Psi \sum_j \mathbf{r}_j \Psi d^3 r \ . \tag{39.162}$$

Now, from Eq. (27.58),

$$\langle \mathbf{d}_{12}\rangle = -e\left[a_1^* a_2 \langle\psi_1|\sum_j \mathbf{r}_j|\psi_2\rangle e^{-\imath\omega_0 t} + a_1 a_2^* \langle\psi_2|\sum_j \mathbf{r}_j|\psi_1\rangle e^{\imath\omega_0 t}\right] \ . \tag{39.163}$$

To simplify the notation we define $\langle \mathbf{r}_{mn}\rangle \equiv \langle\psi_m|\sum_j \mathbf{r}_j|\psi_n\rangle$ and obtain,

$$\langle \mathbf{d}_{12}\rangle = -e[a_1^* a_2 \langle \mathbf{r}_{12}\rangle e^{-\imath\omega_0 t} + a_1 a_2^* \langle \mathbf{r}_{21}\rangle e^{\imath\omega_0 t}] \ . \tag{39.164}$$

Now, we only need to replace the solutions of the coupled equations by relating a_1 and a_2 of the Eqs. (27.63) in (39.164) which, in turn, can be inserted into the equation (39.160). Thus we obtain an expression for the polarization in terms of properties of the atoms and the incident field.
The crucial point now is, that the solution for a_2, Eq. (27.79), does not consider spontaneous emission. Therefore, as already done in Sec. 39.4.1, we will introduce an ad hoc modification of Eq. (27.63) by including a radiative loss constant γ,

$$\Omega^* \cos\omega t e^{\imath\omega_0 t} a_1 - \imath\gamma a_2 = \imath\frac{da_2}{dt} \ . \tag{39.165}$$

This term does NOT EXPLAIN spontaneous emission. It simply takes into account the existence of the effect and characterizes its amplitude through γ: If the incident field is turned off ($\Omega^* = 0$)

$$-\imath\gamma a_2 = \imath\frac{da_2}{dt} \tag{39.166}$$

and

$$a_2(t) = a_2(0)e^{-\gamma t} \ . \tag{39.167}$$

Then, the probability of finding an atom in the excited state (or the fraction of excited atoms in an ensemble) is,

$$N_2/N = |a_2(t)|^2 = |a_2(0)|^2 e^{-2\gamma t} \ . \tag{39.168}$$

Comparing this behavior with the result obtained from the Einstein rate equation, we see immediately,

$$A_{21} = 2\gamma \equiv \Gamma \ . \tag{39.169}$$

Now, the solution for our improved $a_2(t)$ coefficient is,

$$a_2(t) = -\tfrac{1}{2}\Omega^*\left[\frac{e^{\imath(\omega_0+\omega)t}}{\omega_0+\omega-\imath\gamma} + \frac{e^{\imath(\omega_0-\omega)t}}{\omega_0-\omega-\imath\gamma}\right] \ , \tag{39.170}$$

which solves the differential equation (39.165) in the weak field limit, $a_1(t) \simeq 1$, as will be verified in Exc. 39.4.4.10.

Making the weak field approach, replacing the values obtained for $a_{1,2}$ in the transition dipole (39.164) and replacing the average of the orientations, $|\langle r_{12}\rangle|^2 \longrightarrow \frac{1}{3}|\langle r_{12}\rangle|^2$, in the polarization (39.161), we obtain,

$$\begin{aligned}\vec{\tilde{\mathcal{P}}}(t) &= \varepsilon_0 \tilde{\chi}_e \vec{\mathcal{E}} \qquad (39.171)\\ &= \frac{N}{V}\frac{e^2|\langle r_{12}\rangle^2 \vec{\mathcal{E}}_0}{6\hbar}\left[\frac{e^{\imath\omega t}}{\omega_0+\omega-\imath\gamma}+\frac{e^{\imath\omega t}}{\omega_0-\omega+\imath\gamma}+\frac{e^{-\imath\omega t}}{\omega_0-\omega-\imath\gamma}+\frac{e^{-\imath\omega t}}{\omega_0+\omega+\imath\gamma}\right] .\end{aligned}$$

Apparently, the presence of spontaneous emission turns the susceptibility into a complex number [see Eq. (15.133)].
Comparing this result with Eq. (39.160) and identifying the susceptibility $\tilde{\chi}_e(\omega)$ in terms of the atomic properties and the frequency of the incident field, we find,

$$\begin{aligned}\tilde{\chi}_e(\omega) &= \frac{Ne^2|\langle r_{12}\rangle|^2}{3\epsilon_0\hbar V}\left[\frac{1}{\omega_0-\omega-\imath\gamma}+\frac{1}{\omega_0+\omega-\imath\gamma}\right] \qquad (39.172)\\ &= \frac{Ne^2|\langle r_{12}\rangle^2}{3\epsilon_0\hbar V}\left[\frac{\omega_0-\omega}{(\omega_0-\omega)^2+\gamma^2}+\frac{\omega_0+\omega}{(\omega_0+\omega)^2+\gamma^2}\right.\\ &\quad \left.+\imath\gamma\left(\frac{1}{(\omega_0-\omega)^2+\gamma^2}+\frac{1}{(\omega_0+\omega)^2+\gamma^2}\right)\right] .\end{aligned}$$

In most practical situations in the laboratory ω will not be tuned more than some 100 GHz away from ω_0, hence $|\omega_0-\omega| \lesssim 10^{11}$ Hz. With optical frequencies $\omega \simeq 10^{15}$ Hz, it is clear that the second term on the right hand side of Eq. (39.172) will be negligible compared to the first one. Therefore, we can discard the second term and write the susceptibility as,

$$\begin{aligned}\chi_e(\omega) &\simeq \frac{Ne^2|\langle r_{12}\rangle|^2}{3\epsilon_0\hbar V}\frac{1}{\omega_0-\omega-\imath\gamma} \qquad (39.173)\\ &= \frac{Nd_{12}^2}{3\epsilon_0\hbar V}\frac{-\Delta+\imath\Gamma/2}{\Delta^2+(\Gamma/2)^2} = \frac{n\hbar\Omega^2}{3\epsilon_0 E_0^2}\frac{-\Delta+\imath\Gamma/2}{\Delta^2+(\Gamma/2)^2} .\end{aligned}$$

We identify the real and imaginary parts, $\tilde{\chi}_e = \chi_e' + \imath\chi_e''$, and express the absorption coefficient as (see (15.139)),

$$K = \frac{\omega}{c\eta}\chi_e''(\omega) = \frac{\pi N d_{12}^2\omega_0}{3\epsilon_0\hbar c V}\frac{\Gamma/2\pi}{\Delta^2+(\Gamma/2)^2} = \frac{\pi N d_{12}^2\omega_0}{3\epsilon_0\hbar c V}\mathfrak{L}(\omega-\omega_0) . \qquad (39.174)$$

The Lorentzian profile term governs the frequency dependence of the absorption coefficient. We see that K exhibits a peak at the resonance frequency ω_0 and a width of Γ. The factor of π inserted in the numerator and denominator of the right term of Eq. (39.174) allows to normalize the profile. We have also assumed in Eq. (39.174) that the gas is sufficiently dilute for $n \simeq 1$ to hold, and that the line is sufficiently narrow to be able to replace ω with ω_0, such that,

$$\frac{\omega}{c\eta} \longrightarrow \frac{\omega_0}{c} . \qquad (39.175)$$

The absorption cross section has the same lineshape, since from Eqs. (23.72) and (39.174) we have,

$$\sigma_{0a} = \frac{\pi d_{12}^2\omega_0}{3\epsilon_0\hbar c V}\mathfrak{L}(\omega-\omega_0) , \qquad (39.176)$$

consistent with our previous expression for the frequency dependence of the absorption cross-section. We can also write the imaginary component of the susceptibility in terms of the cross section using the Eqs. (23.72) and (39.174)

$$\chi_e'' = \frac{cN}{\omega_0 V}\sigma_{0a} \ . \tag{39.177}$$

The frequency-dependent linear *susceptibility* completely describes the linear propagation of an electromagnetic wave within a medium. It is related to the index of refraction and the absorption coefficient. Nonlinear processes should be described by higher order susceptibilities. Electric fields $\vec{\mathcal{E}} = \vec{\mathcal{E}}_0 e^{\imath\omega t} + c.c.$ induce in media characterized by a given susceptibility $\tilde{\chi}_e$ the polarization $\vec{\mathcal{P}} = \varepsilon_0 \tilde{\chi}_e \vec{\mathcal{E}}$. The polarization is the sum of the dipole moments of the individual atoms, $\vec{\mathcal{P}} = n\langle \mathbf{d}\rangle$, where $n = N/V$ is the atomic density. The susceptibility can therefore be expressed by the Hamiltonian interaction $\hat{H} = -\mathbf{d}\cdot\vec{\mathcal{E}}$,

$$\chi_e = -\frac{n}{|\vec{\mathcal{E}}|^2}\ \langle \hat{H}\rangle \ . \tag{39.178}$$

Using the two-level Hamiltonian (39.172) we obtain,

$$\chi_e = -n\ \frac{\hbar\Omega}{2|\vec{\mathcal{E}}|^2}\ \rho_{12} e^{\imath\Delta t} + c.c. \tag{39.179}$$

for the polarization,

$$\vec{\mathcal{P}} = n\ \mathbf{d}\rho_{12} + c.c. \tag{39.180}$$

and for the susceptibility,

$$\chi_e(\omega) = \frac{2nd^2}{3\varepsilon_0\hbar}\frac{\Delta + \imath\Gamma}{4\Delta^2 + 2|\Omega|^2 + \Gamma^2} \qquad \text{with} \qquad d = \sqrt{\frac{3\pi\varepsilon_0\hbar\Gamma}{k^3}} \ . \tag{39.181}$$

We can insert the new expression (39.151) for ρ_{12} into our previous expression for $\langle d_{12}\rangle$ (39.164) and get new expressions for the polarization $\vec{\mathcal{P}}(t)$, (39.161) and (39.171), and the susceptibility χ (39.173). The modified expression for the susceptibility is,

$$\chi_e = \frac{Nd_{12}^2}{3\epsilon_0\hbar V}\frac{-\Delta + \frac{1}{2}\Gamma}{\Delta^2 + \frac{1}{2}|\Omega|^2 + \frac{1}{4}\Gamma^2} \ . \tag{39.182}$$

In the imaginary component we obtain the new absorption coefficient,

$$K = \frac{\omega}{cn}\chi_e''(\omega) = \frac{\pi N e^2 |\langle \mathbf{r}_{12}\rangle|^2\omega_0}{3\epsilon_0\hbar c V}\frac{\Gamma/2\pi}{\Delta^2 + \frac{1}{2}\Omega^2 + \frac{1}{4}\Gamma^2} \ , \tag{39.183}$$

and the *optical cross-section* for absorption,

$$\sigma_{0a} = \frac{\pi e^2 |\langle \mathbf{r}_{12}\rangle|^2\omega_0}{3\epsilon_0\hbar c}\frac{\Gamma/2\pi}{\Delta^2 + \frac{1}{2}\Omega^2 + \frac{1}{4}\Gamma^2} \ . \tag{39.184}$$

The important new property is the effective width Γ_{eff}, which appears in χ_e, K, and σ_{0a}.

39.4.2 Liouville equation for two levels

In the previous section we chose to include spontaneous emission in the Bloch equations by phenomenological arguments. However, as we will show more ahead, dissipation can be treated from general principles. This treatment, named after *Weisskopf-Wigner*, derives from a Liouville type equation (38.6), but which holds for a total density operator $\rho_{atom:field}$ describing the atom and the electromagnetic modes, an equation for the density operator of only the atom. The price to pay for this simplification is an additional term appearing in the equation now called *master equation*,

$$\boxed{\begin{aligned} \dot{\hat{\rho}}(t) &= (\mathfrak{L}_0 + \mathfrak{L}_{\rm sp})\hat{\rho}(t) \qquad \text{with} \\ \mathfrak{L}_0\hat{\rho}(t) &\equiv \frac{\imath}{\hbar}[\hat{\rho}(t), \hat{H}] \qquad \text{and} \qquad \mathfrak{L}_{\rm sp} = \tfrac{\Gamma}{2}(2\hat{\sigma}^-\hat{\rho}\hat{\sigma}^+ - \hat{\sigma}^+\hat{\sigma}^-\hat{\rho} - \hat{\rho}\hat{\sigma}^+\hat{\sigma}^-) \end{aligned}} \ , \tag{39.185}$$

where $\hat{\sigma}^\pm$ are the Pauli matrices. We show in Exc. 39.4.4.11, that the known Bloch equations can be derived from the master equation.

39.4.3 The effective Hamiltonian approach

In Sec. 39.4.1 we have shown that spontaneous emission can be phenomenologically be included by substituting $\frac{d}{dt} \curvearrowright \frac{d}{dt} + \frac{\Gamma}{2}$ in the Schrödinger equation,

$$\imath\left(\tfrac{d}{dt} + \tfrac{\Gamma}{2}|2\rangle\langle 2|\right)|\psi\rangle = \hat{H}|\psi\rangle \ . \tag{39.186}$$

Rewriting the Schrödinger equation as,

$$\imath\tfrac{d}{dt}|\psi\rangle = (\hat{H} - \imath\tfrac{\Gamma}{2}|2\rangle\langle 2|)|\psi\rangle \equiv \hat{H}_{\rm eff}|\psi\rangle \ , \tag{39.187}$$

it is tempting to study how far we can go [74, 75] with the emulation of dissipative processes by the Schrödinger equation using a non-Hermitian *effective Hamiltonian*.

More generally let us define,

$$\hat{H}_{\rm eff} \equiv \hat{H} - \imath\hat{D} \ . \tag{39.188}$$

Rederiving the master equation from Schrödinger equation with this Hamiltonian, we get,

$$\begin{aligned} \dot{\hat{\rho}} &= |\psi\rangle\frac{d\langle\psi|}{dt} + \frac{d|\psi\rangle}{dt}\langle\psi| = \imath\hat{\rho}\hat{H}^*_{\rm eff} - \imath\hat{H}_{\rm eff}\hat{\rho} \\ &= \imath[\hat{\rho}, \hat{H}] - \{\hat{\rho}, \hat{D}\} \ . \end{aligned} \tag{39.189}$$

And for the Heisenberg equation,

$$\begin{aligned} \tfrac{d}{dt}\langle\hat{A}\rangle &= \langle\dot{\psi}|\hat{A}|\psi\rangle + \langle\psi|\hat{A}|\dot{\psi}\rangle = \imath\langle\psi|\hat{H}^*_{\rm eff}\hat{A}|\psi\rangle - \imath\langle\psi|\hat{A}\hat{H}_{\rm eff}|\psi\rangle \\ &= \imath\langle\psi|[\hat{H}, \hat{A}]|\psi\rangle - \langle\psi|\{\hat{D}, \hat{A}\}|\psi\rangle \ . \end{aligned} \tag{39.190}$$

Apparently, the dissipation term adds an anti-commutator to the evolution equations. It is now interesting to compare the dissipative terms of the expressions (39.185) and (39.189).

39.4.3.1 Saturation effects by the effective Hamiltonian

The eigenvalues of the *effective Hamiltonian* of a two-level system excited by radiation,

$$\hat{H}_{\text{eff}} = \begin{pmatrix} 0 & \frac{1}{2}\Omega \\ \frac{1}{2}\Omega & \Delta - \frac{\imath}{2}\Gamma \end{pmatrix} , \tag{39.191}$$

describe possible effects of line broadening and/or displacement due to coupling,

$$\boxed{E_{\pm} = \frac{1}{2}\left(\Delta - \frac{\imath}{2}\Gamma\right) \pm \frac{1}{2}\sqrt{\left(\Delta - \frac{\imath}{2}\Gamma\right)^2 + \Omega^2}} . \tag{39.192}$$

The real parts of the eigenvalues $\mathfrak{Re}\, E$ describe shifts and/or splittings of the transition line. The imaginary parts $\mathfrak{Im}\, E$ describe broadening effects of the lines.

In the simplest case, $\Delta = 0$ and $\Gamma > 4\Omega$, we find the *saturation broadening* already discussed in (39.152), and we will deepen it in Exc. 39.7.3.2. For the case $\Gamma < 4\Omega$, we observe a splitting of the line called *Autler-Townes splitting*, which will be studied in Exc. 39.7.3.1. If $\Omega \neq 0$, the spectrum becomes asymmetrical. In the case of weak excitation, $\Gamma \gg 4\Omega$, we observe a shift of the transition line with dispersive dependence (near the resonance) on the frequency of the incident radiation. This is the *dynamic Stark shift* (or *light shift*). In the case of strong excitation, $\Gamma \ll 4\Omega$, we observe again at the split spectrum, but now the two lines exhibit an *avoided crossing*-type dependence on the radiation frequency. We study these effects in Excs. 39.4.4.12 and Exc. 39.4.4.13.

Obviously, these effects can be studied by the Bloch equation formalism containing the terms of spontaneous relaxation.

39.4.4 Exercises

39.4.4.1 Ex: Stationary solution of the Bloch equations

Derive the stationary solution of the Bloch equations including spontaneous emission. How does the spectrum $\rho_{22}(\Delta)$ change in the presence of phase noise, $\gamma = \frac{\Gamma}{2} + \beta$, in particular if $\beta \gg \frac{\Gamma}{2}$?

39.4.4.2 Ex: Detuning-dependent phase-shift of the dipole moment

Calculate the phase-shift of the dipole moment with respect to the driving field across resonance.

39.4.4.3 Ex: Determinant of the Bloch matrix

In Sec. 37.2.1 we already saw that $\det \hat{\rho} = 0$ for conservative systems. Now, show explicitly for the Bloch matrix of a two-level system, that $\det \hat{\rho} = 0$ only holds in the absence of spontaneous emission.

39.4.4.4 Ex: Density operator with dissipation

Discuss the phenomenon of dissipation at the example of
a. a thermal sample of two-level systems $|i\rangle = |1\rangle, |2\rangle$ characterized by the density

operator $\hat{\rho} = |i\rangle\langle i| \otimes |v\rangle\langle v|$, where $|v\rangle$ is the velocity state of the atom and
b. a two-level atom coupled to a radiation field, $\hat{\rho} = |i\rangle\langle i| \otimes |n\rangle\langle n|$, where $|n\rangle$ is the number of photons inside the mode.

39.4.4.5 Ex: Bloch vector

A two-level atom with decay rate $\Gamma = 2\pi \times 6\,\mathrm{MHz}$ be excited by a light field detuned by $\Delta = 2\Gamma$ and whose intensity is a quarter of the saturation intensity. Write down the Bloch vector for $t \to \infty$.

39.4.4.6 Ex: Purity of two-level atoms with spontaneous emission

Calculate for a driven two-level atom in the stationary limit $\mathrm{Tr}\,\hat{\rho}$ and $\mathrm{Tr}\,\hat{\rho}^2$.

39.4.4.7 Ex: Bloch sphere

Check the temporal evolution of the norm of the Bloch vector defined by $\vec{\rho} \equiv (2\,\mathfrak{Re}\,\sigma_+\ ,\ 2\,\mathfrak{Im}\,\sigma_-\ ,\ \sigma_z)$, where the σ_k are the Pauli matrices, for a resonantly excited two-level system with and without spontaneous emission.

39.4.4.8 Ex: Atomic beam

An atomic beam is illuminated perpendicular to its propagation direction by (quasi-)monochromatic, collimated laser pulses having the intensity $I = 1\,\mathrm{W/cm^2}$, the wavelength $\lambda = 780\,\mathrm{nm}$, and the duration $200\,\mathrm{ns}$. The laser is tuned to the center of an atomic resonance line ($\Gamma/2\pi = 6\,\mathrm{MHz}$).
a. How does the population of the upper atomic state develop?
b. How does the dynamics change, when the light is detuned by $100\,\mathrm{MHz}$?

39.4.4.9 Ex: Solution of the Bloch equations for resonant excitation

Derive the solution (39.156) of the Bloch equations with spontaneous emission for resonant excitation.

39.4.4.10 Ex: Solution for the susceptibility

Show that the solution of Eq. (39.165) is given by the result (39.170).

39.4.4.11 Ex: General form of the master equation

Show that the general form of the master equation: $\dot{\hat{\rho}} = -\frac{\imath}{\hbar}[\hat{H}, \hat{\rho}] - \frac{\Gamma}{2}(2\hat{\sigma}\hat{\rho}\hat{\sigma}^+ - \hat{\sigma}^+\hat{\sigma}\hat{\rho} - \hat{\rho}\hat{\sigma}^+\hat{\sigma})$, reproduces the Bloch equations including spontaneous emission.

39.4.4.12 Ex: Light-shift

Calculate the light-shift in a driven two-level system from the *effective Hamiltonian*,

$$\hat{H}_{\mathrm{eff}} = \begin{pmatrix} 0 & \frac{1}{2}\Omega \\ \frac{1}{2}\Omega & \Delta - \frac{\imath}{2}\Gamma \end{pmatrix} .$$

Prepare spectra of the eigenvalues for $\Gamma/\Omega = 0$, 0.5, and 2.

39.4.4.13 Ex: Light-shift

In this exercise we study the effect of the dynamic Stark shift (or light shift) of the energy levels of a two-level system $|1\rangle$ and $|2\rangle$ excited by a laser with the Rabi frequency Ω_{12} and the detuning Δ_{12}:
a. From the eigenvalues $E_{1,2}$ of the effective Hamiltonian (39.191) system, find approximations for weak coupling ($\Omega_{12} \ll \Gamma_{12}$) and strong coupling ($\Omega_{12} \gg \Gamma_{12}$). Prepare a graph showing the eigenvalue spectrum (separating the parts $\mathfrak{Re}\, E_{1,2}$ and $\mathfrak{Im}\, E_{1,2}$) as a function of detuning Δ_{12} for various values of Ω_{12}. Also search for approximations valid for large detunings $\Delta_{12} \gg \Gamma_{12}, \Omega_{12}$ and add them to the graph.
The light shift can be experimentally measured in a three-level system in Λ-configuration, as illustrated in Fig. 39.7(a). To reproduce the experiment by numerical simulations of the Bloch equations (39.238),
b. write the Liouville matrix $\mathcal{M}_{\text{red}}$ reduced by the condition to the trace (39.243) and calculate the stationary Bloch vector from equation (39.245) varying the detunings of the two lasers Δ_{12} and Δ_{23}. Choosing the parameters $\Gamma_{23} = \Gamma_{12}$, $\Gamma_{13} = 0.01\Gamma_{12}$, $\Omega_{12} = 2\Gamma_{12}$, and $\Omega_{23} = 0.2\Gamma_{12}$, prepare a 3D curve [similar to Fig. 39.3(a)] of the stationary population $\rho_{22}(\infty)$. Interpret the results.

39.4.4.14 Ex: Line broadening by phase noise and optical repumping

a. For a two-level system calculate ρ_{22} as a function of detuning Δ and a phase noise rate β added to the coherence decay rate $\Gamma/2$, such that $\gamma = \Gamma/2 + \beta$.
b. Check that incoherent optical pumping from the ground into the excited state introduces a transverse decay rate R leading to line broadening, and plot ρ_{22} as a function of detuning Δ and the pump rate R.

39.4.4.15 Ex: Superradiant decay upon fast switch-off

We consider a laser-driven two-level system having reached steady-state and want to study the population decay as a function of the switch-off time of the driving laser light. In certain parameter regimes (low saturation and large detuning) the population decay is found to be faster than Γ, when the switch-off time is chosen on the order of Γ^{-1} [38]. Simulate the evolution of the population as a function of switch-off time and interpret the observations.

39.5 Line broadening mechanisms

The resolution of atomic spectroscopy is generally limited by several perturbative effects, many of them originating in the atomic motion. They manifest themselves as broadening and/or shifts of atomic resonances. Free atoms, as well as atoms confined in potentials, have kinetic energy and evolve on extended phase space trajectories. If the spatial localization is less than the effective cross section of the exciting laser beam, then the interaction time is limited and the resonance lines are broadened by the Fourier effect in a process called *transit time broadening*, and the efficiency of fluorescence collection is reduced. The same happens with the *Doppler effect*: Only those atoms that have a specific velocity along the optical axis defined by the laser

beam can interact. Free as well as confined atoms can only scatter when they are in specific cells of the phase space.

There are two different fundamental types of broadening. The so-called *homogeneous broadening* affects all atoms in the same way regardless of their positions or velocities. It usually gives rise to Lorentzian line profiles and can be incorporated into the Bloch equations by a simple modification of relaxation rates. Examples are the natural linewidth, saturation broadening, collision broadening, or phase noise induced by laser fluctuations.

The so-called *inhomogeneous broadening* is due to a displacement of atomic levels, which may be different for each atom. Averaging over a large sample of atoms, the displacements generate an *effective* broadening usually with a Gaussian line profile. It *can not* be included in the single-atom Bloch equations, but only as an average over all trajectories of all atoms. It does not correspond to an accelerated relaxation. Inhomogeneous broadening is often due to external perturbations, e.g., Doppler broadening and broadening due to temporal fluctuations or spatial inhomogeneities of external electric or magnetic fields. In Exc. 39.5.6.1 we calculate the optical density of atomic clouds. In Exc. 39.5.6.2 we present a spectroscopic technique bypassing the Doppler broadening called *Doppler-free spectroscopy* and calculate the *Lamb-dip* profile. Finally, in Exc. 39.5.6.3, we discuss a cooling technique allowing for the reduction of Doppler broadening, called *Zeeman slower*.

39.5.1 Saturation broadening

Eq. (39.152) shows that when the power of the incident light increases, the population of the excited state saturates at a limit value of $\rho_{22} = \frac{1}{2}$. The *saturation parameter* defined in (39.153) measures the degree of saturation. When the narrowband light source is tuned to resonance, the saturation parameter is basically a measure for the ratio between the stimulated population transfer rate Ω and the spontaneous decay rate A_{21}. We can rewrite the stationary population of the excited level as in (39.154). In resonance and with the saturation parameter $s = 1$, we obtain

$$\Omega = \tfrac{1}{\sqrt{2}}\Gamma \ . \tag{39.193}$$

We can use equation (39.193) to define the *saturation intensity* I_{sat} for an atom with the transition dipole d_{12}. From Eq. (23.41) we have,

$$\mathcal{E}_0 = \sqrt{\frac{2\bar{I}}{\varepsilon_0 c}} \ . \tag{39.194}$$

Therefore, using the definition of the Rabi frequency, $\hbar\Omega = d_{12}\mathcal{E}_0$, and the relationship between d_{12} and Γ given by Eq. (39.41), we have [11],

$$\boxed{I_{\text{sat}} = \frac{g_1}{g_2}\frac{2\pi^2 c\hbar}{3\lambda_0^3}\Gamma} \ , \tag{39.195}$$

taking into account the degeneracies g_j of the levels. In Excs. 39.5.6.4 and 39.5.6.5 we calculate the *saturation intensity* of popular atomic transitions.

[11] Some authors define the saturation for $s = 2$, as happens when $\Omega = \Gamma$.

39.5.2 Collision broadening

The theory of atomic collisions covers a large area of research, including elastic and inelastic, reactive and ionizing processes. In low-pressure gases at room temperature or hotter we need only consider the simpler processes: long-range van der Waals interactions that result in *elastic collisions*. The 'low pressure' criterion requires that the average free path between collisions be greater than any linear dimension of the gas volume. Under these conditions, collisions can be modeled with straight trajectories, along which the interaction time is short and the time between collisions is long in comparison with the radiative lifetime of the excited atomic state. Then, the impact of a collision on the emission of a radiating atom causes a loss of coherence due to a phase interruption of the excited state atomic wavefunction. The term 'elastic' means that the collision does not disturb the populations of the internal states, so we only need to consider the off-diagonal elements of the density matrix,

$$\frac{d\rho_{12}}{dt} = \imath\frac{\Omega_0}{2}e^{\imath(\omega-\omega_0)t}(\rho_{11}-\rho_{22}) - \gamma'\rho_{12} \ , \tag{39.196}$$

where γ' is the sum of the spontaneous emission γ and the collision rate $\gamma_{\rm col}$,

$$\boxed{\gamma' = \gamma + \gamma_{\rm col}} \ . \tag{39.197}$$

The inverse of the collision rate is simply the time between phase interruptions or the time between collisions. Now, for collisions between hard cores of atoms of mass m (with reduced mass $m_{\rm red} = m/2$) and with radius ρ in a gas with density n consisting of a single species, a standard analysis based on the kinetic theory of dilute gases shows that the time between collisions is given by the *collision rate*,

$$\gamma_{\rm col} = \tau_{\rm col}^{-1} = \sigma n \bar{v} \ , \tag{39.198}$$

where $\bar{v} = \sqrt{\frac{8k_{\rm B}T}{\pi m_{\rm red}}}$ is the average collision velocity in a homogeneous gas at the temperature T and $\sigma = \sqrt{8}\pi\rho^2$ the collision cross section. Thereby,

$$\boxed{\gamma_{\rm col} = \frac{8\rho^2 n}{\sqrt{m_{\rm red}/\pi k_{\rm B}T}}} \ . \tag{39.199}$$

We can now relate this simple result of gas kinetics to the phase interruption rate by reinterpreting the meaning of the *collision radius*. When an excited atom propagating through space suffers a collision, the long-range interaction will produce a time-dependent perturbation of the energy levels of the radiating atom and a phase shift in the radiation,

$$\eta = \int_{-\infty}^{\infty}[\omega(t)-\omega_0]dt = \int_{-\infty}^{\infty}\Delta\omega(t)dt \ . \tag{39.200}$$

The long-range van der Waals interaction is expressed by,

$$\Delta E = \hbar\omega = \frac{C_n}{[b^2+(vt)^2]^{n/2}} \ , \tag{39.201}$$

where b is the impact parameter of the collision trajectory and v the collision velocity. The phase shift is then

$$\eta = \frac{1}{\hbar}\int_{-\infty}^{\infty} \frac{C_n}{[b^2+(vt)^2]^{n/2}}dt \ . \tag{39.202}$$

The integral is easily assessed for the two most frequent cases: non-resonant van der Waals interactions $n = 6$ and resonant van der Waals interactions $n = 3$. The phase shifts are,

$$\eta_6(b) = \frac{2\pi}{3\hbar}\frac{C_6}{b_6^5 v} \qquad \text{and} \qquad \eta_3(b) = \frac{4\pi}{3\sqrt{3}\hbar}\frac{C_3}{b_3^2 v} \ . \tag{39.203}$$

Now, if instead of using the *hard core approximation*, we define a collision as an encounter causing a phase shift of at least 1 radians, we have a new condition for the collision radius,

$$b_6 = \left(\frac{2\pi}{3\hbar}\frac{C_6}{v}\right)^{1/5} \qquad \text{and} \qquad b_3 = \left(\frac{4\pi}{3\sqrt{3}\hbar}\frac{C_3}{v}\right)^{1/2} \ . \tag{39.204}$$

Replacing these collision radiuses for the radius ρ in Eq. (39.199) and inserting the average collision velocity, we find the collision rate,

$$\gamma_{c6} = 4n\left(\frac{\sqrt{2}\pi^2 C_6}{3\hbar}\right)^{2/5}\left(\frac{4\pi k_{\rm B}T}{\mu}\right) \qquad \text{and} \qquad \gamma_{c3} = 4n\left(\frac{2}{3}\right)^{3/2}\left(\frac{\pi^2 C_3}{\hbar}\right)^{3/10} \ . \tag{39.205}$$

Substituting the generalized γ' of (39.197) for γ in the Bloch equations (39.151), we find the stationary solutions,

$$\rho_{22} = \frac{\frac{1}{4}\frac{\gamma'}{\gamma}|\Omega|^2}{\Delta^2 + \frac{1}{2}\frac{\gamma'}{\gamma}|\Omega|^2 + \gamma'^2} \qquad \text{and} \qquad \rho_{12} = e^{\imath(\omega-\omega_0)t}\frac{\frac{1}{2}\Omega(\Delta - \imath\gamma')}{\Delta^2 + \frac{1}{2}\frac{\gamma'}{\gamma}|\Omega|^2 + \gamma'^2} \ . \tag{39.206}$$

The effective linewidth (radiative and collisions) is,

$$\Gamma'_{\rm eff} = 2\sqrt{\gamma'^2 + \tfrac{1}{2}\tfrac{\gamma'}{\gamma}|\Omega|^2} \ . \tag{39.207}$$

When the excitation is sufficiently weak, so that power broadening can be neglected in comparison to collision broadening, the second term can be discarded,

$$\Gamma'_{\rm eff} = 2(\gamma + \gamma_{\rm col}) \ . \tag{39.208}$$

The equations (39.152) and (39.208) express the linewidths in the limits of dominating power and collision broadening, respectively. Note that the susceptibility, absorption coefficient, and absorption cross-section retain their Lorentzian profile, but with a larger width due to collisions. Since each atom is subject to the same broadening mechanism, the broadening is homogeneous. Solve Excs. 39.5.6.6.

39.5.3 Doppler broadening

The *Doppler broadening* is simply the apparent frequency distribution of a sample of radiating atoms at temperature T. The contribution of each atom to the radiation

appears detuned by the *Doppler shift* because of its velocity. The frequency shift for a non-relativistically moving particle is $\omega = \omega_0/(1-\frac{v}{c})$, such that,

$$\Delta \equiv \omega - \omega_0 \simeq \omega_0 \frac{v}{c} = \mathbf{k}\cdot\mathbf{v} = kv_z \ , \tag{39.209}$$

where $\mathbf{k}$ is the wavevector of the light and $\mathbf{v}$ is the velocity of the atom. This distribution of Doppler shifts of a gaseous sample in thermal equilibrium follows the probability distribution of velocities,

$$P(v_z)dv_z \propto e^{-mv_z^2/2k_\mathrm{B}T}dv_z = e^{-mc^2\Delta^2/2\omega_0^2 k_\mathrm{B}T}\frac{c}{\omega_0}d\omega \ . \tag{39.210}$$

This frequency distribution is a Gaussian centered at $\omega = \omega_0$ and with the width,

$$\mathrm{FWHM} = 2\omega_0\left(\frac{2k_\mathrm{B}T\ln 2}{mc^2}\right)^2 \ . \tag{39.211}$$

A measure of the width is also the *standard deviation*,

$$2\sigma = \frac{2\omega_0}{c}\sqrt{\frac{k_\mathrm{B}T}{m}} = \frac{\mathrm{FWHM}}{1.177} \ . \tag{39.212}$$

From Eq. (39.210) we can see that the line profile is,

$$\mathcal{D}(\omega-\omega_0) \equiv \frac{1}{\sqrt{2\pi}}\frac{m}{k_\mathrm{B}T}e^{-(\omega-\omega_0)^2/2\sigma^2}d\omega \ . \tag{39.213}$$

The profile compares with the Lorentzian profile Eq. (23.73) associated with natural, power, or collision broadening. Doppler broadening is a property of the atomic ensemble, each atom suffering a unique but different displacement than the other atoms. Hence, it is called *inhomogeneous broadening*.

The Liouville equation (39.104) used to derive the Bloch equations assumes immobile atoms. However, we can easily apply the Galilei transformation to a system, where the atoms move with the given velocity $\mathbf{v}$,

$$(\partial_t + \mathbf{v}\cdot\nabla)\hat{\rho}(\mathbf{r},t) = -\tfrac{\imath}{\hbar}[\hat{H},\hat{\rho}(\mathbf{r},t)] \ . \tag{39.214}$$

Since the light fields propagate as $e^{\imath(\omega t - \mathbf{k}\cdot\mathbf{r})}$, the solution of the above equation simply follows from the immobile solution with the substitution $\Delta \to \Delta - \mathbf{k}\cdot\mathbf{v}$. For a cloud obeying Maxwell's velocity distribution, $P(v) \sim e^{-mv^2/k_\mathrm{B}T}$,

$$\bar{\rho}(\Delta) = \frac{1}{\sqrt{2\pi}\sigma}\int_{\mathbb{R}} e^{-(\mathbf{k}\cdot\mathbf{v})^2/2\delta^2}\hat{\rho}(\Delta - \mathbf{k}\cdot\mathbf{v})d(\mathbf{k}\cdot\mathbf{v}) \ . \tag{39.215}$$

The average of the density operator over all velocities, $\bar{\rho}$, therefore follows as the convolution of the density operator ρ (obtained as the solution of the Bloch equation) and the Gaussian function $G(\Delta) = (2\pi\sigma^2)^{-1/2}e^{-\Delta^2/2\sigma^2}$,

$$\boxed{\bar{\rho}(\Delta) = (G\star\hat{\rho})(\Delta)} \ . \tag{39.216}$$

39.5.4 Voigt profile

It is clear that in many practical circumstances homogeneous and inhomogeneous processes simultaneously contribute to the broadening of lines. In these cases, we can consider that the radiation of each atom, homogeneously broadened by phase-interruption processes (such as spontaneous emission or collisions), is displaced by the Doppler effect within the Maxwell-Boltzmann distribution corresponding to the temperature T. The profile of the gaseous sample, therefore, is a convolution of homogeneous and inhomogeneous profiles. The resulting profile is called *Voigt profile*:

$$\begin{aligned} V(\omega-\omega_0) &= \int_{-\infty}^{\infty} \mathfrak{L}(\omega-\omega_0-\omega')\mathcal{D}(\omega-\omega_0)d\omega' \\ &= \frac{\gamma}{2\sigma\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{e^{-(\omega-\omega_0)^2/2\sigma^2}}{(\omega-\omega_0-\omega')^2+(\gamma/2)^2}d\omega' \ . \end{aligned} \tag{39.217}$$

This integral has no analytical solution, but it is easy to solve numerically. Resolve Excs. 39.5.6.7, 39.5.6.8, and 39.5.6.9.

39.5.5 Bloch equations with phase modulation

In some situations, the atom vibrates thus producing an oscillating Doppler shift. Also, external magnetic fields or oscillating laser frequencies can produce this effect. We incorporate this temporal modulation (frequency Ω_a) of the light frequency shifts, induced by the Doppler effect, into the optical Bloch equations via the substitution [828],

$$\Delta_{ij} \to \Delta_{ij} + \mathbf{k}_{ij}\cdot\mathbf{v}\ \cos\Omega_a t \ . \tag{39.218}$$

The Bloch equations can then be brought into the form,

$$\dot{\hat{\rho}} = (\mathbf{L} + 2\mathbf{X}\ \cos\Omega_a t)\hat{\rho} + \mathbf{b} \ , \tag{39.219}$$

where the matrix $\mathbf{X}$ contains the modulation index of the atomic motion $\mathbf{k}_{ij}\mathbf{v}$. The stationary solution of the differential equation, averaged over the time of an oscillation period, can be expressed as an infinite continuous fraction:

$$\begin{aligned} \hat{\rho}(\infty) &= -(\mathbf{L}+\mathbf{S}^+ + \mathbf{S}^-)^{-1}\mathbf{b} \\ \text{where}\quad \mathbf{S}^{\pm} &= -\mathbf{X}\frac{1}{\mathbf{L}\pm\imath\Omega_a\mathbf{1} - \mathbf{X}\frac{1}{\mathbf{L}\pm\imath\Omega_a\mathbf{1}-\mathbf{X}\frac{1}{\cdots}\mathbf{X}}\mathbf{X}} \ . \end{aligned} \tag{39.220}$$

This solution replicates the correct excitation spectra even for a multilevel system.

Let us be more specific for a two-level system. In this case the Hamiltonian is given by $\hat{H}_{\text{int}} = \frac{1}{2}\hbar\Omega e^{-\imath[\omega t - \mathbf{k}\cdot\mathbf{v}/\Omega_a\ \sin\Omega_a t]}$, such that the Bloch equation is,

$$\begin{pmatrix}\dot\rho_{22}\\ \dot\rho_{12}\\ \dot\rho_{21}\end{pmatrix} = \left[\begin{pmatrix}-\Gamma & -\frac{\imath}{2}\Omega & \frac{\imath}{2}\Omega\\ -\frac{\imath}{2}\Omega & -\Lambda & 0\\ \frac{\imath}{2}\Omega & 0 & -\Lambda^*\end{pmatrix} + 2\cos\Omega_a t\begin{pmatrix}0 & 0 & 0\\ 0 & -\frac{\imath}{2}kv & 0\\ 0 & 0 & \frac{\imath}{2}kv\end{pmatrix}\right]\begin{pmatrix}\rho_{22}\\ \rho_{12}\\ \rho_{21}\end{pmatrix} + \begin{pmatrix}0\\ \frac{\imath}{2}\Omega\\ -\frac{\imath}{2}\Omega\end{pmatrix} \ . \tag{39.221}$$

We look for the stationary solution by expanding $\hat{\rho} = \sum_{n=-\infty}^{\infty}\hat{\rho}_n e^{-\imath n\Omega_a t}$, letting $\dot{\hat{\rho}}_n = 0$, and projecting on $e^{-\imath n\Omega_a t}$ via,

$$(\mathbf{L} + \imath n\Omega_a\mathbf{1})\hat{\rho}_n + \mathbf{X}(\hat{\rho}_{n+1} + \hat{\rho}_{n-1}) + \mathbf{b}\delta_{n0} = 0 \ . \tag{39.222}$$

Now we define $\hat{\rho}_{n\pm1} = \mathbf{S}^{\pm}\hat{\rho}_n$ for $n \gtrless 0$. Then, equation (39.222) becomes,

$$\begin{aligned} \hat{\rho}_0 &= -[\mathbf{L} + \mathbf{X}(\mathbf{S}_0^+ + \mathbf{S}_0^-)]^{-1}\mathbf{b} \qquad \text{for} \qquad n = 0, \\ \mathbf{S}_{n\mp1}^{\pm} &= -[\mathbf{L} + \imath n\Omega_a \mathbf{1} + \mathbf{X}\mathbf{S}_n^{\pm}]^{-1}\mathbf{b} \qquad \text{for} \qquad n \gtrless 0 \ . \end{aligned} \tag{39.223}$$

Substituting the equation below into the equation above,

$$\hat{\rho}_0 = -\left[\mathbf{L} + \left(\frac{-\mathbf{X}|}{|\mathbf{L} + \imath\Omega_a} + \frac{-\mathbf{X}|}{|\mathbf{L} + 2\imath\Omega_a} + \ldots\right) + \left(\frac{-\mathbf{X}|}{|\mathbf{L} + \imath\Omega_a} + \frac{-\mathbf{X}|}{|\mathbf{L} + 2\imath\Omega_a} + \ldots\right)\right]^{-1}\mathbf{b} \ . \tag{39.224}$$

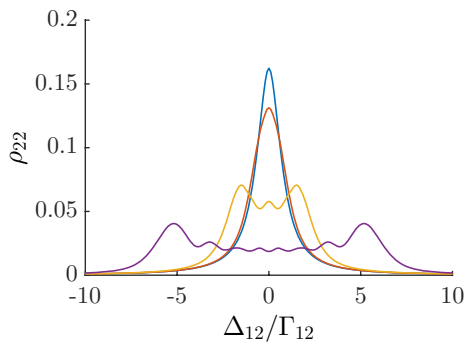

Figure 39.4: (code) Spectral broadening due to the periodic movement of the atom.

39.5.6 Exercises

39.5.6.1 Ex: Optical density of a cold cloud

The cross section of an atom with the resonant frequency ω_0 moving with velocity v and irradiated by a laser beam of frequency ω is,

$$\sigma(v) = \frac{6\pi}{k^2}\frac{\Gamma^2}{4(\omega - \omega_0 - kv)^2 + \Gamma^2} \ .$$

The normalized one-dimensional Maxwell distribution,

$$\rho(v)dv = \sqrt{\frac{m}{2\pi k_{\mathrm{B}}T}}e^{-mv^2/2k_{\mathrm{B}}T}dv \ .$$

a. Calculate the absorption profile of the resonance line at 461 nm ($\Gamma_{461} = (2\pi)\ 30.5$ MHz) of a strontium gas cooled to the Doppler limit ($k_{\mathrm{B}}T_D = \hbar\Gamma$) of this transition.
b. Calculate the absorption profile of the resonance line at 689 nm ($\Gamma_{689} = (2\pi)\ 7.6$ kHz) of a strontium gas cooled to the Doppler limit of the transition at 461 nm.
c. Compare the optical densities in case of resonance.
Help: To evaluate the convolution integral approximate the narrower distribution by a δ-function maintaining the integral over the distribution normalized.

39.5.6.2 Ex: Saturated absorption spectroscopy

Saturated absorption spectroscopy is a technique to avoid Doppler broadening. The setup, shown in Fig. 39.5, consists of a cell filled with a rubidium gas (resonance frequency $\omega_0 = ck = 2\pi c/780\,\text{nm}$, decay rate $\Gamma = (2\pi)\ 6\,\text{MHz}$) and two laser beams with the same frequency ω but counterpropagating, one called saturation and another called probe. The one-dimensional and normalized Maxwell velocity distribution is,

$$\rho(v)dv = \sqrt{\frac{m}{2\pi k_\text{B} T}} e^{-mv^2/2k_\text{B}T} dv \ .$$

The gas is at $T = 300\,\text{K}$, where the partial pressure of rubidium is around $P = 10^{-1}\,\text{mbar}$. The length of the cell is $L = 10\,\text{cm}$. The probe laser has an intensity below the saturation limit, such that the cross section of an atom moving at velocity v is,

$$\sigma(v) = \frac{6\pi}{k^2} \frac{\Gamma^2}{4(\omega - \omega_0 - kv)^2 + \Gamma^2} \ .$$

The saturation laser has high intensity. We suppose here, $\Omega \equiv 10\Gamma$, where Ω is the frequency of Rabi caused by the saturation beam. In this way it creates a population N_e of atoms in the excited state. As this population lacks in the ground state, $N_g = N - N_e$, the absorption of the probe beam is decreased by the factor,

$$\frac{N_e}{N} = \frac{\Omega^2}{4(\omega - \omega_0 + kv)^2 + 2\Omega^2 + \Gamma^2} \ .$$

To obtain the laser probe transmission spectrum, first calculate the optical density, $OD(\omega) = Ln \int_{-\infty}^{\infty} \frac{N_g - N_e}{N} \sigma(v)\rho(v)dv$ where n is the gas density, and then the intensity of light transmitted through the cell using the Lambert-Beer law $\frac{I}{I_0} = e^{-OD}$.

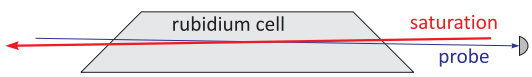

Figure 39.5: Scheme of saturation spectroscopy.

39.5.6.3 Ex: The Zeeman slower

Consider a tube through which passes a collimated beam of atoms, all having the same initial velocity $v = v_0$. In the opposite direction to the atomic motion travels a collimated and monochromatic light beam with frequency $\omega = kc$. The absorption rate for photons by an atom has a Lorentzian profile, which can be written as:

$$W(v) = \frac{W_0}{2\pi} \frac{\Gamma^2}{(\omega - \omega_0 + kv)^2 + (\Gamma/2)^2} \ ,$$

where Γ is the natural width of the spectral line at ω_0, and W_0 is a constant. The frequency of the light is tuned in order to compensate for the Doppler effect at the beginning of the tube, $\delta = \omega - \omega_0 = -kv_0$ (the light is tuned to the red of the resonance). As the atoms are decelerated, they cease to be resonant with the light

beam and fail to absorb photons. This can be avoided by employing the so-called Zeeman-slowing technique, which compensates for the effect using the Zeeman-shift induced by magnetic fields. In this exercise, we will study what happens if this technique is not used.

a. For an atom with velocity v, write an expression for the mean travel distance

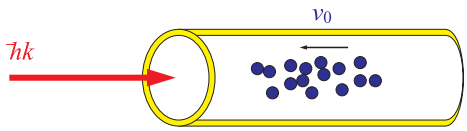

Figure 39.6: Zeeman slower scheme.

$\Delta s(v)$ before it absorbs a photon as a function of the parameters Γ, v_0, k, and W_0. (The mean time it takes to absorb a photon is $W(v)^{-1}$).

b. The velocity of the atom as a function of the number of absorbed photons is $v_n = v_0 - n\frac{\hbar k}{m}$, the second term being the recoil due to the absorption of a single photon. The average total distance traveled by an atom after absorbing N photons is estimated by:

$$S = \sum_{n=0}^{N} \Delta s(v_n) \simeq \int_0^N \Delta s(v_n) dn \ .$$

Calculate the average distance required for the atoms to be slowed down to $v = 0$ (ignoring the Doppler limit). Write the expression as a function of Γ, v_0, k, and W_0. **Help:** Do the following change of variables to simplify the evaluation of the integral: $n \to v$.

c. Typically, the detuning of the light, $|\delta| = kv_0$, is much larger than the natural width Γ of the transition. What happens to S in the limit when $kv_0 \gg \Gamma$? Interpret this result, justifying the need for the Zeeman-slowing technique.

39.5.6.4 Ex: Saturation intensity

Calculate the saturation intensity for the sodium transition $3s\ ^2S_{1/2}, F = 2 \longleftrightarrow 3p\ ^2P_{3/2}, F' = 3$. The natural width of the transition is $\Gamma/2\pi = 9.89\,\text{MHz}$ and the wavelength $\lambda = 590\,\text{nm}$.

39.5.6.5 Ex: Saturation intensity of an octupole transition

Calculate the saturation intensity for the $^2S_{1/2}$-$^2F_{7/2}$ transition in Yb^+-ions (neglecting the Zeeman substructure) at $\lambda = 467\,\text{nm}$ (decay time $\tau = 8\,\text{a}$) and the Rabi frequency, when the transition is resonantly driven by a laser beam of $P = 10\,\text{mW}$ power focused into a $w_0 = 20\,\mu\text{m}$ waist.

39.5.6.6 Ex: Pressure broadening

At what pressure the collision broadening [given by the expression (39.199)] between sodium atoms in the ground state dominates the width of the D2-transition at ambient temperature. The natural width of the D2-line is $\Gamma/2\pi = 6\,\text{MHz}$.

39.5.6.7 Ex: Optical density of a hot cloud

Calculate and draw the effective Lorentz profile, Gauss profile and Voigt profile for the resonance line at 461 nm ($\Gamma = (2\pi)\ 32\,\text{MHz}$) of a strontium gas heated to the temperature 400 C and the pressure $P = 10^{-4}$ mbar inside a 15 cm long cell.

39.5.6.8 Ex: Rate equations as a limiting case of Bloch equations

We show in this exercise that, in the limit $\Gamma \gg \Omega$, we can derive, from the Bloch equations, the Einstein rate equations. Proceed as follows:
a. Apply the condition $\dot{\rho}_{12} = 0$ to the Bloch equations for a two-level system (39.151), determine $\rho_{12}(\infty)$, and replace this stationary value in the equations for the populations $\rho_{kk}(t)$ using, as an abbreviation, the transition rate $R \equiv \gamma s$, where s is the saturation parameter (39.153).
b. Integrate the rate equations over the entire spectrum, i.e. $\Delta \in [-\infty, \infty]$, and derive Einstein's equations using the relations (39.7), (39.41), and (39.42).

39.5.6.9 Ex: Blackbody radiation-induced transitions

Blackbody radiation induces incoherent transitions (see Exc. 39.5.6.8). Show that the Lindbladian of the master equation,

$$\dot{\hat{\rho}} = \mathfrak{L}_{bb}\hat{\rho} = -\tfrac{R}{2}\left([\hat{\rho}\hat{\sigma}, \hat{\sigma}^\dagger] + [\hat{\sigma}, \hat{\sigma}^\dagger\hat{\rho}]\right) - \tfrac{R+\Gamma}{2}\left([\hat{\rho}\hat{\sigma}^\dagger, \hat{\sigma}] + [\hat{\sigma}^\dagger, \hat{\sigma}\hat{\rho}]\right)$$

reproduces the Einstein rate equation for $\Gamma = 2A_{12}$ and $R = B_{12}u(\omega)$.

39.5.6.10 Ex: Lorentzian versus Gaussian line profile

Beyond what detuning is a Doppler-broadened transition dominated by the Lorentzian profile of the transition?

39.6 Bloch equations for multi-level systems

The two-level system represents an idealization of the real atom, since at least one of the levels is usually degenerate. Many important phenomena in quantum optics are not found in this system, but conditioned to the existence of a third level. Examples are optical pumping (essential for laser operation), quantum jumps or dark resonances [which are at the basis of the phenomenon of electromagnetically induced transparency (EIT)].

To derive the Bloch equations for atoms with several levels excited by several lasers and coupled to free space (i.e. without external cavity), we can use the same master equation (39.185), but with a generalized Hamiltonian in the semiclassical

approximation [12] and a Lindblad operator,

$$\boxed{\begin{aligned}
\hat{H}_{\text{atom}} &= \textstyle\sum_i \hbar\omega_i \hat{\sigma}_{ji}\hat{\sigma}_{ij} = \sum_i |i\rangle\hbar\omega_i\langle i| \\
\hat{H}_{\text{atom:field}} &= \tfrac{\hbar}{2}\Omega_{ij}\left(e^{-\imath\omega_{ij}t}\hat{\sigma}_{ij} + e^{\imath\omega_{ij}t}\hat{\sigma}_{ji}\right) = \textstyle\sum_{i<j} |i\rangle \tfrac{\hbar}{2}\Omega_{ij}\langle j| e^{\imath\omega_{ij}t} + c.c. \\
\mathfrak{L}_{\text{decay}}\hat{\rho} &= \mathfrak{L}_\gamma + \mathfrak{L}_R + \mathfrak{L}_\beta \\
\mathfrak{L}_\gamma &= \textstyle\sum_{i,j} \gamma_{ij}\left([\hat{\sigma}_{ij}, \hat{\rho}\hat{\sigma}^\dagger_{ij}] + [\hat{\sigma}_{ij}\hat{\rho}, \hat{\sigma}^\dagger_{ij}]\right) \\
\mathfrak{L}_R &= \textstyle\sum_{i,j} R_{ij}\left([\hat{\sigma}^\dagger_{ij}, \hat{\rho}\hat{\sigma}_{ij}] + [\hat{\sigma}^\dagger_{ij}\hat{\rho}, \hat{\sigma}_{ij}]\right) \\
\mathfrak{L}_\beta &= \textstyle\sum_{i,j} 2\beta_{ij}\left([\hat{\sigma}_{ij}\hat{\sigma}^\dagger_{ij}, \hat{\rho}\hat{\sigma}_{ij}\hat{\sigma}^\dagger_{ij}] + [\hat{\sigma}_{ij}\hat{\sigma}^\dagger_{ij}\hat{\rho}, \hat{\sigma}_{ij}\hat{\sigma}^\dagger_{ij}]\right)
\end{aligned}} \quad . \tag{39.225}$$

Here, $\hat{\sigma}_{ij} \equiv |i\rangle\langle j| = \hat{\sigma}^\dagger_{ji}$. The constants R_{ij} are eventual incoherent pump rates due to optical pumping, β_{ij} take account of homogeneous broadening, e.g. due to finite laser linewidths. The levels have the energy $\hbar\omega_i$ above the ground level. The Rabi frequency Ω_{ij} is a measure for the force at which the levels $|i\rangle$ and $|j\rangle$ are coupled by the resonantly irradiated light field. The master equation can be simplified by applying the rotating wave approximation and transforming to the coordinate system which rotates with the light frequencies ω_{ij}:

$$\rho_{ij} \to \hat{\rho}_{ij} e^{\imath\omega_{ij}t} \quad , \quad \hat{H}_{\text{atom:field}} \to e^{-\imath\hat{H}t/\hbar}\hat{H}_{\text{atom:field}} e^{\imath\hat{H}t/\hbar} \ . \tag{39.226}$$

39.6.1 Liouville equation for many levels

The indices for the atomic levels are joined to a single index, such that the master equation takes a simpler form after having introduced a *Liouville operator*:

$$\begin{aligned}
\hat{\rho} &= (...\rho_k...) \equiv \sum\nolimits_{i,j} |i\rangle\rho_{ij}\langle j| \ , \\
\dot{\hat{\rho}} &= \mathfrak{L}\hat{\rho}, \\
\hat{\rho} &= e^{\mathfrak{L}_{\text{atom}}t}\hat{\rho}_0 \ .
\end{aligned} \tag{39.227}$$

The relation with the *von Neumann equation* with $\hat{H} = \sum_{i,j} |i\rangle H_{ij}\langle j|$ and $\hat{\rho} = \sum_{k,l} |k\rangle\rho_{kl}\langle l|$ and $\hat{\sigma}_{ij} = |i\rangle\langle j|$ is:

$$\mathfrak{L}_{\text{atom}}\hat{\rho} = -\tfrac{\imath}{\hbar}[\hat{H}, \hat{\rho}] = -\imath\sum\nolimits_{k,l,j} H_{kl}\rho_{lj}|k\rangle\langle j| + \imath\sum\nolimits_{k,l,j} H_{lj}\rho_{kl}|k\rangle\langle j| \ . \tag{39.228}$$

For example, for the two-level system with the definition of the external product (23.226):

$$\mathfrak{L}_{\text{atom}}\hat{\rho} = -\imath\hat{H}\otimes\mathbb{I}\hat{\rho} + \imath\mathbb{I}\otimes\hat{H}\hat{\rho} \ . \tag{39.229}$$

The relaxation terms for spontaneous decay obtained from (39.225) are,

$$\mathfrak{L}_{\text{decay}}\hat{\rho} = \sum\nolimits_{i,j,k} \left(2\gamma_{ji}\delta_{kj}\rho_{ii} - \gamma_{ij}\rho_{kj} - \gamma_{ik}\rho_{kj}\right)|k\rangle\langle j| \ . \tag{39.230}$$

[12] That is, the atom is quantized and consists of several levels $|i\rangle$ with energies $\hbar\omega_i$, while the light fields are described by factors $e^{\imath\omega_{ij}t}$, with frequencies ω_{ij} tuned near the transitions $|i\rangle - |j\rangle$.

Example 278 (*Liouville equation for two levels*): For example, for the two-level system,

$$\mathfrak{L}_{\text{atom}} = \begin{pmatrix} 2\gamma_{11} & 0 & 0 & 2\gamma_{21} \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 2\gamma_{12} & 0 & 0 & 2\gamma_{22} \end{pmatrix} - \begin{pmatrix} 2(\gamma_{11}+\gamma_{12}) & 0 & 0 & 0 \\ 0 & \sum_{(kj)} \gamma_{(kj)} & 0 & 0 \\ 0 & 0 & \sum_{(kj)} \gamma_{(kj)} & 0 \\ 0 & 0 & 0 & 2(\gamma_{22}+\gamma_{21}) \end{pmatrix} .$$

Here, we consider $(kj) = (11\ 12\ 21\ 22)$ as a single index.

39.6.1.1 Derivation of the multilevel Bloch equation

Now, inserting the Hamiltonian in the RWA,

$$\hat{H} = \hat{H}_{\text{atom}} + \hat{H}_{\text{atom:field}} = \sum_i \hbar\omega_i |i\rangle\langle i| + \tfrac{\hbar}{2}\sum_{i<j} \Omega_{ij}\hat{\sigma}_{ij} + h.c. \ , \tag{39.231}$$

into the von Neumann equation together with the dissipative Lindbladian (39.230) and $\rho_{jk} \equiv \langle j|\hat{\rho}|k\rangle$, we derive the multilevel master equation,

$$\dot{\rho}_{jk} = \frac{\imath}{\hbar}\langle j|[\hat{\rho}, \hat{H}]|k\rangle + \langle j|\mathfrak{L}_{\text{decay}}\hat{\rho}|k\rangle \ . \tag{39.232}$$

First we calculate the unperturbed Hamiltonian part,

$$\begin{aligned} \langle k|[\hat{\rho}, \hat{H}_{\text{atom}}]|m\rangle &= \hbar\langle k|\hat{\rho}\sum_a |a\rangle\langle a| \sum_i \omega_i |i\rangle\langle i|m\rangle - \hbar\langle k|\sum_i \omega_i |i\rangle\langle i| \sum_a |a\rangle\langle a|\hat{\rho}|m\rangle \\ &= \hbar(\omega_m - \omega_k)\rho_{km} \ . \end{aligned} \tag{39.233}$$

For the interaction part we get,

$$\begin{aligned} &\langle k|[\hat{\rho}, \hat{H}_{\text{atom:field}}]|m\rangle \\ &= \tfrac{\hbar}{2}\sum_a \sum_{i<j} \left[\langle k|\hat{\rho}|a\rangle\langle a| \left(\Omega_{ij}|i\rangle\langle j| + \Omega_{ij}^*|j\rangle\langle i|\right)|m\rangle - \langle k|\left(\Omega_{ij}|i\rangle\langle j| + \Omega_{ij}^*|j\rangle\langle i|\right)|a\rangle\langle a|\hat{\rho}|m\rangle\right] \\ &= \tfrac{\hbar}{2}\sum_{i<j} \left(\Omega_{ij}\rho_{ki}\delta_{jm} + \Omega_{ij}^*\rho_{kj}\delta_{im} - \Omega_{ij}\rho_{jm}\delta_{ki} - \Omega_{ij}^*\rho_{im}\delta_{kj}\right) \ , \end{aligned} \tag{39.234}$$

and for the dissipative part,

$$\begin{aligned} \langle k|\mathfrak{L}_{\text{decay}}\hat{\rho}|m\rangle &= \langle k|\sum_{i,j} \gamma_{ij}(2|i\rangle\langle j|\hat{\rho}|j\rangle\langle i| - |j\rangle\langle i|i\rangle\langle j|\hat{\rho} - \hat{\rho}|j\rangle\langle i|i\rangle\langle j|)|m\rangle \\ &= \sum_j 2\gamma_{mj}\delta_{km}\rho_{jj} - \sum_i (\gamma_{ik} + \gamma_{im})\rho_{km} \ . \end{aligned} \tag{39.235}$$

So all in all,

$$\boxed{\begin{aligned} \dot{\rho}_{km} &= 2\sum_j \gamma_{mj}\rho_{jj}\delta_{km} - \left[\sum_i (\gamma_{ik} + \gamma_{im}) + \imath(\omega_k - \omega_m)\right]\rho_{km} \\ &+ \tfrac{\imath}{2}\sum_{i<j} \left(\Omega_{ij}\rho_{ki}\delta_{jm} + \Omega_{ij}^*\rho_{kj}\delta_{im} - \Omega_{ij}\rho_{jm}\delta_{ki} - \Omega_{ij}^*\rho_{im}\delta_{kj}\right) \end{aligned}} \ , \tag{39.236}$$

where the index j runs over all levels $|j\rangle$ into which a population ρ_{kk} can decay and the index i runs over all levels $|i\rangle$ into which the levels $|k\rangle$ and $|m\rangle$ of a dipole moment ρ_{km} can decay. In Exc. 39.6.5.1 we will apply this formula to three-level systems.

Finally, the master equation can be reformulated by introducing a *generalized Bloch vector* $\vec{\rho}$, and the matrix representation of the Liouville superoperator $\mathfrak{L}$ as a linear system of n^2 coupled differential equations,

$$\frac{d}{dt}\vec{\rho} = \mathcal{M}\vec{\rho} \quad , \quad \vec{\rho} = (\rho_{11} \ \ldots \ \rho_{nn} \ \rho_{12} \ \rho_{21} \ \ldots \ \rho_{n-1\ n} \ \rho_{n\ n-1}) \ , \tag{39.237}$$

where the Bloch matrix $\mathcal{M}$ is obtained from the Liouvillean $\mathfrak{L}$ simply by rearranging the matrix elements.

Alternatively to the complex formulation, the differential equations can be written for the real and imaginary part of the Bloch vector. The components ρ_{ii} correspond to the population probabilities of the levels $|i\rangle$, the non-diagonal elements ρ_{ij} describe the coherences between $|i\rangle$ and $|j\rangle$. Now, we must insert the Hamiltonian (39.225) and the density operator ρ_{ij} into the Liouville equation (38.6) in order to derive the generalized Bloch equations. In practice, these calculations are simple but heavy. Therefore, we describe in Sec. 39.6.4 a simplified recipe for compiling Bloch equations for arbitrary level systems for real atoms.

39.6.2 Bloch equations for three levels

In principle, three-level system can exist in there possible configurations, shown in Fig. 39.7. Note that it is not possible to describe a three-level system with all levels pairwise coupled by three lasers within the formalism of Bloch's equations [13].

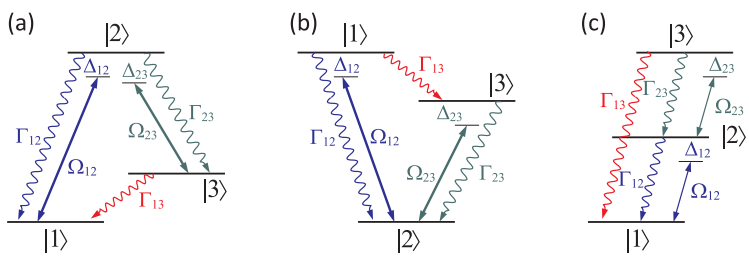

Figure 39.7: Three level system (a) in Λ-configuration, (b) in V-configuration, and (c) in cascade configuration.

Defining the Bloch vector by $\vec{\rho}$, the Bloch equation matrix for three levels in Raman configuration (that is, in Λ-configuration) using the labeling of Fig. 39.7(a),

[13] For the same reason that the three-body problem has no general analytic solution.

is,

$$\dot{\vec{\rho}} = \mathcal{M}\vec{\rho} = \tag{39.238}$$

$$\left(\begin{array}{ccc|ccccccc}
0 & \Gamma_{12} & \Gamma_{13} & \frac{\imath}{2}\Omega_{12} & -\frac{\imath}{2}\Omega_{12} & 0 & 0 & 0 & 0 \\
0 & -\Gamma_{12}-\Gamma_{23} & 0 & -\frac{\imath}{2}\Omega_{12} & \frac{\imath}{2}\Omega_{12} & 0 & 0 & \frac{\imath}{2}\Omega_{23} & -\frac{\imath}{2}\Omega_{23} \\
0 & \Gamma_{23} & -\Gamma_{13} & 0 & 0 & 0 & 0 & -\frac{\imath}{2}\Omega_{23} & \frac{\imath}{2}\Omega_{23} \\
\hline
\frac{\imath}{2}\Omega_{12} & -\frac{\imath}{2}\Omega_{12} & 0 & -\Lambda_{12} & 0 & \frac{\imath}{2}\Omega_{23} & 0 & 0 & 0 \\
-\frac{\imath}{2}\Omega_{12} & \frac{\imath}{2}\Omega_{12} & 0 & 0 & -\Lambda_{12}^* & 0 & -\frac{\imath}{2}\Omega_{23} & 0 & 0 \\
0 & 0 & 0 & \frac{\imath}{2}\Omega_{23} & 0 & -\Lambda_{13} & 0 & -\frac{\imath}{2}\Omega_{12} & 0 \\
0 & 0 & 0 & 0 & -\frac{\imath}{2}\Omega_{23} & 0 & -\Lambda_{13}^* & 0 & \frac{\imath}{2}\Omega_{12} \\
0 & \frac{\imath}{2}\Omega_{23} & -\frac{\imath}{2}\Omega_{23} & 0 & 0 & -\frac{\imath}{2}\Omega_{12} & 0 & -\Lambda_{23} & 0 \\
0 & -\frac{\imath}{2}\Omega_{23} & \frac{\imath}{2}\Omega_{23} & 0 & 0 & 0 & \frac{\imath}{2}\Omega_{12} & 0 & -\Lambda_{23}^*
\end{array}\right)
\begin{pmatrix}
\rho_{11} \\ \rho_{22} \\ \rho_{33} \\ \rho_{12} \\ \rho_{21} \\ \rho_{13} \\ \rho_{31} \\ \rho_{23} \\ \rho_{32}
\end{pmatrix}$$

with $\Lambda_{mn} = \imath\Delta_{mn} + \gamma_{mn}$ and,

$$\Delta_{13} = \Delta_{12} - \Delta_{23} \tag{39.239}$$
$$\gamma_{12} = \tfrac{1}{2}(\Gamma_{12} + \Gamma_{23}) \quad , \quad \gamma_{23} = \tfrac{1}{2}(\Gamma_{12} + \Gamma_{23} + \Gamma_{13}) \quad , \quad \gamma_{13} = \tfrac{1}{2}\Gamma_{13} \ .$$

In Exc. 39.6.5.2 we will derive the matrix (39.238).

The coherent terms of the same matrix can be used for the V- and the cascade configurations shown in Figs. 39.7(b,c). Obviously, the incoherent terms, that is, the submatrix 3×3 separated in the matrix (39.238) containing the population decay rates must be adjusted, as well as the decay rates of the coherences on the diagonal. Finally, the definition of the Raman detuning Δ_{13} must be adjusted. For the system in V-configuration we have,

$$\mathcal{M}_{\text{incoh}} = \begin{pmatrix} -\Gamma_{12} - \Gamma_{13} & 0 & 0 \\ \Gamma_{12} & 0 & \Gamma_{23} \\ \Gamma_{13} & 0 & -\Gamma_{23} \end{pmatrix} \quad , \quad \Delta_{13} = \Delta_{12} - \Delta_{23} \tag{39.240}$$
$$\gamma_{12} = \tfrac{1}{2}(\Gamma_{12} + \Gamma_{13}) \quad , \quad \gamma_{23} = \tfrac{1}{2}\Gamma_{23} \quad , \quad \gamma_{13} = \tfrac{1}{2}(\Gamma_{12} + \Gamma_{13} + \Gamma_{23}) \ .$$

For the cascade system we have,

$$\mathcal{M}_{\text{incoh}} = \begin{pmatrix} 0 & \Gamma_{12} & \Gamma_{13} \\ 0 & -\Gamma_{12} & \Gamma_{23} \\ 0 & 0 & -\Gamma_{13} - \Gamma_{23} \end{pmatrix} \quad , \quad \Delta_{13} = \Delta_{12} - \Delta_{23} \tag{39.241}$$
$$\gamma_{12} = \tfrac{1}{2}\Gamma_{12} \quad , \quad \gamma_{23} = \tfrac{1}{2}(\Gamma_{12} + \Gamma_{23} + \Gamma_{13}) \quad , \quad \gamma_{13} = \tfrac{1}{2}(\Gamma_{13} + \Gamma_{23}) \ .$$

These matrices serve to describe quantitatively a wealth of phenomena, some of them to be discussed in Sec. 39.7.

39.6.3 Numerical treatment of Bloch equations

Since the differential Bloch equations are linear, they can be easily solved. For example, the prescription

$$\boxed{\vec{\rho}(t) = e^{\mathcal{M}t}\vec{\rho}(0)} \tag{39.242}$$

propagates the Bloch vector to later times.

The matrix $\mathcal{M}$ is not invertible, but by applying the condition $\mathrm{Tr}\,\rho = 1$, a component of the density matrix can be eliminated, for example by letting,

$$\rho_{11} = 1 - \sum_k \rho_{kk} \ . \tag{39.243}$$

The resulting state vector, $\vec{\rho}_{\mathrm{red}}$, has the length $n^2 - 1$, and from $\mathcal{M}$ we obtain the (trace-)reduced, now invertible matrix $\mathcal{M}_{\mathrm{red}}$ and the inhomogeneity vector $\mathbf{b}$. The differential equation is now,

$$\frac{d}{dt}\vec{\rho}_{\mathrm{red}} = \mathcal{M}_{\mathrm{red}}\vec{\rho}_{\mathrm{red}} + \mathbf{b} \ , \tag{39.244}$$

with the stationary and time-dependent solutions,

$$\boxed{\vec{\rho}_{\mathrm{red}}(\infty) = -\mathcal{M}_{\mathrm{red}}^{-1}\mathbf{b} \quad , \quad \vec{\rho}_{\mathrm{red}}(t) = e^{\mathcal{M}_{\mathrm{red}}t}\vec{\rho}_{\mathrm{red}}(0) + (1 - e^{\mathcal{M}_{\mathrm{red}}t})\vec{\rho}_{\mathrm{red}}(\infty)} \ . \tag{39.245}$$

Once the matrix $\mathcal{M}$ or the matrix $\mathcal{M}_{\mathrm{red}}$ and the inhomogeneity vector $\mathbf{b}$ are determined for a system, the state of the atom can be calculated at any time, as well as the populations and coherences. The system's free parameters are the natural transition linewidths and the detunings, as well as the intensities and emission bandwidths of the incident light fields.

39.6.3.1 Simulation of the Schrödinger and Bloch equation

Once we have written the solution of the Schrödinger equation in the form (23.244) with a time-independent Hamiltonian $\hat{H}$, or of the Bloch equations in the form (39.242) or (39.245) with a time-independent Liouvillian $\mathcal{M}$, we can easily simulate temporal evolutions of quantum systems. If the Hamiltonian or Liouvillian depend on time, for example, when the Rabi frequencies are pulsed or the detunings are ramped, we must solve the equations iteratively. That is, we chose time intervals Δt sufficiently short, so that the Hamiltonian (or the Liouvillian) can be considered constant during this interval, and we propagate the wavefunction (or the Bloch vector) to later times via:

$$|\psi(t + \Delta t)\rangle = e^{\imath\hat{H}(t)\Delta t}|\psi(t)\rangle \qquad \text{or} \qquad \vec{\rho}(t + \Delta t) = e^{\mathcal{M}(t)\Delta t}\vec{\rho}(t) \ , \tag{39.246}$$

and insert the solution obtained again into equations (39.246) with the Hamiltonian $\hat{H}(t + \Delta t)$ (or the Liouvillian $\mathcal{M}(t + \Delta t)$) adjusted to the new time.

39.6.4 General rules for setting up multilevel Bloch equations

The canonical way of deriving multi-level Bloch equations starts from a von Neumann equation for the total density operator for the atom embedded in the electromagnetic mode structure of the environment including incident laser beams. After tracing over the degrees of freedom of the electromagnetic vacuum and using the Markov and the Born approximations [339], one arrives at a master equation of the form (39.225). Simple but tedious algebraic transformations of the master equation lead, in the rotating wave approximation, to a set of linear first-order differential equations

in the populations of the atomic excitation levels and the coherences between them. The equations are called the optical Bloch equations.

Alternatively, the Bloch equations may be found by breaking down the multi-level scheme into a set of three-level systems. Respecting a few symmetry considerations, the multi-level Bloch equations can then be reassembled from the three-level Bloch equations corresponding to every possible combination of three levels. Based on such considerations, we provide in the following a simple recipe for setting up Bloch matrices for arbitrary level schemes. A movie showing a simulation of multi-level Bloch equations for Li atoms can be watched under the following link: (watch movie).

Let us regard a N-level atom. Its internal state is fully described by the populations ρ_{kk} and the (complex) coherences ρ_{kl}, with $k, l = 1, .., N$. In this work we describe the coherences by their real and imaginary parts. The labeling is such that the levels are sorted according to their excitation energy, $E_k < E_l$ for $k < l$. We define the Bloch vector,

$$\vec{\varrho} \equiv (\rho_{11} ... \rho_{NN} \ \rho_{12} \ \rho_{21} \ \rho_{13} \ \rho_{31} ... \rho_{1N} \ \rho_{N1} \ \rho_{23} \ \rho_{32} ... \rho_{N-1,N} \ \rho_{N,N-1}) \ . \tag{39.247}$$

The Bloch equations then formally read,

$$\dot{\vec{\varrho}} = \mathcal{M} \vec{\varrho} \ , \tag{39.248}$$

where in the given Bloch vector basis the matrix $\mathcal{M}$ has the following structure,

$$\mathcal{M} = \begin{pmatrix} (A) & (B) \\ (-B^\dagger) & \begin{pmatrix} (C) & (D) \\ (D) & (C) \end{pmatrix} \end{pmatrix} \ . \tag{39.249}$$

The different blocks of the matrix have the following significations. Block A handles the transfer of populations by spontaneous decay. Its rank corresponds to the number of levels N. The diagonal elements of this block are the decay rates Γ of the excited states. The off-diagonal elements Γ_{kl} denote the gain of level k from a decaying level l. Conservation of energy thus requires that the sum of the transition rates cancels for every column of matrix A, $\Gamma = \sum_k \Gamma_{kl}$, as it is the case for the two-level Bloch matrix. If the levels are sublevels of a Zeeman and/or hyperfine split multiplet, the rates have to be weighted with Wigner's $(3j)$ and $\{6j\}$ symbols, $\Gamma_{kl} = \Gamma S_{kl}$. The relative oscillator strengths S_{kl} are given in Sec. 39.6.4.2.

The blocks B treat the interdependence of the populations and the coherences. B describes how the coherence between any pair of states driven by a light field generating a Rabi frequency Ω_{kl} influences the populations. The block consists of convoluted 2×2 matrices of the form,

$$\begin{pmatrix} \dot{\rho}_{kk} \\ \dot{\rho}_{ll} \end{pmatrix} \sim \begin{pmatrix} \frac{\imath}{2}\Omega_{kl} & -\frac{\imath}{2}\Omega_{kl} \\ -\frac{\imath}{2}\Omega_{kl} & \frac{\imath}{2}\Omega_{kl} \end{pmatrix} \begin{pmatrix} \rho_{kl} \\ \rho_{lk} \end{pmatrix} \ . \tag{39.250}$$

B_2 describes how the populations in turn influence the coherences,

$$\begin{pmatrix} \dot{\rho}_{kl} \\ \dot{\rho}_{lk} \end{pmatrix} \sim \begin{pmatrix} \frac{\imath}{2}\Omega_{kl} & -\frac{\imath}{2}\Omega_{kl} \\ -\frac{\imath}{2}\Omega_{kl} & \frac{\imath}{2}\Omega_{kl} \end{pmatrix} \begin{pmatrix} \rho_{kk} \\ \rho_{ll} \end{pmatrix} \ . \tag{39.251}$$

The Rabi frequencies have to be weighted not only with the relative oscillator strength S_{kl}, but also with the projection H_{kl} of the laser polarization onto the orientation of the magnetic field and the laser polarization, $\Omega_{kl} = \Omega_x S_{kl} H_{kl}$. Here Ω_x is the Rabi frequency generated by a laser on a transition, whose oscillator strength is 1. The projection is calculated in Sec. 39.6.4.3 for the three possible laser polarizations, i.e. for $\sigma^{\pm}$ and for π light.

The matrix C rules the influence of the decays of the coherences, of the detunings $\Delta_{kl} = \omega_x - \omega_{\text{atom}}$, and the laser linewidths β_{kl}. Note that the detuning of the laser frequency ω_x is negative for red-detuned light. In the chosen basis it breaks down into an array 2×2 matrices aligned along the diagonal of $\mathcal{M}$. Their shape is,

$$\begin{pmatrix} \dot{\rho}_{kl} \\ \dot{\rho}_{lk} \end{pmatrix} \sim \begin{pmatrix} -\frac{\gamma_{kl}}{2} - \imath\Delta_{kl} & 0 \\ 0 & -\frac{\gamma_{kl}}{2} + \imath\Delta_{kl} \end{pmatrix} \begin{pmatrix} \rho_{kl} \\ \rho_{lk} \end{pmatrix} . \tag{39.252}$$

where $\gamma_{kl} = \sum_{m,E_m<E_k,E_l}(\Gamma_{km} + \Gamma_{lm}) + 2\beta_{kl}$. Often the levels are sublevels of a Zeeman and/or hyperfine split multiplets. In this case the frequency shift Z_{kl} of the level is added to the detuning Δ_{kl}. The shift is calculated in Sec. 39.6.4.4 for the example of the ^{6}Li D_2 line.

The block D governs the interdependences of all laser-driven coherences of the atom. The block contains 2×2 submatrices at any place of the matrix $\mathcal{M}$, where the row index pair (mn) and the column index pair (kl) have one index in common provided the two different indices correspond to the Rabi frequency of an incident laser,

$$\begin{pmatrix} \dot{\rho}_{mn} \\ \dot{\rho}_{mn} \end{pmatrix} \sim \begin{pmatrix} \pm\frac{\imath}{2}\Omega_{kl} & \\ 0 & \pm\frac{\imath}{2}\Omega_{kl} \end{pmatrix} \begin{pmatrix} \rho_{pq} \\ \rho_{pq} \end{pmatrix} . \tag{39.253}$$

The submatrix elements indexed by column (pq) and row (mn) are non-zero if one of the indices p or q is equal to one of the indices m or n and the unequal indices correspond to a laser-driven transition. In order to find the correct signs of the submatrix elements, we distinguish four cases:

1. For $m = p$, $n = k$, and $q = l$ the signs are: $(^{-}\ {}_{+})$;
2. for $n = q$, $m = k$, and $p = l$ the signs are: $(^{+}\ {}_{-})$;
3. for $m = q$, $n = k$, and $p = l$ the signs are: $(^{+}\ {}_{+})$; and
4. for $n = p$, $m = k$, and $q = l$ the signs are: $(^{-}\ {}_{-})$.

A proper parametrization is proposed in the next section.

39.6.4.1 Recipe for D transitions in alkalines

In order to give a simple algorithm we parametrize the particular choice of sorting the components of the vector, we define a new index μ running from 1 to N^2 by setting $(\varrho_\mu) \equiv (\rho_{kl})$, where,

$$\mu(k,l) = k\delta_{kl} + (2Nk - N - k^2 - k + 2l - 1)\delta_{k<l} + (2Nk - N - k^2 - k + 2l)\delta_{k>l} , \tag{39.254}$$

so that,

$$\varrho_{\mu(k,k)} = \rho_{kk} \quad , \quad \varrho_{\mu(k,l)} = \rho_{kl} \quad , \quad \varrho_{\mu(k,l)+1} = \rho_{lk} . \tag{39.255}$$

The Bloch equations then formally read,

$$\boxed{\dot{\varrho}_\mu = \mathcal{M}_{\mu\nu}\varrho_\nu} \ . \tag{39.256}$$

Let us now study the case of a multiplet G of ground states coupled by various light fields to a multiplet E of excited states.

Example 279 (*Lithium D_2 line*): To illustrate the procedure we may have in mind the case of the ^{6}Li D_2 line with 6 ground states $k \in G \equiv \{1, ..., 6\}$ belonging to the $^2S_{1/2}$ hyperfine levels $F = \frac{1}{2}, \frac{3}{2}$ and 12 excited states $k \in E \equiv \{7, ..., 18\}$ belonging to the $^2P_{3/2}$ hyperfine levels $F = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}$.

According to the parametrization (39.248) block A of the matrix $\mathcal{M}$ is filled with the following components,

$$\mathcal{M}_{\mu(k,k),\mu(k,k)} = \Gamma S_{kl}\delta_{k\in G}\delta_{l\in E} - \Gamma\delta_{kl}\delta_{k\in E} \ , \tag{39.257}$$

where the relative oscillator strengths S_{kl} will be given by Eq. (39.262).

Block B of the matrix $\mathcal{M}$ is filled with the components,

$$\begin{aligned}\mathcal{M}_{\mu(k,k),\nu(k,l)} &= -\mathcal{M}_{\mu(l,l),\nu(k,l)} \\ &= -2\mathcal{M}_{\mu(k,l),\nu(k,k)} = 2\mathcal{M}_{\mu(k,l),\nu(l,l)} \\ &= -\Omega_{kl}S_{kl}H_{kl} \ ,\end{aligned} \tag{39.258}$$

for $k \in G$ and $l \in E$. The projection onto the quantization axis $H_{kl} = H_{kl}\left(\frac{\hat{\epsilon}_{kl}}{|\hat{\epsilon}_{kl}|}, \vec{\mathcal{B}}, m_l - m_k\right)$ is given by Eq. (39.265).

Block C contains the components,

$$\begin{aligned}\mathcal{M}_{\mu(k,l)\mu(k,l)} &= \mathcal{M}^*_{\mu(l,k)\mu(l,k)} \\ &= -\sum_{m\in G}\tfrac{\Gamma S_{ml}}{2}\delta_{k\in G}\delta_{l\in E} \\ &\quad -\beta_{\rm pb}\delta_{2<k<7} - \beta_{\rm rp}\delta_{k\leq 2} \\ &\quad -\imath\Delta_{\rm pb}\delta_{k>2} - \imath\Delta_{\rm rp}\delta_{k<3} + \imath Z_{kl}(\mathcal{B})\end{aligned} \tag{39.259}$$

for $k \in G \cup E$ and $l \in E$. $\beta_{\rm pb}$ and $\beta_{\rm rp}$ are the laser linewidths of probe and pump lasers. $\Delta_{\rm pb}$ and $\Delta_{\rm rp}$ are the detunings of the probe and pump lasers from their respective transitions in the absence of Zeeman splitting. The Zeeman shift Z_{kl} is given by Eq. (39.266).

Finally, the block D is filled with the components,

$$\begin{aligned}\mathcal{M}_{\mu(k,f),\mu(f,l)+1} &= (\delta_{f<k} - \tfrac{1}{2})\Omega_{kl}S_{kl}H_{kl} \\ \mathcal{M}_{\mu(k,f)+1,\mu(f,l)} &= (\delta_{l<f} - \tfrac{1}{2})\Omega_{kl}S_{kl}H_{kl} \\ \mathcal{M}_{\mu(l,f),\mu(f,k)+1} &= (\delta_{l<f} - \tfrac{1}{2})\Omega_{kl}S_{kl}H_{kl} \\ \mathcal{M}_{\mu(l,f)+1,\mu(f,k)} &= (\delta_{f<k} - \tfrac{1}{2})\Omega_{kl}S_{kl}H_{kl} \ ,\end{aligned} \tag{39.260}$$

where,

$$\begin{aligned}\Omega_{kl} &\equiv (\Omega_{\rm rp}\delta_{k\leq 2} + \Omega_{\rm pb}\delta_{k\geq 3})\delta_{l\geq 7} \\ \hat{\epsilon}_{kl} &\equiv (\hat{\epsilon}_{\rm rp}\delta_{k\leq 2} + \hat{\epsilon}_{\rm pb}\delta_{k\geq 3})\delta_{l\geq 7}\ .\end{aligned} \tag{39.261}$$

for $k \in G \cup E$ and $l \in E$ and $f \in G \cup E$ but $f \neq k, l$. The projection onto the quantization axis $H_{kl} = H_{kl}\left(\frac{\hat{\epsilon}_{kl}}{|\hat{\epsilon}_{kl}|}, \vec{\mathcal{B}}, m_l - m_k\right)$ is given by Eq. (39.265).

The Eqs. (39.257)-(39.260) form together an algorithm to generate the matrix allowing one to numerically solve the Bloch equations (39.256), as has been done in the main text.

39.6.4.2 Relative forces of oscillators

Spontaneous transitions between hyperfine- and Zeeman split levels have to be weighted according to the Wigner-Eckardt theorem using Clebsch-Gordan $(3j)$ and Wigner $\{6j\}$ symbols. Consider the transition $|(J_k, I)F_k, m_k\rangle \leftrightarrow |(J_l, I)F_l, m_l\rangle$. The relative oscillator strength is,

$$S_{kl} = \begin{pmatrix} F_k & \kappa & F_l \\ m_k & \text{sign}\ (m_l - m_k) & -m_l \end{pmatrix}^2 \begin{Bmatrix} J_l & J_k & \kappa \\ F_k & F_l & I \end{Bmatrix}^2 \frac{(2F_k+1)(2J_l+1)(2\kappa+1)}{2I+1}\ . \tag{39.262}$$

39.6.4.3 Elliptical laser polarization

The transition rates additionally depend on the relative orientation of the laser polarizations and the magnetic field direction. This dependence is accounted for by decomposing the polarization vector into the,

$$\hat{\mathbf{e}}_3 = \frac{\vec{\mathcal{B}}}{B} \quad , \quad \hat{\mathbf{e}}_2 = \frac{\hat{\mathbf{e}}_3 \times \hat{\mathbf{g}}}{|\hat{\mathbf{e}}_3 \times \hat{\mathbf{g}}|} \quad , \quad \hat{\mathbf{e}}_1 = \frac{\hat{\mathbf{e}}_2 \times \hat{\mathbf{e}}_3}{|\hat{\mathbf{e}}_2 \times \hat{\mathbf{e}}_3|}\ , \tag{39.263}$$

where $\hat{\mathbf{g}}$ is an arbitrarily chosen direction, e.g. gravity. The relative amplitude of the transitions $\Delta m_J = 0$ is proportional to the projection of the polarization vector on the magnetic field axis $\zeta_0 = (\hat{\varepsilon} \cdot \hat{\mathbf{e}}_3)^2$ for π-polarized light. To estimate the amplitude of the transitions $\Delta m_J = \pm 1$, we must project onto the coordinates,

$$\hat{\mathbf{e}}_\pm = \tfrac{1}{\sqrt{2}}(\mp\hat{\mathbf{e}}_1 - \imath\hat{\mathbf{e}}_2)\ , \tag{39.264}$$

and we obtain $\zeta_{\pm 1} = (\hat{\varepsilon} \cdot \hat{\mathbf{e}}_\pm)^2$ for $\sigma^\pm$-polarized light. Hence,

$$H_{kl} = \zeta_{\Delta m_J} = \zeta_{m_l - m_k}\ . \tag{39.265}$$

With this generalization the Bloch equations can e.g. be employed to calculate Hanle resonances quantum mechanically. The Hanle effect occurs when a magnetic and an optical field compete for the quantization axis.

39.6.4.4 Hyperfine and Zeeman splitting

The nuclear spin of the ^{6}Li atom is $I = 1$, its electron spin is $S = \frac{1}{2}$. The excitation states are characterized by quantum numbers J_k, F_k, m_k. The electron angular orbital momentum is $L_k = \delta_{k\geq 7}$, and the electron angular orbital momentum is $J_k = \frac{1}{2}\delta_{k\leq 6} + \frac{3}{2}\delta_{k\geq 7}$. The hyperfine structure of the excited state $^2P_{3/2}$ can be written as $\nu_{hf1} = -2.8\,\mathrm{MHz}$, $\nu_{hf2} = 0\,\mathrm{MHz}$, and $\nu_{hf3} = 1.7\,\mathrm{MHz}$. Hence, the hyperfine splitting is inferior to the natural decay rate $\Gamma = (2\pi)\,6\,\mathrm{MHz}$,

$$Z_{kl} = \frac{\mu_\mathrm{B}|\vec{\mathcal{B}}|}{2\pi\hbar}(g_{F_k}m_k - g_{F_l}m_l) + \nu_\mathrm{hf1}\delta_{7\leq l\leq 8} + \nu_\mathrm{hf2}\delta_{8\leq l\leq 13} + \nu_\mathrm{hf3}\delta_{13\leq l\leq 16}\ , \quad (39.266)$$

where g_{F_k} is the Landé factor of hyperfine level F_k.

39.6.5 Exercises

39.6.5.1 Ex: Derivation of three-level Bloch equations

Derive from the general formula (39.236) the three-level Bloch equations for the system $|1\rangle \overset{\Omega_{12}}{\longleftrightarrow} |2\rangle \overset{\Omega_{23}}{\longleftrightarrow} |3\rangle$.

39.6.5.2 Ex: Bloch equations for three levels

An excited Λ-shaped atom consists of two ground states $|1\rangle$ and $|3\rangle$, which are coupled by two lasers with Rabi frequencies and detunings Ω_{12} and Δ_{12} respectively Ω_{23} and Δ_{23} through an excited level $|2\rangle$. Derive the Bloch equations from this system from the general master equation.

39.6.5.3 Ex: Adiabatic elimination

Derive the effective two-level Bloch equations for a Λ-type three-level system adiabatically eliminating the excited state under the Raman condition. **Help**: Start from the Liouvillean (39.238), set $\rho_{22} = 0$, assume $\Gamma_{13} \ll \Gamma_{12}, \Gamma_{23} \ll |\Delta_{12}|, |\Delta_{23}|$, and $\Delta_{12} = -\Delta_{23}$.

39.7 Multi-level phenomena

The multi-level Bloch equations, and in particular the three-level Bloch equations (39.238), allow for the theoretical description of many phenomena beyond the two-level approximation. Among them are the phenomena of *light shift* treated in Excs. 39.4.4.12 and 39.4.4.13, the *Autler-Townes splitting* treated in Exc. 39.7.3.1, the *dark resonances* treated in Excs. 39.7.3.3 to 39.7.3.6, the *STIRAP* method treated in Exc. 39.7.3.7, *adiabatic sweeps* treated in Exc. 39.7.3.8, the dispersive interaction between atoms and light treated in Exc. 39.7.3.9, *Fano resonance*-type line profiles of dark resonances treated in Exc. 39.7.3.10, and the *quantum jumps*, which will be studied in later chapters. In Excs. 39.7.3.11 and 39.7.3.12 we will show, that an atomic gas may have *negative permittivity* and *negative permeability* and, consequently, properties usually only found in artificial metamaterials, as for example, a *negative refractive index*.

39.7.1 Electromagnetically induced transparency

In some special cases, the three-level Bloch equations can be solved analytically. The system in Λ-configuration schematized in Fig. 39.7(a), where the two lasers satisfy the condition $\Delta_{12} = \Delta_{23}$ can exhibit a *dark resonance* leading to the phenomena of *electromagnetically induced transparency* (*EIT*) and *electromagnetically induced absorption*. In these resonances a dramatic change of the refractive index is observed despite the fact that the atom becomes transparent, $\mathfrak{Re}\,\chi \gg 0$ and $|\mathfrak{Im}\,\chi| \ll \mathfrak{Re}\,\chi$:

$$\mathfrak{Re}\, n = \sqrt{1 + \mathfrak{Re}\,\chi} \gg 1 \ , \tag{39.267}$$

resulting in a high group velocity,

$$v_g = \frac{c}{n + \omega \frac{dn}{d\omega}} \ . \tag{39.268}$$

EIT is usually studied in Λ-type systems, but similar phenomena can be found in cascade-type systems [1004, 988], which will be studied here. Disregarding the decay rate Γ_{13}, the Bloch equations (39.238) and (39.241) give the coherences,

$$\begin{aligned}
\dot\rho_{12} &= -\Lambda_{12}\rho_{12} + \tfrac{\imath\Omega_{12}}{2}(\rho_{11} - \rho_{22}) - \tfrac{\imath\Omega_{23}}{2}\rho_{13} \\
\dot\rho_{13} &= -\Lambda_{13}^*\rho_{13} - \tfrac{\imath\Omega_{12}}{2}\rho_{23} - \tfrac{\imath\Omega_{23}}{2}\rho_{12} \\
\dot\rho_{23} &= -\Lambda_{23}\rho_{23} + \tfrac{\imath\Omega_{23}}{2}(\rho_{22} - \rho_{33}) - \tfrac{\imath\Omega_{12}}{2}\rho_{13} \ .
\end{aligned} \tag{39.269}$$

Assuming stationarity and negligible depletion of the ground state, $\rho_{11} = 1$,

$$\begin{aligned}
0 &= -\Lambda_{12}\rho_{12} + \tfrac{\imath\Omega_{12}}{2} - \tfrac{\imath\Omega_{23}}{2}\rho_{13} \\
0 &= -\Lambda_{13}^*\rho_{13} - \tfrac{\imath\Omega_{12}}{2}\rho_{23} - \tfrac{\imath\Omega_{23}}{2}\rho_{12} \\
0 &= -\Lambda_{23}\rho_{23} - \tfrac{\imath\Omega_{12}}{2}\rho_{13} \ .
\end{aligned} \tag{39.270}$$

Substituting the third into the first equation,

$$\begin{aligned}
0 &= -\Lambda_{12}\rho_{12} + \tfrac{\imath\Omega_{12}}{2} - \tfrac{\imath\Omega_{23}}{2}\rho_{13} \\
0 &= -\Lambda_{13}^*\rho_{13} - \tfrac{\Omega_{12}^2}{4\Lambda_{23}}\rho_{13} - \tfrac{\imath\Omega_{23}}{2}\rho_{12} \ .
\end{aligned} \tag{39.271}$$

and finally,

$$\boxed{\rho_{12} = \frac{\imath\Omega_{12}}{2}\frac{4\Lambda_{13}^*\Lambda_{23} + \Omega_{12}^2}{\Lambda_{12}\left(4\Lambda_{13}^*\Lambda_{23} + \Omega_{12}^2\right) + \Omega_{23}^2\Lambda_{23}}} \ . \tag{39.272}$$

The macroscopic polarization is now $\mathcal{P} = \frac{N}{V} d_{12}\rho_{21}$, with the number of atoms N. In the limit of weak probes, the *dressed* susceptibility follows from $\mathcal{P} = \varepsilon_0\chi\mathcal{E}_{12} = \frac{N}{V} d_{12}\rho_{21}$,

$$\chi = \frac{N d_{12}}{V\varepsilon_0\mathcal{E}_{12}}\rho_{21} = \frac{N|d_{12}|^2}{V\varepsilon_0\hbar\Omega_{12}}\rho_{21} \ . \tag{39.273}$$

For a resonant probe laser, $\Delta_{23} = 0$ and with $\Gamma_{13} \simeq 0$, we have $\Lambda_{13} = \frac{1}{2}\Gamma_{23} + \imath\Delta_{12}$ and $\Lambda_{23} = \frac{1}{2}(\Gamma_{23} + \Gamma_{12})$. The susceptibility in the probe transition is now, using

$\Theta \equiv \Gamma_{23} + \frac{\Omega_{12}^2}{2\Lambda_{23}}$,

$$\chi = \frac{N|d_{12}|^2}{V\varepsilon_0\hbar\Omega_{12}}\imath\Omega_{12}\frac{\Gamma_{23}+\frac{\Omega_{12}^2}{2\Lambda_{23}}-2\imath\Delta_{12}}{\left(\Gamma_{23}+\frac{\Omega_{12}^2}{2\Lambda_{23}}-2\imath\Delta_{12}\right)(\Gamma_{12}+2\imath\Delta_{12})+\Omega_{23}^2} \tag{39.274}$$

$$= \frac{N|d_{12}|^2}{V\varepsilon_0\hbar\Omega_{12}}\imath\Omega_{12}\frac{\Theta-2\imath\Delta_{12}}{(\Theta-2\imath\Delta_{12})(\Gamma_{12}+2\imath\Delta_{12})+\Omega_{23}^2} = \chi' + \imath\chi'' \ .$$

Example 280 (*EIT in a cascade system*): We consider, for example, the intercombination line of atomic strontium $^1S_0$-$^3P_1$ ($\lambda_{12} = 689\,\text{nm}$ and $\Gamma_{12} = (2\pi)\ 7.6\,\text{kHz}$) be the 'dressing' transition $^3P_1$-(5s4d)$^3D_1$ ($\lambda_{23} = 2700\,\text{nm}$ and $\Gamma_{23} = (2\pi)\ 90.3\,\text{kHz}$), be the 'dressing' transition $^3P_1$-(5s5d)$^3D_1$ ($\lambda_{23} = 497\,\text{nm}$ and $\Gamma_{23} = (2\pi)\ 2.3\,\text{MHz}$), both characterized by $\Gamma_{23} \gg \Omega_{12}, \Gamma_{12}, |\Delta_{12}|$, such that $\Theta \simeq \Gamma_{23}$. Hence,

$$\chi' + \imath\chi'' = \frac{N|d_{12}|^2}{V\varepsilon_0\hbar}\frac{2\Delta_{12}+\imath\Gamma_{23}}{\Omega_{23}} \ .$$

The refraction index follows with,

$$n = \sqrt{1+\chi} \simeq 1 + \tfrac{1}{2}\chi \ .$$

Its imaginary part originates from the decay term of the atom: it is here responsible for the absorbing nature of the cloud. EIT is characterized by a pronounced dispersion and a small concomitant absorption.

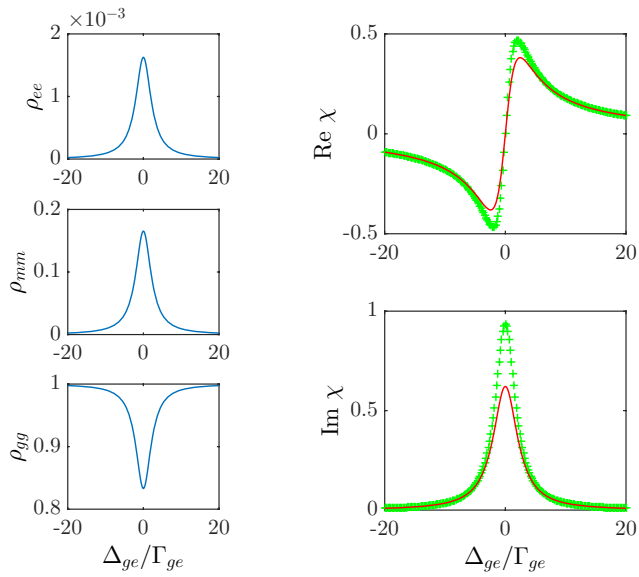

Figure 39.8: (code) EIT signal for the cascade system of strontium with the transitions at 689 nm and 497 nm with $\Omega_{12} = \Gamma_{12}$, $\Omega_{23} = \Gamma_{23}$ and $\Delta_{23} = 0$. The red lines are calculated by numerical integration of the Bloch equations. The dotted lines are obtained from analytical formulas based on the assumptions of weak ground state depletion (which is not really correct in the chosen parameter regime).

39.7.2 Polarization, alignment, and orientation

39.7.2.1 Polarization and helicity

Photons may have the angular momenta $\hat{\mathbf{L}}$, $\hat{\mathbf{S}}$, and $\hat{\mathbf{J}}$, but due to the fact that photons have zero mass, only $\hat{\mathbf{J}}$ is of importance. The *helicity* is defined as,

$$\hat{\mathbf{J}} \cdot \mathbf{k} = (\hat{\mathbf{L}} + \hat{\mathbf{S}}) \cdot \mathbf{k} = \hat{\mathbf{S}} \cdot \mathbf{k} = m_s = \pm 1 \ , \tag{39.275}$$

in beam direction and the *polarization* is,

$$\hat{\mathbf{J}} \cdot \hat{\mathbf{e}}_z = m_j = -j, ...j \ . \tag{39.276}$$

Polarizers prepare the photon in its eigenstate. The angular momentum with respect to $\hat{\mathbf{J}}$ in a basis $\hat{\mathbf{e}}_z$ orthogonal to $\mathbf{k}$ is,

$$\hat{\mathbf{J}} \cdot \mathbf{k} |m\rangle_y = a_m |1\rangle_z + b_m |-1\rangle_z \ . \tag{39.277}$$

The state $|0\rangle_z$ does not exist. For example,

$$\hat{\mathbf{J}} \cdot \mathbf{k} |1\rangle_y = \hat{J}_z \left(\tfrac{1}{2} |1\rangle_z + \imath |0\rangle_z - \tfrac{1}{2} |-1\rangle_z \right) = \tfrac{1}{2} (|1\rangle_z + |-1\rangle_z) \ . \tag{39.278}$$

39.7.2.2 Orientation and alignment

A level $|j\rangle$ with Zeeman degeneracy $|jm\rangle$ can be irreducibly described by Cartesian polarization tensors. Those are the *orientation* and the *alignment* [514, 907],

$$\boxed{\begin{aligned} O_i &\equiv \langle \hat{J}_i \rangle \\ A_{ij} &\equiv \tfrac{3}{2} \langle [\hat{J}_i, \hat{J}_j]_+ \rangle - \langle \hat{\mathbf{J}}^2 \rangle \delta_{ij} \end{aligned}} \ , \tag{39.279}$$

with $i, j = x, y, z$. The expectation value is calculated as usual, $\langle ... \rangle = \operatorname{Tr} \hat{\rho} ... = \sum_m \langle jm | \hat{\rho} ... | jm \rangle$. If $O_i \neq 0$ then the system is said *oriented*, if $A_{ij} \neq 0$ the system is said *aligned* and if either $O_i \neq 0$ or $A_{ij} \neq 0$ then the system is said *polarized*.

The orientation and the alignment depend on the choice of the quantization axis and on the Zeeman splitting of level $|j\rangle$. Choosing z as quantization axis and disregarding Zeeman coherences $\langle m | \hat{\rho} | m' \rangle \sim \delta_{mm'}$, we get the orientation,

$$\mathbf{O} = \hbar \hat{\mathbf{e}}_z \sum_m m \rho_{mm} \tag{39.280}$$

and the alignment,

$$(A_{ij}) = -\hbar^2 j(j+1) - \begin{pmatrix} -\frac{3}{2} & 0 & 0 \\ 0 & -\frac{3}{2} & 0 \\ 0 & 0 & 3 \end{pmatrix} \sum_m \hbar^2 m^2 \rho_{mm} \ , \tag{39.281}$$

if the atom is with certainty in level $|j\rangle$ so that $\operatorname{Tr} \hat{\rho} = 1$. These results will be derived in Exc. 39.7.3.14.

39.7.2.3 Hanle effect

The *Hanle effect* occurs when a magnetic and an optical field compete for the quantization axis. Imagine an atom irradiated by a laser from direction $\mathbf{k} = k\hat{\mathbf{e}}_x$, linearly polarized $\varepsilon = \hat{\mathbf{e}}_y$ and subject to a magnetic field $\vec{\mathcal{B}} = \mathcal{B}\hat{\mathbf{e}}_z$. The fluorescence is detected in direction $\hat{\mathbf{e}}_y$ through a linear polarizer [245]. If $\mathcal{B} = 0$, no light is emitted into the detector since the dipole radiation pattern is a torus with symmetry axis $\hat{\mathbf{e}}_y$. If $\mathcal{B}$ is now increased, the quantization axis is tilted and the torus slowly precesses about the $\hat{\mathbf{e}}_x$ axis. Plotting the time-averaged fluorescence as a function of the magnetic field $\mathcal{B}$, we observe a *dark resonance*. These arguments are rather classical.

Quantum mechanically, Hanle resonances are easily calculated. The transition rates additionally depend on the relative orientation of the laser polarization and the magnetic field direction. This dependence is accounted for by decomposing the polarization vector into the coordinates defined by,

$$\hat{\mathbf{e}}_3 = \frac{\vec{\mathcal{B}}}{\mathcal{B}} \quad , \quad \hat{\mathbf{e}}_2 = \frac{\hat{\mathbf{e}}_3 \times \hat{\mathbf{g}}}{|\hat{\mathbf{e}}_3 \times \hat{\mathbf{g}}|} \quad , \quad \hat{\mathbf{e}}_1 = \frac{\hat{\mathbf{e}}_2 \times \hat{\mathbf{e}}_3}{|\hat{\mathbf{e}}_2 \times \hat{\mathbf{e}}_3|} \ , \tag{39.282}$$

where $\hat{\mathbf{g}}$ is an arbitrarily chosen direction, e.g. gravity. The relative amplitude of the transitions $\Delta m_J = 0$ is proportional to the projection of the polarization vector on the magnetic field axis $\zeta_\pi = (\hat{\varepsilon} \cdot \hat{\mathbf{e}}_3)^2$. To estimate the amplitude of the transitions $\Delta m = \pm 1$, we must project onto the coordinates,

$$\hat{\mathbf{e}}_\pm = \tfrac{1}{\sqrt{2}}(\mp\hat{\mathbf{e}}_1 - \imath\hat{\mathbf{e}}_2) \ , \tag{39.283}$$

and we obtain $\zeta_{\sigma^\pm} = (\hat{\varepsilon} \cdot \hat{\mathbf{e}}_\pm)^2$.

Example 281 (*Hanle effect with rate equations*): As long as the Zeeman splitting is inferior to the atomic decay width, the Hanle effect can be described without coherences, i.e. using only rate equations. Fig. 39.9 shows such a simulation for the case of three ground Zeeman states $|1\rangle = |g, m = +1\rangle$, $|2\rangle = |g, m = 0\rangle$, and $|3\rangle = |g, m = -1\rangle$, and one excited state $|4\rangle = |e, m = 0\rangle$. The rate equations are,

$$\dot{\rho}_{kk} = \mathcal{M}\rho_{kk} \tag{39.284}$$

$$\text{with} \quad \mathcal{M} = \begin{pmatrix} -\Omega_{14} & 0 & 0 & \Omega_{14} + \frac{1}{3}\Gamma \\ 0 & -\Omega_{24} & 0 & \Omega_{24} + \frac{1}{3}\Gamma \\ 0 & 0 & -\Omega_{34} & \Omega_{34} + \frac{1}{3}\Gamma \\ \Omega_{14} & \Omega_{24} & \Omega_{34} & -\Omega_{14} - \Omega_{24} - \Omega_{34} - \Gamma \end{pmatrix}$$

$$\text{and} \quad \Omega_{14} = \Omega_{34} = \zeta_{\sigma^\pm}\Omega \quad \text{and} \quad \Omega_{24} = \zeta_\pi\Omega \ .$$

In Exc. 39.7.3.15 we study the Hanle effect at the Ca^+ Zeeman degenerate level system.

39.7.3 Exercises

39.7.3.1 Ex: Autler-Townes splitting

In this exercise we study the Autler-Townes effect in a two-level system $|1\rangle$ and $|2\rangle$ resonantly excited ($\Delta_{12} = 0$) by a laser with the Rabi frequency Ω_{12}:

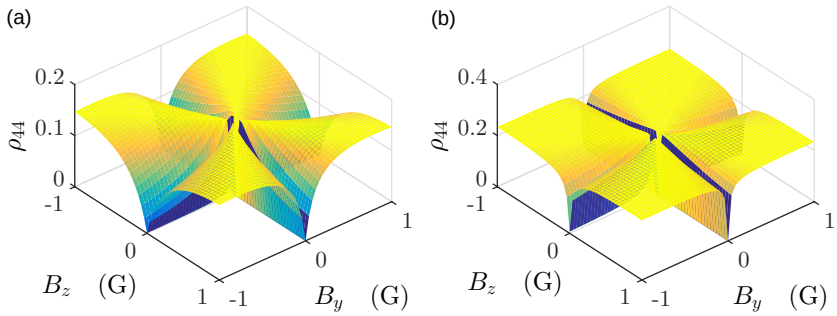

Figure 39.9: (code) Hanle effect in a four-level system with three ground and one excited state with $\hat{\varepsilon} = \hat{\mathbf{e}}_y$ and (a) $\Omega = 0.5\Gamma$ and (b) $\Omega = 5\Gamma$.

a. From the eigenvalues $E_{1,2}$ of the effective Hamiltonian (39.191) of the system, describe the behavior of the real part (energy shift) and the imaginary part (linewidth) as a function of the Rabi frequency. Prepare diagrams Ω_{12} versus $\mathfrak{Re}\, E_{1,2}$ and versus $\mathfrak{Im}\, E_{1,2}$ and discuss the limits $\Omega_{12} > \frac{1}{2}\Gamma_{12}$ and $\Omega_{12} < \frac{1}{2}\Gamma_{12}$.
The Autler-Townes effect can be measured experimentally by probing the population of level $|2\rangle$ via excitation of a third (higher) level by a second laser with the Rabi frequency Ω_{23}. Thus, we obtain a three-level system in cascade configuration, as shown in Fig. 39.7(c). In order to reproduce the experiment by numerical simulations of the Bloch equations (39.238),
b. write down the Liouville matrix $\mathcal{M}_{\text{red}}$ reduced by the trace condition (39.243) and
c. compute the stationary Bloch vector from equation (39.245) varying the detuning of the probe laser Δ_{23} and the Rabi frequency Ω_{12} of the system under study ($|1\rangle$ and $|2\rangle$). Choosing the parameters $\Gamma_{23} = 0.5\Gamma_{12}$, $\Gamma_{13} = 0.01\Gamma_{12}$, $\Omega_{23} = 0.1\Gamma_{12}$, prepare a 3D curve [similar to Fig. 39.3(a)] of the stationary population $\rho_{22}(\infty)$. Interpret the results.

39.7.3.2 Ex: Quantum Zeno effect and saturation broadening

In this exercise we study saturation broadening effect in a three-level system $|1\rangle$, $|2\rangle$, and $|3\rangle$ in V-configuration, as shown in Fig. 39.7(b), excited by two resonant lasers with the Rabi frequencies Ω_{12} and Ω_{23}.
a. From the eigenvalues $E_{1,2}$ of the effective Hamiltonian (39.191) of the system, describe the behavior of the real part (energy shift) and the imaginary part (linewidth) as a function of the Rabi frequency. Prepare diagrams Ω_{12} versus $\mathfrak{Re}\, E_{1,2}$ and versus $\mathfrak{Im}\, E_{1,2}$ and discuss the limits $\Omega_{12} > \frac{1}{2}\Gamma_{12}$ and $\Omega_{12} < \frac{1}{2}\Gamma_{12}$.
Saturation broadening can be measured experimentally in a three-level system in V-configuration. To reproduce the experiment by numerical simulations of the Bloch equations (39.238),
b. write down the Liouville matrix $\mathfrak{L}$ of the system and calculate the time evolution of the Bloch vector via equation (39.242) varying the Rabi frequency Ω_{12}. Choosing the parameters $\Gamma_{23} = 0.01\Gamma_{12}$, $\Gamma_{13} = 0.0001\Gamma_{12}$, $\Omega_{23} = 400\Gamma_{23}$, and $\Delta_{12} = 0 = \Delta_{23}$, prepare a 3D curve [similar to Fig. 39.3(a)] of the population $\rho_{33}(t)$ as a function of time and the Rabi frequency Ω_{12}.

c. Interpret the results in terms of broadening by saturation. The broadening can also be understood in terms of the quantum Zeno effect, where the transition $|1\rangle$-$|2\rangle$ plays the role of the 'observed system' and the transition $|2\rangle$-$|3\rangle$ the role of the measuring device or 'meter' (for example, we can observe the light scattered on the 'meter transition' to infer the evolution of the 'system transition').

39.7.3.3 Ex: EIT and dark resonances

In this exercise we study so-called *dark resonances*, which are responsible for the phenomenon of *electromagnetically induced transparency* (EIT). Such resonances are observed in three-level systems $|1\rangle$-$|2\rangle$-$|3\rangle$ in Λ-configuration, as shown in Fig. 39.7(a), when the laser detunings are chosen so as to satisfy $\Delta_{12} = \Delta_{23}$.
a. From the Bloch equations (39.238) show analytically that, in a stationary situation, the population of the excited state is $\rho_{22}(\infty) = 0$ in the center of the dark resonance. Dark resonances can be observed experimentally. To reproduce the experiment by numerical simulations of the Bloch equations (39.238), write down the Liouville matrix $\mathcal{M}_{\text{red}}$ reduced by the trace condition (39.242) and calculate the stationary Bloch vector from equation (39.243) varying the detunings of the two lasers Δ_{12} and Δ_{23}. Choosing the parameters such that $\Gamma_{23} = \Gamma_{12}$, $\Gamma_{13} = 0.01\Gamma_{12}$, $\Omega_{12} = 2\Gamma_{12}$, and $\Omega_{23} = 0.2\Gamma_{12}$, prepare a 3D curve [similar to Fig. 39.3(a)] of the population $\rho_{22}(\infty)$. Interpret the results.

39.7.3.4 Ex: Coherent trapping and dark states

Consider a three-level system $|1\rangle$, $|2\rangle$, and $|3\rangle$ in Λ-configuration interacting with two electromagnetic fields with frequencies ω_a and ω_b. The two states $|1\rangle$ and $|3\rangle$ of lower energies $\hbar\omega_1$ and $\hbar\omega_3$ are coupled to a state $|2\rangle$ of higher energy $\hbar\omega_2$, as illustrated in Fig. 39.7(a). Assume that the transition $|1\rangle \leftrightarrow |3\rangle$ is forbidden and that the Hamiltonian of the system has the form $\hat{H} = \hat{H}_0 + \hat{H}_{\text{int}}$ where,

$$\hat{H}_0 = E_1|1\rangle\langle 1| + E_2|2\rangle\langle 2| + E_3|3\rangle\langle 3|$$
$$\hat{H}_{\text{int}} = -\tfrac{\hbar}{2}(\Omega_{12}e^{-\imath\omega_a t}|2\rangle\langle 1| + \Omega_{12}^* e^{\imath\omega_a t}|1\rangle\langle 2|) - \tfrac{\hbar}{2}(\Omega_{23}e^{-\imath\omega_b t}|2\rangle\langle 3| + \Omega_{23}^* e^{\imath\omega_b t}|3\rangle\langle 2|)\ .$$

a. Assuming that the system's state is described by $|\psi\rangle = c_1|1\rangle + c_2|2\rangle + c_3|3\rangle$ find the system of equations that describe the dynamics of probability amplitudes c_i with $(i = 1, 2, 3)$.
b. Rewrite the equations for the case where the frequencies of the applied fields are resonant (that is, $\omega_a = \omega_2 - \omega_1$ and $\omega_b = \omega_2 - \omega_3$). Simplify the system by writing in terms of the variables $u_i = c_i e^{\imath\omega_i t}$.
c. Assuming the initial condition $|\psi(0)\rangle = (|1\rangle + |3\rangle)/\sqrt{2}$, solve the system of equations for the resonant case and interpret the result.

39.7.3.5 Ex: Cascade EIT scheme in strontium

Consider the Bloch equations for the ^{88}Sr 7-level system consisting of the following levels: $|1\rangle \equiv (5s^2)\ ^1S_0$, $|2-4\rangle \equiv (5s5p)\ ^3P_1$, and $|5-7\rangle \equiv (5s5d)\ ^3D_1$, and check under which circumstances it is possible to observed dark resonances. The Sr level scheme can be consulted under (Sr level scheme). The Liouvillean can be consulted at (Sr Liouvillean).

39.7.3.6 Ex: Dark resonances with Zeeman splitting

Calculate the dark resonance spectrum for the Ca^+ three-level system with Zeeman sub-structure consisting of the levels $|1\rangle \equiv {}^2S_{1/2}$, $|2\rangle \equiv {}^2P_{1/2}$, and $|3\rangle \equiv {}^2D_{3/2}$ using optical Bloch equations. **Help:** The decay rates are $\Gamma_{12}/2\pi = 23\,\text{MHz}$, $\Gamma_{23}/2\pi = 1.6\,\text{MHz}$, and $\Gamma_{13}/2\pi = 1\,\text{Hz}$. Assume that both incident lasers saturate the transitions, $\Omega_{12} = \Gamma_{12}$ and $\Omega_{23} = \Gamma_{23}$.

39.7.3.7 Ex: STIRAP

In experiments with cold atoms it is often necessary to transfer populations between ground states, for example, between specific levels of a hyperfine structure. One possible procedure is the method of optical pumping, from the initial ground state to an excited state, which subsequently decays to the final state by spontaneous emission. The problem with this incoherent procedure is, that one can control into which ground state level the atom will decay, and that it heats atoms due to the photonic recoil associated with the scattering of light. In this exercise we studied an alternative method, called *Stimulated Raman Adiabatic Passage* (STIRAP), which allows the coherent transfer of population between two states by counter-intuitive pulse sequences:
a. Consider a three-level system in Λ-configuration, as shown in Fig. 39.7(a), initially being in the state $|1\rangle$. Write the system's Hamiltonian in the interaction picture. Now, choose $\Delta_{12} = 0 = \Delta_{23}$, and a temporal variation of the Rabi frequencies described by $\Omega_{12}(t) = \Gamma_{12}(\frac{1}{2} + \frac{1}{\pi}\arctan\Gamma_{12}t)$ and $\Omega_{23}(t) = \Gamma_{12}(\frac{1}{2} - \frac{1}{\pi}\arctan\Gamma_{12}t)$. With this, solve the Schrödinger equation (39.246) iteratively within the time interval $t \in [-40/\Gamma_{12}, 40/\Gamma_{12}]$, while continuously adjusting the Rabi frequencies.
b. The dynamics can also be calculated via a numerical simulations of the Bloch equations (39.238). Write down the Liouville matrix and prepare a simulation using the same parameters as in (b) and additionally $\Gamma_{23} = \Gamma_{12}/2$, $\Gamma_{13} = \Gamma_{12}/500$.
c. Interpret the results.

39.7.3.8 Ex: Adiabatic sweeps

In experiments with cold atoms it is often necessary to transfer populations between ground states, for example, between specific levels of a Zeeman structure. One possible procedure is the method of optical pumping, from the initial ground state to an excited state, which subsequently decays to the final state by spontaneous emission. The problem with this incoherent procedure is, that one can control into which ground state level the atom will decay, and that it heats atoms due to the photonic recoil associated with the scattering of light. In this exercise we study an alternative method, called *adiabatic sweep*, which allows the coherent transfer of population between the two outer states of a degenerate multiplet, as shown in Fig. 39.10, via an adiabatic ramp of the frequency of the incident radiation:
a. Write down the Hamiltonian of the system in the interaction picture. Now, choose $\Omega/2\pi = 8\,\text{kHz}$ and apply a linear ramp of the radiation detuning between $-50\,\text{kHz} < \Delta(t)/2\pi < 50\,\text{kHz}$ during a time interval of $2\,\text{ms}$. With this, solve the Schrödinger equation (39.238) iteratively varying the detuning.
b. Write down the Liouville matrix of the system and do a numerical simulation

of the Bloch equations (39.238) using the same parameters as in (a). Interpret the results. What you observe when you introduce a decay rate between adjacent levels of $\Gamma/2\pi = 200\,\text{Hz}$?

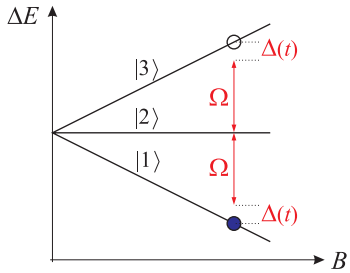

Figure 39.10: Energy levels of an atom in the ground state with Zeeman structure (for example, $|J = 1, m_J = -1, 0, +1\rangle$) as a function of the applied magnetic field.

39.7.3.9 Ex: Dispersive interaction between an atom and light

Radiation which is tuned far from a resonance can change the phase of an atomic dipole moment without changing the populations [14]. We study this effect in a three-level system in cascade configuration excited by two radiation fields, as illustrated in Fig. 39.7(c), simulating the Schrödinger equation and the Bloch equations.
a. Write down the Hamiltonian $\hat{H}$ for this system letting $\Delta_{12} = 0$.
b. Now, consider the subsystem $|2\rangle$-$|3\rangle$, write down its Hamiltonian $\hat{H}_{23}$, determine the eigenvalues, and assume that this transition be excited very far-off resonance. That is, for $\Delta_{23} \gg \Omega_{23}, \Gamma_{23}$ expand the eigenvalues of $\hat{H}_{23}$ up to second order in Ω_{23}. Finally, replace the submatrix $\hat{H}_{23}$ in the complete Hamiltonian $\hat{H}$ by the matrix of the expanded eigenvalues. This procedure corresponds to treating the transition $|2\rangle$-$|3\rangle$ as a perturbation of the transition $|1\rangle$-$|2\rangle$ until second order.
c. Assume that the atom is initially in the ground state and compute the time evolution of the state via the Schrödinger equation (39.246) using (a) the perturbed Hamiltonian and (b) the exact Hamiltonian for the following *sequence of pulses*:
(i) a $\pi/2$-pulse on the transition $|1\rangle$-$|2\rangle$,
(ii) a pulse with a variable duration between 0 and $\Delta t = \Omega_{23}^2/4\pi\Delta_{23}$ applied to the transition $|2\rangle$-$|3\rangle$,
(iii) a $\pi/2$-pulse on the transition $|1\rangle$-$|2\rangle$. What you observe?
d. Establish the Liouville matrix $\mathfrak{L}$ for the same system and calculate the time evolution of the Bloch vector during the sequence by the Bloch equations (39.246) choosing the same parameters as in (c) and additionally $\Gamma_{23} = 1$, $\Gamma_{13} = \Gamma_{23}$, $\Gamma_{12} = 0.01\Gamma_{23}$, and $\Omega_{12} \ggg \Delta_{23}, \Gamma_{23}$. Prepare a 3D curve [similar to Fig. 39.3(b)] of the population $\rho_{22}(t)$. Interpret the results.

39.7.3.10 Ex: Fano profile of a dark resonance

The dark resonance studied in Exc. 39.7.3.3 may in some circumstances adopt an asymmetric profile. Calculate, for a three-level system in Λ-configuration, as shown

[14] This type of interaction is used in the implementation of quantum gates in quantum computing.

in Fig. 39.7(a), starting from the Bloch equations (39.238) with the Liouville matrix $\mathcal{M}_{\text{red}}$ reduced by the trace condition (39.242), the spectrum $\rho_{22}(\Delta_{23})$ for the following set of parameters: $\Gamma_{12} = 2$, $\Gamma_{23} = \Gamma_{12}/2$, $\Gamma_{23} = 0.1\Gamma_{12}$, $\Omega_{12} = 10\Gamma_{12}$, $\Omega_{23} = 5\Gamma_{23}$, $\Delta_{12} = -5\Gamma_{12}$ and $\Delta_{23} = [-1 : .01 : 1]\Gamma_{23}$. Interpret the spectrum in terms of a Fano resonance.

39.7.3.11 Ex: Gas with negative permittivity

Study EIT on the strontium cascade system consisting of the transitions 689 nm and 497 nm and draw a spectrum of the permittivity. Compare with the permittivity of the 689 nm two-level system. What densities are necessary to get a negative permittivity?

39.7.3.12 Ex: Gas with negative permeability

Theoretically, under certain conditions, gases may exhibit *negative* permittivity and permeability, and therefore refraction [841, 839, 840, 701, 550]. To study this phenomenon we consider a three-level system in Λ-configuration with an electric dipole transition and another magnetic dipole transition. The objective is to balance the electrical dipole moment excited by a probe laser and the magnetic dipole moment excited via a Raman transition by both, the probe laser and a control laser. The Raman transition simulates an effective magnetic field. Since the magnetic moment is smaller by a factor of α^2, the electric moment must be reduced by detuning the probe laser, as shown in Fig. 39.11.

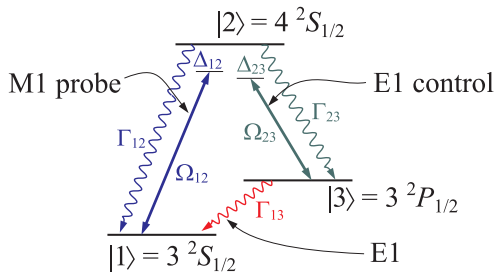

Figure 39.11:

a. Consider a three-level system in Λ-configuration. The transitions $|1\rangle$-$|2\rangle$ and $|2\rangle$-$|3\rangle$ are assumed to be electric dipoles and $|1\rangle$-$|3\rangle$ a magnetic dipole, such that, $\Gamma_{12}, \Gamma_{23} \gg \Gamma_{13}$. Extract from the Bloch equation (39.238) the equations for the coherences ρ_{12}, ρ_{13}, and ρ_{23}.
b. Suppose, that the excitation on the probe transition be so weak, $\Omega_{12} \ll \Gamma_{12}$, that it does not succeed to empty the ground state. In this approximation eliminate the dynamics of ρ_{23} and deduce the stationary solution for ρ_{12} and ρ_{13}.
c. Calculate the magnetic susceptibility χ_m [840] with the following parameters $\Gamma_{12} = 7 \cdot 10^7\,\text{s}^{-1}$, $\Gamma_{23} = 3 \cdot 10^7\,\text{s}^{-1}$, $\Gamma_{13} = 2 \cdot 10^7\,\text{s}^{-1}$, $\Omega_{12} = 0.1\Gamma_{12}$, $\Omega_{23} = 2 \cdot 10^8\,\text{s}^{-1}$, $\Delta_{23} = 0$ in the regime $\Delta_{12} = [-15\Gamma_{23}, 15\Gamma_{23}]$.
d. Simulate the Bloch equations (39.238) and compare with the numerical solution.

39.7.3.13 Ex: Magnetic dipole transitions in strontium

Magnetic dipole transitions are characterized by the selection rules $\Delta J = 0, \pm 1$, $\Delta S = 0$, $\Delta L = 0$, and $\Delta n = 0$. There are several transitions starting from the $5s5p\ ^3P_J$ metastable states going to the $5p^2\ 3P_J$ states with strong linewidths:

- $5s5p\ ^3P_1^o \leftrightarrow 5p^2\ ^3P_2$ at 472.2278 nm with $\Gamma = (2\pi)\ 5.7\,\text{MHz}$
- $5s5p\ ^3P_1^o \leftrightarrow 5p^2\ ^3P_1$ at 478.4320 nm with $\Gamma = (2\pi)\ 4.8\,\text{MHz}$

Check whether it is possible to reach negative permeability in a cold strontium gas.

39.7.3.14 Ex: Orientation and alignment

Derive the formulas (39.280) and (39.281).

39.7.3.15 Ex: Hanle effect in Ca

Simulate the Hanle effect for the Ca^+ three-level system of Exc. 39.7.3.6 using optical Bloch equations.

39.7.3.16 Ex: Control of saturation via quenching

In this exercise we study the possibility of '*quenching*' a narrow transition, i.e. homogeneously broadening its transversal decay width without affecting the longitudinal one, with the goal of obtaining control over the saturation parameter on the narrow transition by coupling it via a strong transition to a third level.

a. Set up the Bloch equations for the three-level cascade system sketched in Fig. 39.12.

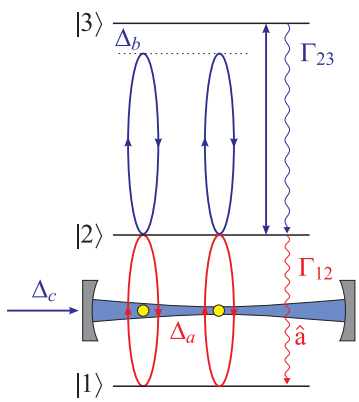

Figure 39.12: Strontium level scheme with $|1\rangle \equiv (5s^2)^1S_0$, $|2\rangle \equiv (5s5p)^3P_1$, and $|3\rangle \equiv (5s6s)^3S_1$.

b. Based on the assumptions $\Gamma_{23} \gg \Gamma_{12} \gg \Gamma_{13} = 0$ and tuning the control laser to resonance, $\Delta_{23} = 0$, calculate the diagonal elements Λ_{ij} of the Liouvillean $\mathcal{M}$ of the Bloch equations.

c. Now, assume that the control laser be sufficiently weak not to deplete the state $|2\rangle$.

Neglecting $\rho_{33} = 0 = \rho_{23}$ derive the reduced Bloch equations for the system ρ_{22}, ρ_{12}, and ρ_{13} and solve it by ρ_{22}.
d. Calculate the 'generalized saturation parameter'.
e. Recover the two-level saturation parameter in the limit $\Omega_{23}^2 \ll \Gamma_{12}\Gamma_{13}$. Plot the population ρ_{22} as a function of the saturation parameters s_{12} and s_{23}.

Chapter 40

Atoms in quantized radiation fields

So far we have treated the light-atom interaction always assuming the light field as a stationary or propagating classical wave, while our two-level atom has been regarded as an entity obedient to the laws of quantum mechanics and subject to an induced perturbation by an oscillatory electromagnetic field. This procedure naturally leads to oscillations of the atomic states' populations and the coherences between them. However, in strong fields, when atomic energy spectrum is significantly modified, a non-perturbative, time-independent approach can be fruitful. Time-independent solutions for the Schrödinger equation for atoms coupled to fields is called *dressed states*. They were used for the first time to interpret the *splitting* of rotational molecular spectra in the presence of intense classical radiofrequency fields. While the semi-classical treatment is suitable for a wide variety of phenomena and has the virtue of mathematical simplicity and familiarity, it is sometimes worth considering the field as a quantum entity as well. In the dressed states picture, the atom-field interaction corresponds to an exchange of energy quanta between the field (photons) and the atom. This approach allows us to express photonic *number states*, also called *Fock states*, on equal footings with the discrete states of atom excitation and to write the state functions of the coupled atom-field system in a basis of photonic and atomic product states. Diagonalization of the dipole coupling terms in the system's Hamiltonian generates time-independent solutions of dressed states in a completely quantum Schrödinger equation.

We begin this chapter expressing the atom-field interaction in a fully quantized form. We will examine some examples illustrating how the dressed states picture can provide useful information on the light-matter interactions.

40.1 Interaction of quantized fields with atoms

40.1.1 Hamiltonian for interaction of quantized fields with atoms

With the results of the previous section the complete field Hamiltonian reads,

$$\hat{H}_{\text{field}} = \sum_{\mathbf{k}} \hbar\omega_{\mathbf{k}}(\hat{a}^{\dagger}_{\mathbf{k}}\hat{a}_{\mathbf{k}} + \tfrac{1}{2}) \ . \tag{40.1}$$

Now, that we have a clear picture of the quantized field with the energies in the modes given by Eq. (37.9) and the photon number states given by the eigenstates $|n\rangle$ of the quantized harmonic oscillator, we are in a position to consider our two-level atom interacting with this quantized radiation field. If for the moment, we exclude spontaneous emission and stimulated processes, the Hamiltonian of the combined atom-field system is,

$$\hat{H} = \hat{H}_{\text{atom}} + \hat{H}_{\text{field}} + \hat{H}_{\text{atom:field}} \ . \tag{40.2}$$

We describe the atom by a two-level system,

$$\hat{H}_{\text{atom}} = \hbar\omega_g|g\rangle\langle g| + \hbar\omega_e|e\rangle\langle e| = \hbar\omega_g|g\rangle\langle g| + \hbar(\omega_g + \omega_0)|e\rangle\langle e| \ , \tag{40.3}$$

where $\hat{H}_{\text{field}}$ is the Hamiltonian of the quantized field, expressed by Eq. (37.6), and $\hat{H}_{\text{atom:field}}$ the atom-field interaction. For the Hamiltonian without interaction, $\hat{H} = \hat{H}_{\text{atom}} + \hat{H}_{\text{field}}$, the eigenstates are simply product states of the atomic states and the photon number states,

$$|g, n\rangle = |g\rangle|n\rangle \qquad \text{and} \qquad |e, n\rangle = |e\rangle|n\rangle \ . \tag{40.4}$$

The left side of Fig. 40.1 shows, how the eigenenergies of the product states consist of two ladders, being displaced by the energy difference $\hbar\Delta$, which corresponds to the detuning. We write the Hamiltonian of the atom Eq. (40.3) as the sum of projectors on unperturbed eigenstates using the completeness relation and the orthogonality of eigenstates. With the same idea we can rewrite the dipole operator defined in Eq. (39.33),

$$\begin{aligned}\hat{\mathbf{d}} &= \sum_i |\psi_i\rangle\langle\psi_i|\hat{\mathbf{d}}|\sum_j |\psi_j\rangle\langle\psi_j| = \sum_{i,j} |i\rangle\langle i|e^{\imath(\omega_i-\omega_j)t}\hat{\mathbf{d}}|j\rangle\langle j| \\ &= \sum_{i,j} e^{\imath(\omega_i-\omega_j)t}\mathbf{d}_{ij}|i\rangle\langle j| = \sum_{i<j} e^{\imath(\omega_i-\omega_j)t}\mathbf{d}_{ij}|i\rangle\langle j| + e^{-\imath(\omega_i-\omega_j)t}\mathbf{d}_{ij}|j\rangle\langle i| \equiv \hat{\mathbf{d}}^{(+)} + \hat{\mathbf{d}}^{(-)} \ .\end{aligned} \tag{40.5}$$

using $|\psi_n(t)\rangle = e^{-\imath\omega_n t}|n\rangle$. Note that $\hat{\mathbf{d}}$ only has non-diagonal elements.

Now, let us use the electric field of Eqs. (37.8) to describe the atom-field interaction through the Hamiltonian $\hat{H}_{\text{atom:field}} = -\hat{\mathbf{d}} \cdot \hat{\vec{\mathcal{E}}}$,

$$\hat{H}_{\text{atom:field}} = \imath \sum_{\mathbf{k}} \sum_{i,j} \sqrt{\tfrac{\hbar\omega_{\mathbf{k}}}{2\varepsilon_0 V}}\mathbf{d}_{ij} e^{\imath(\omega_j-\omega_i)t}|i\rangle\langle j| \cdot \vec{\epsilon}_{\mathbf{k}} \left[\hat{a}_{\mathbf{k}} e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t)} - \hat{a}^\dagger_{\mathbf{k}} e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t)}\right] \ . \tag{40.6}$$

For our two-level atom interacting with a single mode radiation field, we only have,

$$\begin{aligned}\hat{H}_{\text{atom:field}} = \imath\sqrt{\tfrac{\hbar\omega_{\mathbf{k}}}{2\varepsilon_0 V}}\mathbf{d}_{ge} \left[e^{\imath(\omega_e-\omega_g)t}|g\rangle\langle e| + e^{\imath(\omega_g-\omega_e)t}|e\rangle\langle g|\right] \cdot \\ \cdot \vec{\epsilon}_{\mathbf{k}} \left[\hat{a}_{\mathbf{k}} e^{-\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t)} - \hat{a}^\dagger_{\mathbf{k}} e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t)}\right] \ .\end{aligned} \tag{40.7}$$

40.1.1.1 Rotating wave approximation for dressed states

We can simplify the notation by identifying $\hat{\sigma}^+ = |e\rangle\langle g|$ and $\hat{\sigma}^- = |g\rangle\langle e|$ of the Eqs. (39.124) and introducing as an abbreviation the *Rabi frequency*,

$$\tfrac{1}{2}\hbar\Omega_1(\mathbf{r}) \equiv \sqrt{\tfrac{\hbar\omega_{\mathbf{k}}}{2\varepsilon_0 V}}\mathbf{d}_{ge} \cdot \vec{\epsilon}_{\mathbf{k}} e^{\imath\mathbf{k}\cdot\mathbf{r}} \ . \tag{40.8}$$

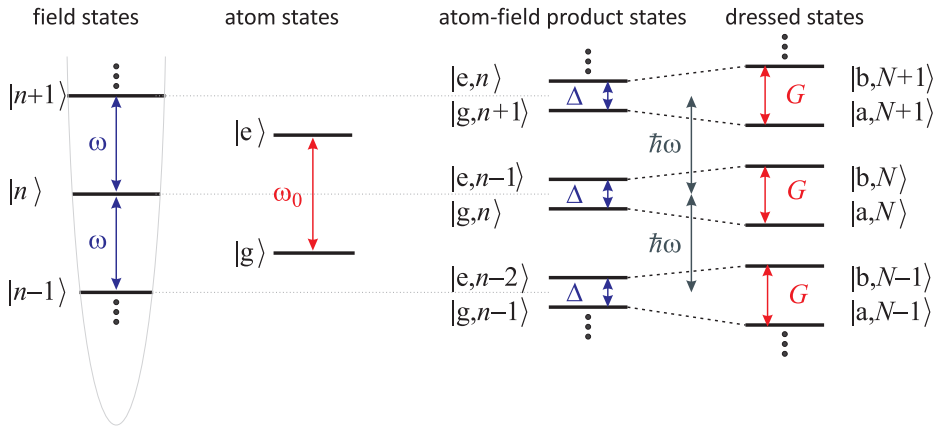

Figure 40.1: (Left) Photons number states and the two stationary states of the two-levels atom. (Center) Double ladder showing the basis of products states of photon number and atomic states. (Right) Dressed states constructed by diagonalization of the full Hamiltonian in the basis of the product states.

The interaction Hamiltonian then becomes,

$$\begin{aligned}\hat{H}_{\text{atom:field}} &= \tfrac{\imath}{2}\hbar\Omega_1(\mathbf{r})e^{\imath(\omega_{\mathbf{k}}-\omega_0)t}\hat{\sigma}^+\hat{a}_{\mathbf{k}} + \tfrac{\imath}{2}\hbar\Omega_1(\mathbf{r})e^{\imath(\omega_{\mathbf{k}}+\omega_0)t}\hat{\sigma}^-\hat{a}_{\mathbf{k}} \\ &- \tfrac{\imath}{2}\hbar\Omega_1^*(\mathbf{r})e^{-\imath(\omega_{\mathbf{k}}+\omega_0)t}\hat{\sigma}^+\hat{a}_{\mathbf{k}}^\dagger - \tfrac{\imath}{2}\hbar\Omega_1^*(\mathbf{r})e^{-\imath(\omega_{\mathbf{k}}-\omega_0)t}\hat{\sigma}^-\hat{a}_{\mathbf{k}}^\dagger\ .\end{aligned} \tag{40.9}$$

This Hamiltonian contains four terms describing the following processes [1],

$|g,n\rangle \longrightarrow |e,n-1\rangle$ the atom is excited by the absorption of a photon;

$|e,n\rangle \longrightarrow |g,n-1\rangle$ the atom is deexcited by the absorption of a photon;

$|g,n\rangle \longrightarrow |e,n+1\rangle$ the atom is excited by the emission of a photon;

$|e,n\rangle \longrightarrow |g,n+1\rangle$ the atom is deexcited by the emission of a photon.

Obviously, only the first and forth terms respect energy conservation (in first-order processes) and can serve as initial and final states in real physical processes. Fig. 40.3 shows schemes of these four terms. We see, that neglecting the second and third process (i.e., terms $\propto \hat{\sigma}^\pm\hat{a}^\pm$ of the Hamiltonian) is equivalent to making the rotating wave approximation (RWA), where we despise the terms rotating with the frequency $\pm(\omega_{\mathbf{k}}+\omega_0)$, and that we really only need to consider the coupling between the two dressed states $|g,n\rangle$ and $|e,n-1\rangle$.

Finally, within the RWA the Hamiltonian reads,

$$\boxed{\hat{H}_{\text{atom:field}} = \tfrac{\imath}{2}\hbar\Omega_1(\mathbf{r})e^{-\imath\Delta_{\mathbf{k}}t}\hat{\sigma}^+\hat{a}_k - \tfrac{\imath}{2}\hbar\Omega_1^*(\mathbf{r})e^{\imath\Delta_{\mathbf{k}}t}\hat{\sigma}^-\hat{a}_k^\dagger}\ , \tag{40.10}$$

where we introduced the detuning $\Delta_{\mathbf{k}} \equiv \omega_{\mathbf{k}} - \omega_0$ as short hand notation.

[1] Remember that the four processes contained in the Hamiltonian are all coherent (absorption and stimulated emission), and that spontaneous emission must be treated separately see next Sec. 40.4.

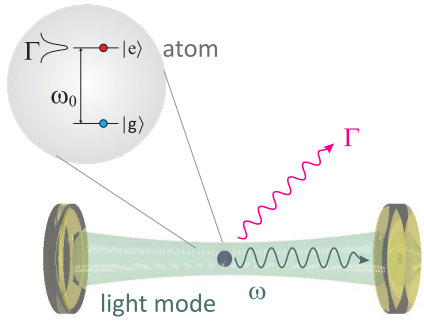

Figure 40.2: Two-level atom interacting with a cavity mode.

It is important to note that the first and fourth term can be important in higher order processes, such as multiphotonic absorption or Raman scattering processes, where the excited state would be a virtual level. In fact, when the Rabi frequency is very large, $\Omega_1 \simeq \omega$, the excitation and deexcitation processes follow each other so rapidly, that energy conservation can be violated for short times. The energy shift caused by terms neglected in the RWA are called *Bloch-Siegert shift* [2].

40.1.2 Dressed states

Within the new dressed states basis, the atom-light coupling problem is reduced to diagonalizing the Hamiltonian of a quasi-degenerate two-level atom ($|\Delta| \ll \omega_0$), in which the non-diagonal elements are given by $\frac{1}{2}\hbar\Omega_1$. The eigenenergies of the complete Hamiltonian $\hat{H}$ are,

$$E_\pm = \tfrac{\hbar}{2}(\omega_{g,n} + \omega_{e,n-1}) \pm \tfrac{\hbar}{2} G_n \ . \tag{40.11}$$

where $\hbar\omega_{g,n}$ and $\hbar\omega_{e,n-1}$ are the energies of the product states $\hbar\omega_g + n\hbar\omega_{\mathbf{k}}$ and $\hbar\omega_e + (n-1)\hbar\omega_{\mathbf{k}}$. The separation between constituents of the same dressed state is $G_n = \sqrt{n\Omega_1^2 + \Delta^2}$. Fig. 40.4 illustrates how the coupling between a field mode and a two-level atom leads to an avoided crossing.

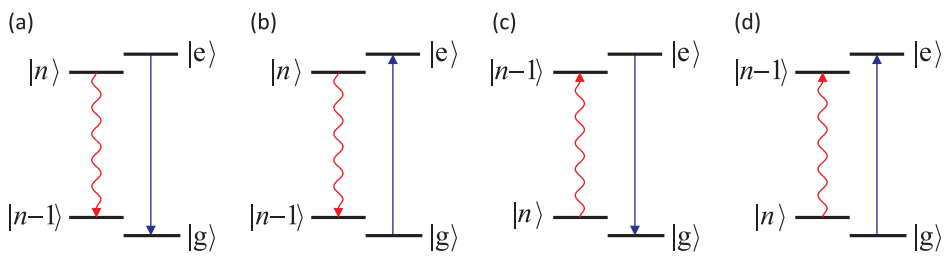

Figure 40.3: Illustration of the four processes in the atom-field interaction. Terms (b) and (c) conserve energy in first-order processes, while (a) and (d) do not conserve.

The atom-field product states offer a natural basis for the Hamiltonian of Eq. (40.2).

[2] The shift is not observed, when the non-rotating terms $\sigma^\pm a^\pm$ are forbidden by other conservation or selection rules. For example, when a resonance is excited by $\sigma^\pm$ light, the RWA is accurate.

The states resulting from the diagonalization of the Hamiltonian on this basis are called *dressed states*. As indicated in Fig. 40.1, the neighboring doublets the double ladder 'repel' each other under the influence of the interaction $\hat{H}_{\text{atom:field}}$ in Eq. (40.2). The mixed coefficients form the familiar problem of two levels, now called $|a\rangle$ and $|b\rangle$. Note that the semiclassical product state picture and the dressed states picture follow from each other via unitary transformation,

$$\boxed{\begin{pmatrix} |a,N\rangle \\ |b,N\rangle \end{pmatrix} = \mathcal{U} \begin{pmatrix} |g,n\rangle \\ |e,n-1\rangle \end{pmatrix}} \,, \tag{40.12}$$

and, hence, are equivalent descriptions of the same reality. But while in the product state picture the system Hamiltonian is diagonal in the *absence* of atom-light interaction, in the dressed states picture the Hamiltonian is diagonal in the *presence* of interaction. The numbers n denote the amount of photons in the laser beam, the numbers N denote the amount of energy packets within the system, that is, the photons *plus* the possible excitation of the atom. The expression of the unitary transformation matrix will be derived in Sec. 40.2.1.

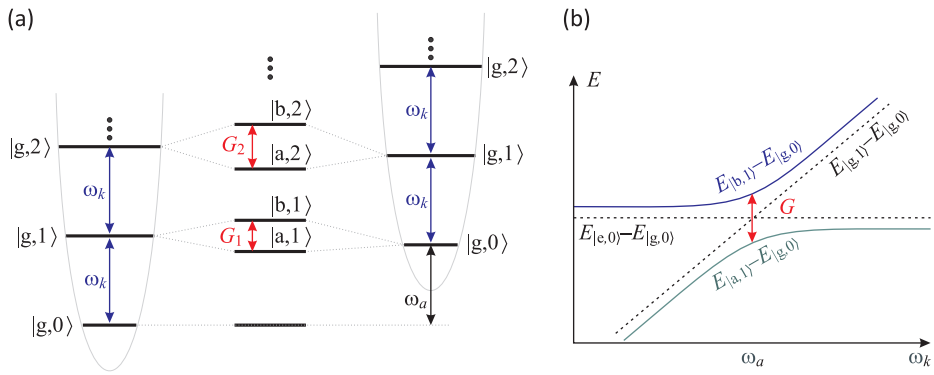

Figure 40.4: (a) Rabi splitting of the lowest dressed states. (b) Avoided crossing of dressed states.

40.1.3 Dipole moments for vector transitions

Until now, we restricted to transitions between two levels without accounting for their possible substructure, which interacts with the vectorial nature of the driving light fields. Resuming the discussion of Sec. 39.2.3, we generalize the treatment of the preceding section considering a two-level atom with an arbitrary hyperfine level substructure $|g,(I,J)F,m\rangle \leftrightarrow |e,(I,J')F',m'\rangle$. The Hamiltonian is,

$$\hat{H} = \sum_{\alpha,\beta} \hbar\omega_{g\alpha}|g_\alpha\rangle\langle g_\alpha| + \hbar\omega_{e\beta}|g_\beta\rangle\langle g_\beta| \,. \tag{40.13}$$

Generalizing the expression (40.5) to vectorial transitions, the electric dipole operator reads,

$$\begin{aligned}\hat{\mathbf{d}} &= \sum_{i,j} |i\rangle\langle i|e^{\imath(\omega_i-\omega_j)t}\hat{\mathbf{d}}|j\rangle\langle j| \\ &= \sum_{\alpha,\beta} |g_\alpha\rangle\langle g_\alpha|e^{\imath(\omega_{g\alpha}-\omega_{e\beta})t}\hat{\mathbf{d}}|e_\beta\rangle\langle e_\beta| + |e_\beta\rangle\langle e_\beta|e^{-\imath(\omega_{g\alpha}-\omega_{e\beta})t}\hat{\mathbf{d}}|g_\alpha\rangle\langle g_\alpha| \ .\end{aligned} \tag{40.14}$$

Example 282 (*Vector transition in strontium*): The simplest possible vectorial level scheme consists of one ground and three excited Zeeman states, such as realized, for instance, in the strontium $^1S_0$-$^1P_1$ transition,

$$\hat{H}_{strontium} = \sum_\beta \hbar\omega_{e\beta}|g_\beta\rangle\langle g_\beta| \ , \tag{40.15}$$

setting $\omega_{ga} \equiv 0$. For strontium, we may introduce the vectorial lowering operator [255],

$$\hat{\vec{\sigma}} = \hat{\sigma}_x\hat{\mathbf{e}}_x + \hat{\sigma}_y\hat{\mathbf{e}}_y + \hat{\sigma}_z\hat{\mathbf{e}}_z \quad \text{with} \quad \hat{\sigma}_\beta = |g\rangle\langle e_\beta| \quad \text{with} \quad \beta = x, y, z \ . \tag{40.16}$$

In this case, the electric dipole operator reads,

$$\begin{aligned}\hat{\mathbf{d}}_{strontium} &= \sum_\beta |g\rangle\langle g|e^{-\imath\omega_{e\beta}t}\hat{\mathbf{d}}|e_\beta\rangle\langle e_\beta| + |e_\beta\rangle\langle e_\beta|e^{\imath\omega_{e\beta}t}\hat{\mathbf{d}}|g\rangle\langle g| \\ &= d\sum_\beta e^{-\imath\omega_{e\beta}t}|g\rangle\langle e_\beta|\hat{\mathbf{e}}_\beta + c.c. = de^{-\imath\omega_e t}\hat{\vec{\sigma}} + c.c. \ ,\end{aligned} \tag{40.17}$$

with $\langle g|\hat{\mathbf{d}}|e_\beta\rangle = d\hat{\mathbf{e}}_\beta$ and $\omega_{e\beta} = \omega_e$.

40.1.4 Exercises

40.1.4.1 Ex: Converting a pure state into a mixture by incomplete measurement

Consider a dressed two-level atom with the atomic states $|1\rangle$ and $|2\rangle$ and the photon number state $|n\rangle$.
a. Write down the general normalized dressed state and the density operator.
b. Now, perform a measurement of the atomic state tracing over the atomic degree of freedom and verify whether the resulting density operator represents a pure state.
c. Now, perform a measurement of the photon number and verify whether the resulting density operator represents a pure state.

40.2 The Jaynes-Cummings model

The *Jaynes-Cummings model* describes the dynamics of a single dressed two-level atom in a single monochromatic laser mode in the absence of spontaneous emission processes. The model, illustrated in Fig. 40.2 has become a paradigm of quantum mechanics with applications in quantum information, where it applies to the formulation of entanglement protocols of atomic states and the implementation of quantum gates, which will be discussed in Sec. 47.1. In the following, we will first study the

interaction of an atom with an optical mode neglecting dissipation effects and leave the discussion on the impact of dissipation processes to later sections.

The dynamic evolution of pure states is then obtained from the Schrödinger equation. The Hamiltonian of this system is given by (40.10). Letting $\hbar = 1$ and assuming that the atom is located at the origin [such that $\Omega_1(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} = \Omega_1(\mathbf{0})$], we can write the time-dependent Hamiltonian in the *interaction picture* as,

$$\boxed{\begin{aligned}\hat{H}_{\text{atom:field}} &= \tfrac{\imath}{2}\Omega_1 e^{-\imath\Delta t}\hat{\sigma}^+\hat{a} - \tfrac{\imath}{2}\Omega_1 e^{\imath\Delta t}\hat{\sigma}^-\hat{a}^\dagger \\ &= \begin{pmatrix} 0 & \tfrac{\imath}{2}\Omega_1 e^{-\imath\Delta t}\hat{a} \\ -\tfrac{\imath}{2}\Omega_1 e^{\imath\Delta t}\hat{a}^\dagger & 0 \end{pmatrix}\end{aligned}} \ . \tag{40.18}$$

where ω is the frequency of the radiation, ω_0 the frequency of the atomic transition, $\Delta \equiv \omega - \omega_0$ the detuning, and Ω_1 the Rabi frequency generated by a single photon. The atomic operators $\sigma^\pm$ are related to the *Pauli spin matrices* (23.154), and we use the conventions $\hat{\sigma}^z = [\hat{\sigma}^+, \hat{\sigma}^-] = |2\rangle\langle 2| - |1\rangle\langle 1| = 2\hat{\sigma}^+\hat{\sigma}^- - \mathbb{I}$ and $\omega_0 \equiv \omega_2 - \omega_1 > 0$.

Starting from this Hamiltonian the Jaynes-Cummings model is translated into the *Schrödinger picture* via the unitary transform,

$$\mathcal{U} = e^{-\imath(\hat{n}+1/2)\omega t} e^{\imath\hat{\sigma}^z\omega_0 t/2} \ , \tag{40.19}$$

for which we find the relationships,

$$\begin{aligned} -\imath\mathcal{U}\dot{\mathcal{U}}^\dagger &= \omega(\hat{n} + \tfrac{1}{2}) - \tfrac{1}{2}\omega_0\hat{\sigma}^z \\ \mathcal{U}\hat{a}\mathcal{U}^\dagger &= \Sigma_{n'}|n'\rangle e^{-\imath n'\omega t}\langle n'|\hat{a}\Sigma_n|n\rangle e^{\imath n\omega t}\langle n| = e^{\imath\omega t}\hat{a} \\ \mathcal{U}\hat{\sigma}^-\mathcal{U}^\dagger &= e^{\imath\omega_0 t}\hat{\sigma}^- \ . \end{aligned} \tag{40.20}$$

Obviously, the dynamics of the states is now given by $|\psi(t)\rangle = \mathcal{U}|\psi_I(t)\rangle$, and the new Hamiltonian in the Schrödinger picture reads,

$$\boxed{\begin{aligned}\tilde{H}_{\text{atom:field}} &= \mathcal{U}\hat{H}_{\text{atom:field}}\mathcal{U}^\dagger - \imath\mathcal{U}\dot{\mathcal{U}}^\dagger \\ &= \omega(\hat{n} + \tfrac{1}{2}) - \tfrac{1}{2}\omega_0\hat{\sigma}^z + \tfrac{1}{2}\Omega_1(\hat{a}\hat{\sigma}^+ + \hat{a}^\dagger\hat{\sigma}^-) \\ &= \begin{pmatrix} (\hat{n} + \frac{1}{2})\omega - \frac{1}{2}\omega_0 & \frac{1}{2}\Omega_1\hat{a}^\dagger \\ \frac{1}{2}\Omega_1\hat{a} & (\hat{n} + \frac{1}{2})\omega + \frac{1}{2}\omega_0 \end{pmatrix}\end{aligned}} \ . \tag{40.21}$$

We choose the Fock representation (24.90) for the radiation mode, we represent the atomic transitions by the Pauli matrices (23.152), and we span the product space $\hat{\rho}_{\text{field}} \otimes \hat{\rho}_{\text{atom}}$ generalizing the operators $\hat{a}^\pm \curvearrowright \hat{a}^\pm \otimes \mathbb{I}$ and $\hat{\sigma}^\pm \curvearrowright \mathbb{I} \otimes \hat{\sigma}^\pm$. Explicitly we get,

$$\begin{aligned} \hat{a}^\dagger &= \sum_n \sqrt{n+1}|n+1\rangle \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \langle n| \quad \text{and} \quad \hat{\sigma}^+ = \sum_n |n\rangle \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \langle n| \\ \hat{a} &= \sum_n \sqrt{n}|n-1\rangle \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \langle n| \quad \text{and} \quad \hat{\sigma}^- = \sum_n |n\rangle \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \langle n| \ . \end{aligned} \tag{40.22}$$

40.2.1 Dressed states representation

The basis

$$|1,n\rangle = \begin{pmatrix}1\\0\end{pmatrix}|n\rangle \quad , \quad |2,n-1\rangle = \begin{pmatrix}0\\1\end{pmatrix}|n-1\rangle \tag{40.23}$$

spans a sub-space of two energetically nearly degenerate states with n photons in the system one out of which can have been absorbed by the atom. The density operator for the subspace is,

$$\hat{\rho}_n = \begin{pmatrix} |n\rangle|1\rangle\langle 1|\langle n| & |n\rangle|1\rangle\langle 2|\langle n-1| \\ |n-1\rangle|2\rangle\langle 1|\langle n| & |n-1\rangle|2\rangle\langle 2|\langle n-1| \end{pmatrix} . \tag{40.24}$$

We project the Hamiltonian onto that basis via the projectors $\hat{P} = |1,n\rangle\langle 1,n| + |2,n-1\rangle\langle 2,n-1|$,

$$\boxed{\hat{H}_n = \hat{P}\tilde{H}_{\text{atom:field}}\hat{P} = \begin{pmatrix} n\omega + \frac{\Delta}{2} & \frac{1}{2}\Omega_1\sqrt{n} \\ \frac{1}{2}\Omega_1\sqrt{n} & n\omega - \frac{\Delta}{2} \end{pmatrix}} . \tag{40.25}$$

That is, the Hamiltonian can be decomposed into sub-hyperspaces which are all orthogonal, because the Hamiltonian $\tilde{H}_{\text{atom:field}}$ only contains terms conserving the total number of photons + excitations.

Example 283 (*Orthogonality of submatrices with same numbers of excitations*): This can be seen by expanding the Hamiltonian matrix:

$$\tilde{H}_{\text{atom:field}} = \bigoplus_n \hat{H}_n \tag{40.26}$$

$$= \sum_n \left[|n\rangle \begin{pmatrix} n\omega + \frac{\Delta}{2} & 0 \\ 0 & n\omega - \frac{\Delta}{2} \end{pmatrix} + |n-1\rangle \begin{pmatrix} 0 & 0 \\ \frac{\Omega_1}{2}\sqrt{n} & 0 \end{pmatrix} + |n+1\rangle \begin{pmatrix} 0 & \frac{\Omega_1}{2}\sqrt{n+1} \\ 0 & 0 \end{pmatrix} \right] \langle n|$$

$$= \begin{pmatrix} \frac{\Delta}{2} & & & & & \\ & \omega + \frac{\Delta}{2} & \frac{\Omega_1}{2} & & & \\ & \frac{\Omega_1}{2} & \omega - \frac{\Delta}{2} & & & \\ & & & 2\omega + \frac{\Delta}{2} & \frac{\Omega_1}{2}\sqrt{2} & \\ & & & \frac{\Omega_1}{2}\sqrt{2} & 2\omega - \frac{\Delta}{2} & \\ & & & & & 3\omega + \frac{\Delta}{2} & \cdots \\ & & & & & \vdots & \ddots \end{pmatrix} .$$

The eigenvalues can be easily calculated by [3],

$$\det \sum_n \hat{H}_n = \sum_n \det \hat{H}_n \ , \tag{40.27}$$

[3] The following rules apply to determinants,

$$\det(AB) = \det A \det B \quad \text{and} \quad (\det A)^{-1} = \det A^{-1} .$$

defining the generalized n-photon Rabi frequency, $\varpi_n \equiv \sqrt{\Delta^2 + n\Omega_1^2} = |\varpi_n| e^{\imath \mathbf{k}\cdot\mathbf{R}}$, which contains the spatial mode function of the radiation field. Using the standard procedure outlined in Sec. 23.5.4 we find the diagonal matrix of eigenvalues,

$$\hat{E}_n = \begin{pmatrix} n\omega + \frac{\varpi_n}{2} & 0 \\ 0 & n\omega - \frac{\varpi_n}{2} \end{pmatrix} . \tag{40.28}$$

From the transformation $\hat{H}_n \mathcal{U}_n = \mathcal{U}_n \hat{E}_n$, under the condition that $\mathcal{U}_n$ is unitary and Hermitian, $\mathcal{U}_n^\dagger \mathcal{U}_n$, and using the abbreviation $\tan 2\phi_n \equiv \sqrt{n}\Omega_1/\Delta$, we obtain:

$$\mathcal{U}_n = \begin{pmatrix} \cos\phi_n & \sin\phi_n \\ -\sin\phi_n & \cos\phi_n \end{pmatrix} . \tag{40.29}$$

The unitary matrix $\mathcal{U}_n$ describes the transform from the product state basis (40.23) to the dressed state basis (40.12), as illustrated in Fig. 40.4.

The temporal evolution of the Jaynes-Cummings state, $|\psi(t)\rangle = e^{-\imath \tilde{H}_{\text{atom:field}} t} |\psi(0)\rangle$, is described by the transformation,

$$\boxed{\begin{aligned} & e^{-\imath \hat{H}_n t} = \mathcal{U}_n e^{-\imath \hat{E}_n t} \mathcal{U}_n^\dagger = e^{-\imath n\omega t} \times \\ & \times \begin{pmatrix} \cos^2\phi_n e^{-\imath\varpi_n t/2} + \sin^2\phi_n e^{\imath\varpi_n t/2} & \cos\phi_n \sin\phi_n (e^{\imath\varpi_n t/2} - e^{-\imath\varpi_n t/2}) \\ \cos\phi_n \sin\phi_n (e^{\imath\varpi_n t/2} - e^{-\imath\varpi_n t/2}) & \sin^2\phi_n e^{-\imath\varpi_n t/2} + \cos^2\phi_n e^{\imath\varpi_n t/2} \end{pmatrix} \end{aligned}} , \tag{40.30}$$

which is essentially the same formula as for the time evolution of a two-level atom driven by a classical light field derived in Exc. 23.6.7.1. The transition probability between dressed states is,

$$|\langle 2, n-1 | e^{-\imath \hat{H}_n t} | 1, n \rangle|^2 = \frac{n\Omega_1^2}{\varpi_n^2} \sin^2 \frac{\varpi_n t}{2} . \tag{40.31}$$

The temporal evolution follows with [484],

$$\hat{\rho}(t) = e^{-\imath \hat{H}_n t} \hat{\rho}(0) e^{\imath \hat{H}_n t} \equiv \mathcal{L}(t) \hat{\rho}(0) . \tag{40.32}$$

Alternatively to the master equation (40.32) we could describe the time evolution of the system by Heisenberg equations, as done in Exc. 40.2.5.1.

40.2.2 Classical and quantum limits

40.2.2.1 The limit of high laser intensities and resonant interaction

The classical limit is recovered for $n \to \infty$, where a single photon makes no difference, that is, we can treat the states $|n\rangle$ and $|n+1\rangle$ as equivalent. Then, we can approximate the Hamiltonian of the system (40.21) by the trace of this same Hamiltonian taken over the number of photons,

$$\hat{H}_{\text{atom:field}} \simeq \hat{H}_{\text{semi}} = \lim_{n\to\infty} \text{Tr}_{\text{field}} \hat{\rho} \tilde{H}_{\text{atom:field}} = \sum_m \langle m | \hat{\rho} \tilde{H}_{\text{atom:field}} | m \rangle . \tag{40.33}$$

This situation, as illustrated in Fig. 40.5, describes well the state of a laser as a coherent state, $|\alpha\rangle = \sum_n \frac{\alpha^n}{\sqrt{n!}}|n\rangle e^{-|\alpha|^2/2}$. For $n \to \infty$, the uncertainty of the Poisson distribution is small, $\Delta n/\bar{n} = 1/\sqrt{n} \to 0$, such that the light mode is characterized by the average number of photons, and fluctuations are negligible. This allows us to replace the Poisson distribution, $P_n = |\langle n|\alpha\rangle|^2 = \delta_{n\bar{n}}$. The Hamiltonian (40.25) then becomes,

$$\hat{H}_{\text{semi}} = \hat{H}_{\text{field}} + \hat{H}_{\text{atom}} + \hat{H}_{\text{atom:field}} = \sum_m \langle m|\alpha\rangle\langle\alpha|\hat{H}|m\rangle = \langle\alpha|\hat{H}|\alpha\rangle \simeq \langle\bar{n}|\hat{H}|\bar{n}\rangle$$
$$= \hat{H}_{\bar{n}} = \begin{pmatrix} \bar{n}\omega & 0 \\ 0 & (\bar{n}-1)\omega \end{pmatrix} + \begin{pmatrix} -\frac{\omega_0}{2} & 0 \\ 0 & \frac{\omega_0}{2} \end{pmatrix} + \begin{pmatrix} 0 & \frac{\varpi_{\bar{n}}}{2} \\ \frac{\varpi^*_{\bar{n}}}{2} & 0 \end{pmatrix} . \tag{40.34}$$

Now, in the case of a resonant interaction, $\Delta = 0$, the Jaynes-Cummings evolution is,

$$\boxed{e^{-\imath\hat{H}_{\bar{n}}t} = \frac{1}{\sqrt{2}} e^{-\imath(\bar{n}-1/2)\omega t} \begin{pmatrix} \cos\frac{1}{2}\varpi_{\bar{n}}t & \imath\sin\frac{1}{2}\varpi_{\bar{n}}t \\ \imath\sin\frac{1}{2}\varpi_{\bar{n}}t & \cos\frac{1}{2}\varpi_{\bar{n}}t \end{pmatrix}} , \tag{40.35}$$

which is a result already obtained in Exc. 23.6.7.1.

Example 284 (*Resonant $\pi/2$-pulse*): In this example, we consider resonant $\pi/2$-pulses, that is, $\sqrt{\bar{n}}\Omega_1 t = \frac{1}{2}\pi$. The Jaynes-Cummings evolution now simplifies to,

$$e^{-\imath\hat{H}_{\bar{n}}t} = \frac{1}{2} e^{-\imath(\bar{n}-1/2)\omega t} \begin{pmatrix} 1 & \imath \\ \imath & 1 \end{pmatrix} . \tag{40.36}$$

For large $\bar{n}$, a resonant $\pi/2$-pulse does (ignoring irrelevant dynamical phases),

$$\begin{pmatrix} |1\rangle|\bar{n}\rangle \\ |2\rangle|\bar{n}-1\rangle \end{pmatrix} \overset{\pi/2}{\curvearrowright} \begin{pmatrix} (\imath|2\rangle|\bar{n}-1\rangle + |1\rangle|\bar{n}\rangle) \\ (|2\rangle|\bar{n}-1\rangle + \imath|1\rangle|\bar{n}\rangle) \end{pmatrix} , \tag{40.37}$$

that is, for a coherent field,

$$\begin{pmatrix} |1\rangle|\alpha\rangle \\ |2\rangle|\alpha\rangle \end{pmatrix} \overset{\pi/2}{\curvearrowright} \begin{pmatrix} (\imath|2\rangle + |1\rangle)|\alpha\rangle \\ (|2\rangle + \imath|1\rangle)|\alpha\rangle \end{pmatrix} . \tag{40.38}$$

Obviously, the structure of the field $|\alpha\rangle$ is not affected, and we recover the dynamics of a two-level atom excited by a resonant classical *radiation* as described by the Bloch equations (39.114). In the language of quantum computation the operation (40.36) corresponds to a Hadamard gate.

40.2.2.2 Dispersive interaction, the limit of large detunings

The dispersive Jaynes-Cummings dynamics can be implemented by irradiating a light field, which is sufficiently detuned to avoid Rayleigh scattering processes, as shown in Fig. 40.5. This interaction results in a phase shift of the atomic levels. For $|\Delta| \gg \sqrt{n}\Omega_1$ we consider the radiative coupling as a small perturbation,

$$\hat{H}_n = \hat{H}_n^{(0)} + \hat{H}_n^{(1)} = \begin{pmatrix} n\omega - \frac{\Delta}{2} & 0 \\ 0 & n\omega + \frac{\Delta}{2} \end{pmatrix} + \begin{pmatrix} 0 & \frac{\Omega_1}{2}\sqrt{n} \\ \frac{\Omega_1}{2}\sqrt{n} & 0 \end{pmatrix} . \tag{40.39}$$

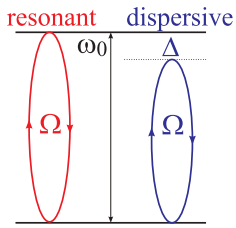

Figure 40.5: Atomic level scheme for the implementation of resonant interactions with classical radiation fields (on the lower transition) and dispersive interactions with quantum fields (on the upper transition).

In the unperturbed case we have, $\hat{H}_n^{(0)}|\psi_{j,n}\rangle = E_{j,n}|\psi_{j,n}\rangle$, where the n-photon subspace is spanned by the basis $|j\rangle = (1\ 0)$ and $(0\ 1)$. In second perturbation order,

$$\langle\psi_{j,n}|\hat{H}_n^{(1)}|\psi_{j,n}\rangle \simeq \cancelto{0}{\langle j|\hat{H}_n^{(1)} + \hat{H}_n^{(2)}|j\rangle} + \sum_{j\neq i} \frac{\langle j|\hat{H}_n^{(1)}|i\rangle\langle i|\hat{H}_n^{(1)}|j\rangle}{E_{j,n}^{(0)} - E_{i,n}^{(0)}} = \mp\frac{n\Omega_1^2}{4\Delta}\ , \quad (40.40)$$

where the upper sign holds for $|j\rangle = (1\ 0)$. This result was already obtained in the Excs. 27.1.3.4 and 39.4.4.13. In matrix notation [4],

$$\hat{H}_n^{(1)} \simeq \begin{pmatrix} n\Omega_1^2/4\Delta & 0 \\ 0 & -n\Omega_1^2/4\Delta \end{pmatrix}\ . \quad (40.41)$$

The temporal propagation operator (40.30) then simplifies to,

$$\boxed{e^{-\imath\hat{H}_n^{(1)}t} = \begin{pmatrix} e^{\imath n\Omega_1^2 t/4\Delta} & 0 \\ 0 & e^{-\imath n\Omega_1^2 t/4\Delta} \end{pmatrix}}\ . \quad (40.42)$$

The fact that the ground and excited atomic states evolve with different phase factors is important, as we will show in the following example.

Example 285 (*Dispersive π-pulse*): As in the previous case, we consider a two-level atom subject to a coherent field, but now tuned out of resonance. Introducing the abbreviation $\varphi \equiv \Omega_1^2 t/4\Delta$, the Jaynes-Cummings evolution is,

$$e^{-\imath\hat{H}_n^{(1)}t} = \begin{pmatrix} e^{\imath n\varphi} & 0 \\ 0 & e^{-\imath n\varphi} \end{pmatrix}\ . \quad (40.43)$$

The fact that the phase shift $n\varphi$ depends on the number of photons, and that it goes in opposite directions for the ground and excited states, is crucial. We

[4]Note, that the same perturbation expansion applied to the complete Hamiltonian in the interaction picture yields,

$$\tilde{H}_I^{(1)} = \begin{pmatrix} 0 & \frac{1}{2}\Omega_1\hat{a}^\dagger \\ \frac{1}{2}\Omega_1\hat{a} & 0 \end{pmatrix} = \tfrac{1}{2}\Omega_1\hat{a}\hat{\sigma}^+ + \tfrac{1}{2}\Omega_1\hat{a}^\dagger\hat{\sigma}^-$$
$$\simeq \frac{\tilde{H}_I^{(1)}|2\rangle\langle 2|\tilde{H}_I^{(1)}}{\omega_2-\omega_1} + \frac{\tilde{H}_I^{(1)}|1\rangle\langle 1|\tilde{H}_I^{(1)}}{\omega_1-\omega_2} = \tfrac{\Omega_1^2}{4\Delta}(\hat{\sigma}^-\hat{\sigma}^+\hat{a}^\dagger\hat{a} - \hat{\sigma}^+\hat{\sigma}^-\hat{a}\hat{a}^\dagger) = \tfrac{\Omega_1^2}{4\Delta}\begin{pmatrix} -\hat{a}^\dagger\hat{a} & 0 \\ 0 & \hat{a}\hat{a}^\dagger \end{pmatrix}\ .$$

have already studied in Exc. 39.7.3.9, that the dispersive interaction of the atom with a radiation field can phase-shift the Bloch vector. Now, we observe that in addition, it causes a phase shift of the probability amplitude of having n photons in the radiation field by a value proportional to n, i.e. (ignoring irrelevant dynamical phases),

$$\begin{pmatrix} |1\rangle|n\rangle \\ |2\rangle|n-1\rangle \end{pmatrix} \overset{n\varphi}{\curvearrowright} \begin{pmatrix} e^{-\imath n\varphi}|1\rangle|n\rangle \\ e^{\imath n\varphi}|2\rangle|n-1\rangle \end{pmatrix} . \tag{40.44}$$

Applying this result to Glauber states,

$$\begin{pmatrix} |1\rangle|\alpha\rangle \\ |2\rangle|\alpha\rangle \end{pmatrix} \overset{n\varphi}{\curvearrowright} \begin{pmatrix} |1\rangle \sum_n \frac{\alpha^n}{\sqrt{n!}} e^{-\imath n\varphi}|n\rangle \\ |2\rangle \sum_n \frac{\alpha^n}{\sqrt{n!}} e^{\imath n\varphi}|n\rangle \end{pmatrix} = \begin{pmatrix} |1\rangle|\alpha e^{-\imath\varphi}\rangle \\ |2\rangle|\alpha e^{\imath\varphi}\rangle \end{pmatrix} . \tag{40.45}$$

Apparently, the phase of the radiation field is shifted by a value φ, which depends on the state of the atom.

We note here, that the dynamics studied in the last example provides a method of *transferring coherence from an atomic superposition to a quantum correlation of a radiation field*. All we have to do, is to bring the atom into a superposition of states $|1\rangle + |2\rangle$, and the field will automatically evolve toward a Schrödinger cat state $|\alpha e^{\imath\varphi}\rangle + |\alpha e^{-\imath\varphi}\rangle$. The transfer of quantum correlations between coupled degrees of freedom can induce a temporal complete disappearance of any signatures of quantum coherence in the light field. This phenomenon termed *quantum collapse and revival* is genuine of the Jaynes-Cummings model and will be studied in Excs. 40.2.5.2 and 40.2.5.3. Another phenomenon is *vacuum Rabi splitting*, which will be studied in 40.2.5.4.

40.2.3 Observables and correlations of the Jaynes-Cummings dynamics

In the limit of low laser intensities we must consider photonic distributions that are not necessarily coherent. The stationary solution of the Schrödinger equation consists of the dressed states $|1, n\rangle$ and $|2, n-1\rangle$. If we now expand a general Jaynes-Cummings state in amplitudes $c_{jn}(t)$,

$$|\psi\rangle = \sum_n (c_{1,n}|1, n\rangle + c_{2,n-1}|2, n-1\rangle) , \tag{40.46}$$

they will follow the Schrödinger equation,

$$\imath\hbar \frac{d}{dt} \begin{pmatrix} c_{1,n} \\ c_{2,n-1} \end{pmatrix} = \hat{H}_n \begin{pmatrix} c_{1,n} \\ c_{2,n-1} \end{pmatrix} . \tag{40.47}$$

The evolution of the coefficients c_{jn} completely describes the Jaynes-Cummings dynamics of the system through the formula (40.30). Obviously, the Jaynes-Cummings state is normalized because,

$$\langle\psi|\psi\rangle = \mathrm{Tr}_{\text{field}}\ |\psi\rangle\langle\psi| = \sum_{n=0}^{\infty} (|c_{1,n}|^2 + |c_{2,n}|^2) = 1 . \tag{40.48}$$

As dissipation processes are neglected, we get a pure state described by,

$$\hat{\rho} = |\psi\rangle\langle\psi| \ . \tag{40.49}$$

The Jaynes-Cummings dynamics involves two coupled degrees of freedom characterized by with their respective observables. If we are interested in them, we can do two things: (a) We ignore the degrees of freedom NOT under study by NOT DOING a measurement of the other degrees. That is, we simply remove the non-interesting degrees of freedom from the state. For example, if our focus is on the optical mode, we ignore the atomic state,

$$|\gamma\rangle \equiv \sum_{j=1,2} \langle j|\psi\rangle = \sum_n c_{1,n}|n\rangle + c_{2,n-1}|n-1\rangle \ . \tag{40.50}$$

Our new density operator remains pure, that is,

$$\hat{\rho}^{(\text{pure})}_{\text{field}} = \sum_{i,j=1,2} \langle j|\hat{\rho}|i\rangle = \sum_{i,j=1,2} \langle j|\psi\rangle\langle\psi|i\rangle = |\gamma\rangle\langle\gamma| \ . \tag{40.51}$$

On the other hand, ignoring the optical mode via,

$$|\gamma\rangle \equiv \sum_n \langle n|\psi\rangle = \sum_n c_{1,n}|1\rangle + c_{2,n-1}|2\rangle \ . \tag{40.52}$$

Again, our new density operator remains pure, that is,

$$\hat{\rho}^{(\text{pure})}_{\text{atom}} = \sum_{m,n} \langle m|\hat{\rho}|n\rangle = \sum_{m,n} \langle m|\psi\rangle\langle\psi|n\rangle = |\gamma\rangle\langle\gamma| \ . \tag{40.53}$$

(b) We trace over the degrees of freedom NOT under study by DOING a measurement. For example, if again our focus is on the optical mode, we trace over the atomic states,

$$\begin{aligned} \hat{\rho}^{(\text{mix})}_{\text{field}} &= \text{Tr}_{\text{atom}}\ \hat{\rho} = \sum_{j=1,2} \langle j|\hat{\rho}|j\rangle = \sum_{j=1,2} \langle j|\psi\rangle\langle\psi|j\rangle \\ &= \sum_{n,m} c^*_{1,m} c_{1,n} |n\rangle\langle m| + c^*_{2,m-1} c_{2,n-1} |n-1\rangle\langle m-1| \neq \hat{\rho}^{(\text{pure})}_{\text{field}} \ . \end{aligned} \tag{40.54}$$

It is clear, that this incomplete measurement converts the reduced density operator into a statistical mixture, which is free of inneratomic correlations of the type $c^*_{2,m}c_{1,n}$, but this means that we also loose possible field correlations. On the other hand, tracing over the field mode,

$$\begin{aligned} \hat{\rho}^{(\text{mix})}_{\text{atom}} &= \text{Tr}_{\text{field}}\ \hat{\rho} = \sum_{n=0}^{\infty} \langle n|\hat{\rho}|n\rangle = \sum_{n=0}^{\infty} \langle n|\psi\rangle\langle\psi|n\rangle \\ &= \sum_n \left(c_{1,n}|1\rangle + c_{2,n}|2\rangle\right)\left(c^*_{1,n}\langle 1| + c^*_{2,n}\langle 2|\right) \neq \hat{\rho}^{(\text{pure})}_{\text{atom}} \ . \end{aligned} \tag{40.55}$$

After these preliminary remarks let us have a look a some interesting observables.

40.2.3.1 Temporal evolution of the Bloch vector

The expectation value for field observables $\hat{A}|n\rangle = A_n|n\rangle$ is,

$$\langle\psi|\hat{A}|\psi\rangle = \mathrm{Tr}\ \hat{\rho}\hat{A}\sum_{i,n}\langle i|\langle n|\psi\rangle\langle\psi|\hat{A}|n\rangle|i\rangle = \sum_n A_n(|c_{1,n}|^2 + |c_{2,n}|^2)\ . \tag{40.56}$$

An example for a field observable is the photon number operator $\hat{n}$. And for the annihilation operator $\hat{a}|n\rangle = \sqrt{n}|n\rangle$ we have,

$$\langle\psi|\hat{a}|\psi\rangle = \sum_n \sqrt{n}(c^*_{1,n-1}c_{1,n} + c^*_{2,n-1}c_{2,n})\ . \tag{40.57}$$

To determine the internal state of the atom, we must trace over the light field. The populations and coherences are, therefore,

$$\boxed{\rho_{ij} = \langle i|\mathrm{Tr}_{\mathrm{field}}\ \hat{\rho}|j\rangle = \langle i|\sum_n\langle n|\psi\rangle\langle\psi|n\rangle|j\rangle = \sum_n c_{i,n}c^*_{j,n}}\ . \tag{40.58}$$

The projection onto the atomic state is done by,

$$\frac{|j\rangle\langle j|\psi\rangle}{\langle\psi|j\rangle\langle j|\psi\rangle} = \frac{\sum_m c_{j,n}|j,n\rangle}{\sum_m |c_{j,m}|^2}\ . \tag{40.59}$$

With (40.58), we can calculate the atomic Bloch vector (39.126), whose norm is interestingly NOT preserved, since,

$$\begin{aligned}|\vec{\rho}| = \left\|\begin{pmatrix} 2\ \mathfrak{Re}\,\rho_{12} \\ 2\ \mathfrak{Im}\,\rho_{12} \\ \rho_{22}-\rho_{11}\end{pmatrix}\right\| &= 2|\rho_{12}|^2 - 2\rho_{11}\rho_{22} = -2\det\hat{\rho} \\ &= 2\sum_n c_{1,n}c^*_{2,n}\sum_n c^*_{1,n}c_{2,n} - 2\sum_n|c_{2,n}|^2\sum_n|c_{1,n}|^2 \neq 1\ .\end{aligned} \tag{40.60}$$

40.2.3.2 The photon number distribution

To determine the state of the light field, we must trace over the atomic state. For example, the probability amplitude of encountering the state $|\psi\rangle$ in $|n\rangle$ is,

$$\langle n|\psi\rangle = c_{1,n}|1\rangle + c_{2,n}|2\rangle\ , \tag{40.61}$$

such that,

$$\boxed{p_n = \langle n|\mathrm{Tr}_{\mathrm{atom}}\ \hat{\rho}|n\rangle = \langle n|\sum_{i=1,2}\langle i|\psi\rangle\langle\psi|i\rangle|n\rangle = |\langle n|\psi\rangle|^2 = |c_{1,n}|^2 + |c_{2,n}|^2}\ . \tag{40.62}$$

40.2.3.3 The Glauber-Sudarshan Q-function

To characterize the optical field separately from the atomic state, we can try, by a calculation similar to (40.56), to project the Jaynes-Cummings state onto a basis of

coherent states. Thus, the probability amplitude of encountering the state $|\psi\rangle$ in $|\alpha\rangle$ is,

$$\langle\alpha|\psi\rangle = e^{-|\alpha|^2/2}\sum_n \frac{\alpha^{*n}}{\sqrt{n!}}(c_{1,n}|1\rangle + c_{2,n}|2\rangle) \tag{40.63}$$

$$|\langle\alpha|\psi\rangle|^2 = e^{-|\alpha|^2}\sum_n \frac{\alpha^{*n}\alpha^m}{\sqrt{n!}\sqrt{m!}}(c^*_{1,m}c_{1,n} + c^*_{2,m}c_{2,n}) \ ,$$

such that,

$$\boxed{\pi Q(\alpha) \equiv \langle\alpha|\mathrm{Tr}_{\mathrm{atom}}\ \hat{\rho}|\alpha\rangle = e^{-|\alpha|^2}\left(\left|\sum_n c_{1,n}\frac{\alpha^n}{\sqrt{n!}}\right|^2 + \left|\sum_n c_{2,n}\frac{\alpha^n}{\sqrt{n!}}\right|^2\right)} \ . \tag{40.64}$$

We will derive this result in Exc. 40.2.5.5. This quantity, called *Q-function*, allows the illustration of the state in a coordinate system spanned by $\mathfrak{Re}\,\alpha$ and $\mathfrak{Im}\,\alpha$ [103]. It is generally easy to calculate, but does not exhibit much information, e.g., on interference phenomena caused by quantum correlations. In the following section, we will calculate the Wigner function, which can also be evaluated from the Jaynes-Cummings coefficients [291].

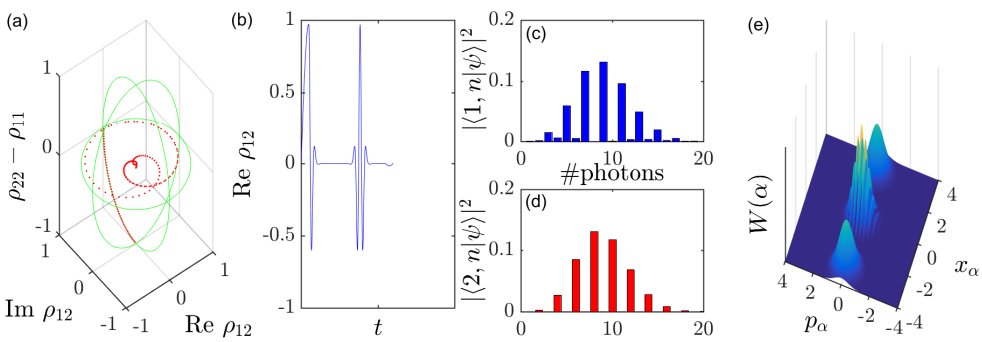

Figure 40.6: (code) Evolution of the state during a Jaynes-Cummings type interaction: (a) Bloch vector, (b,c) photon distribution after projection on the ground and excited atomic state, (d) time evolution of the coherence ρ_{12} showing the phenomenon of collapse and revival, and (e) $W(\alpha)$ function.

The Jaynes-Cummings dynamics illustrated in Fig. 40.6 demonstrates the transfer of coherence between an atom and a light field. In Exc. 40.2.5.6 we study how to create, via a sequence of Ramsey pulses, a Schrödinger cat state in a light field.

40.2.3.4 The Wigner function in the Glauber picture

We found in (40.42) that a dispersive phase shift of the atomic state $|2\rangle$ leads to a time-dependent phase shift of the Glauber field,

$$|\psi\rangle = \sum_{\mathrm{N}}(c_{1,n}|1,n\rangle + c_{2,n-1}|2,n-1\rangle) = |1,\beta\rangle + e^{\imath\varphi(t)}|2,\beta\rangle \quad \text{or} \quad \hat{\rho} = |\psi\rangle\langle\psi| \ , \tag{40.65}$$

with

$$c_{1,n} = e^{-|\beta|^2/2}\frac{\beta^n}{\sqrt{n!}} \qquad \text{and} \qquad c_{2,n} = e^{-|\beta|^2/2}\frac{(e^{\imath\varphi(t)}\beta)^n}{\sqrt{n!}} \ . \tag{40.66}$$

We will now concentrate on the field state by explicitly IGNORING the atomic states $|j\rangle$,

$$|\gamma\rangle = \sum_{j=1,2}\langle j|\psi\rangle = |\beta\rangle + |e^{\imath\varphi}\beta\rangle \qquad \text{or} \qquad \hat{\rho}^{(\text{pure})}_{\text{field}} = \sum_{i,j=1,2}\langle j|\psi\rangle\langle\psi|i\rangle = |\gamma\rangle\langle\gamma| \ . \tag{40.67}$$

From the optical cat pure state wavefunction (40.67), we can easily calculate the Wigner function in the Glauber picture, as done in (37.90) and Exc. 37.3.5.10,

$$\boxed{W(\alpha) = \frac{2}{C^2\pi}\left(e^{-2|\alpha-\beta|^2} + e^{-2|\alpha-\beta e^{\imath\varphi}|^2} \pm 2e^{-|\beta|^2}\mathfrak{Re}\, e^{-2(\beta e^{\imath\varphi}-\alpha)(\beta^*-\alpha^*)+|\beta|^2 e^{\imath\varphi}}\right)} \ . \tag{40.68}$$

Now, what happens if we MEASURE the atomic state before we analyze the field state? The incomplete measurement corresponds to tracing over the atomic degrees of freedom, which transforms our initially pure state (40.65) into a statistical mixture. With $|\psi\rangle$ given by (40.65),

$$\hat{\rho}^{(\text{mix})}_{\text{field}} = \text{Tr}_{\text{atom}}\hat{\rho} = \sum_{j=1,2}\langle j|\psi\rangle\langle\psi|j\rangle = |\beta\rangle\langle\beta| + |e^{\imath\varphi}\beta\rangle\langle e^{\imath\varphi}\beta| \neq |\gamma\rangle\langle\gamma| \ . \tag{40.69}$$

Calculating the Wigner function from this density operator consequently must yield a different result, because any correlations are lost. A movie of the dynamics can be watched here (watch movie) [151, 233, 10, 931].

40.2.3.5 The Wigner function in the Fock picture

Let us now calculate the Wigner function in the Fock state picture. This will allow us to consider more general states later on. We start from the expansion,

$$|\psi\rangle = \sum_n c_{1,n}|1,n\rangle + c_{2,n-1}|2,n-1\rangle \ . \tag{40.70}$$

As before, we can now choose to DO or NOT DO a measurement of the atomic state. If we do a measurement tracing over the atomic states, we calculate the normally ordered characteristic function using the density operator (40.54),

$$\begin{aligned}\chi_{\text{N}}(\lambda) &= \text{Tr}\ \hat{\rho}^{(\text{mix})}_{\text{field}} e^{\lambda\hat{a}^\dagger} e^{-\lambda^*\hat{a}} = \sum_{n'}\langle n'|\hat{\rho}^{(\text{mix})}_{\text{field}} e^{\lambda\hat{a}^\dagger} e^{-\lambda^*\hat{a}}|n'\rangle \\ &= \sum_{n,m} c^*_{1,m}c_{1,n}\langle m|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n\rangle + c^*_{2,m-1}c_{2,n-1}\langle m-1|e^{\lambda\hat{a}^\dagger}e^{-\lambda^*\hat{a}}|n-1\rangle \ .\end{aligned} \tag{40.71}$$

Obviously, this formula does not contain inneratomic correlations and, since non-classical field correlation would be entangled with atomic superposition states, we expect no interesting field correlations, neither.

If on the other hand we decide to ignore the atomic state, we calculate the normally ordered characteristic function using the density operator (40.51),

$$\begin{aligned}\chi_{\rm N}(\lambda) &= {\rm Tr}\ \hat\rho^{\rm (pure)}_{\rm field} e^{\lambda\hat a^\dagger} e^{-\lambda^*\hat a} = \langle\gamma|e^{\lambda\hat a^\dagger} e^{-\lambda^*\hat a}|\gamma\rangle \\ &= \sum_{n,m}\Big(c^*_{1,m}c_{1,n}\langle m|e^{\lambda\hat a^\dagger} e^{-\lambda^*\hat a}|n\rangle + c^*_{2,m-1}c_{2,n-1}\langle m-1|e^{\lambda\hat a^\dagger} e^{-\lambda^*\hat a}|n-1\rangle \\ &\qquad + c^*_{1,m}c_{2,n-1}\langle m|e^{-\lambda\hat a^\dagger} e^{\lambda^*\hat a}|n-1\rangle + c^*_{2,m-1}c_{1,n}\langle m-1|e^{\lambda\hat a^\dagger} e^{-\lambda^*\hat a}|n\rangle\Big)\ ,\end{aligned} \tag{40.72}$$

which now contains field correlations. Inserting the results derived in (37.81) we can express the characteristic functions by Laguerre polynomials and obtain the Wigner function as the two-dimensional FFT according to Eq. (40.68). This will be done in Exc. 40.2.5.8.

40.2.4 Jaynes-Cummings model with dissipation

Applying the numerical method of *quantum Monte Carlo wavefunction simulation* to the Jaynes-Cummings model, we write the effective Hamiltonian of the light field as [343],

$$\hat H_{\rm eff} = \omega\hat a^\dagger\hat a + \omega_0\left(\hat\sigma^+\hat\sigma - \tfrac12\right) + \tfrac{\Omega_1}{2}\left(\hat a\hat\sigma^+ + \hat a^\dagger\hat\sigma^-\right) + \tfrac{\imath\Gamma}{2}\hat\sigma^+\hat\sigma^-\ . \tag{40.73}$$

Or in matrix notation,

$$H_{\rm eff} = \begin{pmatrix} -\frac12\omega_0 & 0 & & & & & \\ 0 & \omega-\frac12\omega_0 & \frac12\Omega_1 & & & & \\ & \frac12\Omega_1 & \frac12\omega_0-\frac{\imath}{2}\Gamma & 0 & & & \\ & & 0 & 2\omega-\frac12\omega_0 & \sqrt2\frac12\Omega_1 & & \\ & & & \sqrt2\frac12\Omega_1 & \omega+\frac12\omega_0-\frac{\imath}{2}\Gamma & 0 & \\ & & & & 0 & 3\omega-\frac12\omega_0 & \\ & & & & & & \ddots \end{pmatrix}\ . \tag{40.74}$$

The simulation flowchart is,

$$\boxed{\begin{aligned}&|\psi\rangle \to \tfrac{|1\rangle(\langle 1|+\langle 2|)|\psi\rangle}{|(\langle 1|+\langle 2|)|\psi\rangle|} \\ &= \tfrac{|1\rangle\sum_n(c_{1n}|n\rangle)+c_{2n-1}|n-1\rangle)}{\sqrt{\sum_n|c_{1n}+c_{2n}|^2|}}\end{aligned}}$$

projection

$$\boxed{\begin{aligned}&|\psi\rangle \to \tfrac{|\psi\rangle}{||\psi\rangle|} \\ &= \tfrac{\sum_n c_{1n}|1\rangle|n\rangle+c_{2n-1}|2\rangle|n-1\rangle}{\sqrt{\sum_n(|c_{1n}|^2+|c_{2n}|^2)}}\end{aligned}}$$

renormalization

↘ ↙

dynamic evolution

$$\boxed{|\psi(t+dt)\rangle = e^{-\imath H_{\rm eff}dt}|\psi\rangle}$$

↓

$$\boxed{\zeta \overset{?}{>} \langle\psi(t+dt)|\psi(t+dt)\rangle}$$

random variable

↖ yes ↗ no

Absorption or scattering of light causes the optical field to decay as $\alpha(t) \propto e^{-\kappa t/2}$. The projection (in component notation) is implemented by,

$$c'_{jn} \equiv \frac{1}{\sqrt{\sum_n(|c_{1n}|^2+|c_{2n}|^2)}}c_{jn}\ , \tag{40.75}$$

and the dynamical evolution by $c'_{jn} \equiv e^{-\kappa n t/2} c_{jn}$. Note, that the dissipation due to cavity losses can also be taken into account by a *master equation*.

40.2.5 Exercises

40.2.5.1 Ex: Time-evolution in the Jaynes-Cummings model

Derive the equations of motion for $\hat{\sigma}^-$, $\hat{\sigma}_z$, and $\hat{a}$ in the Jaynes-Cummings model. Show that the number of photons is not a constant of motion, but the total number of excitations.

40.2.5.2 Ex: The Jaynes-Cummings model

Consider the Jaynes-Cummings Hamiltonian.
a. Determine from the Schrödinger equation the system of differential equations for the temporal evolution of the coefficients $c_{2,n}(t)$ and $c_{1,n+1}(t)$ in the interaction picture within the rotating wave approximation (RWA).
b. Calculate the time evolution for the start condition $c_{2,n}(0) = 1$ and $c_{1,n+1}(0) = 0$ for the particular case $\omega = \omega_0$.
c. Generalize the result of item (a) for a multimode field, for which initially (i) all modes of field $\mathbf{k}$ are empty $|0\rangle$ and (ii) the atom is in the excited state $|a\rangle$. Use the ansatz,

$$|\psi(t)\rangle = c_2(t) e^{-\imath E_2 t/\hbar} |2, 0\rangle + \sum_{\mathbf{k}} c_{1,\mathbf{k}}(t) e^{-\imath [E_1/\hbar + \omega_{\mathbf{k}}] t} |1, 1_{\mathbf{k}}\rangle \ ,$$

and determine the equations of motion for the amplitudes c_2 and $c_{1,\mathbf{k}}$.

40.2.5.3 Ex: Quantum collapse and revival in the Jaynes-Cummings model

Consider the Jaynes-Cummings Hamiltonian and show that the quantum coherence between the two atomic levels can disappear altogether for long periods and reappear later. Explain how this is possible.

40.2.5.4 Ex: Vacuum Rabi splitting

Calculate the Autler-Townes splitting for an excited atom interacting with an empty cavity.

40.2.5.5 Ex: The Q-function in a Jaynes-Cummings state

Calculate the Q-function for a Jaynes-Cummings state from its definition (40.64).

40.2.5.6 Ex: Creation of quantum correlations in an optical mode

a. We will show in this exercise how, via coherent operations in a three-level system, we can create Schrödinger-type quantum-type correlations in an optical mode. In the system shown in Fig. 40.7 we imagine the lower transition excited by $\pi/2$-pulses of a classical resonant microwave radiation (as described by the operation (40.35)). The upper transition is excited by quantum laser pulses tuned very far out of resonance,

thus creating a dispersive dynamics (as described by the operation (40.35)). At time $t = 0$ the atom is in state $|1\rangle$. Now, we apply the following pulse sequence: (i) a microwave pulse with $\sqrt{\bar{n}}\Omega_{12}t = \pi/2$, (ii) an optical pulse with $\Omega_{23}^2 t/4\Delta_{23} = \pi$, (iii) another microwave $\pi/2$-pulse, and finally (iv) an optical pulse of light which is resonant with the transition $|2\rangle$-$|3\rangle$ and projects the population of the atom into one of the states of the microwave transition. Describe the evolution of the state of the system during the sequence and determine the final state of the optical mode.
b. Calculate the number of photons for the two cases that, after a measurement, the atom is found in (i) the lower state and (ii) the upper state. Interprete the results.

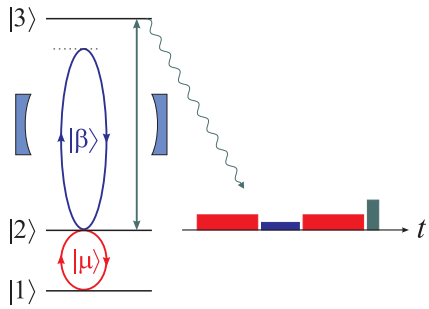

Figure 40.7: (a) Level scheme and (b) pulse sequence.

40.2.5.7 Ex: Master equation derived from JC model Hamiltonian for two-level systems

Write down the Liouvillean for a JC system in matrix form for a density operator defined like,

$$\begin{pmatrix} \cdots & \rho_{11}^{n-1} & \rho_{22}^{n} & \rho_{12}^{n} & \rho_{21}^{n} & \rho_{11}^{n} & \rho_{22}^{n+1} & \cdots \end{pmatrix} .$$

40.2.5.8 Ex: Laguerre polynomials

Calculate the Wigner function for the field generated by a Jaynes-Cummings dynamics in the photon picture.

40.3 Correlation functions

In the preceding sections and in Sec. 37.3 we have learned, how to characterize quantum fields by (quasi-)probability distribution functions, and how to represent correlations in the Fock or the Glauber basis. But we did not propose experimental schemes allowing to detect them. Experimental devices, such as interferometers or photon correlators, necessarily involve space or time coordinates. Hence, we need to devise quantities for the characterization of correlations, that are compatible with experimental devices. The *correlation functions* are such quantities, and in the next section we will focus our attention them.

In order to be able to distinguish classical from genuinely quantum correlations, we will first a classical description, before introducing a quantum description of the light field [590].

40.3.1 Classical first and second order coherence

The coherence properties of a light field (or a matter wave) are measured by n^{th} space time order correlation functions. In quantum mechanics, these are defined by,

$$g^{(n)}(\mathbf{r}_1,t_1,..,\mathbf{r}_{2n},t_{2n}) \equiv \frac{\langle \hat{\mathcal{E}}^-(\mathbf{r}_1,t_1)..\hat{\mathcal{E}}^-(\mathbf{r}_n,t_n)\hat{\mathcal{E}}^+(\mathbf{r}_{n+1},t_{n+1})..\hat{\mathcal{E}}^+(\mathbf{r}_{2n},t_{2n})\rangle}{\sqrt{\langle \hat{\mathcal{E}}^-(\mathbf{r}_1,t_1)\hat{\mathcal{E}}^+(\mathbf{r}_1,t_1)\rangle..\langle \hat{\mathcal{E}}^-(\mathbf{r}_{2n},t_{2n})\hat{\mathcal{E}}^+(\mathbf{r}_{2n},t_{2n})\rangle}} \ . \tag{40.76}$$

In the following, we will only consider temporal coherences, e.g. one or more collinear light beams, $\mathbf{k}_m \parallel \mathbf{k}_n$, impinging on a photodetector, $(t_m - \frac{z_m}{c}) - (t_n - \frac{z_n}{c}) = \tau$, since $\hat{\mathcal{E}}(\mathbf{r},t) = \hat{\mathcal{E}}(\omega t - \mathbf{k}\cdot\mathbf{r})$, we can define the the 1st and 2nd order correlation functions $g^{(1)}$ and $g^{(2)}$, which are particularly important,

$$\boxed{g^{(1)}(\tau) \equiv \frac{\langle \hat{\mathcal{E}}^-(t)\hat{\mathcal{E}}^+(t+\tau)\rangle}{\langle \hat{\mathcal{E}}^-(t)\hat{\mathcal{E}}^+(t)\rangle} \qquad \text{and} \qquad g^{(2)}(\tau) \equiv \frac{\langle \hat{\mathcal{E}}^-(t)\hat{\mathcal{E}}^-(t+\tau)\hat{\mathcal{E}}^+(t+\tau)\hat{\mathcal{E}}^+(t)\rangle}{\langle \hat{\mathcal{E}}^-(t)\hat{\mathcal{E}}^+(t)\rangle^2}} \ . \tag{40.77}$$

Ignoring the quantized nature of light, we may substitute the field operators by complex numbers, $\hat{\mathcal{E}}^+ \to \mathcal{E}$ and $\hat{\mathcal{E}}^- \to \mathcal{E}^*$ and interprete the brackets as pure time averages,

$$\langle \cdots \rangle_t = \lim_{t\to\infty} \frac{1}{t}\int_0^t \cdots dt' \ . \tag{40.78}$$

Defining the intensity as $I = 2\varepsilon_0 c \mathcal{E}^*\mathcal{E}$, the coherences become,

$$g^{(1)}(\tau) \equiv \tfrac{2\varepsilon_0 c}{I}\langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle \qquad \text{and} \qquad g^{(2)}(\tau) \equiv \left(\tfrac{2\varepsilon_0 c}{I}\right)^2 \langle I(t)I(t+\tau)\rangle \ . \tag{40.79}$$

The correlation functions must be calculated from the field operators simultaneously respecting *time order* and *normal order*. These functions are useful quantities to describe phenomena such as photon *bunching* or to understand the fluorescence spectra or the scattering of light from correlated atoms. $g^{(1)}$ measures the *coherence* of a light field (how much it resembles a sine wave). $g^{(2)}$ measures, for a given degree of coherence, the deviation of the light field from the quantum state that most closely approximates a classical light (how much it resembles a laser).

The correlation functions $g^{(1)}$ and $g^{(2)}$ are experimentally measured in *Young's experiment* and in the *Hanbury Brown-Twiss experiment*. The experimental schemes are explained in Figs. 40.8.

Coherence and chaos are contrary properties of light. They leave their imprint in the spectrum of the light or in the autocorrelation functions. The emission spectrum of a light source generally emerges as a combination of various physical effects: The active medium gives rise resonances and broadenings, a resonator containing the active medium imprints a modal structure, and the coupling to a thermal bath gives rise to a thermal distribution of the radiation energy according to $P_n = e^{-\hbar\omega(n+1/2)/k_BT} / \sum_n e^{-\hbar\omega(n+1/2)/k_BT}$.

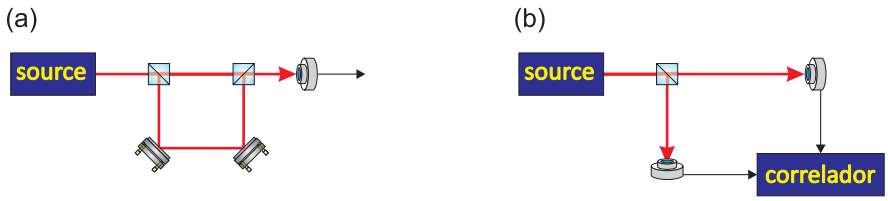

Figure 40.8: (a) Scheme of Young's experiment. (b) Scheme of the experiment of Hanbury, Brown, and Twiss. Young's experiment reveals the coherence of a field, that is, its ability to interfere. In contrast, the Hanbury-Brown-Twist experiment reveals correlations between the (quasi-)particles constituting the field, that is, effects due to quantum statistics or interactions.

40.3.2 The Wiener-Khintchine theorem

When the time dependence of a wave is given by $\mathcal{E}(t)$, we call

$$R_{\mathcal{E}}(\tau) = \langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle_t \tag{40.80}$$

the autocorrelation function and the power density

$$S_{\mathcal{E}}(\omega) = (\mathcal{F}R_{\mathcal{E}})(\omega) = |(\mathcal{F}\mathcal{E})(\omega)|^2 \tag{40.81}$$

the *spectrum*. This relation is called the *Wiener-Khintchine theorem*. We may also consider the normalized quantities, dividing (40.80) and (40.81) by $R_{\mathcal{E}}(0) = \langle \hat{\mathcal{E}}^*(t)\hat{\mathcal{E}}(t)\rangle_t = \int_{-\infty}^{\infty} |(\mathcal{F}\mathcal{E})(\omega)|^2 d\omega = \int_{-\infty}^{\infty} S_{\mathcal{E}}(\omega)d\omega$. We obtain,

$$g^{(1)}(\tau) = \frac{R_{\mathcal{E}}(\tau)}{R_{\mathcal{E}}(0)} \ , \tag{40.82}$$

and,

$$\boxed{F_{\mathcal{E}}(\omega) \equiv (\mathcal{F}g^{(1)})(\omega) = \frac{S_{\mathcal{E}}(\omega)}{R_{\mathcal{E}}(0)} = \frac{1}{2\pi}\int_{-\infty}^{\infty} g^{(1)}(\tau)e^{\imath\omega\tau}d\tau} \ . \tag{40.83}$$

The quantity $F_{\mathcal{E}}(\omega)$ is called line profile or *spectrum*. Note that, since,

$$g^{(1)}(-\tau) = g^{(1)}(\tau)^* \ , \tag{40.84}$$

we may also write,

$$F_{\mathcal{E}}(\omega) = \mathfrak{Re}\,\frac{1}{\pi}\int_0^{\infty} g^{(1)}(\tau)e^{\imath\omega\tau}d\tau \ . \tag{40.85}$$

Furthermore,

$$g^{(2)}(-\tau) = g^{(2)}(\tau) \ . \tag{40.86}$$

40.3.3 Coherent and chaotic light

The temporal and spectral properties of a light field are largely determined by the processes leading to its generation in the light source, that is, whether the light is

generated by stimulated or spontaneous emission, by a laser or by blackbody radiation, by a single atom or by atomic gases subject to collisional and Doppler-broadening. As we have seen above, these properties can be characterized by correlation functions, which can be calculated from models describing the temporal behavior of the electric field $\vec{\mathcal{E}}(t)$.

Before we do this for some examples, let us anticipate some important results. Zero delay correlation functions are easy to calculate for states whose density operator is known. For some systems we derived them previously:

Table 40.1: Zero delay correlation functions for various types of light fields.

correlation function	first order	second order
coherent	$g^{(1)}(0) = 1$	$g^{(2)}(0) = 1$
2nd order coherent	$g^{(1)}(0) = 1$	$g^{(2)}(0) \geq 1$
thermal	$g^{(1)}(0) = 1$	$g^{(2)}(0) = 2$
squeezed	$g^{(1)}(0) = 1$	$g^{(2)}(0) = 3 + \frac{1}{\sinh^2 r}$
bunched	$g^{(1)}(0) = 1$	$g^{(2)}(0) > 1$
anti-bunched	$g^{(1)}(0) = 1$	$g^{(2)}(0) < 1$

The temporal behavior of the correlation functions is more tricky and requires some modeling of the light emission processes: Let us now look at some specific

Table 40.2: Time dependent correlation functions for various types of light fields.

correlation function	first order	second order
perfectly coherent monochrom.	$\lvert g^{(1)}(\tau)\rvert = 1$	$\begin{cases} 0 \leq g^{(2)}(\tau) \leq \infty \\ g^{(2)}(0) \geq g^{(2)}(\tau) \xrightarrow{\tau \gg \tau_c} 1 \end{cases}$
perfectly chaotic (incoherent)	$\lvert g^{(1)}(\tau)\rvert = \delta(0)$	$g^{(2)}(\tau) = 1 + \lvert g^{(1)}(\tau)\rvert^2$
partially coherent	$\lvert g^{(1)}(\tau)\rvert < \infty$	
bichromatic or modulated	Excs. 40.3.6.1 to 40.3.6.3	

cases, for which the correlation functions and spectra can be calculated.

40.3.3.1 Correlation functions for laser light

With the definitions (40.77) it is easy to calculate the autocorrelation functions and the spectrum of a *laser* light field,

laser

$$\begin{aligned}
\mathcal{E}(t) &= e^{\imath\omega_0 t} \\
\Longrightarrow \quad g^{(1)}(\tau) &= \frac{t^{-1}\int e^{-\imath\omega_0\tau}dt}{t^{-1}\int dt} = e^{-\imath\omega_0\tau} \\
\Longrightarrow \quad \mathcal{F}\left[g^{(1)}(\tau)\right] &= \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{\imath(\omega-\omega_0)\tau}d\tau = \delta(\Delta) \\
g^{(2)}(\tau) &= 1
\end{aligned} \quad . \tag{40.87}$$

We see that the absolute values of the first and second-order coherences are constant, and that the spectrum is narrow like a δ-function.

40.3.3.2 Correlation functions for chaotic light

For a totally emission *chaotic light*,

chaotic light

$$\begin{aligned}
g^{(1)}(\tau) &= \delta(0) \\
\mathcal{F}[g^{(1)}(\tau)] &= 1 \\
g^{(2)}(\tau) &= 1 + |g^{(1)}(\tau)|
\end{aligned} \quad . \tag{40.88}$$

The last expression is known as *Siegert relation*. Mono-mode chaotic light can be seen as incoherent multi-mode light, where all modes except a single mode are filtered by a Fabry-Pérot etalon. This light is characterized by $|g^{(1)}(\tau)| = 1$ and $g^{(2)}(\tau) = 2$, despite the coherence length being $\tau \to \infty$. Do the Excs. 40.3.6.1 to 40.3.6.3.

40.3.3.3 Correlation functions for laser light subject to white noise

For a laser subject to *white phase noise* (ζ be a normally distributed random number) we have (see also Sec. 58.3.2),

noisy laser

$$\begin{aligned}
\mathcal{E}(t) &= e^{\imath[\omega_0 t+\zeta(t)]} \\
\Longrightarrow \quad g^{(1)}(\tau) &= \frac{\int e^{-\imath[\omega_0\tau+\zeta(t+\tau)-\zeta(t)]}dt}{\int dt} = e^{\imath\omega_0\tau-\gamma|\tau|} \\
\Longrightarrow \quad \mathcal{F}[g^{(1)}(\tau)] &= \frac{\gamma/\pi}{\Delta^2+\gamma^2} \\
g^{(2)}(\tau) &= 1
\end{aligned} \quad . \tag{40.89}$$

We see, that the first-order coherence decays exponentially, $|g^{(1)}(\tau)| = e^{-\gamma|\tau|}$ [5], such that the spectrum has a *Lorentzian profile*. For this reason light having this characteristic is also called *Lorentzian chaotic light*. This result has already been

[5] Note that, in order to satisfy (40.84), we must take the absolute value of the delay $|\tau|$.

derived in Eq. (39.28) for the natural linewidth of a transition subject to spontaneous emission. We understand the connection by interpreting spontaneous emission as being induced by *vacuum fluctuations, which do have a white noise spectrum*, indeed.

Example 286 (*Laser broadening due to spontaneous emission*): Laser light is generated by stimulated emission on a transition between two quantized levels. The alternance of absorption and stimulated emission induces coherent Rabi oscillations ensuring the coherence of the emitted light. But we have seen earlier that spontaneous emission leads to randomly occurring interruptions of the coherent Rabi oscillations. The probability of finding a coherent interval decreases exponentially with the evolution time,

$$p(\tau)d\tau = \gamma e^{-\gamma\tau} d\tau \ ,$$

where γ is the spontaneous decay rate of the dipole moment. From $\mathcal{E}(t) = e^{\imath\omega_0 t + \imath\zeta(t)}$ we calculate,

$$\begin{aligned} R_{\mathcal{E}}(\tau) &= \langle e^{\imath\omega_0 t+\imath\zeta(t)} e^{-\imath\omega_0(t+\tau)-\imath\zeta(t+\tau)}\rangle = e^{-\imath\omega_0\tau} \lim_{t\to\infty} \frac{1}{t}\int_0^t e^{\imath[\zeta(t)-\zeta(t+\tau)]} dt \\ &= e^{-\imath\omega_0\tau} \int_\tau^\infty p(\tau')d\tau' = e^{-\imath\omega_0\tau} e^{-\gamma|\tau|} \ , \end{aligned}$$

and,

$$F_{\mathcal{E}}(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{R_{\mathcal{E}}(\tau)}{R_{\mathcal{E}}(0)} e^{\imath\omega\tau} d\tau = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-\imath\omega_0\tau} e^{-\gamma|\tau|} e^{\imath(\omega-\omega_0)\tau} d\tau = \frac{\gamma/\pi}{\Delta^2+\gamma^2} \ .$$

An alternative derivation from Bloch or rate equations is shown in Excs. 40.4.4.3 and 40.4.4.4.

40.3.3.4 Correlation functions for light emitted from pressure-broadened atomic clouds

In Sec. 39.5.2 we have already seen, that collision or *pressure broadening* can be treated by assuming that the light is emitted as a superposition of coherent waves all having the same frequency, but being randomly interrupted by phase jumps,

$$\mathcal{E}(t) = \sum_n \mathcal{E}_n(t) \qquad \text{with} \qquad \mathcal{E}_n(t) = e^{\imath\omega_0 t + \imath\phi_n(t)} \ . \tag{40.90}$$

The autocorrelation function is then,

$$\begin{aligned} \langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle &= \frac{1}{t}\int \sum_n e^{-\imath\omega_0 t - \imath\phi_n(t)} \sum_m e^{\imath\omega_0 t + \imath\omega_0\tau + \imath\phi_m(t+\tau)} dt \\ &= e^{\imath\omega_0\tau} \sum_{n,m} \frac{1}{t}\int e^{\imath\phi_m(t+\tau)-\imath\phi_n(t)} dt = N\langle \mathcal{E}_n^*(t)\mathcal{E}_m(t+\tau)\rangle \delta_{nm} \ . \end{aligned} \tag{40.91}$$

The crossed terms $n \neq m$ of this expressions vanish. The pressure broadening is homogeneous, but the fact that the wavepackets are scattered by different atoms results in a modified first-order coherence,

$$\langle \mathcal{E}_n^*(t)\mathcal{E}_n(t+\tau)\rangle = e^{\imath\omega_0\tau} \sum_n \int e^{\imath\phi_n(t+\tau)-\imath\phi_n(t)} dt = e^{\imath\omega_0\tau} \int_\tau^\infty p(\tau) d\tau \ . \tag{40.92}$$

The probability density of finding a coherent interval of duration τ is $p(\tau)d\tau = \gamma_c e^{-\gamma_c \tau} d\tau$, which finally gives,

$$\langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle = N e^{\imath\omega_0\tau - \gamma_c|\tau|} \ . \tag{40.93}$$

The calculation for the 2nd order correlation function (40.79) is analogous,

$$\begin{aligned}
&\langle \mathcal{E}^*(t)\mathcal{E}^*(t+\tau)\mathcal{E}(t+\tau)\mathcal{E}(t)\rangle = \sum_{n,m,n',m'} \langle \mathcal{E}^*_m(t)\mathcal{E}_n(t)\mathcal{E}^*_{m'}(t+\tau)\mathcal{E}_{n'}(t+\tau)\rangle \qquad (40.94)\\
&= \sum_n \langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\mathcal{E}^*_n(t+\tau)\mathcal{E}_n(t+\tau)\rangle \\
&+ \left(\sum_{n\neq m} \langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\mathcal{E}^*_m(t+\tau)\mathcal{E}_m(t+\tau)\rangle + \langle \mathcal{E}^*_m(t)\mathcal{E}_n(t)\mathcal{E}^*_n(t+\tau)\mathcal{E}_m(t+\tau)\rangle \right) \ ,
\end{aligned}$$

neglecting all terms which do not satisfy either $\mathcal{E}^*_n(t)\mathcal{E}_n(t)$ or $\mathcal{E}^*_n(t)\mathcal{E}_n(t+\tau)$. Now, assuming a large amount of identical atoms,

$$\begin{aligned}
&\langle \mathcal{E}^*(t)\mathcal{E}^*(t+\tau)\mathcal{E}(t+\tau)\mathcal{E}(t)\rangle \qquad (40.95)\\
&= N\langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\mathcal{E}^*_n(t+\tau)\mathcal{E}_n(t+\tau)\rangle + N(N-1)\left(\langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\rangle^2 + |\langle \mathcal{E}_n(t)\mathcal{E}^*_n(t+\tau)\rangle|^2\right)\\
&\simeq N^2\left(\langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\rangle^2 + |\langle \mathcal{E}_n(t)\mathcal{E}^*_n(t+\tau)\rangle|^2\right) \ .
\end{aligned}$$

Finally, exploiting the result (40.91) and the definitions of the 1st and 2nd order correlations functions,

$$g^{(2)}(\tau) = \frac{\langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\rangle^2 + |\langle \mathcal{E}_n(t)\mathcal{E}^*_n(t+\tau)\rangle|^2}{\langle \mathcal{E}^*_n(t)\mathcal{E}_n(t)\rangle^2} = 1 + |g^{(1)}(\tau)|^2 \ . \tag{40.96}$$

In summary,

light emitted from pressure-broadened atomic clouds

$$\begin{aligned}
\mathcal{E}(t) &= \textstyle\sum_n e^{\imath\omega_0 t + \imath\phi_n(t)} \\
\Longrightarrow \quad g^{(1)}(\tau) &= e^{\imath\omega_0\tau - \gamma_c|\tau|} \\
\Longrightarrow \quad \mathcal{F}\left[g^{(1)}(\tau)\right] &= \frac{\gamma/\pi}{\Delta^2 + \gamma_c^2} \\
g^{(2)}(\tau) &= 1 + e^{-\gamma_c|\tau|}
\end{aligned} \ . \tag{40.97}$$

The spectrum is a Lorentzian with the full linewidth $\gamma' = \gamma + \gamma_c$.

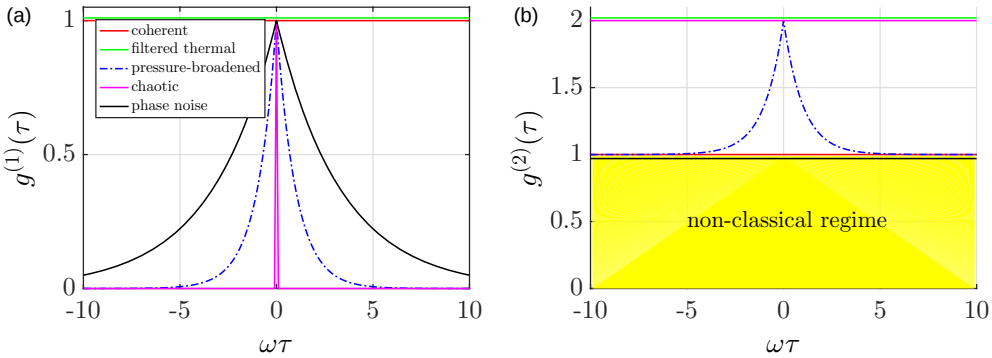

Figure 40.9: (code) First and second-order correlation functions for (red) a laser, (cyan) a laser subject to phase noise, (blue) a laser subject to collision broadening, (magenta) chaotic light, and (green) spectrally filtered thermal light.

40.3.3.5 Correlation functions for light emitted from Doppler-broadened atomic clouds

For light emitted by an ensemble of non-colliding atoms in thermal motion, we must allow for different frequencies, $\mathcal{E}_n(t) = e^{\imath\omega_n t+\imath\phi_n}$, but time-independent phases,

$$\begin{aligned}\langle\mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle &= \int\sum_n e^{-\imath\omega_n t-\imath\phi_n}\sum_m e^{\imath\omega_m t+\imath\omega_m\tau+\imath\phi_m}dt \\ &= \sum_{n,m}\int e^{-\imath\omega_n t-\imath\phi_n+\imath\omega_m t+\imath\omega_m\tau+\imath\phi_m}dt = \sum_n e^{\imath\omega_n\tau}\ .\end{aligned} \tag{40.98}$$

The crossed terms $n \neq m$ of this expressions vanish. *Doppler broadening* is inhomogeneous. Hence, the probability density for frequencies emitted by thermal atoms is a Gaussian, $p(\omega)d\omega = (2\pi\delta)^{-1/2}e^{-(\omega_n-\omega_0)^2/2\delta^2}d\omega$. For this reason light having this characteristic is also called *Gaussian chaotic light*. With the definitions (40.77) it is easy to calculate the autocorrelation functions and the spectrum of a laser light field,

light emitted from Doppler-broadened atomic clouds

$$\begin{aligned}\langle\mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle &= \frac{N}{\sqrt{2\pi\delta}}\int e^{\imath\omega_n\tau}e^{-(\omega_n-\omega_0)^2/2\delta^2}d\omega_n \\ \Longrightarrow\quad g^{(1)}(\tau) &= e^{\imath\omega\tau-\delta^2\tau^2/2} \\ \Longrightarrow\quad \mathcal{F}[g^{(1)}(\tau)] &= \sqrt{\frac{\ln 2}{\pi\delta^2}}e^{-\ln 2\cdot\omega^2/\delta^2} \\ g^{(2)}(\tau) &= 1+e^{-\delta^2\tau^2/2}\end{aligned}\ . \tag{40.99}$$

In Exc. 40.3.6.5 we calculate the correlation functions at zero delay.

40.3.4 Quantum signatures in first and second order coherence

All calculations of correlation functions made up to this point assumed classical light fields, except for the anti-bunched $g^{(2)}(0)$ listed in Tab. 40.1. We will see in the following that a quantum calculation yields some features of the second order coherence that cannot be explained by assuming classical fields. But this does not mean that we can always decide whether a beam is quantum just by looking at $g^{(2)}(0)$: A light beam may have quantum correlations that do not violate the classical rules exhibited in Tabs. 40.1 and 40.2. This is the case, e.g. for squeezed light.

40.3.5 Photon counting statistics

The physical quantities measured in practice are intensities of light fields, i.e. energies propagating through finite areas of space during finite integration times. Very sensitive detectors may sense the arrival of single photons during finite times (called dead times) needed to process the information. In semiclassical theory we ignore the existence of photons, nevertheless the photoeffect signal is delivered by single electrons, amplified to avalanches of electrons that we will call 'photocount', and that sum up to currents for long enough integration times.

40.3.5.1 Quantum correlations

Defining the intensity as $\hat{I} = 2\varepsilon_0 c\hat{\mathcal{E}}^+\hat{\mathcal{E}}^-$, the coherences become,

$$g^{(1)}(\tau) \equiv \tfrac{2\varepsilon_0 c}{I}\langle \mathcal{T}\mathcal{N}\hat{\mathcal{E}}^-(t)\hat{\mathcal{E}}^+(t+\tau)\rangle \qquad \text{and} \qquad g^{(2)}(\tau) \equiv \left(\tfrac{2\varepsilon_0 c}{I}\right)^2 \langle \mathcal{T}\mathcal{N}\hat{I}(t)\hat{I}(t+\tau)\rangle \ . \tag{40.100}$$

The correlation functions must be calculated from the field operators simultaneously respecting *time order* and *normal order*.

One rule is easy to derive,

$$g^{(2)}(0) = \frac{\langle \hat{a}^\dagger\hat{a}^\dagger\hat{a}\hat{a}\rangle}{\langle \hat{a}^\dagger\hat{a}\rangle^2} = \frac{\langle \hat{n}^2\rangle - \langle \hat{n}\rangle}{\langle \hat{n}\rangle^2} = 1 - \frac{1}{\langle \hat{n}\rangle} + \frac{(\Delta\hat{n})^2}{\langle \hat{n}\rangle^2} \geq 1 - \frac{1}{\langle \hat{n}\rangle} \geq 0 \ , \tag{40.101}$$

for $\langle \hat{n}\rangle \geq 1$. For $\langle \hat{n}\rangle < 1$ we have $g^{(2)}(0) = 0$.

40.3.5.2 Applications of correlated photons

Correlated photons have many applications in modern *quantum sensing*. Correlations can be encoded in space, colors, polarization, or time giving rise to phenomena such as ghost imaging, spooky spectra, time-correlated spectroscopy, two-photon absorption with femtosecond time resolution, and virtual state spectroscopy among others.

40.3.6 Exercises

40.3.6.1 Ex: Correlation functions for two light modes

a. Calculate $|g^{(1)}(\tau)|$, $F_{\mathcal{E}}(\omega)$, and $|g^{(2)}(\tau)|$ for two interfering and non-interfering modes neglecting fluctuations.
b. What changes when one mode is broadened by random noise, e.g. induced by spontaneous emission?

40.3.6.2 Ex: Correlation functions and spectra of phase- and amplitude-modulated light

a. Calculate $g^{(1)}(\tau)$, $S_{\mathcal{E}}(\omega)$, and $g^{(2)}(\tau)$ for amplitude-modulated light: $\mathcal{E}_{am}(t) = e^{\imath\omega_0 t}(1 + M\cos\Omega t)$.
b. Calculate $g^{(1)}(\tau)$, $S_{\mathcal{E}}(\omega)$, and $g^{(2)}(\tau)$ for phase-modulated light: $\mathcal{E}_{pm}(t) = e^{\imath\omega_0 t + \imath M\cos\Omega t}$.
c. Repeat the calculation (a) for exponentially decaying amplitude-modulated light: $\mathcal{E}_{dam}(t) = e^{-\gamma t}e^{\imath\omega_0 t}(1 + M\cos\Omega t)$. See also 54.3.3.1.

40.3.6.3 Ex: Phase modulation

a. Show that it is not possible to construct a periodic phase modulation function such that the signal has only two sidebands.
b. From $1 = |e^{\imath M\sin\Omega t}|^2$ derive a sum rule for the Bessel functions.
c. Discuss the difference of the spectra $\sum_{k=-\infty}^{\infty} J_k(M)e^{\imath k\Omega t}$ and $\sum_{k=-\infty}^{\infty} |J_k(M)|e^{\imath k\Omega t}$.

40.3.6.4 Ex: Non-classicality of antibunched states

Quantized radiation fields can exhibit the feature of antibunching, which is incompatible with the classical concept of radiation. Show that $g^{(2)}(0) < 1$ entails the possibility of negative values for the Glauber-Sudarshan P-function, that is, $P(\alpha) < 0$ at least for some α.

40.3.6.5 Ex: Zero delay correlation functions

Calculate the zero delay correlation functions for (a) Fock states and (b) thermal light.

40.4 Spontaneous emission and light scattering

40.4.1 Interaction of atoms with vacuum modes

The Jaynes-Cummings Hamiltonian (40.2), discussed in Sec. 40.2, describes the purely coherent dynamics of a single immobile two-level atom interacting with a single cavity mode. The model is simple enough to allow for analytical solutions. However, it does not include processes of spontaneous emission, which can be understood as the interaction of the atom with the light modes of the vacuum. That is, we must extend the Hamiltonian,

$$\hat{H} = \hat{H}_{\text{atom}} + \hat{H}_{\text{field}} + \hat{H}_{\text{atom:field}} + \hat{H}_{\text{vacuum}} + \hat{H}_{\text{atom:vacuum}} \ . \tag{40.102}$$

The evolution of the system represented by the Hamiltonian (40.102) is described by a total density operator, $\hat{\rho}_{\text{total}}(t)$, obeying the *von Neumann equation*,

$$\boxed{\frac{d\hat{\rho}_{\text{total}}}{dt} = -\frac{\imath}{\hbar}[\hat{H}, \hat{\rho}_{\text{total}}]} \ , \tag{40.103}$$

which has the solution,

$$\hat{\rho}_{\text{total}}(t) = e^{-\imath \hat{H} t/\hbar} \hat{\rho}_{\text{total}}(0) e^{\imath \hat{H} t/\hbar} \equiv e^{-\imath \mathcal{L} t} \hat{\rho}_{\text{total}}(0) \ . \tag{40.104}$$

Often, we are only interested in *either* the evolution of the light field, *or* the internal state of the atom. In these cases, we calculate the trace over all those degrees of freedom, which are we are NOT interested in,

$$\hat{\rho}_{\text{atom}} = \text{Tr}_{\text{vacuum}} \ \hat{\rho}_{\text{total}} \ . \tag{40.105}$$

The procedure is the following. We begin choosing the initial state of the electromagnetic vacuum as the photonic vacuum $\hat{\rho}_{\text{vacuum}} = |\{0\}\rangle\langle\{0\}|$ and defining a projection operator onto this state, $\hat{P}... \equiv \hat{\rho}_{\text{vacuum}}(0)\text{Tr}_{\text{vacuum}} \ ... = \hat{P}^2....$ Then we apply to the von Neumann equation the rotating wave, the Markov and the Born approximations. Finally, tracing over the vacuum field variables, we obtain after some calculations the *Bloch-Lindbladt equation* or *master equation* [759] for the atom interacting with the driving field. For a discussion of the validity of the Born-Markov approximation [675]. For the relation between the Markov approximation and the Fermi's Golden Rule [11].

We emphasize that the Hamiltonian (40.102) describes the interaction of light with a *single immobile atom* at the most fundamental level. However, it excludes many-body effects introduced by quantum statistics or interatomic interactions (to be discussed in Chp. 50), as well as the center-of-mass motion of the atom and the impact of photonic recoil (to be discussed in Chp. 43).

In the following section we give a simplified derivation concentrating us on the situation of a single motionless atom, excited by a laser and emitting photons into the electromagnetic vacuum.

40.4.1.1 Spontaneous emission

Spontaneous emission can be understood as an energy diffusion process from a system with a restricted number of degrees of freedom into a large thermal bath. For example, although a two-dimensional Hilbert space is sufficient to describe a laser-driven two-level atom, this atom couples to a huge phase-space by spontaneously emitting photons into arbitrary directions. We account for his fact by including in the Hamiltonian not only the interaction of the atom with the incident laser (wavevector $\mathbf{k}_0$, frequency $\omega_{\mathbf{k}_0}$), but also with the modes of the electromagnetic vacuum (wavevector $\mathbf{k}$, frequency $\omega_{\mathbf{k}}$). We will see, that with this Hamiltonian, we can derive, in a calculation is known as *Weisskopf-Wigner theory*, the Schrödinger equation for the amplitudes of the atomic levels (39.147) including spontaneous emission.

Denoting the frequency of the atomic resonance by ω_a, the interaction part of the Hamiltonian is,

$$\boxed{\begin{aligned} \hat{H} &= \hbar g_{\mathbf{k}_0} \left(\hat{\sigma}^- e^{-\imath\omega_a t} + \hat{\sigma}^+ e^{\imath\omega_a t}\right) \left(\hat{a}^\dagger_{\mathbf{k}_0} e^{\imath\omega_0 t - \imath\mathbf{k}_0\cdot\mathbf{r}} + \hat{a}_{\mathbf{k}_0} e^{-\imath\omega_0 t + \imath\mathbf{k}_0\cdot\mathbf{r}}\right) \\ &+ \sum_{\mathbf{k}} \hbar g_{\mathbf{k}} \left(\hat{\sigma}^- e^{-\imath\omega_a t} + \hat{\sigma}^+ e^{\imath\omega_a t}\right) \left(\hat{a}^\dagger_{\mathbf{k}} e^{\imath\omega_{\mathbf{k}} t - \imath\mathbf{k}\cdot\mathbf{r}} + \hat{a}_{\mathbf{k}} e^{-\imath\omega_{\mathbf{k}} t + \imath\mathbf{k}\cdot\mathbf{r}}\right) \end{aligned}} \ . \tag{40.106}$$

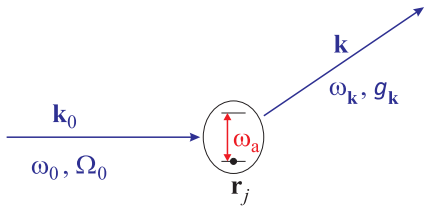

Figure 40.10: Scattering of a laser beam by an atom.

$g_{\mathbf{k}_0}$ is the coupling strength of the interaction between the atom and the pump mode, $\hat{\sigma}^-$ is the atomic deexcitation operator, $\hat{a}_{\mathbf{k}}$ is the annihilation operator of a photon, and $g_{\mathbf{k}} = d\sqrt{\omega/(\hbar\varepsilon_0 V)}$ describes the coupling between the atom and a vacuum mode whose volume is V. The atom has two states, the ground state $|g\rangle$ and excited state $|e\rangle$. Since we are considering only one atom fixed in space [6], we can as well locate it at the origin $\mathbf{r} = 0$. In addition, considering a high power incident laser,

$$\hat{a}_{\mathbf{k}_0}|n_0\rangle_{\mathbf{k}_0} = \sqrt{n_0}|n_0 - 1\rangle_{\mathbf{k}_0} \simeq \sqrt{n_0}|n_0\rangle_{\mathbf{k}_0} \ , \tag{40.107}$$

$\hat{a}_{\mathbf{k}_0}$ is approximately an observable proportional to the root of the intensity. As $[\hat{a}_{\mathbf{k}_0}, \hat{a}^\dagger_{\mathbf{k}_0}] \simeq 0$, we can disregard the quantum nature of the incident field and replace, $\Omega_0 \equiv 2\sqrt{n_0}g_{\mathbf{k}_0}$. Within the rotating wave approximation (RWA), the Hamiltonian becomes,

$$\hat{H} = \tfrac{\hbar}{2}\Omega_0\left[\hat{\sigma}^- e^{\imath\Delta_0 t} + h.c.\right] + \hbar\sum_{\mathbf{k}}\left[g_{\mathbf{k}}\hat{\sigma}\hat{a}^\dagger_{\mathbf{k}}e^{\imath\Delta_{\mathbf{k}}t} + h.c.\right] \ , \tag{40.108}$$

where we introduced the abbreviations,

$$\Delta_0 \equiv \omega_0 - \omega_a \qquad \text{and} \qquad \Delta_{\mathbf{k}} \equiv \omega_{\mathbf{k}} - \omega_a \ . \tag{40.109}$$

The general state of the system is given by,

$$|\Psi(t)\rangle = \alpha(t)|g\rangle_a|0\rangle_{\mathbf{k}} + \beta(t)|e\rangle_a|0\rangle_{\mathbf{k}} + \sum_{\mathbf{k}}\gamma_{\mathbf{k}}(t)|g\rangle_a|1\rangle_{\mathbf{k}} \ , \tag{40.110}$$

where $|j\rangle_a$ denotes the atomic state and $|n\rangle_{\mathbf{k}}$ the number of photons in the scattering mode.

The temporal evolution of the amplitudes is obtained by inserting the Hamiltonian (40.108) and the ansatz (40.110) into the Schrödinger equation,

$$\frac{\partial}{\partial t}|\Psi(t)\rangle = -\frac{\imath}{\hbar}\hat{H}|\Psi(t)\rangle \ . \tag{40.111}$$

As verified in Exc. 40.4.4.1, we obtain,

$$\begin{aligned}\dot{\alpha}(t) &= -\imath\tfrac{\Omega_0}{2}e^{\imath\Delta_0 t}\beta(t) \\ \dot{\beta}(t) &= -\imath\tfrac{\Omega_0}{2}\alpha(t)e^{-\imath\Delta_0 t} - \sum\nolimits_{\mathbf{k}}\imath g_{\mathbf{k}}\gamma_{\mathbf{k}}(t)e^{-\imath\Delta_{\mathbf{k}}t} \\ \dot{\gamma}_{\mathbf{k}}(t) &= -\imath g_{\mathbf{k}}e^{\imath\Delta_{\mathbf{k}}t}\beta(t) \ .\end{aligned} \tag{40.112}$$

[6] We do not let the atom be accelerated by photonic recoil.

Now, we chose the initial conditions,

$$\alpha(0) = 1 \qquad \text{and} \qquad \beta(0) = 0 \qquad \text{and} \qquad \gamma_{\mathbf{k}}(0) = 0 \ , \tag{40.113}$$

we integrate the third equation,

$$\gamma_{\mathbf{k}}(t) = -\imath g_{\mathbf{k}} \int_0^t e^{\imath \Delta_{\mathbf{k}} t'} \beta(t') dt' \ , \tag{40.114}$$

and we substitute it in the second equation,

$$\dot{\beta}(t) = -\imath \tfrac{\Omega_0}{2} \alpha(t) e^{-\imath \Delta_0 t} - \sum_{\mathbf{k}} g_{\mathbf{k}}^2 \int_0^t e^{\imath \Delta_{\mathbf{k}}(t'-t)} \beta(t') dt' \ . \tag{40.115}$$

40.4.1.2 The Markov approximation

For small systems (which certainly is the case of a single atom), we can apply the *Markov approximation* [7] claiming that the temporal variation of the amplitudes $\beta(t')$ is slower than the evolution of the system given by $e^{\imath(\omega_{\mathbf{k}}-\omega_a)t}$ in the integro-differential equation, which is equivalent to an arbitrarily high-order equation. Hence, substituting $\beta(t') \to \beta(t)$ into the integro-differential equation, we reduce it to a simple first-order differential equation.

In practice, we redefine the integration variable, $t'' \equiv t - t'$, to obtain,

$$\begin{aligned} \frac{d}{dt}\beta(t) &= -\imath \tfrac{\Omega_0}{2} \alpha(t) - \sum_{\mathbf{k}} g_k^2 \int_0^t e^{\imath(\omega_{\mathbf{k}}-\omega_a)(t'-t)} \beta(t') dt' \\ &= -\imath \tfrac{\Omega_0}{2} \alpha(t) - \sum_{\mathbf{k}} g_k^2 \int_0^t e^{-\imath(\omega_{\mathbf{k}}-\omega_a)t''} \beta(t-t'') dt'' \ , \end{aligned} \tag{40.116}$$

and implement the Markov approximation by setting $\beta(t-t'') \simeq \beta(t)$, and with $\lim_{t\to\infty} \int_0^t e^{-\imath(\omega_{\mathbf{k}}-\omega_a)t'} dt' = \pi\delta(\omega_{\mathbf{k}} - \omega_a)$, and replacing $\sum_{\mathbf{k}} \longrightarrow \frac{V}{(2\pi)^3} \int d^3\mathbf{k}$, we arrive at,

$$\begin{aligned} \frac{d}{dt}\beta(t) &\simeq -\imath \tfrac{\Omega_0}{2} \alpha(t) - \sum_{\mathbf{k}} g_{\mathbf{k}}^2 \beta(t) \pi\delta(\omega_{\mathbf{k}} - \omega_a) \\ &= -\imath \tfrac{\Omega_0}{2} \alpha(t) - \tfrac{V}{(2\pi)^3} \beta(t) \int g_{\mathbf{k}}^2 \pi\delta(\omega_{\mathbf{k}} - \omega_a) d^3\mathbf{k} \\ &= -\imath \tfrac{\Omega_0}{2} \alpha(t) - \tfrac{V}{(2\pi)^3} \beta(t) 4\pi g_{\mathbf{k}_a}^2 \pi k_a^2 \tfrac{1}{c} = -\imath \tfrac{\Omega_0}{2} \alpha(t) - \tfrac{\Gamma}{2} \beta(t) \ . \end{aligned} \tag{40.117}$$

In the last step we introduced, as an abbreviation, the spontaneous emission rate,

$$\Gamma \equiv \sum_{\mathbf{k}} 2 g_{\mathbf{k}}^2 \pi\delta(\omega_{\mathbf{k}} - \omega_a) = \tfrac{V}{\pi c} k_a^2 g_{\mathbf{k}_a}^2 \ , \tag{40.118}$$

Finally,

$$\boxed{\frac{d}{dt}\alpha(t) = -\imath \frac{\Omega_0}{2} \beta(t) \qquad \text{and} \qquad \frac{d}{dt}\beta(t) = -\imath \frac{\Omega_0}{2} \alpha(t) - \frac{\Gamma}{2} \beta(t)} \ . \tag{40.119}$$

[7] The approximation does not necessarily hold for large clouds of atoms.

These are exactly the equations for the probability amplitudes (39.147) derived from the Schrödinger equation, only that now, the spontaneous emission term has been derived explicitly. Solve the Exc. 40.4.4.2.

Example 287 (*Emission stimulated by vacuum fluctuations*): Spontaneous emission can be regarded as an emission stimulated by vacuum fluctuations. To see this, we write down the resonant optical cross section ($\omega_0 = \omega_a$) of a driven two-level atom without degeneracies, $\sigma_0 = \lambda^2/2\pi$, and the intensity of an incident laser field, $\bar{I} = cN\hbar\omega_0/V$, generating the Rabi frequency (see (23.107)),

$$\Omega_0^2 = \sigma_0 \frac{\bar{I}}{\hbar\omega_a}\Gamma = \frac{2\pi c}{k_a^2}\frac{N}{V}\Gamma \ . \tag{40.120}$$

Now, we assume that the field is, in fact, a vacuum mode containing only half a photon, $N = 1/2$, which corresponds to vacuum fluctuations in the mode k_0. Then,

$$\Omega_{1/2}^2 = \frac{\pi c}{k_a^2 V}\Gamma = g^2 \ . \tag{40.121}$$

40.4.2 Resonance fluorescence and (in-)coherent light scattering

The typical situation for a spectroscopy experiment is illustrated in Fig. 40.11: When a beam of light, understood as a plane wave, strikes an atom (or a cloud of many atoms), a part of the light is absorbed and reemitted into a direction indicated by a solid angle $d\Omega$. Light scattering is, of course, a second order process involving two atomic transitions, one absorption and one emission.

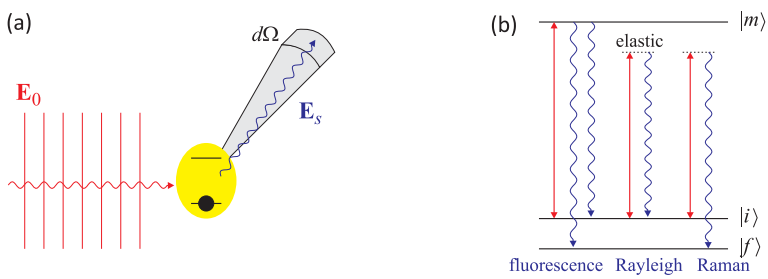

Figure 40.11: (a) Geometry of a scattering experiment. (b) Spectral contributions of light scattered elastically and inelastically by a three-level atom.

Radiation can be absorbed or scattered by an atom in different ways, depending on whether the interaction is an *elastic scattering* or an *inelastic scattering* process, a coherent or incoherent, a spontaneous or (bosonically) stimulated process. These properties characterize many processes, in particular, resonance fluorescence (i.e. absorption and reemission), *Rayleigh scattering*, or *Raman scattering*. In the following, we will clarify this classification.

Every scattering process is either spontaneous or stimulated [8]. Rayleigh scattering is elastic, that is, the kinetic energy of the scattering atom is the same, before and

[8] Classical theories of light scattering through the excitation of an electronic motion based on the

after the scattering process. In contrast, Raman scattering is inelastic. Spontaneous emission is due to the decay of population from an excited state, and spontaneous Rayleigh scattering is due to the decay of an induced dipole moment. Both spontaneous processes can be regarded as being stimulated by vacuum fluctuations.

40.4.2.1 Deriving the source field expression

We will now calculate the electric field due to spontaneous emission by an atom from the interaction Hamiltonian for atom-vacuum coupling (40.106) in the RWA,

$$\hat{H} = \sum_{\mathbf{k}} \hbar g_{\mathbf{k}} \hat{\sigma}^- \hat{a}^\dagger_{\mathbf{k}} e^{\imath\omega_{\mathbf{k}} t - \imath\omega_a t - \imath \mathbf{k}\cdot\mathbf{R}} + h.c. \ . \tag{40.122}$$

Now, we assume isotropic coupling, $g_{\mathbf{k}} = g_k$, and $\omega_{\mathbf{k}} = \omega_k$, and for simplicity we position the atom in the origin, $\mathbf{R} = 0$. We use the Heisenberg equation with the commutation rule $[\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = \delta_{\mathbf{k},\mathbf{k}'}$ to derive the temporal evolution of the field operators,

$$\frac{d\hat{a}_{\mathbf{k}}}{dt} = \tfrac{1}{\imath\hbar}[\hat{a}_{\mathbf{k}}, \hat{H}] = -\imath\hat{\sigma}^- g_k e^{\imath(\omega_k - \omega_a)t} \ . \tag{40.123}$$

Neglecting for simplicity polarization, the electric field is given by,

$$\hat{\mathcal{E}}^+_{sct}(\mathbf{r}, t) = \sum_{\mathbf{k}} \mathcal{E}_1 \hat{a}_{\mathbf{k}}(t) e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega_k t)} \ , \tag{40.124}$$

where $\mathbf{r}$ is now the observation point of the electric field. We restrict to the far-field and substitute the annihilation operator with the integral of Eq. (40.123) using the initial condition $\hat{a}_{\mathbf{k}}(0) = 0$,

$$\hat{\mathcal{E}}^+_{sct}(\mathbf{r}, t) = \sum_{\mathbf{k}} \mathcal{E}_1 g_k \int_0^t \hat{\sigma}^-(t') e^{\imath(\omega_k - \omega_a)t'} dt' e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega_k t)} \ . \tag{40.125}$$

Now, we substitute the sum over $\mathbf{k}$ by an integral, as done in (40.117),

$$\hat{\mathcal{E}}^+_{sct}(\mathbf{r}, t) = -\imath \frac{V}{(2\pi)^3} \int_{\mathbb{R}^3} \mathcal{E}_1 g_k \int_0^t \hat{\sigma}^-(t') e^{\imath(\omega_k - \omega_a)t'} dt' e^{\imath(\mathbf{k}\cdot\mathbf{r} - \omega_k t)} d^3k \ . \tag{40.126}$$

Using the relationships,

$$g_k = \frac{d_{12}\mathcal{E}_1}{\hbar} \qquad \text{and} \qquad \mathcal{E}_1 = \sqrt{\frac{\hbar\omega_k}{2\varepsilon_0 V}} \ , \tag{40.127}$$

the final result of the integration yields [590],

$$\hat{\mathcal{E}}^+_{sct}(\mathbf{r}, t) \simeq -\imath \frac{d_{12} k_a^2}{4\pi\varepsilon_0 r} \hat{\sigma}^-(t - \tfrac{r}{c}) \ . \tag{40.128}$$

models of Lorentz or Drude can be found in Secs. 15.2.3 . Although being classical, these model are useful for a deeper understanding of many aspects of *Compton scattering*, *Thomson scattering*, and *Rayleigh scattering*.

40.4.2.2 Resonance fluorescence

When we introduced the second quantization (37.8) we learned that the field of light emitted by a radiator in the radiation zone ($\lambda \ll r$) is, taking into account retardation [9], given by,

$$\langle \hat{\vec{\mathcal{E}}}_{\rm s}^{+}(\mathbf{r},t)\rangle \propto \langle \hat{\sigma}^{-}\rangle \propto \tilde{\rho}_{21} \qquad \text{and} \qquad \langle \hat{\vec{\mathcal{E}}}_{\rm s}^{-}(\mathbf{r},t)\hat{\vec{\mathcal{E}}}_{\rm s}^{+}(\mathbf{r},t)\rangle \propto \langle \hat{\sigma}^{+}\hat{\sigma}^{-}\rangle \propto \rho_{22}\ . \tag{40.129}$$

Therefore, the electric field emitted by an atom and the intensity of scattered light are given by,

$$\boxed{\begin{aligned} \langle \hat{\vec{\mathcal{E}}}_{\rm s}^{+}(\mathbf{r},t)\rangle &= -\frac{e\omega_a^2 \hat{\epsilon}\cdot\mathbf{r}_{12}}{4\pi\varepsilon_0 c^2 r}\tilde{\rho}_{21}(t-\tfrac{r}{c})e^{-\imath\omega(t-r/c)} \\ \bar{I}_{\rm s} = c\varepsilon_0\langle \hat{\vec{\mathcal{E}}}_{\rm s}^{-}(\mathbf{r},t)\hat{\vec{\mathcal{E}}}_{\rm s}^{+}(\mathbf{r},t)\rangle &= \frac{\alpha\hbar\omega_a^4|\hat{\epsilon}\cdot\mathbf{r}_{12}|^2}{4\pi c^2 r^2}\rho_{22}(t-\tfrac{r}{c}) \end{aligned}}\ , \tag{40.130}$$

with the definition of the Sommerfeld constant $\alpha = e^2/4\pi\varepsilon_0\hbar c$. We calculate the total flux of emitted photons,

$$\begin{aligned} W_{fi}^{(sp)} &= \int \frac{\bar{I}_{\rm s} r^2}{\hbar\omega_a} d\Omega = \frac{1}{\hbar\omega_a}\int \frac{\alpha\hbar\omega_a^4|\mathbf{r}_{12}|^2\cos^2\theta}{4\pi c^2}\rho_{22}(t-\tfrac{r}{c})\sin\theta d\theta d\phi \\ &= \frac{8\pi}{3\hbar\omega_a}\frac{\alpha\hbar\omega_a^4|\mathbf{r}_{12}|^2}{4\pi c^2}\rho_{22}(t-\tfrac{r}{c}) = \frac{2\alpha}{3c^2}\omega_a^3|\mathbf{r}_{12}|^2\rho_{22}(t-\tfrac{r}{c})\ . \end{aligned} \tag{40.131}$$

The result *coincides with the spontaneous emission rate* Γ calculated in (39.40).

A *differential scattering cross section* can be defined by,

$$\frac{d\sigma}{d\Omega} \equiv \frac{\omega \bar{I}_{\rm s} r^2}{\omega_s \bar{I}_0}\ . \tag{40.132}$$

40.4.2.3 Coherently scattered light and saturation

The total intensity of the scattered light being $\bar{I}_{\rm s}$, the fraction of the coherently scattered light is,

$$\frac{\bar{I}_{\rm s}^{\rm coh}}{\bar{I}_{\rm s}} = \frac{\langle \hat{\vec{\mathcal{E}}}_{\rm s}^{-}(\mathbf{r},t)\rangle\langle \hat{\vec{\mathcal{E}}}_{\rm s}^{+}(\mathbf{r},t)\rangle}{\langle \hat{\vec{\mathcal{E}}}_{\rm s}^{-}(\mathbf{r},t)\hat{\vec{\mathcal{E}}}_{\rm s}^{+}(\mathbf{r},t)\rangle}\ . \tag{40.133}$$

Inserting the expressions (40.130) and the stationary solution of the Bloch equations (39.151) with the saturation parameter defined in (39.153),

$$\frac{\bar{I}_{\rm s}^{\rm coh}}{\bar{I}_{\rm s}} = \frac{|\tilde{\rho}_{21}(\infty)|^2}{\rho_{22}(\infty)} = \frac{1}{1+s} = 1 - \frac{\bar{I}_{\rm s}^{\rm incoh}}{\bar{I}_{\rm s}}\ . \tag{40.134}$$

That is, since the resonance fluorescence is proportional to the excited state population, we may define a quantity $S_{tot} \equiv \rho_{22}(\infty)$, so that the coherent and incoherent parts of the fluorescence are,

$$\boxed{S_{\rm coh} = |\rho_{21}(\infty)|^2 = \frac{s/2}{(1+s)^2} \qquad \text{and} \qquad S_{\rm incoh} = \rho_{22}(\infty) - |\rho_{21}(\infty)|^2 = \frac{s^2/2}{(1+s)^2}}\ . \tag{40.135}$$

Hence, $S_{\rm incoh} = sS_{\rm coh}$.

[9] The classical version of this formula is (16.41) .

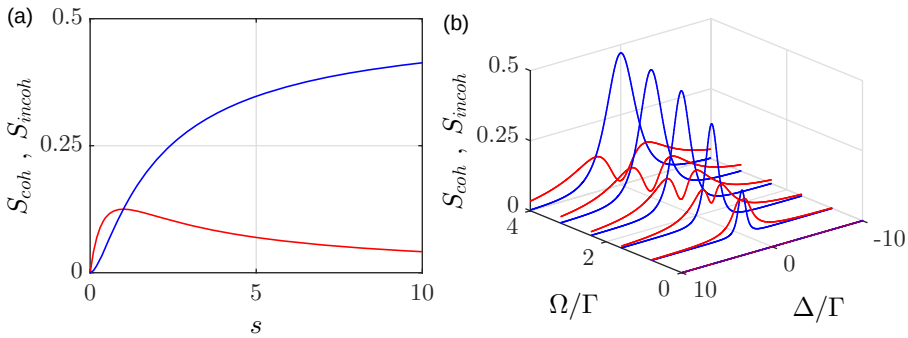

Figure 40.12: (code) Elastic (red) versus inelastic scattering (blue) as a function of the saturation parameter (a) at resonance and (b) for various detunings.

The result (40.135), illustrated in Fig. 40.12(a), means that *below saturation* scattering is dominated by elastic scattering. Incident light excites the atomic dipole moment ρ_{12}, that is, charge oscillations which, in turn, emit electromagnetic radiation like a classical antenna. *Above saturation* the excited atomic state accumulates an considerable amount of population ρ_{22} giving rise to spontaneous emission, which is interpreted as inelastic scattering. This intrinsically quantum feature is a consequence of the quantized nature of the atomic energy levels and has no classical counterpart. Another interesting feature seen in Fig. 40.12(b) is that, when the incident light is tuned sufficiently far from resonance, elastic scattering will dominate at any saturation parameter.

40.4.3 The spectrum of resonance fluorescence

The *correlation functions* defined in (40.77) represent an interesting concept for describing resonance fluorescence and for phenomena such as *antibunching* observed in resonance fluorescence.

40.4.3.1 The quantum regression theorem

From (40.83) we see that, to compute the spectra of *resonance fluorescence*, we only need to compute the correlation function $g^{(1)}$, i.e. the amplitudes of the field $\hat{\mathcal{E}}(t)$, which in turn are related to the field operators (37.8). The field operators follow the solutions of the Bloch equation, which, being linear, have the following generic form,

$$\rho_{ij}(t+\tau) = \sum_{k,l} \alpha_{ijkl}(\tau)\rho_{ij}(t) + \beta_{ij}(\tau) \ . \tag{40.136}$$

The trace condition is satisfied, when $(i,j),(k,l) \neq (1,1)$.

To be able to explore the above relationship to calculate correlation functions, we have to invoke the so-called *quantum regression theorem*,

$$\boxed{\langle \hat{A}(t+\tau)\rangle = \sum_i \xi_i(\tau)\langle \hat{A}_i(t)\rangle \quad \Longrightarrow \quad \langle \hat{B}(t)\hat{A}(t+\tau)\hat{C}(t)\rangle = \sum_i \xi_i(\tau)\langle \hat{B}(t)\hat{A}_i(t)\hat{C}(t)\rangle} \ . \tag{40.137}$$

Example 288 (*Quantum regression applied to the Langevin equation*): We have,

$$\dot{A}_\mu = D_\mu(t) + F_\mu(t) \qquad (40.138)$$
$$\langle F_\mu(t)F_\nu(t)\rangle = 2\langle D_{\mu\nu}\rangle\delta(t-t') \ .$$

We know,

$$\langle A_\mu(t)F_\nu(t)\rangle = \langle D_{\mu\nu}\rangle \quad \text{and} \quad \langle F_\mu(t)A_\nu(t)\rangle = \langle D_{\mu\nu}\rangle \qquad (40.139)$$

and the quantum regression theorem gives,

$$\frac{d}{dt}\langle A_\mu(t)A_\nu(t')\rangle = \langle D_\mu(t)A_\nu(t')\rangle \ , \qquad (40.140)$$

because if $t' < t$, the term $\langle F_\mu(t)A_\nu(t')\rangle$ vanishes for a *Markovian process*.

40.4.3.2 Bloch equation for a two-level system

The Fourier transform of the first-order coherence, $g^{(1)}(\tau) = e^{-\imath\omega\tau}G(\tau)$, gives,

$$F(\nu) = (\mathcal{F}g^{(1)})(\nu) = \mathcal{F}[e^{-\imath\omega\tau}] \star \mathcal{F}[G(\tau)] = \delta(\nu-\omega) \star \mathcal{F}[G(\tau)] = (\mathcal{F}G)(\nu-\omega) \ . \qquad (40.141)$$

Therefore, we can look at the unshifted spectrum, $(\mathcal{F}G)(\nu)$. Since the fluorescence spectrum is determined by the first-order coherence, which depends on the field operators, which in turn depend on the atomic populations and coherences, we have to solve the Bloch equation.

For a two-level atom the Bloch equations, having been reduced by the normalization condition (39.243) are,

$$\dot{\vec{\rho}}_{\text{red}} = \mathcal{M}\vec{\rho}_{\text{red}} + \mathbf{b} = \begin{pmatrix} -\Gamma & -\frac{\imath}{2}\Omega & \frac{\imath}{2}\Omega \\ -\imath\Omega & -\frac{1}{2}\Gamma - \imath\Delta & 0 \\ \imath\Omega & 0 & -\frac{1}{2}\Gamma + \imath\Delta \end{pmatrix} \begin{pmatrix} \rho_{22} \\ \rho_{12} \\ \rho_{21} \end{pmatrix} + \begin{pmatrix} 0 \\ \frac{\imath}{2}\Omega \\ -\frac{\imath}{2}\Omega \end{pmatrix} \qquad (40.142)$$

with the solution (39.245), that is, $\vec{\rho}(t+\tau) = e^{\mathcal{M}\tau}\vec{\rho}(t) + (1-e^{\mathcal{M}\tau})\vec{\rho}(\infty)$ with $\rho(\infty) = -\mathcal{M}^{-1}b$. This solution can be cast in the following form,

$$\rho_{kl}(t+\tau) = \sum_{(mn)} \alpha_{(kl)(mn)}(\tau)\rho_{mn}(t) + \beta_{(kl)}(\tau) \ , \qquad (40.143)$$

where $(mn), (kl) = (22), (12), (21)$ identifying,

$$\alpha_{(kl)(mn)}(\tau) = \begin{pmatrix} \alpha_{22,22} & \alpha_{12,22} & \alpha_{21,22} \\ \alpha_{22,12} & \alpha_{12,12} & \alpha_{21,12} \\ \alpha_{22,21} & \alpha_{12,21} & \alpha_{21,21} \end{pmatrix} \equiv \begin{pmatrix} (e^{\mathcal{M}\tau})_{11} & . & . \\ . & . & . \\ . & . & . \end{pmatrix} = e^{\mathcal{M}\tau} \qquad (40.144)$$

$$\beta_{(kl)}(\tau) = \begin{pmatrix} \beta_{22} \\ \beta_{12} \\ \beta_{21} \end{pmatrix} \equiv \begin{pmatrix} -[(1-e^{\mathcal{M}\tau})\mathcal{M}^{-1}\mathbf{b}]_1 \\ . \\ . \end{pmatrix} = -(1-e^{\mathcal{M}\tau})\mathcal{M}^{-1}\mathbf{b} \ .$$

Using quantum operators in the interaction image, $|k\rangle\langle l| = \hat{\sigma}_{kl}$, we have,

$$\langle\hat{\sigma}_{12}(t)\rangle = \langle\hat{\sigma}_{21}^\dagger(t)\rangle = \rho_{12}(t)e^{\imath\omega_0 t} \quad \text{and} \quad \langle\hat{\sigma}_{22}(t)\rangle = \langle\hat{\sigma}_{12}(t)\hat{\sigma}_{21}(t)\rangle = \rho_{22}(t) \ . \qquad (40.145)$$

yielding,

$$\langle e^{(k-l)\imath\omega_0(t+\tau)}\hat{\sigma}_{kl}(t+\tau)\rangle = \sum_{(mn)} \alpha_{(kl)(mn)}(\tau)\langle e^{(m-n)\imath\omega_0 t}\hat{\sigma}_{mn}(t)\rangle + \beta_{(mn)}(\tau)\langle 1\rangle \ , \tag{40.146}$$

or,

$$\begin{aligned}&\langle \hat{\sigma}_{kl}(t+\tau)\rangle \\ &= \sum_{(mn)} e^{(l-k)\imath\omega_0\tau}\alpha_{(kl)(mn)}(\tau)\langle e^{(l-k+m-n)\imath\omega_0 t}\hat{\sigma}_{mn}(t)\rangle + e^{(l-k)\imath\omega_0\tau}\beta_{(mn)}(\tau)\langle e^{(l-k)\imath\omega_0 t}\rangle \ .\end{aligned} \tag{40.147}$$

Applying the quantum regression theorem to the Bloch equations, we get for an arbitrary time-dependent operator $\hat{B}(t)$,

$$\boxed{\begin{aligned}\langle \hat{B}(t)\hat{\sigma}_{kl}(t+\tau)\rangle \quad = \quad &\sum_{(mn)} e^{(l-k)\imath\omega_0\tau}\alpha_{(kl)(mn)}(\tau)\langle e^{(l-k+m-n)\imath\omega_0 t}\hat{B}(t)\hat{\sigma}_{mn}(t)\rangle \\ &+e^{(l-k)\imath\omega_0\tau}\beta_{(mn)}(\tau)\langle e^{(l-k)\imath\omega_0 t}\hat{B}(t)\rangle\end{aligned}} \ . \tag{40.148}$$

40.4.3.3 Correlation functions

We now look at the radiation field, which is related to the dipole moment operator via,

$$\hat{\mathcal{E}}^- = \gamma\hat{\sigma}_{21} \ , \tag{40.149}$$

where γ is simply a constant. Substituting this relation in the correlation functions (40.77) we obtain,

$$\begin{aligned}g^{(1)}(\tau) &= \frac{\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{12}(t+\tau)\rangle}{\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{12}(t)\rangle} = \frac{\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{12}(t+\tau)\rangle}{\langle \hat{\sigma}_{22}(t)\rangle} \\ g^{(2)}(\tau) &= \frac{\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{21}(t+\tau)\hat{\sigma}_{12}(t+\tau)\hat{\sigma}_{12}(t)\rangle}{\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{12}(t)\rangle^2} = \frac{\langle \hat{\sigma}_{22}(t)\hat{\sigma}_{22}(t+\tau)\rangle}{\langle \hat{\sigma}_{22}(t)\rangle^2} \ .\end{aligned} \tag{40.150}$$

Now we can calculate, letting $\xi_i(\tau) \equiv \alpha_{(12)(mn)}$, $\hat{C}(t) \equiv 1$, and $\hat{B}(t) \equiv \hat{\sigma}_{21}(t)$,

$$\begin{aligned}g^{(1)}(\tau) &= \frac{\sum_{(mn)} e^{\imath\omega_0(t+\tau)}e^{(m-n)\imath\omega_0 t}\alpha_{(12)(mn)}(\tau)\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{mn}(t)\rangle + e^{\imath\omega_0(t+\tau)}\beta_{(12)}(\tau)\langle \hat{\sigma}_{21}(t)\rangle}{\langle \hat{\sigma}_{22}(t)\rangle} \\ g^{(2)}(\tau) &= \frac{\sum_{(mn)} e^{(m-n)\imath\omega_0 t}\alpha_{(22)(mn)}(\tau)\langle \hat{\sigma}_{22}(t)\hat{\sigma}_{mn}(t)\rangle + \beta_{(22)}(\tau)\langle \hat{\sigma}_{22}(t)\rangle}{\langle \hat{\sigma}_{22}(t)\rangle^2} \ .\end{aligned} \tag{40.151}$$

Using $\hat{\sigma}_{21}\hat{\sigma}_{mn} = \hat{\sigma}_{2n}\delta_{m1}$,

$$\begin{aligned}g^{(1)}(\tau) &= e^{\imath\omega_0\tau}\frac{\alpha_{(12)(12)}(\tau)\langle \hat{\sigma}_{21}(t)\hat{\sigma}_{12}(t)\rangle + \beta_{(12)}(\tau)\langle e^{\imath\omega_0 t}\hat{\sigma}_{21}(t)\rangle}{\langle \hat{\sigma}_{22}(t)\rangle} \\ g^{(2)}(\tau) &= \frac{\alpha_{(22)(21)}(\tau)\langle e^{\imath\omega_0 t}\hat{\sigma}_{22}(t)\hat{\sigma}_{21}(t)\rangle + \alpha_{(22)(22)}(\tau)\langle \hat{\sigma}_{22}(t)\hat{\sigma}_{22}(t)\rangle + \beta_{(22)}(\tau)\langle \hat{\sigma}_{22}(t)\rangle}{\langle \hat{\sigma}_{22}(t)\rangle^2} \ .\end{aligned} \tag{40.152}$$

Returning to the density operator and letting $t \to \infty$,

$$g^{(1)}(\tau) = e^{\imath\omega_0\tau}\left[\alpha_{(12)(12)}(\tau) + \beta_{(12)}(\tau)\frac{\rho_{21}(\infty)}{\rho_{22}(\infty)}\right] \qquad \text{and} \qquad g^{(2)}(\tau) = e^{\imath\omega_0\tau}\frac{\beta_{(22)}(\tau)}{\rho_{22}(\infty)}\,, \tag{40.153}$$

that is,

$$\boxed{\begin{aligned} g^{(1)}(\tau) &= e^{\imath\omega_0\tau}\left[\left[e^{\mathcal{M}\tau}\right]_{(12)(12)} - \left[(\mathbb{I}-e^{\mathcal{M}\tau})\mathcal{M}^{-1}\mathbf{b}\right]_{(12)}\frac{\left[\mathcal{M}^{-1}\mathbf{b}\right]_{(21)}}{\left[\mathcal{M}^{-1}\mathbf{b}\right]_{(22)}}\right] \\ g^{(2)}(\tau) &= e^{\imath\omega_0\tau}\frac{\left[(\mathbb{I}-e^{\mathcal{M}\tau})\mathcal{M}^{-1}\mathbf{b}\right]_{(22)}}{\left[\mathcal{M}^{-1}\mathbf{b}\right]_{(22)}} \end{aligned}} \,. \tag{40.154}$$

These correlation functions can easily be calculated via a numerical resolution of the Bloch equations (40.142). Fig. 40.13 shows the correlation functions and the fluorescence spectrum derived by Fourier transform of the first-order correlation function (40.82). Assuming resonant excitation, $\Delta = 0$, analytic formulas can be derived, as will be exercised in Excs. 40.4.4.3 and Exc. 40.4.4.4.

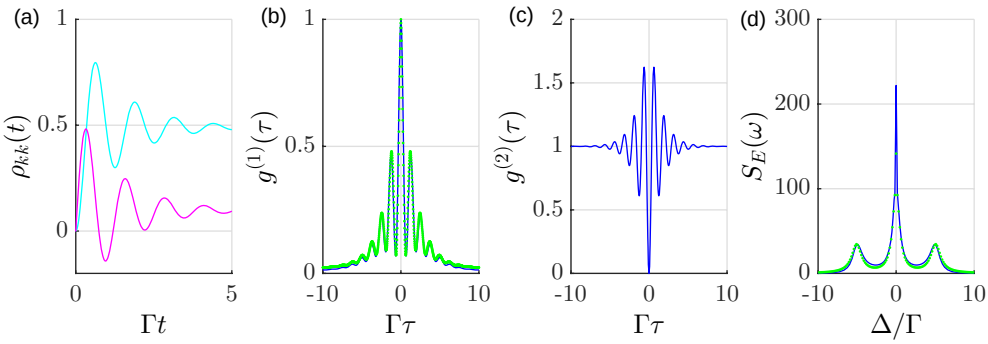

Figure 40.13: (code) (a) Temporal evolution of the excited state population $\rho_{22}(t)$ (cyan) and coherence $\rho_{12}(t)$ (magenta) of a laser-driven two-level atom with $\Omega = 5\Gamma$. (b) Correlation function $g^{(1)}(\tau)$ and (c) $g^{(2)}(\tau)$. The blue curves in (b-c) are obtained by numerical simulations of the Bloch equations and subsequent application of the quantum regression theorem (40.154). The green dots are obtained from an analytic solution derived in Exc. 40.4.4.3. (d) Mollow spectrum obtained by numerical FFT of $g^{(1)}(\tau)$.

The spectrum 40.13(d) exhibits three lines known as the *Mollow triplet*. Note that the spontaneous emission triplet is only observed in the presence of a driving laser, because it is the laser excitation which causes the splitting. Indeed, the splitting and the position of the lines are easily understood in the dressed states picture visualized in Fig. 40.1: The coupling of the two-level atom to a light field splits up the levels $|n\rangle$ and $|n+1\rangle$ by an amount corresponding to the Rabi frequency Ω. Now, the transition from the two excited state $|n+1\rangle$ levels to the ground state $|n\rangle$ levels can occur on three different frequencies. In Exc. 40.4.4.5 we calculate the Mollow spectrum for a transition between one ground and three excited Zeeman states. Fig. 40.14 illustrates the various methods to analyze scattered light, but not all of them yield information on the Mollow triplet.

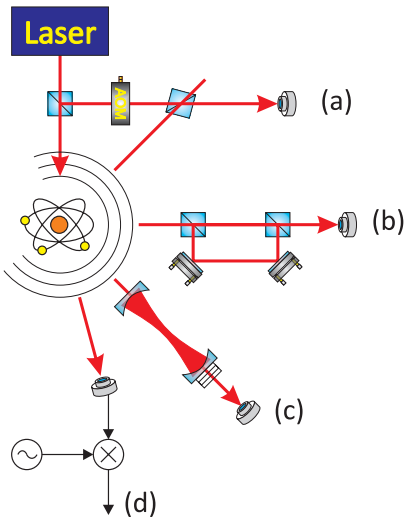

Figure 40.14: Schemes for analyzing resonance fluorescence: (a) Heterodyning [708], (b) temporal correlation, (c) spectrum [871, 709], (d) demodulation. Only the schemes (b) and (c) yield information on the Mollow triplet.

40.4.3.4 Mollow spectrum from effective Hamiltonian

The Mollow triplet is easily understood in the dressed states picture. On the other hand, we know that (for classical light) the semi-classical picture is totally equivalent (its just a unitary transform of the dressed states picture). Developing a physical picture the Mollow triplet in the semi-classical framework may give us a deeper insight. Generally, the Mollow spectrum is anyhow calculated using the semi-classical Bloch equations, via the correlation function $g^{(1)}(\tau)$ and the Wiener-Khintchine theorem, but the on the way the physical intuition is lost.

For example, looking at the stationary solution of the Bloch equations (39.151), we see that $\vec{\rho}(\infty)$ is time-independent, so that we might be *surprised to see correlations in time domain* (and consequently a structured spectrum) at all. This surprise results from a common misconception that may arise considering the damping of $\vec{\rho}(t)$ predicted by the Bloch model, as illustrated e.g. in Fig. 39.3: It seems that the atoms eventually cease oscillating between the ground and excited states. In most experiments, measurement are made on a large number of atoms and indeed the oscillations are damped.

In fact, however, every individual atom undergoes a complicated unpredictable trajectory alternating times of coherent evolution with spontaneous emission events (called quantum jumps). The damped behavior only results as an average over many such quantum trajectories. In this light, the reason for $g^{(1)}$-type correlations is a subtle interplay between coherently and incoherently scattered light: *The spontaneous emission probability is amplitude-modulated with the Rabi frequency.*

An alternative way to calculate the Mollow spectrum consists in solving the Schrödinger equation with the effective Hamiltonian, as done in Exc. 40.4.4.2 and 40.4.4.6. The results are shown in Fig. 40.15. While providing an intuitive picture

of the origin of of the Mollow triplet a quantitatively correct treatment requires a Monte-Carlo wavefunction simulation [661] (see Sec. 41.1.2).

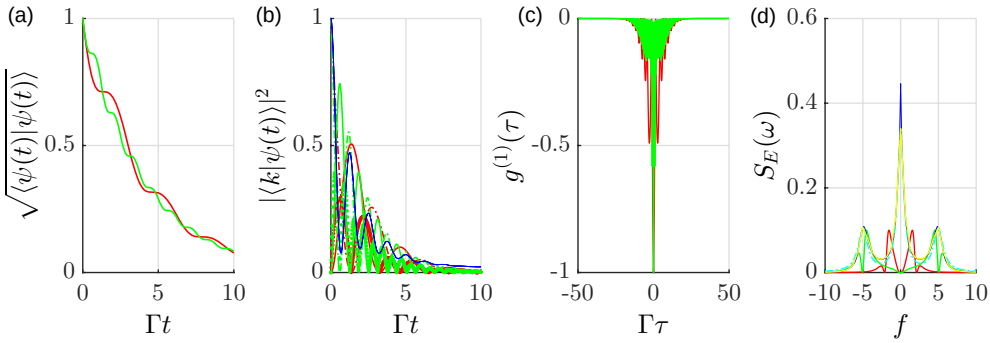

Figure 40.15: (code) (a) Time evolution of the norm of a decaying driven two-level atom. (b) Time evolution of the ground and excited state amplitudes. (c) First-order auto-correlation function, and (d) spectrum.

40.4.3.5 Weak excitation and the role of collisions

For the case of a weakly excited two-level atom, $|\Omega| \ll \Gamma$, we have analytic solutions (39.157) of the Bloch equation. We can then take the coefficients α_{ijkl} and β_{ij} and insert them into the correlation functions,

$$\begin{aligned} g^{(1)}(\tau) &= e^{-\imath\omega\tau} \ , \\ g^{(2)}(\tau) &= 1 + e^{-2\gamma\tau} - 2\cos\Delta\tau \ , \\ F(\omega_s) &= (\mathcal{F}g^{(1)})(\omega_s) = \delta(\omega_s - \omega) \ . \end{aligned} \tag{40.155}$$

These functions show that the spectrum is essentially composed of *Rayleigh scattering* at the frequency of the incident light. The δ-shaped fluorescence spectrum shows, that the contribution of elastically scattered light dominates below saturation, which confirms the results (40.135) illustrated in Fig. 40.12. The light is 'antibunched' and, at higher τ exhibits a damped oscillation around the value 1.

If pressure broadening is taken into account, the two-level Bloch equations are given by (39.151), where $\gamma' = \gamma + \gamma_{coll}$ is the width of the collision-broadened line. Within this model and in the limit $\Omega \ll \Gamma$, the resonance fluorescence spectrum is given by [590],

$$F(\omega_s) = \frac{\gamma' - \Gamma}{\gamma'} \frac{\gamma'/\pi}{(\omega_0 - \omega_s)^2 + \gamma'^2} + \frac{\Gamma}{\gamma'}\delta(\omega_s - \omega) \ . \tag{40.156}$$

So, we find that, even at low intensities, a continuous spectrum due to *inelastic scattering* appears around the resonance frequency ω_0 additionally to the elastic Rayleigh peak.

40.4.4 Exercises

40.4.4.1 Ex: Derivation of the rate equations for two-level atoms

Inserting the ansatz (40.110) into the Schrödinger equation, derive the equations of motion (40.112) for the wavefunction amplitudes.

40.4.4.2 Ex: Non-Hermitian time evolution

Study the time evolution $|\psi(t)\rangle = e^{-\imath \hat{H}_{\text{eff}} t/\hbar}|\psi(0)\rangle$ with the effective Hamiltonian,

$$\hat{H}_{\text{eff}} = \begin{pmatrix} 0 & \frac{\hbar}{2}\Omega \\ \frac{\hbar}{2}\Omega & -\frac{\imath\hbar}{2}\Gamma \end{pmatrix}$$

starting from the initial condition $\langle 2|\psi(0)\rangle = 1$. Calculate the evolution of $|\psi(t)\rangle$ and the norm $\langle\psi(t)|\psi(t)\rangle$. Plot the time evolution of the norm for various ratios Ω/Γ and interpret the curves. **Alternative solution:**
We set $\hbar = 1$ and calculate the eigenvalues $E_\pm$ and the unitary transformation matrix $\mathcal{U}$, where $\mathcal{U}\hat{H}_{\text{eff}} = \hat{E}\mathcal{U}$ and

$$\hat{E} \equiv \begin{pmatrix} E_+ & 0 \\ 0 & E_- \end{pmatrix} .$$

The eigenvalues are,

$$E_\pm = -\tfrac{\imath\Gamma}{4} \pm \tfrac{1}{4}\sqrt{4\Omega^2 - \Gamma^2} \overset{\Omega\to 0}{\longrightarrow} 0, -\tfrac{\imath}{2}\Gamma .$$

The unitary transformation matrix is nothing else than the eigenvector matrix,

$$\mathcal{U} = \begin{pmatrix} \frac{2E_+ + \imath\Gamma}{\Omega} & \frac{2E_- + \imath\Gamma}{\Omega} \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} \frac{\imath\Gamma}{2\Omega} + \sqrt{1 - \frac{\Gamma^2}{4\Omega^2}} & \frac{\imath\Gamma}{2\Omega} - \sqrt{1 - \frac{\Gamma^2}{4\Omega^2}} \\ 1 & 1 \end{pmatrix} .$$

We get for the evolution,

$$\begin{aligned}
e^{-\imath\hat{H}_{\text{eff}}t}\begin{pmatrix} 0 \\ 1 \end{pmatrix} &= \mathcal{U}e^{-\imath\hat{E}t}\mathcal{U}^{-1}\begin{pmatrix} 0 \\ 1 \end{pmatrix} \\
&= \begin{pmatrix} \frac{2E_+ + \imath\Gamma}{\Omega} & \frac{2E_- + \imath\Gamma}{\Omega} \\ 1 & 1 \end{pmatrix} \begin{pmatrix} e^{-\imath E_+ t} & 0 \\ 0 & e^{-\imath E_- t} \end{pmatrix} \begin{pmatrix} \frac{2E_+ + \imath\Gamma}{\Omega} & \frac{2E_- + \imath\Gamma}{\Omega} \\ 1 & 1 \end{pmatrix}^{-1} \begin{pmatrix} 0 \\ 1 \end{pmatrix} \\
&= \begin{pmatrix} -\frac{(2E_+ + \imath\Gamma)(2E_- + \imath\Gamma)}{2\Omega(E_+ - E_-)}\left(e^{-\imath E_+ t} - e^{-\imath E_- t}\right) \\ -\frac{(2E_- + \imath\Gamma)}{2(E_+ - E_-)}e^{-\imath E_+ t} + \frac{(2E_+ + \imath\Gamma)}{2(E_+ - E_-)}e^{-\imath E_- t} \end{pmatrix} \\
&= \begin{pmatrix} \frac{\Omega}{\sqrt{4\Omega^2 - \Gamma^2}}\left(e^{-\imath E_+ t} - e^{-\imath E_- t}\right) \\ \frac{1}{2}\left(1 - \frac{\imath\Gamma}{\sqrt{4\Omega^2 - \Gamma^2}}\right)e^{-\imath E_+ t} + \frac{1}{2}\left(1 + \frac{\imath\Gamma}{\sqrt{4\Omega^2 - \Gamma^2}}\right)e^{-\imath E_- t} \end{pmatrix} \\
&= e^{-\Gamma t/4}\begin{pmatrix} \frac{-2\imath\Omega}{\sqrt{4\Omega^2 - \Gamma^2}} \sin\frac{t\sqrt{4\Omega^2 - \Gamma^2}}{4} \\ \cos\frac{t\sqrt{4\Omega^2 - \Gamma^2}}{4} - \frac{\Gamma}{\sqrt{4\Omega^2 - \Gamma^2}} \sin\frac{t\sqrt{4\Omega^2 - \Gamma^2}}{4} \end{pmatrix} .
\end{aligned}$$

The result is identical to the one previously derived.

40.4.4.3 Ex: Resonance fluorescence and antibunching via Bloch equations

a. Derive the analytic solution of the Bloch equations for a resonantly driven two-level atom.
b. Calculate the 1st-order correlation function $g^{(1)}(\tau)$ from the formula (40.154).
c. Derive the spectrum of resonance fluorescence [660].
d. Derive the 2nd-order correlation function $g^{(2)}(\tau)$ from the formula (40.154).

40.4.4.4 Ex: Resonance fluorescence via rate equations

Repeat Exc. 40.4.4.3 neglecting coherences, i.e. replacing the Bloch equations by rate equations,

$$\dot{\vec{\rho}} = \begin{pmatrix} -R & R+\Gamma & 0 & 0 \\ R & -R-\Gamma & 0 & 0 \\ 0 & 0 & -\gamma & 0 \\ 0 & 0 & 0 & -\gamma \end{pmatrix} \vec{\rho} \ ,$$

where $R = \Omega^2/2\gamma$ is the pump rate.

40.4.4.5 Ex: Fluorescence spectrum of a four-level system

A more realistic transition, allowing for a vectorial nature of the radiation field, involves one ground and three excited Zeeman states (e.g. the strontium ${}^1S_0$-${}^1P_1$ transition). In this case, the emitted light is,

$$\hat{\mathcal{E}}^-(t) = \hat{\mathcal{E}}^-_{\sigma^-}(t) + \hat{\mathcal{E}}^-_{\pi}(t) + \hat{\mathcal{E}}^-_{\sigma^+}(t) \ .$$

Calculate the first-order correlation function and the fluorescence spectrum of this transition.

40.4.4.6 Ex: Semi-classical picture of the Mollow triplet

Calculate the first-order correlation function from the solution of the Schrödinger equation with the effective Hamiltonian derived in Exc. 40.4.4.2.

40.4.4.7 Ex: Monte-Carlo simulation of the Mollow triplet

Implement a Monte-Carlo simulation of the Mollow triplet for a driven two-level atom according to [218, 661].

40.5 Light scattering from multi-level atoms

40.5.1 Quantum beats

The phenomenon of *quantum beats* is another simple example of effects beyond semi-classical theory, requiring a full second-quantized calculation. In semi-classical theory (SCT), there is an interference or beat note term for both V-type and Λ-type atoms, while in quantum electrodynamics (QED) only V-type atoms exhibits a beat term.

In the semi-classical picture, the state vector of electrons is [835],

$$\psi(t)\rangle = c_1 e^{-\imath\omega_1 t}|1\rangle + c_2 e^{-\imath\omega_2 t}|2\rangle + c_3 e^{-\imath\omega_3 t}|3\rangle \ . \tag{40.157}$$

Writing the non-vanishing dipole matrix elements as $d_{12} = e\langle 1|r|2\rangle$, $d_{23} = e\langle 2|r|3\rangle$ a three-level atom has two microscopic oscillating dipoles,

$$\mathcal{P}(t) = d_{12}(c_1^* c_2)e^{\imath\omega_{12}t} + d_{23}(c_2^* c_3)e^{\imath\omega_{23}t} + c.c. \ . \tag{40.158}$$

In the semi-classical picture, the radiated field will be a sum of these two terms,

$$\mathcal{E}^+ = \mathcal{E}_1 e^{-\imath\omega_{12}t} + \mathcal{E}_2 e^{-\imath\omega_{23}t} \ . \tag{40.159}$$

This leads to an interference or beat note term in a square-law detector,

$$|\mathcal{E}^+|^2 = |\mathcal{E}_{12}|^2 + |\mathcal{E}_{23}|^2 + \mathcal{E}_{12}^* \mathcal{E}_{23} e^{[\imath(\omega_{12}-\omega_{23})t]} + c.c. \ , \tag{40.160}$$

regardless of whether state $|2\rangle$ decays simultaneously to $|1\rangle$ and $|3\rangle$ or vice versa.

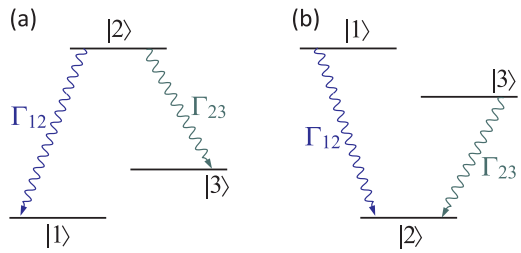

Figure 40.16: Level configuration of a Λ-system (left) and a V-system (right).

40.5.1.1 Quantum electrodynamics calculation

For the quantum electrodynamical calculation, we use the creation and annihilation operators from second quantization of quantum mechanics. Let $\hat{\mathcal{E}}_n^+ = \hat{a}_n e^{-\imath\omega_n t}$ be the annihilation operator and $\hat{\mathcal{E}}_n^- = \hat{a}_n^\dagger e^{\imath\omega_n t}$ be the creation operator with $n = (12)$ or $n = (23)$. Then the beat note becomes,

$$\langle\psi_V(t)|\hat{\mathcal{E}}_{12}^-(t)\hat{\mathcal{E}}_{23}^+(t)|\psi_V(t)\rangle \qquad \text{and} \qquad \langle\psi_\Lambda(t)|\hat{\mathcal{E}}_{12}^-(t)\hat{\mathcal{E}}_{23}^+(t)|\psi_\Lambda(t)\rangle \tag{40.161}$$

for the Λ and the V-system, respectively. The state vector for each type of system is,

$$|\psi_V(t)\rangle = \sum_{i=1,2,3} c_i|i,0\rangle + c_1|c,1_{12}\rangle + c_2|c,1_{23}\rangle \tag{40.162}$$

and,

$$|\psi_\Lambda(t)\rangle = \sum_{i=1,2,3} c_i'|i,0\rangle + c_1'|b,1_{12}\rangle + c_2'|c,1_{23}\rangle \ . \tag{40.163}$$

The beat note term becomes,

$$\begin{aligned}\langle\psi_V(t)|\hat{\mathcal{E}}_1^-(t)\hat{\mathcal{E}}_2^+(t)|\psi_V(t)\rangle &= \kappa\langle 1_{12}0_{23}|a_1^\dagger a_2|0_{12}1_{23}\rangle e^{[\imath(\omega_{12}-\omega_{23})t]}\langle 3|3\rangle \\ &= \kappa e^{[\imath(\omega_{12}-\omega_{23})t]}\langle 3|3\rangle\end{aligned} \tag{40.164}$$

for the V-system and

$$\begin{aligned}\langle\psi_\Lambda(t)|\hat{\mathcal{E}}_1^-(t)\hat{\mathcal{E}}_2^+(t)|\psi_\Lambda(t)\rangle &= \kappa'\langle 1_{12}0_{23}|a_1^\dagger a_2|0_{12}1_{23}\rangle e^{[\imath(\omega_{12}-\omega_{23})t]}\langle 2|3\rangle \\ &= \kappa' e^{[\imath(\omega_{12}-\omega_{23})t]}\langle 2|3\rangle\end{aligned} \tag{40.165}$$

for the Λ-system. However, orthogonality of the eigenstates requires $\langle 3|3\rangle = 1$ and $\langle 2|3\rangle = 0$. Therefore, there is a quantum beat note term for V-type atoms, but not for Λ-type atoms.

This difference originates in quantum mechanical uncertainty. A V-type atom decays to state $|3\rangle$ via the emission with ω_{12} and ω_{23}. Since both transitions decayed to the same state, one cannot determine along which path each decayed, similar to Young's double-slit experiment. However, Λ-type atoms decay to two different states. Therefore, in this case we can identify the path by the end product.

Quantum beat spectroscopy is a technique which allows for Doppler-free resolution provided the separation of the adjacent levels is less than the Doppler width. It consists in generating a coherently distributed population of two upper states, e.g. via a short laser pulse, and detecting the beat frequency.

40.5.2 Two-photon transitions

We will now apply the *Kramers-Heisenberg formula* (27.111) to photon scattering processes $\omega \to \omega_s$. The states are then product states of atomic excitations and photonic modes $|m, n, n_s\rangle$. In particular, the final state must take into account the mode into which light is scattered,

$$\begin{aligned}\frac{1}{\tau} = \frac{2\pi}{\hbar^2}\sum_f\sum_{\mathbf{k}_s}\Bigg|&\langle f, n-1, 1|\hat{H}^{(2)}|i, n, 0\rangle \\ &+\frac{1}{\hbar}\sum_m \frac{\langle f, n-1, 1|\hat{H}^{(1)}|m\rangle\langle m|\hat{H}^{(1)}|i, n, 0\rangle}{\omega_i - \omega_m}\Bigg|^2 \delta(\omega_f - \omega_i)\ .\end{aligned} \tag{40.166}$$

The initial energy is $\omega_i \to n\omega$, the final energy $\omega_f \to (n-1)\omega + \omega_s + \omega_f$, two intermediate states are possible, $|m\rangle \to |m, n-1, 0\rangle$ and $|m\rangle \to |m, n, 1\rangle$ over which we must sum, that is $\omega_m \to \omega_m + (n-1)\omega$ and $\omega_m \to \omega_m + n\omega + \omega_s$. They are illustrated by the Feyman diagrams in Fig. xx. Hence, and neglecting the non-linear contribution $\hat{H}^{(2)}$,

$$\begin{aligned}\frac{1}{\tau} = \frac{2\pi}{\hbar^3}\sum_f\sum_{\mathbf{k}_s}\Bigg|\sum_m &\frac{\langle f, n-1, 1|\hat{H}^{(1)}|m, n, 0\rangle\langle m, n, 0|\hat{H}^{(1)}|i, n, 0\rangle}{\omega - \omega_m} \\ &+\frac{\langle f, n-1, 1|\hat{H}^{(1)}|m, n-1, 1\rangle\langle m, n-1, 1|\hat{H}^{(1)}|i, n, 0\rangle}{-\omega_m - \omega_s}\Bigg|^2 \delta(\omega_f - \omega + \omega_s)\ .\end{aligned} \tag{40.167}$$

Evaluated far from resonance, $\omega \gg \omega_m$, this result leads to Thomson and Compton scattering. Close to resonance the second term of the sum may neglected.

The matrix elements can be evaluated by the electric dipole Hamiltonian in second quantization,

$$\frac{1}{\tau} = \frac{2\pi}{\hbar}\sum_{\mathbf{k}_s}\left|\sum_m \frac{\Omega_{fm}\Omega_{mi}}{\omega - \omega_m}\right|^2 \delta(\omega_f - \omega + \omega_s)\ . \tag{40.168}$$

We convert the transition rate into a cross section via,

$$\sum_{\mathbf{k}_s} \to \frac{V}{(2\pi)^3} \int\int k_s^2 dk_s d\Omega = \frac{V}{(2\pi c)^3} \int\int \omega_s^2 d\omega_s d\Omega \ . \tag{40.169}$$

40.5.2.1 Transition rates for n-photon processes

It is adequate to move to a continuum of final states of the field. The sum over the final states includes a sum over the modes $\mathbf{k}$ and the polarizations λ,

$$\sum_f = \sum_{\mathbf{k}} \sum_\lambda \longrightarrow \frac{1}{h^3} \int_{\mathbb{R}^6} d^3p d^3r \sum_\lambda = \frac{V}{(2\pi c)^3} \int_\Omega d\Omega \ d\omega \ \omega^2 \sum_\lambda \ . \tag{40.170}$$

We now insert for the matrix element (first term in ()) the cartesian multipole expansion () and obtain,

$$\begin{aligned} \frac{1}{\tau} &= \frac{2\pi}{\hbar^2} \sum_f \left| \langle f| - \imath e \sqrt{\frac{\hbar\omega}{2\varepsilon_0 V}} [\hat{\varepsilon} \cdot \mathbf{d}_E + ...] |i\rangle \right|^2 \delta(\omega - \omega_f) \sum_\lambda \\ &\longrightarrow \frac{2\pi}{\hbar^2} \frac{V}{(2\pi c)^3} \frac{e^2 \hbar\omega}{2\varepsilon_0 V} \omega^2 \sum_\lambda \int \left| \hat{\varepsilon} \cdot \langle g|\mathbf{d}_E|e\rangle + \imath \hat{\varepsilon} \cdot \langle g|\mathbf{q}_E|e\rangle \cdot \mathbf{k} ...] - ... \right|^2 d\Omega \ . \end{aligned} \tag{40.171}$$

Finally, letting $\sum_\lambda = 2$,

$$\frac{1}{\tau} = \frac{\alpha\omega^3}{\pi c^2} \int \left| \hat{\varepsilon} \cdot \langle g|\text{multipole-tensor}|e\rangle \text{wavenumber-tensor} \right|^2 d\Omega \ . \tag{40.172}$$

For example, for dipole radiation, letting $\hat{\varepsilon} = \hat{\mathbf{e}}_z$,

$$\begin{aligned} \frac{1}{\tau} &= \frac{\alpha\omega^3}{\pi c^2} \int \left| \hat{\varepsilon} \cdot \langle g|\mathbf{d}_E|e\rangle \right|^2 d\cos\theta d\phi \\ &= \frac{\alpha\omega^3}{\pi c^2} |\langle g|\mathbf{d}_E|e\rangle|^2 \int |\cos\theta|^2 d\cos\theta d\phi = \frac{4\alpha\omega^3}{3c^2} |\langle g|\mathbf{d}_E|e\rangle|^2 \ . \end{aligned} \tag{40.173}$$

40.5.2.2 Absorption

In first order perturbation theory we have Fermi's Golden rule,

$$\frac{1}{\tau} = \frac{2\pi}{\hbar^2} \sum_f |\langle f|\hat{H}_{\text{int}}|i\rangle|^2 \delta(\omega_f - \omega_i) \ . \tag{40.174}$$

In the dipolar approximation, $\hat{H}_{\text{int}} = -\mathbf{d} \cdot \vec{\mathcal{E}}$, and separating the field and atomic degrees of freedom, $|f\rangle = |N_f\rangle|A_f\rangle$, we get for absorption processes,

$$\frac{1}{\tau} = \frac{2\pi e^2}{\hbar^2} \sum_{N_f} \left| \langle N_f|\hat{\mathcal{E}}^-|N_i\rangle \cdot \langle A_f|\hat{\varepsilon} \cdot \hat{\mathbf{d}}|A_i\rangle \right|^2 \delta(\omega_f - \omega_i) \ . \tag{40.175}$$

Generalizing to a statistical mixture of Fock states via $\sum_{N_f,N_i}\langle N_i|\hat{E}^+|N_f\rangle p_i\langle N_f|\hat{E}^-|N_i\rangle = \mathrm{Tr}\ (\hat{\rho}\hat{\mathcal{E}}^+\hat{\mathcal{E}}^-)$, we may also write,

$$\frac{1}{\tau} = \frac{2\pi e^2}{\hbar^2}|M_{\rm abs}|^2\delta(\omega_f-\omega_i)\mathrm{Tr}\ (\hat{\rho}\hat{\mathcal{E}}^+\hat{\mathcal{E}}^-)\ , \tag{40.176}$$

where

$$|M_{\rm abs}|^2 \equiv \langle A_f|\hat{\varepsilon}\cdot\hat{\mathbf{d}}|A_i\rangle\ . \tag{40.177}$$

For an incoming photon ω, we get $\omega_f = E_f$ and $\omega_i = E_i + \omega$. See Fig. 40.17(a).

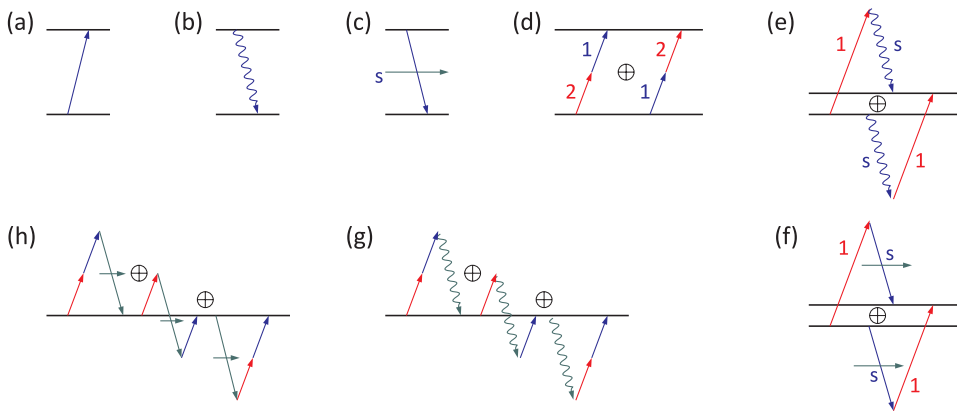

Figure 40.17: Feynman graphs for (a) absorption, (b) spontaneous emission, (c) stimulated emission, (d) two-photon absorption, (e) spontaneous Raman, (f) stimulated Raman, (g) spontaneous second harmonic generation, (h) and stimulated second harmonic generation.

40.5.2.3 Spontaneous and stimulated emission

In complete analogy to the absorption process, but now using the scattered field, $\hat{H}_{\rm int} = -\mathbf{d}\cdot\hat{\vec{\mathcal{E}}}_{\rm s}$, we get for emission processes,

$$\frac{1}{\tau} = \frac{2\pi e^2}{\hbar^2}|M_{\rm em}|^2\delta(\omega_f-\omega_i)\mathrm{Tr}\ (\hat{\rho}\hat{\mathcal{E}}_{\rm s}^+\hat{\mathcal{E}}_{\rm s}^-)\ , \tag{40.178}$$

where

$$|M_{\rm em}|^2 \equiv \langle A_f|\hat{\varepsilon}_s\cdot\hat{\mathbf{d}}|A_i\rangle\ . \tag{40.179}$$

For an outgoing photon ω_s, we get $\omega_f = E_f + \omega_s$ and $\omega_i = E_i$.

40.5.2.4 Two-photon absorption

In second order perturbation theory we have the Kramers-Heisenberg rule,

$$\frac{1}{\tau} = \frac{2\pi}{\hbar^2}\sum_f\left|\sum_m\frac{\langle f|\hat{H}_{\rm int}|m\rangle\langle m|\hat{H}_{\rm int}|i\rangle}{\omega-\omega_m}\right|^2\delta(\omega_f-\omega_i)\ . \tag{40.180}$$

In the dipolar approximation, $\hat{H}_{\rm int} = -\mathbf{d}\cdot\hat{\vec{\mathcal{E}}}_1 - \mathbf{d}\cdot\hat{\vec{\mathcal{E}}}_2$, and separating the field and atomic degrees of freedom, $|f\rangle = |N_f\rangle|A_f\rangle$, we get for two-photon absorption processes,

$$\frac{1}{\tau} = \frac{2\pi e^4}{\hbar^4}\sum_{N_f}\left|\sum_{N_m,A_m}\frac{\langle N_f|\mathcal{E}_2^-|N_m\rangle\langle N_m|\mathcal{E}_1^-|N_i\rangle\langle A_f|\hat{\varepsilon}_2\cdot\hat{\mathbf{d}}|A_m\rangle\langle A_m|\hat{\varepsilon}_1\cdot\hat{\mathbf{d}}|A_i\rangle}{\omega_1-\omega_m}\right. \tag{40.181}$$

$$\left. + \frac{\langle N_f|\mathcal{E}_1^-|N_m\rangle\langle N_m|\mathcal{E}_2^-|N_i\rangle\langle A_f|\hat{\varepsilon}_1\cdot\hat{\mathbf{d}}|A_m\rangle\langle A_m|\hat{\varepsilon}_2\cdot\hat{\mathbf{d}}|A_i\rangle}{\omega_2-\omega_m}\right|^2 \delta(\omega_f-\omega_1-\omega_2)\ .$$

Generalizing to a statistical mixture of Fock states via $\sum_{N_f,N_i} p_i|\langle N_f|\hat{\mathcal{E}}_2^-\hat{\mathcal{E}}_1^-|N_i\rangle = \mathrm{Tr}\,(\hat{\rho}\hat{\mathcal{E}}_1^+\hat{\mathcal{E}}_2^+\hat{\mathcal{E}}_2^-\hat{\mathcal{E}}_1^-)$, we may also write,

$$\frac{1}{\tau} = \frac{2\pi e^4}{\hbar^4}|M_{tpa}|^2\delta(\omega_f-\omega_i)\mathrm{Tr}\,(\hat{\rho}\hat{\mathcal{E}}_1^+\hat{\mathcal{E}}_2^+\hat{\mathcal{E}}_2^-\hat{\mathcal{E}}_1^-)\ , \tag{40.182}$$

where

$$M_{tpa} \equiv \langle A_f|\hat{\varepsilon}_2\cdot\hat{\mathbf{d}}G(E_i+\omega_1)\hat{\varepsilon}_1\cdot\hat{\mathbf{d}}|A_i\rangle + \langle A_f|\hat{\varepsilon}_1\cdot\hat{\mathbf{d}}G(E_i+\omega_2)\hat{\varepsilon}_2\cdot\hat{\mathbf{d}}|A_i\rangle\ . \tag{40.183}$$

For two incoming photons ω, we get $\omega_f = E_f$ and $\omega_i = E_i+\omega_1+\omega_2$. Here, G denotes the *photon propagator*,

$$G(\omega) = \sum_m \frac{|A_m\rangle\langle A_m|}{\omega - E_m}\ . \tag{40.184}$$

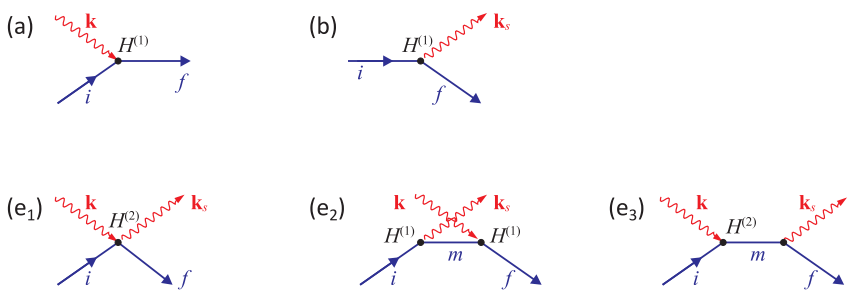

Figure 40.18: Feynman graphs for (a) absorption, (b) spontaneous emission, (c) stimulated emission, (e)(i-iii) spontaneous Raman.

40.5.2.5 Spontaneous and stimulated Raman process

In complete analogy to the two-photon absorption process, but now using the incident and the scattered fields, $\hat{H}_{\rm int} = -\mathbf{d}\cdot\vec{\mathcal{E}}_1 - \mathbf{d}\cdot\vec{\mathcal{E}}_{\rm s}$, we get for spontaneous and stimulated Raman processes,

$$\frac{1}{\tau} = \frac{2\pi e^4}{\hbar^4}|M_{ram}|^2\delta(\omega_f-\omega_i)\mathrm{Tr}\,(\hat{\rho}\hat{\mathcal{E}}_1^+\hat{\mathcal{E}}_{\rm s}^-\hat{\mathcal{E}}_{\rm s}^+\hat{\mathcal{E}}_1^-)\ , \tag{40.185}$$

where

$$M_{ram} \equiv \langle A_f|\hat{\varepsilon}_s \cdot \hat{\mathbf{d}} G(E_i + \omega_1)\hat{\varepsilon}_1 \cdot \hat{\mathbf{d}}|A_i\rangle + \langle A_f|\hat{\varepsilon}_1 \cdot \hat{\mathbf{d}} G(E_i - \omega_s)\hat{\varepsilon}_s \cdot \hat{\mathbf{d}}|A_i\rangle \ . \quad (40.186)$$

For an incoming photon ω_1 and a scattered photon ω_s, we get $\omega_f = E_f + \omega_s$ and $\omega_i = E_i + \omega_1$.

40.5.2.6 General n-photon processes

The transition probability in n-th order perturbation theory can be formulated in a general way as,

$$\frac{1}{\tau} = \frac{2\pi e^2}{\hbar^{2n}} |M_{fi}^{(n)}|^2 \delta(\omega_f - \omega_i) \mathrm{Tr}\ (\hat{\rho}\hat{\mathcal{E}}_1^{\pm}\hat{\mathcal{E}}_2^{\pm} ... \hat{\mathcal{E}}_2^{\mp}\hat{\mathcal{E}}_1^{\mp}) \ , \quad (40.187)$$

where

$$\begin{aligned} M_{fi}(\omega_n, ..., \omega_1) \equiv \mathcal{S}_p \langle A_f|\hat{\varepsilon}_n \hat{\mathbf{d}} G(E_i \pm \omega_1 \pm ... \pm \omega_{n-2} \pm \omega_{n-1}) \ ... \\ ... \ \hat{\varepsilon}_{n-1} \hat{\mathbf{d}} G(E_i \pm \omega_1 \pm ... \pm \omega_{n-2}) \ ... \\ ... \ \hat{\varepsilon}_1 \cdot \hat{\mathbf{d}} G(E_i \pm \omega_1)|A_i\rangle \ . \end{aligned} \quad (40.188)$$

The upper signs hold for absorbed photons (up to n), the lower for emitted photons, $\omega_f = E_f + \omega_1 + ... + \omega_n$ and $\omega_i = E_i + \omega_1 + ... + \omega_n$.

For n-photon processes, there are theoretically up to $n + 1$ different types, each one with $n!$ possible temporal sequences, which can be illustrated in Feynman graphs. Additionally, for every emitted photon can be either spontaneous or stimulated. The number of possible time sequences is reduced, if some absorbed or emitted photons have the same frequency by $m!$ (if m is the number og identical photons).

For example there are (3+1) different types of three-photon processes: 3 photons in, 2 photons in 1 out, 1 photon in 2 out, 3 photons out.

For example second harmonic generation: 3! possible time sequences, 2 processes, 2 equivalent photons = $\frac{3!2}{2!}$ possible Feynman graphs.

40.5.3 Exercises

40.5.3.1 Ex: Two-photon transitions in rubidium

Considering the following transitions of rubidium, $5S_{1/2} - 5P_{1/2}$ at 795 nm with $\Gamma_{795} = (2\pi)$ 6 MHz linewidth $5S_{1/2} - 5P_{3/2}$ at 780 nm with $\Gamma_{780} = (2\pi)$ 6MHz, and $5P_{3/2} - 5D_{5/2}$ at 776 nm with $\Gamma_{776} = (2\pi)$ 700 kHz linewidth. Calculate the rate for resonant two-photon transitions from the ground state to the $5D_{5/2}$ level without bothering about hyperfine splitting induced by a laser intensity of $I = 1$ mW/cm^2.

40.5.3.2 Ex: Spin relaxation in a dipole trap

Consider a transition in a hypothetical atomic species without nuclear spin between two levels $^2S_{1/2}$ and $^2P_{1/2}$ driven far-off resonance. Calculate the spin relaxation rate as a function of the detuning.

40.5.3.3 Ex: Rayleigh scattering and spin relaxation

Derive the rates for Rayleigh scattering and spin relaxation for ^{87}Rb driven far-off resonance. **Help**: Determine the hyperfine structure of the D1 and D2 lines and calculate the transition rates between sublevels from the Kramers-Heisenberg formula.

Chapter 41

Quantum measurement

Since its foundation, the theory of quantum mechanics was driven by the urge to clarify the relationship between the world and what we can learn about it, that is, between reality and the observer. Scientists such as Bohr, Heisenberg, Schrödinger, and Einstein defended controversial positions and struggled for the correct interpretation of quantum mechanics. The *measurement* process is supposed to provide information about the world out there, but it is not clear whether this information can be complete and accurate, or whether there are limitations or hidden variables. Also, it was unclear, to what extend a measurement can be non-invasive or whether it would always perturb the phenomenon under investigation. The most important step in this question was the *Copenhagen interpretation* formulated by Bohr, Heisenberg and Born in 1927 and elaborated later by von Neumann and Dirac. Although contested many times in the past, it's essence still remains valid today.

In this chapter we will study the measurement process from the viewpoint quantum mechanics and discuss some seemingly paradoxical effects, that will allow us to deepen our understanding. Among them are the quantum jump, Schrödinger's cat, the quantum Zeno effect, and the Einstein-Podolski-Rosen paradox.

41.1 The reality and the observer

According to the Copenhagen interpretation, theoretical predictions have a probabilistic character. However, this is not an expression of the imperfection of the theory, but of the intrinsically indeterministic character of quantum processes [1]. Moreover, the Copenhagen interpretation desists to attribute to objects of the quantum formalism, such as wavefunctions and operators, an immediate reality. Instead, the objects of the formalism only represent vehicles for a probabilistic prediction of the results of measurements. These results are *only truly real* elements of quantum theory. It is obvious, that the quantum theory and its interpretations are of fundamental importance to the scientific view of the world and our concept of nature.

41.1.1 Schrödinger's cat

In the microscopic world, the relationship between the sample and the observer is very delicate. And this delicacy is at the origin of quantum effects that seem paradoxical

[1] Note that it is problematic to identify unpredictability and indeterminism. We may be unable to predict specific events, without having to assume that these events occur in a random manner.

through our classical concept of the world. It is, thus, not surprising that one of the most fascinating areas of investigations is the *interface* between the classical and the quantum, the macroscopic and the microscopic worlds. For the pioneers of quantum mechanics the most important questions were of the type: 'How is it possible that a microscopic particle flies simultaneously through two slits?' Nowadays, we are accustomed to such paradoxes, and we simply accept the fact that we have to consider a particle as a wave. Nevertheless, we still do not understand very well, why the classical and the quantum world behave so differently. 'Why does quantum mechanics allow for quantum superpositions states, which are absolutely forbidden in classical physics?', 'Why are the fundamental laws of the quantum world invariant to the arrow of time, while the macroscopic world always evolves from the past to the future?, 'How can it be that quantum mechanics allows for effects having no cause, like spontaneous emission, while the everyday world seems to be deterministic?'

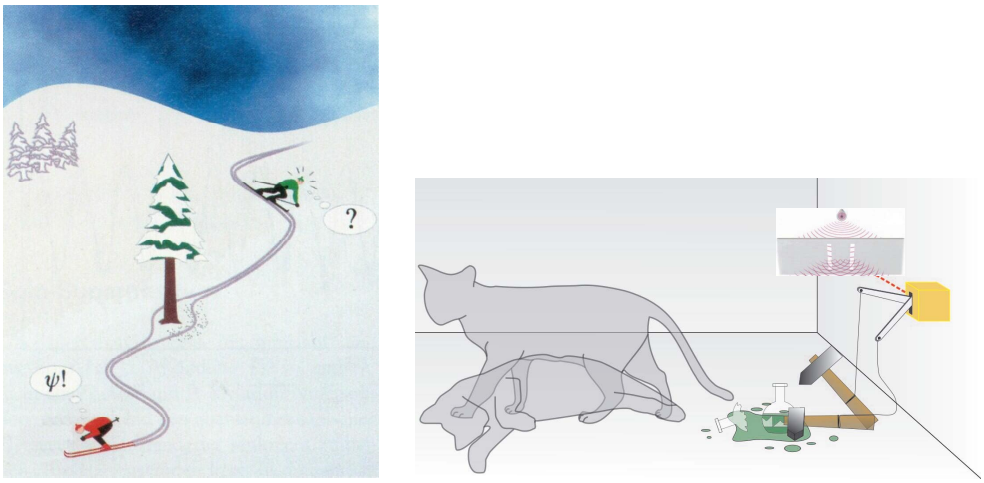

Figure 41.1: Double slit and Schrödinger's cat.

Quantum mechanics must, in some limit, clearly encompass classical physics. But in spite of *Ehrenfest's correspondence principle*, this fact is far from being trivial. Some predictions of classical and quantum physics are fundamentally different and, in some cases, even contradictory. The famous *Schrödinger cat* states are the epitome of this fact: In one version of this paradox, a particle crosses a double slit. Behind one of the slits is a detector which, as soon as it registers a particle, actuates a device killing a cat. We know that in quantum reality the particle crosses both slits in a superposition state, so that the cat should be in a superposition state as well. Hence, quantum cats can be in a superposition of 'dead' and 'alive'.

We believe nowadays that the answers to the above questions are somehow buried in processes that destroy the quantum superposition of Schrödinger cats during the transition from the microscopic to the macroscopic world. However, the details of these quantum coherence destruction processes, called *decoherence*, are very complicated and the subject of serious efforts in contemporary research. It is one of the motivations for trying to create in laboratories the largest possible (quasi-macroscopic) quantum systems, bring them in Schrödinger cat-like superposition states and study

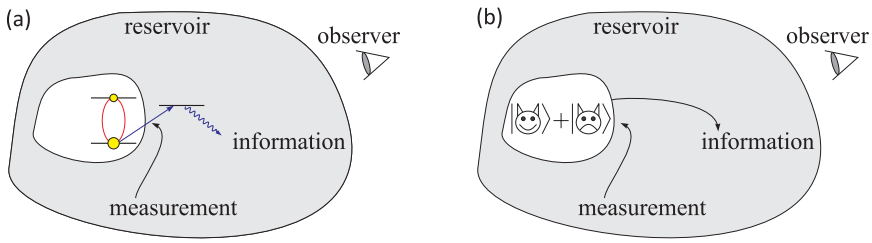

Figure 41.2: The measurement of a quantum system presupposes the interaction of the system with a reservoir, which disturbs its dynamics.

their decoherence [2].

41.1.1.1 Quantum measurement

Every unperturbed system follows the Schrödinger equation. Once its Hamiltonian has been determined, the formal solution,

$$|\psi\rangle = e^{-\imath \hat{H} t/\hbar} |\psi_0\rangle \ , \tag{41.1}$$

allows to calculate the time evolution, that is, the trajectory of the wavefunction. The evolution is *coherent and reversible* in time.

Now, the process of measuring a pure quantum state includes –according the Copenhagen interpretation and as discussed in Sec. 23.4.7– two consecutive steps: In the *first step*, the interaction of the quantum sample with the measuring device (which from now on we will call *meter*) destroys all coherences and projects the pure state into a statistical mixture of eigenstates of the meter. Following von Neumann, the impact of the meter on the quantum system is so strong, that its coherent evolution is interrupted and it is projected onto the degree of freedom that the apparatus wants to measure, e.g. its position or its momentum, but not both in the same time. The projection transforms a pure quantum state $|\psi\rangle$ into a statistical mixture ρ of eigenstates,

$$\hat{\rho}_{\text{sample}} = |\psi(t)\rangle\langle\psi(t)| \curvearrowright \hat{\rho}_{\text{proj}} = \sum\nolimits_k |\langle\psi|k\rangle|^2 |k\rangle\langle k| \ . \tag{41.2}$$

This process is irreversible, that is, it separates the past from the future. The projection is *not* described by the Schrödinger equation. Instead, the sudden reduction of the state must be postulated, as done by von Neumann's famous axiom.

In a *second step*, the observer looks at the measuring device and confirms one of the possible results. Thus, he transforms the state into a eigenstate of the device [3]:

$$\hat{\rho}_{\text{proj}} \curvearrowright \hat{\rho}_{\text{meter}} = |k\rangle\langle k| \ . \tag{41.3}$$

From this moment, we can again leave the quantum system alone until the next measure.

[2] There are attempts to introduce the concept of the time arrow also in the microscopic world: 'In an isolated system, spontaneous processes occur in the direction of increasing entropy.' [649, 348].

[3] We note that, only if *all* commuting observables of the system are measured *and* acknowledged, $\hat{\rho}_{\text{meter}}$ becomes a pure state. Otherwise ρ_{meter} remains a partial mixture.

From the viewpoint of the quantum system, the evolution of the measurement process appears *discontinuous*, because it destroys all possible coherences between its states. In fact, the problem comes from the non-ideal behavior of the measuring device (symbolized by $|\uparrow\rangle$ before the measurement). An ideal non-invasive measurement [4] would leave the quantum state $|\psi\rangle$ unchanged:

$$|\psi\rangle|\uparrow\rangle \xrightarrow{H} |\psi\rangle|\nearrow\rangle \ , \tag{41.4}$$

while the measuring device changes to a state ($|\nearrow\rangle$ after the measurement) indicating the current state of the system. However, this is normally impossible without previously established correlation between $|\psi\rangle$ and $|\uparrow\rangle$. In a real meter device, the coupling between $|\psi\rangle$ and $|\uparrow\rangle$ requires that the meter and the system to be non-orthogonal.

41.1.1.2 Measurement-induced decoherence

A more modern view of the quantum measurement is the following: When the outer world (called reservoir, observer or meter) *reads* a quantum system, it causes, due to this transfer of information, an irreversible demolition of coherence. Consequently, the density operator condenses to its diagonal. On the other hand, the system as a whole (including the sample and the reservoir) always evolves coherently according to the von Neumann equation with the Hamiltonian of everything $\hat{H}_{\text{all}}$:

$$\dot{\hat{\rho}} = \frac{\imath}{\hbar}[\hat{\rho}, \hat{H}_{\text{all}}] \ . \tag{41.5}$$

If $\hat{H}_{\text{sample}}$ is the small quantum system under investigation, a complete description of the measurement process requires the inclusion of the observer, that is, the total Hamiltonian is,

$$\hat{H} = \hat{H}_{\text{sample}} \otimes \hat{H}_{\text{meter}} = \begin{pmatrix} \text{sample} & 0 \\ 0 & \text{meter} \end{pmatrix} \ . \tag{41.6}$$

Ideally, the system evolves independently without being disturbed by the meter. Unfortunately, this also means that the meter evolves independently, that is, it is not influenced by the system and thus does not provide information about the system. To allow a transfer of information, we need to couple the respective spaces by an interaction Ω, such that,

$$\hat{H} = \begin{pmatrix} \text{sample} & \Omega \\ \Omega & \text{meter} \end{pmatrix} \ . \tag{41.7}$$

Tracing over all degrees of freedom of the universe *except* those of the quantum system, the von Neumann equation (41.5) turns into a master equation,

$$\dot{\hat{\rho}}_{\text{sample}} = \frac{\imath}{\hbar}[\hat{\rho}, \hat{H}_{\text{sample}}] + \mathcal{L}_{\text{reserv}}\rho \ . \tag{41.8}$$

[4] See the discussion of the *quantum non-demolition measurement*.

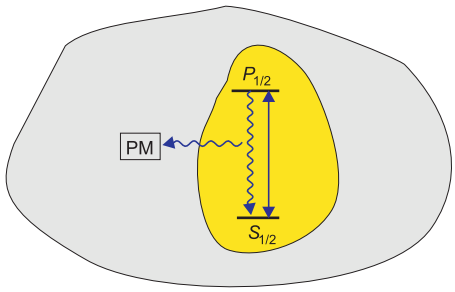

Figure 41.3: Spontaneous emission can be seen as a coupling of the system under investigation to an external meter, because it delivers information to the meter, even if only to tell us: 'The system was in an excited state, but now it's in a ground state.'

Example 289 (*Quantum measurement in a two-qubit system*): To discuss this at an example, we consider the simplest imaginable system: Two two-level atoms, the first one representing the quantum system under investigation and the second the meter. We introduce the following basis:

$$|1\rangle \equiv |\downarrow\rangle|\downarrow\rangle = \begin{pmatrix}1\\0\\0\\0\end{pmatrix}, \; |2\rangle \equiv |\uparrow\rangle|\downarrow\rangle = \begin{pmatrix}0\\1\\0\\0\end{pmatrix}, \; |3\rangle \equiv |\downarrow\rangle|\uparrow\rangle = \begin{pmatrix}0\\0\\1\\0\end{pmatrix}, \; |4\rangle \equiv |\uparrow\rangle|\uparrow\rangle = \begin{pmatrix}0\\0\\0\\1\end{pmatrix}.$$

The Hamiltonian of independent atoms is,

$$\hat{H} = |\downarrow\rangle\langle\downarrow| \otimes |\uparrow\rangle\langle\uparrow| \, .$$

The discussion about the correct interpretation of the measurement process is still ongoing. Modern theories describe the state reduction in terms of *quantum decoherence* due to interactions of the system with the environment. Other interpretations involve *decoherent histories* or assume *multiple worlds* [718]. On the practical side, the current interest in quantum decoherence is motivated by the fact that this phenomenon may turn out to be the fundamental factor limiting the useful operation of quantum computers. Another interesting area where quantum mechanics meets classical physics is the phenomenon of quantum chaos.

41.1.2 The quantum jump

Obviously, the whole quantum measurement process, including the discontinuity of the state projection, could be fully understood within a grand model of the complete system, which would include the measuring device. In practice, this is illusory, because of the excessive number of degrees of freedom of the classical measuring device (e.g. a Schrödinger cat).

On the other hand, many characteristics of quantum measurement can be illustrated in a simple *three-level atom* with a weak transition representing the quantum sample and a strong transition representing the meter. The assertion defended in

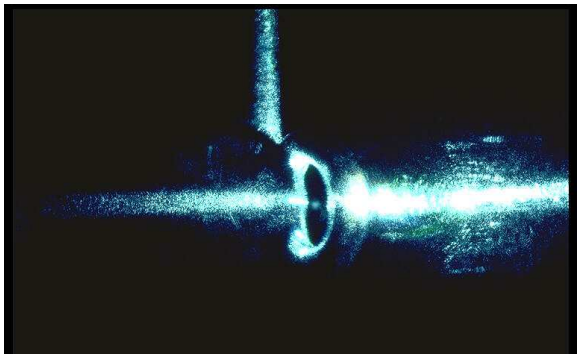

Figure 41.4: One of the first pictures of a single Ba^+ ion.

the following is, that this three-level system, called *quantum amplifier*, gives a deep insight into what happens during the process of state reduction and, therefore, can be considered as paradigmatic for theories on quantum measurement.

To be able to discuss the dynamics of this system on a firmer ground, we will first introduce the quantum Monte Carlo wavefunction simulation method (MCWF).

41.1.2.1 Quantum Monte-Carlo wavefunction simulation of a two-level system

The possible occurrence of spontaneous emission produces a dynamics called *quantum trajectory*, which can be described by a non-hermitian *effective Hamiltonian*,

$$\hat{H}_{\text{eff}} = \hbar\Delta\sigma_z + \hbar\Omega\sigma^+ + c.c. - \frac{\imath}{2}\Gamma\sigma_z = \begin{pmatrix} 0 & \Omega \\ \Omega & \Delta - \imath\frac{\Gamma}{2} \end{pmatrix} , \tag{41.9}$$

aiming at including energy dissipation processes. The problem with this Hamiltonian is that, for being non-hermitian, $[\hat{H}_{\text{eff}}, \hat{H}^\dagger_{\text{eff}}] \neq 0$, it also generates a non-unitary dynamics, $e^{-\imath\hat{H}_{\text{eff}}t} \neq e^{\imath\hat{H}^\dagger_{\text{eff}}t}$. This means that the mere *possibility* of spontaneous emission prevents the reversibility of the dynamics. We observe a temporal decrease of the norm $\langle\psi(t)|\psi(t)\rangle$ indicating a loss of energy,

$$\langle\psi|\psi\rangle = \langle\psi_0|e^{-\imath\hat{H}_{\text{eff}}t}e^{\imath\hat{H}_{\text{eff}}t}|\psi_0\rangle \longrightarrow e^{-\Gamma t} . \tag{41.10}$$

The loss of normalization during the evolution, until the next quantum jump occurs, is due to the dissipation of energy toward the reservoir,

$$\text{Tr}\ \rho_{\text{sample}} \to 0 \qquad \text{while} \qquad \text{Tr}\begin{pmatrix} \rho_{\text{sample}} & 0 \\ 0 & \rho_{\text{reserv}} \end{pmatrix} = 1 , \tag{41.11}$$

and represents a measure of the probability that an irreversible process has occurred during the evolution time.

Dissipative processes can be simulated by playing dices with random numbers ζ. We divide time into small intervals dt and propagate the wavefunction from $\psi(t)$ to $\psi(t + dt)$. After each interval we evaluate the probability $p = 1 - \langle\psi(t)|\psi(t)\rangle$

accumulated during the time period $[0, t + dt]$ that a dissipative process (such as spontaneous emission) has occurred. Now, we generate a random number ζ, uniformly distributed between 0 and 1, which we compare to probability the probability p. In case, $\zeta > 1 - \langle\psi(t)|\psi(t)\rangle$, we conclude that there was no dissipative process, and we let the system proceed in peace, only renormalizing the wavefunction to compensate for the losses [647, 218]. Otherwise, if $\zeta < 1 - \langle\psi(t)|\psi(t)\rangle$, we conclude that there was a dissipative process, and the system is projected into the eigenstate ψ_0. This projection is abrupt and called *quantum jump*. Now, the evolution restarts from zero, ruled by the effective Hamiltonian. The simulation implemented via,

$$|\psi(t)\rangle \curvearrowright |\psi(t+dt)\rangle \equiv \begin{pmatrix} \frac{(1-\imath\hat{H}dt)|\psi(t+dt)\rangle}{\sqrt{\langle\psi(t)|\psi(t)\rangle}} & \text{if} \quad \zeta > 1 - \langle\psi(t)|\psi(t)\rangle \\ |\psi_0\rangle \quad \text{if} & \zeta < 1 - \langle\psi(t)|\psi(t)\rangle \end{pmatrix} . \tag{41.12}$$

This is the method called *quantum Monte Carlo wavefunction simulation*.

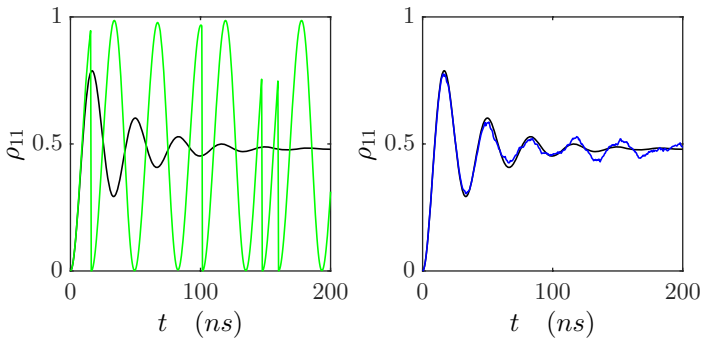

Figure 41.5: (code) a) Quantum Monte Carlo wavefunction simulation. It is important to be aware, that a trajectory generated by a MCWF simulation (41.12) only represents *one* of many possible trajectories of the system. (b) The evolution of the density matrix $\rho(t) = |\psi(t)\rangle\langle\psi(t)|$ (blue curve) is nothing else, than the average (black curve) over all possible MCWF trajectories for the system. A movie of this simulation can be watched here (watch movie).

The effective two-level Hamiltonian (41.9) dissipates via spontaneous emission, which is included in the dynamics through the *possibility* for the system to suffer a *state reduction*. The modification of $|\psi(t)\rangle$ by *non-observation* of spontaneous emission, reduces the population of the state excited by $1 - \frac{1}{2}\Gamma dt$, while the ground state population remains unchanged. Every quantum jump projecting the system into the ground state constitutes a measurement, because it corresponds to a detected fluorescence photon.

41.1.2.2 Three-level systems: The epitome of quantum measurement

Let us now return to the mysterious interaction between the sample and the meter, which we want to unravel by comparing two possible procedures: 1. treating the sample and the meter separately and explain the extraction of information following the von Neumann postulate; 2. treating the sample and the meter by a global theory.

As said above, the inclusion of the meter in a global theory is, in general, difficult. For this reason, to perform the comparison, we choose the simplest imaginable system: the *three-level system* with two transitions connecting to a common ground state and excited by radiation fields. As shown in Fig. 41.6(a) this three-level system can be an atom with a strong transition and a weak transition, for example, the dipolar transition $S_{1/2} - P_{1/2}$ and the forbidden quadrupolar transition $S_{1/2} - D_{5/2}$ in a single Ba^+ ion. We will now name the 'strong transition' as *meter* and the 'weak transition' as *sample* and show that this system allows to study the von Neumann measurement process including the direct observation of quantum jumps [5]. At the same time, the system is simple enough for a complete theoretical description. In this sense, the three-level system becomes the *epitome of a quantum measurement device*.

We turn our attention to the three-level atom: Obviously, the atom will preferentially scatters photons on its strong dipolar transition. However, at times when the valence electron is 'shelved' in the metastable state excited by the quadrupole transition, no fluorescence can be observed on the strong transition.

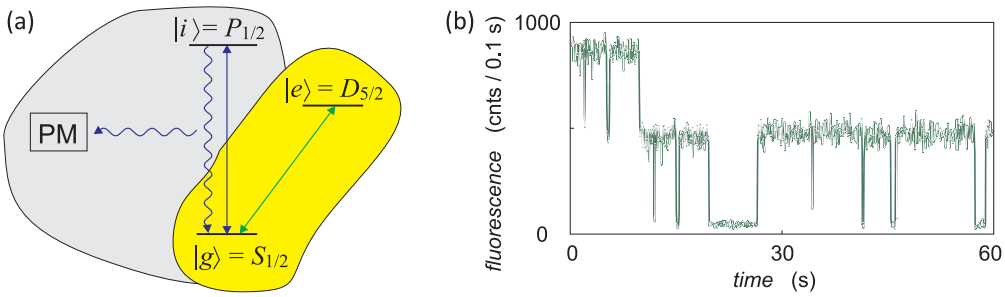

Figure 41.6: (a) Quantum measurement at the example of a three-level atom incorporating a weak (sample) transition and a strong (meter) transition. (b) *Random Telegraph signal* in the resonance fluorescence due to quantum jumps.

Quantum jumps were experimentally observed in single trapped ions, whose lowest energies form a three-level systems [684, 813, 814, 85].

41.1.2.3 Quantum Monte-Carlo wavefunction simulation of the quantum amplifier

When both lasers driving the weak and the strong transition are irradiated simultaneously, the coherence on the weak transition is easily perturbed by the dynamics of the strong transition. To resolve this problem *Dehmelt* invented what he called the *quantum amplifier*. The idea consists in alternately irradiating the *sample* laser (at stage $S - D$ in Fig. 41.7) and the *meter* laser (at stage $S - P$ in Fig. 41.7) [6].

[5] The observability of quantum jumps as manifestations of sudden state reductions has been the object of long-standing debates: 'If we have to go on with these damned quantum jumps, then I'm sorry that I ever got involved with quantum mechanics.' [827].

[6] The absence of the 'meter' laser during the 'sample' stage avoids saturation broadening and light-shifts of the ground state. Since the ground state is shared by both transitions, its broadening would reduce the spectral overlap between the 'sample' transition and the driving laser and therefore the probability to excite the metastable level. This inhibition of the coherent dynamic by too strong or too frequent measurements is known as *quantum Zeno effect*: The more an observer tries to

The alternating irradiation of the lasers $S-D$ and $S-P$ can also be treated by the Monte Carlo quantum wavefunction simulation method (41.12) using the effective Hamiltonian,

$$\hat{H}_{\text{eff}} = \begin{pmatrix} 0 & \frac{1}{2}\Omega_{sp} & \frac{1}{2}\Omega_{sd} \\ \frac{1}{2}\Omega_{sp} & -\Delta_{sp} - \frac{\imath}{2}\Gamma_{sp} & 0 \\ \frac{1}{2}\Omega_{sd} & 0 & -\Delta_{sd} \end{pmatrix} , \tag{41.13}$$

where the Rabi frequencies Ω_{sd} and Ω_{sd} are switched on alternately.

In the simulation 41.7 the quantum jumps to the shelved metastable state $D_{5/2}$ appear as long periods without population in the $P_{1/2}$ level (first period $S-P$, where the population of $S_{1/2}$, illustrated by the red curve, gradually tends to 0 for long times). The reduction of the system to the shelved state actually occurs by *non-observation* of fluorescence on the strong transition. The projection needs a finite time, simply because we can not be sure whether the non-observation is actually due to shelving or the incidental absence of scattering events on the $S-P$ transition: After all, it is not predictable, when the next photon will be spontaneously emitted, even though the lifetime of the excited state is short. But for longer observation times it becomes increasingly unlikely that the absence of photons is *not* due to shelving. It is this unlikeliness, which lets the population rapidly converge towards the metastable state. In the second $S-P$ period, Fig. 41.7 shows fast transitions to the $P_{1/2}$ followed by sudden decays to the ground state. These processes correspond to photon absorption and spontaneous reemission by the strong transition. The succession of the photon scattering events is so fast, that the signal recorded by photodetectors appears as a continuous fluorescence. The sudden transitions between bright and dark periods shown in Fig. 41.6(b), which occur totally randomly, are interpreted as quantum jumps.

41.1.2.4 Comparison with Bloch equations and interpretation of quantum jumps

We already mentioned in Fig. 41.5, that a trajectory generated by a MCWF simulation (41.12) represents *one* possible evolution of the system. In Chp. 39 we got to know an alternative way of predicting the evolution of a system, based on density operator obeying a *master equation*, which in the context of atomic excitation levels is called Bloch equation. Comparing MCWF trajectories (red curves in Fig. 41.7) with Bloch vector evolutions (green curves) it becomes apparent, that the Bloch vector evolution does not produce quantum jumps, but is always smooth and continuous.

In most cases, our knowledge about the actual state of an atom comes from the collection of spontaneously emitted photons. The observation of a photon projects the atomic state into the ground state. However, this concept is not included in the Bloch equations, as we just saw in Fig. 41.7. So, as it seems, we have to take back our statement, that the three-level Bloch equation describe the complete system, although they somehow contain spontaneous emission.

Let us go one step back and ask, where the Bloch equations came from. In fact, as we learned in Sec. 40.4 and will deepen in Sec. 38.1, they are derived from a von Neumann equation for the three-level system *plus* the degrees of freedom of the

extract information from a system, the more he inhibits its evolution. We will discuss this effect in more detail in Sec. 58.3.2.2.

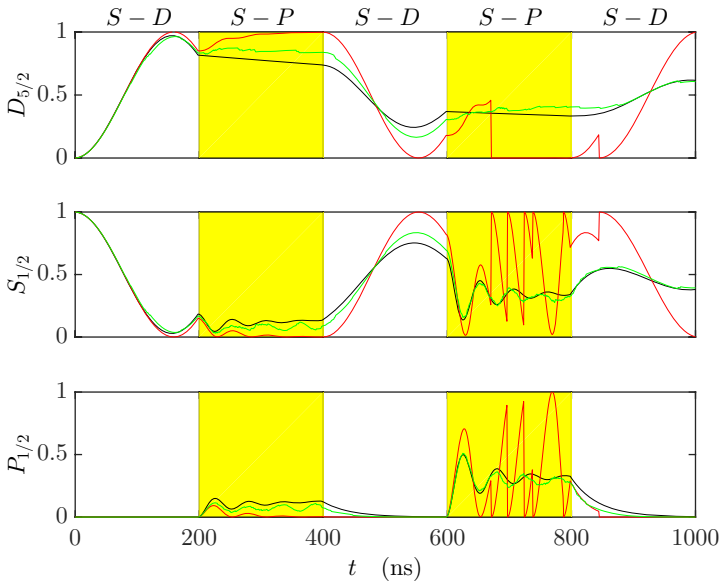

Figure 41.7: (code) Quantum amplifier comparing Monte-Carlo quantum simulations (red lines) and Bloch equations (black lines), which coincide well with the averages over 100 Monte-Carlo trajectories (green lines). The periods $S-D$ (white background) represent the free evolution of the quantum system, the periods $S-P$ (yellow background) represent the measurement periods.

vacuum modes receiving the spontaneously emitted photons by *tracing over the latter ones*.

We will not be able to handle all degrees of freedom. However, we can generalize the Bloch equations in the following way [660, 1016]. We project the total density operator ρ_{AFR} of the atom plus the driving field plus the reservoir of vacuum modes into the subspace of the atom and the driving field consisting of exactly n photons,

$$\rho^{(n)} = \mathrm{Tr}_R \left(P^{(n)} \rho_{\mathrm{AFR}} \right) , \tag{41.14}$$

and derive, from the von Neumann equation, the master equation for the atomic state $\rho^{(n)}$ under the constraint of a fixed number of photons n in the field. The master equation differs only in one term from the usual Bloch equations: The expression $\Gamma_{12}\rho_{22}^{(n)}$, which describes the spontaneous decay of the population of the excited state of the meter transition, is replaced by the expression $\Gamma_{12}\rho_{22}^{(n-1)}$:

$$\frac{d}{dt}\rho^{(n)} = (\mathcal{L}|1\rangle\Gamma_{12}\langle 2|)\rho_{(n)} + |1\rangle\Gamma_{12}\langle 2|\rho^{(n-1)} , \tag{41.15}$$

The substate with of n photons violates the trace condition, $\sum_j \rho_{jj}^{(n)} \neq 1$. The physical explanation for this is the following: While induced emission and absorption maintain the number of photons in the combined light-atom system (like in the Jaynes-Cummings model), spontaneous emission decreases the number of photons, leading to an irreversible loss of energy. The quantum jump observed in MCWF model

corresponds, in the modified equations (41.15), to a collapse of the subspace described by $\rho^{(n)}$ with the time constant Γ_{12} and a birth of another subspace $\rho^{(n-1)}$, whose evolution is guided by another (analogous) Bloch equation, now for $n-1$ photons. Each fluorescence detection at time $t=0$ determines the initial condition for the future development of the system: $\rho^{(n)}(0)=0$ and $\rho^{(n-1)}(0)=|1\rangle\langle 1|$. The probability density $c(t)$ for a new observation of spontaneous emission at time t with detection efficiency η, or in other words, the histogram of the durations of dark periods in the fluorescence signal is related to the solution $\rho^{(n)}$ of the homogeneous part of the equation (41.14) via,

$$c(t)=\eta\Gamma_{12}\tilde{\rho}_{22}^{(n)}(t)=\eta\sum_{j=1}^{4}\frac{d}{dt}\tilde{\rho}_{jj}^{(n)}(t)\ , \tag{41.16}$$

The second step immediately follows from the homogeneous part of equation (41.15).

41.1.2.5 Final remarks

The explanations of the last sections show that Bohr's and Schrödinger's views can be reconcealed. They simply depend on whether the measuring transition is excluded or included in the description of the dynamics. *The quantum jump is an* ***artifact*** *arising from the separation of the quantum system under study (object) from the meter (observer) assumed to strongly interact with the system!* In any case (strong or weak interaction), this separation is not compulsory once a more complete model including the meter is at hand. However, as the dynamics of the meter and the object evolve on different time scales, a separation of the dynamics leading to apparently discontinuous trajectories is *only meaningful for strong meter interactions.*

As soon as this has been understood, that is since the 1980-th, the apparent paradox is simply not on the agenda any more. Recent claims of having unraveled the mystery [653] are just not timely and only show that the author did not understand the full meaning of a 'quantum jump' or, at most, did not read the pertinent literature.

41.1.2.6 Kraus operator for position measurement

As a canonical example of a Kraus operator [60, 160] we take $\hat{H}=\hat{x}\otimes\hat{p}$, where the position and the momentum satisfy the commutation relation, $[\hat{x},\hat{p}]=\imath$. The initial state of the ancilla be a Gaussian distribution,

$$|\phi\rangle=\frac{1}{(2\pi\sigma^2)^{1/4}}\int dq' e^{-q'^2/4\sigma^2}|q'\rangle\ . \tag{41.17}$$

The position wavefunction of the ancilla is,

$$\phi(q)=\langle q|\phi\rangle=\frac{1}{(2\pi\sigma^2)^{1/4}}e^{-q^2/4\sigma^2}\ . \tag{41.18}$$

The Kraus operators are (compared to the previous discussion, we now let $\lambda=1$),

$$M(q)=\langle q|e^{-\imath\hat{x}\otimes\hat{p}}|\phi\rangle=\frac{1}{(2\pi\sigma^2)^{1/4}}e^{-(q-x)^2/4\sigma^2}\ , \tag{41.19}$$

since the operator $e^{-\imath\hat{x}\otimes\hat{p}}$ makes a spatial translation when applied to the degree of freedom of the position. The corresponding POVM elements are,

$$E(q) = M_q^\dagger M_q = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-(q-x)^2/2\sigma^2} \ , \tag{41.20}$$

which obey $\int dq E(q) = \mathbb{I}$.

Calculate $\langle\psi_q|\psi_q\rangle = \langle\psi'|M(q)^\dagger M(q)|\psi'\rangle$.

Note that $\lim_{\sigma\to 0} E(q) = |x = q\rangle\langle x = q|$. That is, in a particular limit, these operators converge to a strong measurement of position. For $\sigma \to \infty$, we speak of weak measurement.

Another example would be the three-level atom of Dehmelt's quantum amplifier.

41.1.3 *Welcher Weg* information

41.1.3.1 The Elitzur and Vaidman bomb testing problem

Mixing the concepts of particles and waves we sometimes arrive at seemingly paradoxical conclusions. One example is Elitzur and Vaidman's *bomb testing problem*. They imagined a Mach-Zehnder interferometer with the particularity that the reflecting mirror of one of the arms be connected to a device measuring the photonic recoil. That is, when a photon passes through this arm, the mirror undergoes a small acceleration, which is sufficient to activate an explosive bomb.

Now, we distinguish two cases: 1. The recoil detector *does not work*, i.e. the bomb is not armed. 2. The bomb is *armed*. We now adjust the interferometer in a way to produce destructive interference in one of the two interferometer output ports. If, having sent many photons through the interferometer, we never saw any photons in the 'dark' port, we can be almost sure that the bomb is *not operational*.

In case the bomb is operational, the observation of a photonic recoil destroys the interference pattern at the interferometer outputs. It *has* to do so, because the exploding bomb informs us, in which arm the photon has passed. However, with an operational bomb the interference pattern is *also* destroyed, when the photon passes through the other arm, since the fact that the bomb didn't explode tells us, that the photon went the other way.

The funny conclusion is now, that it may happen, that a photon traverses the interferometer in the arm that does *not* contain the bomb and exits through the 'dark port'. The probability of this happening is only 25%, but nevertheless the observation of a photon in the 'dark port' informs to us that the pump is operative without ever having interacted with it [7].

41.1.4 Exercises

41.1.4.1 Ex: Schwartzeneggers cat

Explain why we will never observe a real cat in a dead-alive superposition.

[7] See https://www.thorlabs.com/newgrouppage9.cfm?objectgroup_id=6635

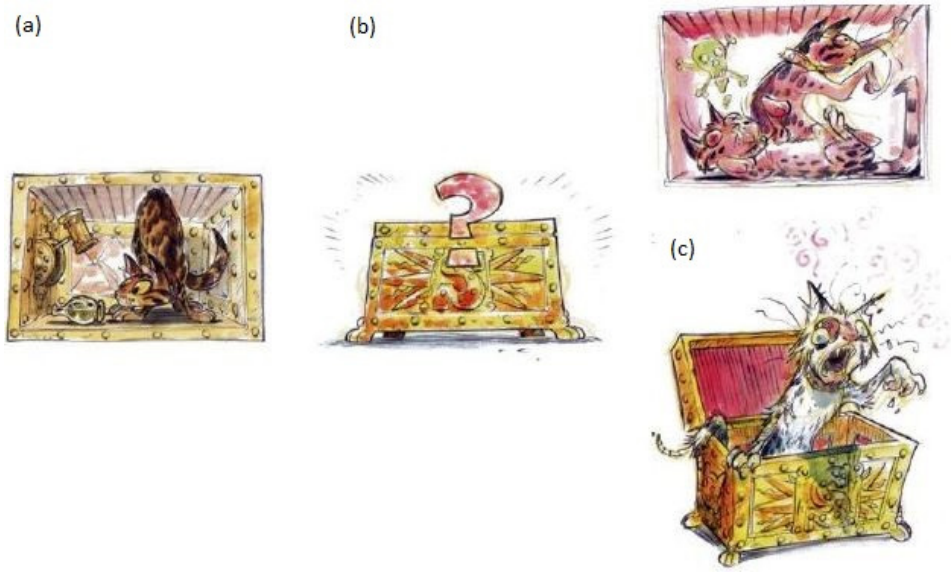

Figure 41.8: Schrödinger's cat according to *Ekhö, Le monde miroir* by Arleston and Barbucco: Quantum superposition or zombie cat?

41.1.4.2 Ex: Dispersive quantum jumps

Consider a three-level system in V-configuration, as depicted in Fig. 39.7(b), with an unstable state $|1\rangle$, a ground state $2\rangle$, and a metastable state $|3\rangle$. Discuss whether the atom shelved in state $|3\rangle$ is sensitive to light-shift and power broadened induced by a laser resonant to the $|1\rangle - |2\rangle$ transition. E.g. will power-broadening only effect the transition rate $|1\rangle \longrightarrow |3\rangle$ or also $|3\rangle \longrightarrow |1\rangle$?

41.2 Repeated measurements

41.2.1 The quantum Zeno effect

A famous problem raised by the Greek philosopher (490-430 AC)*Zeno* goes like this: Achilles and a turtle organize a race. The arrogant Achilles leaves a 100-meter lead to the turtle. The race begins. Achilles soon covers the 100 meters, only to find out that meanwhile the turtle has advanced by 10 meters. He continues running to cover the 10 meters, only to find out that meanwhile the turtle has advanced by 1 meter, and so on [8]. A presentation on the subject is available at (watch talk).

Interestingly, Zeno's problem has a counterpart in quantum mechanics. Let us do the following Gedankenexperiment: A laser beam passes through a dense series of n

[8] In another version of his paradox, Zeno questions the possibility of motion at the example of a flying arrow: At any instant of time it occupies a space equal to its size. That is, at any particular moment of its flight, it is at rest, in a space that does not move. That is, any kind of motion is impossible. Nowadays, we know that this paradox is false, because time and motion are not discrete. But this can only be understood on the basis of infinitesimal calculus [654].

polarizers, each one being rotated by an angle $\frac{\pi}{2n}$ with respect to the preceding one. Each polarizer performs a local measurement of beam polarization. The result of this arrangement is that, in the limit of an infinitely dense series, the continuous measurement of the system completely governs its evolution and rotates the polarization by an angle of $\pi/2$ [9].

In every version of the *Zeno effect*, the system is inhibited from evolving freely, because of too frequent measurements of its current state. Achilles would surely be able to overtake the turtle, if he did not always check on her to assess the remaining distance [468] [10].

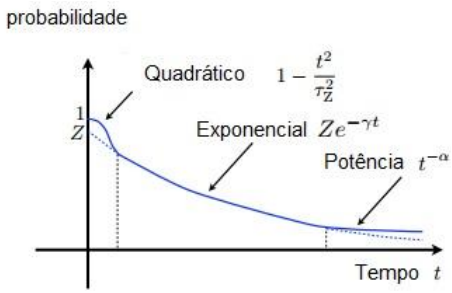

Figure 41.9: Quadratic time dependence of an excited state population.

The temporal evolution of the wavefunction of a system described by the Hamiltonian $\hat{H}$ is $|\psi(t)\rangle = e^{-\imath\hat{H}t/\hbar}|\psi_0\rangle$. We can then calculate the amplitude and probability for the system to stay in the initial state,

$$\langle\psi_0|\psi(t)\rangle = \langle\psi_0|e^{-\imath\hat{H}t/\hbar}|\psi_0\rangle \qquad \text{and} \qquad P(t) = |\langle\psi_0|\psi(t)\rangle|^2 \ . \tag{41.21}$$

For short times we can expand,

$$\langle\psi_0|\psi(\delta t)\rangle = |\psi_0\rangle - \frac{\imath}{\hbar}\hat{H}\delta t/\hbar|\psi_0\rangle - \frac{1}{2\hbar^2}\hat{H}^2\delta t^2|\psi_0\rangle + ... = |\psi_0\rangle + |\delta\psi\rangle \ , \tag{41.22}$$

such that,

$$\langle\psi_0|\psi(\delta t)\rangle \simeq 1-\frac{\imath}{\hbar}\hat{H}\delta t-\frac{1}{2\hbar^2}\hat{H}^2\delta t^2 \quad \text{and} \quad P(\delta t) \simeq 1-\frac{1}{\hbar^2}(\langle\hat{H}^2\rangle_0-\langle\hat{H}\rangle_0^2)\delta t^2 \ . \tag{41.23}$$

In this way we can extract the Zeno time from the above equations, $\tau_Z = \hbar^2/\sqrt{\langle\hat{H}^2\rangle_0 - \langle\hat{H}\rangle_0^2}$. We now make N successive von Neumann measurements within a time t, which leads to a measurement frequency of τ^{-1}. The measurements are conceived as to verify, whether the system is still in its initial state, but each measurement projects our

[9] An analogous experiment can be imagined by a series of Stern-Gerlach measurements of the spin of an atom.

[10] The quantum Zeno effect was often used to justify the physical relevance of the state reduction postulate. It was shown, however, that this postulate is not essential for understanding the quantum Zeno effect [71]. The effect already follows directly from the Schrödinger equation and therefore has a purely dynamical nature. This shows that the projection is a purely mathematical construct without physical reality (see Sec. 41.1.2).

system back to its initial state, from where it has to start the transition process from scratch. Under these conditions, the population of the initial state will evolve like,

$$P^{(N)}(\tau) = P^{(N)}(t/N)^N \ . \tag{41.24}$$

Fig. 41.10 shows the evolution for five measurements separated by time intervals τ. In comparison with the evolution, when no measurements are taken (dashed line), the evolution with measurements inhibits the depletion of the initial state. Extrapolating the number of measurements to infinity, the probability (41.24) converges to 1,

$$\left[1 - \left(\frac{t}{N\tau_Z}\right)^2\right]^N \overset{N\ large}{\longrightarrow} e^{-t^2/N\tau_Z^2} \overset{N\to\infty}{\longrightarrow} 1 \ . \tag{41.25}$$

See Excs. 41.2.4.1 and 41.2.4.2.

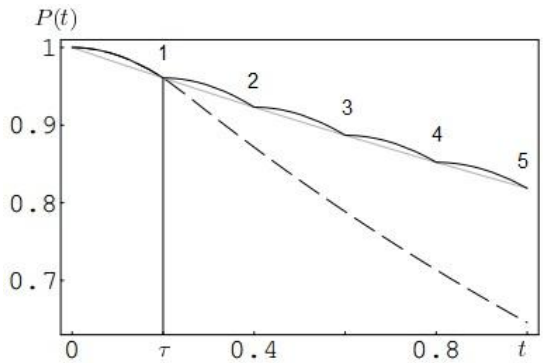

Figure 41.10: Inhibition of the decay of a state by repeated measurements (here $N = 5$). The dashed (solid) line represents the survival probability with (without) measurements. The gray line represents an exponential interpolation function.

Suppression of the evolution of a quantum system due to the quantum Zeno effect was observed experimentally [468] using beryllium ions. Nevertheless, the discussion about the correct interpretation of this effect and its relationship to trivial power broadening is not closed. Some works have even proposed the possibility of an anti-Zeno effect [18, 944], where observation would accelerate the evolution of the system. Currently the quantum Zeno effect is also studied for possible applications in metrology, computation, and quantum information [515].

When the quantum Zeno effect was proposed for the first time, it was considered a paradox: How could an unstable particle never decay, just by being continually observed? And what would happen to Schrödinger's cat, whose live depends on state of the particle? Could we save it from its cruel fate just by observing it?

Another interesting question concerns the quantum nature of the quantum Zeno effect. Is it really non-classical? On one hand, the quantum Zeno effect supposes the complete reduction of the system to an eigenstate. However, we can imagine classical measurements that also reduce the state (such as the above-mentioned measurement of the polarization of a beam of light).

41.2.2 Quantum projection noise

The intrinsic indeterminism of quantum mechanics has serious consequences for metrology. To show this, we consider the example of a system of two levels $|+\rangle$ and $|-\rangle$. This system can be in a superposition state $|\psi\rangle$. The probability [11] to find the system in one of the two states $|\pm\rangle$ is,

$$p_\pm = \langle \hat{P}_\pm \rangle = |\langle \psi|\pm\rangle|^2 = 1 - p_\mp \ , \tag{41.26}$$

where $\hat{P}_\pm$ is the projection operator. The result of a measurement of the population is afflicted by an inherent uncertainty expressed by the variance,

$$(\Delta p_\pm)^2 = \langle \hat{P}_\pm^2 \rangle - \langle \hat{P}_\pm \rangle^2 = \langle \pm|\psi\rangle\langle\psi|\psi\rangle\langle\psi|\pm\rangle - (\langle \pm|\psi\rangle\langle\psi|\pm\rangle)^2 = p_\pm(1-p_\pm) \ . \tag{41.27}$$

In other words, the random projection of the system on the eigenstate basis induces a noise called *quantum projection noise* [12]. This noise inhibits the determination of the probabilities $p_\pm$ in a single measurement. On the other hand, by measuring populations on a sample of N atoms or by repeating the measurement N times with a single atom under identical conditions, we can reduce the uncertainty. The probability of finding an atom r times in the state $|+\rangle$ is [467],

$$\boxed{P_{N,r,+} = \binom{N}{r} p_+^r (1-p_+)^{N-r}} \ . \tag{41.28}$$

The expectation value and variance of this binomial distribution are [467],

$$\bar{r} = \sum_{r=0}^{N} r P_{N,r,+} = N p_+ \quad , \quad (\Delta r)^2 = \sum_{r=0}^{N} (r - N p_+)^2 P_{N,r,+} = N p_+ (1-p_+) \ . \tag{41.29}$$

Thus, the standard deviation decreases with the number of atoms or measurements,

$$\sigma = \frac{\Delta r}{\bar{r}} \sim \frac{1}{\sqrt{N}} \ . \tag{41.30}$$

The increase of knowledge on the population of a two-level system by repeated measurements can be illustrated by a simple simulation exhibited in Fig. 41.11(a). Experiments are performed by comparing p_2 with a random number η. Two outcomes are possible $r = 0, 1$. The histograms narrow as the number of experiments increases. In practice, a measurement is performed using the quantum amplifier method illustrated in Fig. 41.6 [459].

In a sense, the coin behaves as quantum, which is not surprising. It is more surprising that an atom behaves in a quantum way as well, which is the message of Bohr's quantization postulate. However, the atoms have a crucial advantage over coins: they can be entangled with other atoms. Entanglement comes down to a violation of the statistical independence assumption underlying the binomial distribution and all results and consequences derived from it, e.g. the standard quantum limit.

[11] We adopt here the viewpoint of the Copenhagen interpretation of the quantum state reduction, but we note that a discussion based on statistical mixtures described by density matrices gives the same results.

[12] Projection noise can be interpreted as *shot noise*. However, the optical shot noise in photodetectors is generated by the repartition of the field energy into discrete photons, the projection noise is the consequence of the discretization of the electronic excitation levels.

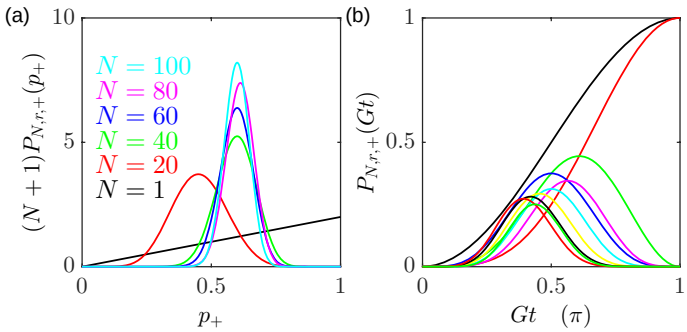

Figure 41.11: (code) (a) Simulation of the increase of knowledge on the population of a two-level system by repeated measurement, $P_{N,r,+}(p_+)/\int_0^1 P_{N,r,+}(p_+)dp_+$. The population of the state $|+\rangle$ was set to $p_+ = 0.2$. (b) Determination of the most likely Rabi pulse length $Gt = 2\arcsin(r/N)^{1/2}$.

Example 290 (*Quantumness and discreteness*): Quantum mechanics is generally associated with phenomena like (i) a wave-like propagation of matter and the ensuing possibility of superposition states, (ii) a discretization of eigenvalue spectra resulting from localization, and (iii) the possibility of entanglement. Criteria (i) and (ii) are, however, not exactly unique to quantum mechanics.
(i)
(ii) We may define discrete states in classical physics, as well. In this sense, quantum projection noise and the quantum Zeno effect are not intrinsically quantum effects. They result from a *discretization* of states, but are not conditioned to the Schrödinger equation. For example, projection noise can be observed when tossing a coin, and the 'quantum' Zeno effect can be observed by repeatedly projecting a laser beam onto one of two polarization axes.

Example 291 (*Spontaneous emission and saturation*): Another more subtle example is the saturation of strongly driven two-level systems. Only 'quantum' emitters are saturable, but their quantumness really only comes from their discrete level structure, so that one might be tempted to consider classical saturable emitters with discrete levels. The problem which arises here is, however, that transitions between orthogonal states are classically forbidden.
What do we mean when we say that the phenomenon of saturation is an intrinsic 'quantum' feature! ? (See example 294.)
An atomic two-level system is 'quantum' in the sense that is has discrete states. On the other hand, a coin also does.
An atom weakly driven by radiation can be described in the linear optics regime like a classical antenna.
Strongly driven, the atom can evolve into a superposition of those two states. The evolution is grasped by Bloch equations. But the evolution of a classical spinning top subject to torque (or a classical electric dipole inside an electric field) is described by the same equations.
We observe Ramsey fringes with a spinning top! So, interference fringes are not

necessarily associated with a wave-like nature of some degree of freedom, light wave or matter wave! However, we need something oscillating (like a wave). In the case of an excited spinning top it is the precessional motion.
In this sense, atomic clocks operate in a classical regime?!? How to recognize quantumness 1.0? In which regime does any classical description fails? Can a spinning top be saturated? Is it really impossible to simulate a classical system exhibiting saturation?
Saturability is not essential, because clock transitions are saturable and yet behave classical. More relevant is spontaneous emission. At weak saturation spontaneous emission can be neglected because the excited state is not populated, which justifies classical description by linear optics. At strong saturation spontaneous emission can be neglected because stimulated emission is overwhelming, which also justifies classical description.

41.2.2.1 Rabi experiments

The method of repeated measurements can be extended to map time-dependent dynamics of the two-level system. Under the influence of a radiation field, the population of the two-level system (which we assume free of spontaneous emission) performs Rabi oscillations, $\rho_{++}(t) = \frac{\Omega^2}{G^2}\sin^2\frac{Gt}{2}$, where $G = \sqrt{\Delta^2+\Omega^2}$. The probability of finding the system in state $|2\rangle$, therefore, varies in time, $p_+(t) = \rho_{++}(t)$, and the binomial distribution (41.28) becomes,

$$P_{N,r,+}(t) = \binom{N}{r}\left(\tfrac{\Omega}{G}\right)^{2N}\sin^{2r}\tfrac{Gt}{2}\cos^{2N-2r}\tfrac{Gt}{2}\ . \tag{41.31}$$

When we increase the number of measurements, $N\to\infty$, this function condenses around a narrow peak at the position $Gt = 2\arcsin\sqrt{r/N}$. The width of the peak evolves like $2\arccos(2^{-1/2N})$. Fig. 41.11(b) shows a simulation demonstrating how repeated measurements gradually pin down the pulse area Ωt.

In summary, even for perfectly efficient population measurements (e.g. using the microwave-optical double resonance method) it is impossible to measure the probability p_+ with a single atom in a single experiment. As such an observation only admits two possible results, 'fluorescence observed' or 'fluorescence not observed', i.e. $\rho_{++}=1$ or $\rho_{++}=0$, a whole range of possible populations between 0 and 1 is excluded. Therefore, a single observation only provides 'partial' information, which can be gradually improved with each consecutive observation.

A presentation on this topic is available here (watch talk).

41.2.2.2 Ramsey experiments

The Ramsey experiment is basically equivalent to the Rabi experiment described above except for an additional rotation in configuration space allowing for the measurement of the phase precession of the coherence between the Ramsey pulses via population spectroscopy. The Ramsey fringes are approximated by $p_+ = 0.5(1+\cos[(\omega-\omega_0)T])$. The interesting magnitude is the frequency uncertainty,

$$\frac{\Delta r}{(\partial r/\partial\omega)|_{(\omega-\omega_0)T=\pi/2}} = \frac{\sqrt{Np_+(1-p_+)}}{N(\partial p_+/\partial\omega)} = \frac{1}{T\sqrt{N}}\ . \tag{41.32}$$

41.2.2.3 Spin squeezing and the Heisenberg limit

The above considerations apply to *independent measurements*. When the atoms are maximally correlated they occupy EPR-like states, $|\psi\rangle = p_+|+++..\rangle + p_-|---..\rangle$, such that it is sufficient to measure a single atom to know the state of all others. This means that the ratio $\Delta r/\bar{r}$ is just the one of a single measurement, but the signal strength and hence the signal-to-noise ratio increase by the factor N. Thus the standard deviation scales with $1/N$ rather than with $1/\sqrt{N}$. This is the so-called *Heisenberg limit*. For Ramsey interferometers we get [974, 107, 120, 643],

$$\frac{\Delta r}{(\partial r/\partial\omega)|_{(\omega-\omega_0)T=\pi/2}} = \frac{1}{TN} \ . \tag{41.33}$$

Example 292 (*Interferometry with condensates*): It is an interesting question, whether condensates can improve metrology and enhance the precision of atomic clocks. The answer is *no*, if we only replace the thermal atomic cloud by a condensate! To see this, we consider an interferometer in configuration space measuring a phase (and therefore a frequency shift) by the method of Ramsey spectroscopy. The states are coupled by a radiation adjusted for $\pi/2$ pulses. The condensate *Fock state* factorizes the Schrödinger equation with the Hamiltonian $\hat{H} = \sum_{i=1}^{N}(H^{(i)} + V_{12}^{(i)})$ into N identical equations for every single atom. The dynamic evolution of this state will be the same as the one for a thermal state. However, this is not true for two Fock state condensates in both entrance channels of the interferometer.
The first radiative beamsplitter divides N_1. This division produces an atom number uncertainty in each state, which come together with a well-defined phase relationship between the two states. By providing at the second port of the interferometer another Fock state N_2, one increases the atom number uncertainty and therefore (because entropy must be conserved in coherent processes) the phase precision. It's a bit like a massive parallel computing for every possible repartition of the populations of both states. Of course the two Fock states cannot be obtained by dividing a single condensate in two in a coherent manner, except if the repartition is measured afterward.
The Fock state is a maximally *spin-squeezed state* (sub-Poissonian statistics). The beam-splitters (which only perform unitary rotations) create starting from the Fock state a quantum entanglement, which is the deeper reason for the improvement of the resolution of the interferometer up the the Heisenberg limit by reducing the *quantum projection noise* [120].

Quantum correlations and spin-squeezed states are the same phenomena seen in different bases. Often the term of *quantum entanglement* is used in an energy bases, while spin squeezing is described in a Dicke state bases.

We may also consider real space interferometers. This allows us to use for creating the Fock states the recently discovered method of transforming BECs into *Mott insulator* states. Of course it is important to use condensates. First of all, we need Fock states, i.e. states with strong on-site quantum correlations with well-defined phase relations between every pair of atoms from the same site. Furthermore, Mott insulators have thus far only been seen with CBEs.

41.2.3 Quantum non-demolition measurements

41.2.4 Exercises

41.2.4.1 Ex: The quantum Zeno effect

Discuss the quantum Zeno effect at the example of a laser beam passing through a birefringent medium. Compare the situations without polarizers and with an infinite number of vertical polarizers.

41.2.4.2 Ex: The quantum Zeno effect

A two-level atom resonantly driven by a laser can be described by the Hamiltonian:

$$H = \begin{pmatrix} 0 & \frac{1}{2}\Omega \\ \frac{1}{2}\Omega & 0 \end{pmatrix} .$$

The solution of the Schrödinger equation gives,

$$|\psi(t)\rangle = e^{-\imath t\hat{H}/\hbar}|\psi_0\rangle = \begin{pmatrix} \cos\frac{1}{2}\Omega t & \imath\sin\frac{1}{2}\Omega t \\ \imath\sin\frac{1}{2}\Omega t & \cos\frac{1}{2}\Omega t \end{pmatrix}\begin{pmatrix} 1 \\ 0 \end{pmatrix}$$

provided the atom is initially in the ground state $\langle\psi_0| = \begin{pmatrix} 1 & 0 \end{pmatrix}$. A measurement of the ground state population can only be done by a projection of the wavefunction, that is, the measurement yields the result $\|\,|1\rangle\langle 1|\psi(t)\rangle\|^2$. What is the final state of the atom,
a. when the ground state population is measured once after an evolution time of $t = \pi/\Omega$;
b. when the ground state population is measured once after n time intervals $t_n = \pi/n\Omega$;
c. when the ground state population is measured n times after evolution times of $t_n = \pi/n\Omega$;
d. when $n \to \infty$.

41.2.4.3 Ex: The quantum Zeno effect

Consider a system described by a time-independent Hamiltonian $\hat{H}$.
a. Calculate the probability $P(t)$ of the system to remain in its initial state $|\Psi_0\rangle$ in the short time approximation, that is, considering until the second-order expression expansion term for the probability. Use the simplification:

$$\tau_z = \frac{\hbar}{\sqrt{\langle\hat{H}^2\rangle - \langle\hat{H}\rangle^2}} ,$$

where the term τ_z is called the Zeno time.
b. If N measurements are performed during a time t, we have the time interval $T = t/N$ between measurements. When a measurement is performed, the system is projected on the initial state and the temporal evolution must start from zero. Thus, after N measurements, the probability of the system remaining in the initial state is given by $[P(T)]^N$. Show that for an infinite number of measurements, $N \to \infty$, the

system remains in the initial state without loss of probability: $[P(T)]^N = 1$. Interpret the result.
c. One of the simplest imaginable systems, a laser-driven two-level system executing Rabi oscillation, is described by the Hamiltonian:

$$\hat{H} = \begin{pmatrix} 0 & \Omega \\ \Omega & 0 \end{pmatrix} .$$

Find the expression for τ_z as a function of the Rabi frequency Ω for the initial state $(1 \;\; 0)^\dagger$.
d. Choosing the evolution time $t = 0.01\tau_z \ll \tau_z$ and performing $N = 5$ measurements during this time interval, how likely is the system to remain in the initial state?
e. Let us now include a decay channel for the state $(0 \;\; 1)^\dagger$ with $\Gamma = 4\gamma$, such as to simulate a system with continuous measurement. The system is initially prepared in the state $(1 \;\; 0)^\dagger$. If we now observe emission by decay, it means that the system *left* the initial state. We now have the effective Hamiltonian:

$$\hat{H} = \begin{pmatrix} 0 & \Omega \\ \Omega & -2\imath\gamma \end{pmatrix} .$$

For this system, the probability amplitude for the initial state is:

$$\langle \Psi_0 | \Psi(t) \rangle = \frac{1}{2}\left(1 + \frac{\gamma}{\Delta}\right) e^{-(\gamma-\Delta)t/\hbar} + \frac{1}{2}\left(1 - \frac{\gamma}{\Delta}\right) e^{-(\gamma+\Delta)t/\hbar} ,$$

with $\Delta = \sqrt{\gamma^2 - \Omega^2}$. For a decay rate $\gamma \ll \Omega$, calculate the probability that the system remains in the initial state. Interpret the result.
Formulas:

$$e^x = 1 + x + \tfrac{x^2}{2} + \mathcal{O}(x^3) \quad , \quad (1-x)^N = 1 - Nx + \mathcal{O}(x^2)$$

$$\cos^2(x) = 1 - x^2 + \mathcal{O}(x^3) \quad , \quad \hat{H} = \begin{pmatrix} 0 & \Omega \\ \Omega & 0 \end{pmatrix} \to e^{-i\hat{H}t/\hbar} = \begin{pmatrix} \cos\frac{\Omega t}{\hbar} & -\imath \sin\frac{\Omega t}{\hbar} \\ -\imath\sin\frac{\Omega t}{\hbar} & \cos\frac{\Omega t}{\hbar} \end{pmatrix} .$$

41.3 Geometric and topological phases

We consider a Hamiltonian $\hat{H}(\mathbf{R}(t))$, which only depends implicitly on time, that is, via some time-dependent parameter $\mathbf{R}(t)$. Then the Hamiltonian evolves by developing a *non-measurable* dynamic phase and additionally accumulates a *geometric phase* (also called *topological phase* or *Berry phase*. This geometric phase, which *depends on the trajectory*, is adiabatically followed in parameter space. Let us consider the time-evolution of a state $|\psi(t)\rangle$ [87],

$$\hat{H}|\psi(t)\rangle = \imath\hbar\partial_t|\psi(t)\rangle , \tag{41.34}$$

assuming that at any instant of time the system stays in a eigenstate $|n(\mathbf{R})\rangle$,

$$\hat{H}|n(\mathbf{R})\rangle = E_n(\mathbf{R})|n(\mathbf{R})\rangle . \tag{41.35}$$

When $\hat{H}$ moves along a trajectory $C : t \to \mathbf{R}(t)$, then we see from,

$$\boxed{|\psi(t)\rangle = \exp\left[-\tfrac{\imath}{\hbar}\int_0^t E_n(\mathbf{R}(t'))dt'\right]\exp(\imath\gamma_n(C))|n(\mathbf{R}(t))\rangle} \ , \tag{41.36}$$

that, while the first exponential describes the standard dynamical phase, the phase $\gamma_n : C \to \gamma_n(C)$ is not integrable, i.e. γ_n cannot be expressed as a function of $\mathbf{R}(t)$ and is not single-valued meaning that from $\mathbf{R}(T) = \mathbf{R}(0)$ we cannot infer $\gamma_n(T) = \gamma_n(0)$. Substituting (41.36) in (41.34), we find,

$$\hat{H}(\mathbf{R}(t))|\psi(t)\rangle = \imath\hbar|\dot{\psi}(t)\rangle = \left(E_n + \imath\hbar\dot{\gamma}_n(t) + \imath\hbar\dot{\mathbf{R}}(t)\cdot\nabla_{\mathbf{R}}\right)|\psi(t)\rangle \ . \tag{41.37}$$

Since for a particular eigenstate,

$$\hat{H}(\mathbf{R}(t))|n(\mathbf{R}(t))\rangle = E_n|n(\mathbf{R}(t))\rangle \ , \tag{41.38}$$

we infer,

$$\dot{\gamma}_n(t) = \imath\dot{\mathbf{R}}(t)\cdot\langle n(\mathbf{R}(t))|\nabla_{\mathbf{R}}|n(\mathbf{R}(t))\rangle \ . \tag{41.39}$$

The integrated phase change upon evolution of the state from $|\psi(0)\rangle$ to $|\psi(T)\rangle$ around a closed loop is then,

$$\boxed{\gamma_n(C) = \imath\oint_C \langle n(\mathbf{R})|\nabla_{\mathbf{R}}|n(\mathbf{R})\rangle\cdot d\mathbf{R} \equiv \oint_C \vec{\mathcal{A}}(\mathbf{R})\cdot d\mathbf{R}} \ , \tag{41.40}$$

where $\vec{\mathcal{A}}$ is known as *Berry connection*.

The condition of adiabaticity is essential for emergence of geometric phases. The system always remains in an eigenstate (fixed quantum numbers) when we vary parameters of the environment more slowly than all characteristic constants of the system, even when the Hamiltonian is time-dependent (variable eigenvalues).

41.3.1 Properties of the Berry phase

41.3.1.1 Gauge invariance

We have seen in 23.7.4 that the gauge transformation (23.325), $U_{cl}(\xi) = e^{-\imath\xi(\mathbf{R})}$, leaves the Schrödinger equation invariant. Applied to an eigenstate,

$$|\tilde{n}(\mathbf{R})\rangle = e^{-\imath\xi(\mathbf{R})}|n(\mathbf{R})\rangle \ , \tag{41.41}$$

the Berry connection becomes,

$$\tilde{\vec{\mathcal{A}}}(\mathbf{R}) = \imath\langle e^{\imath\xi(\mathbf{R})}n(\mathbf{R})|\nabla_{\mathbf{R}}|e^{-\imath\xi(\mathbf{R})}n(\mathbf{R})\rangle = \vec{\mathcal{A}}(\mathbf{R}) + \nabla_{\mathbf{R}}\xi(\mathbf{R}) \ . \tag{41.42}$$

It is apparently gauge-dependent, so that the local Berry connection $\vec{\mathcal{A}}_n(\mathbf{R})$ can never be physically observable. On the other hand, the Berry phase is,

$$\tilde{\gamma}_n(C) = \gamma_n(C) + \int_C \nabla_{\mathbf{R}}\xi\cdot d\mathbf{R} = \gamma_n(C) + \xi(t) - \xi(0) \ . \tag{41.43}$$

For a *closed loop*, continuity of the gauge field requires $\xi(T) - \xi(0) = 2\pi m$. Hence, up to an integer multiple of 2π, *closed loop Berry phases remain gauge-invariant* under arbitrary gauge transformation and may be related to physical observables.

41.3.1.2 Berry curvature

It is often advantageous to convert the path integral (41.40) into a surface integral using Stokes' theorem. Defining the Berry curvature as,

$$\vec{\mathcal{V}}_n(\mathbf{R}) \equiv \nabla_{\mathbf{R}} \times \mathbf{A}_n(\mathbf{R}) \ , \tag{41.44}$$

we obtain,

$$\gamma_n(C) = \iint_S \vec{\mathcal{V}}_n(\mathbf{r}) \cdot d\mathbf{S} \ . \tag{41.45}$$

The Berry curvature can be expressed as [87],

$$\mathbf{V}_n(\mathbf{r}) = \mathrm{Im} \sum_{m \neq n} \frac{\langle n(\mathbf{r})|\nabla_{\mathbf{r}} \hat{H}(\mathbf{r})|m(\mathbf{r})\rangle \cdot \langle m(\mathbf{r})|\nabla_{\mathbf{r}} \hat{H}(\mathbf{r})|n(\mathbf{r})\rangle}{(E_m(\mathbf{r}) - E_n(\mathbf{r}))^2} \ . \tag{41.46}$$

This will be shown in Exc. 41.3.3.1.

Example 293 (*Geometric phase in a two-level system*): We consider the following state [769],

$$n_\pm(\mathbf{r}) = \cos\theta|g\rangle \pm e^{\pm\imath\phi} \sin\theta|e\rangle \ .$$

Now, we want to calculate the geometric phase,

$$\gamma_\pm = \oint_C \imath\langle n_\pm(\mathbf{r})|\nabla_{\mathbf{r}}|n_\pm(\mathbf{r})\rangle d\mathbf{r} \ .$$

Applying the gradient in spherical coordinates,

$$\nabla_{\mathbf{r}} = \hat{\mathbf{e}}_\theta \frac{1}{r}\frac{\partial}{\partial\theta} + \hat{\mathbf{e}}_\phi \frac{1}{\mathbf{r}\sin\theta}\frac{\partial}{\partial\phi} + \hat{\mathbf{e}}_r \frac{\partial}{\partial r}$$

to the function $|n_+\rangle$, we find,

$$\nabla_{\mathbf{r}}|n_+(\mathbf{r})\rangle = -\hat{\mathbf{e}}_\theta \frac{\sin\theta}{r}|g\rangle + \hat{\mathbf{e}}_\theta \frac{e^{\pm\imath\phi}\cos\theta}{\mathbf{r}}|e\rangle + \hat{\mathbf{e}}_\phi \frac{\imath e^{\imath\phi}}{r}|e\rangle \ ,$$

and,

$$\imath\langle n_\pm(\mathbf{r})|\nabla_{\mathbf{r}}|n_\pm(\mathbf{r})\rangle = \imath\hat{\mathbf{e}}_\phi \frac{\imath\sin\theta}{r} \ .$$

Finally,

$$\gamma_+ = \oint_C \frac{-\sin\theta}{r}\hat{\mathbf{e}}_\phi d\mathbf{R} = \oint_C \frac{-\sin\theta}{r} r\sin\theta d\phi = \oint_C \sin^2\theta\dot{\phi}dt \ .$$

Example 294 (*Berry phase on the Bloch sphere*): We consider the example of a two-level system without decay described by the Bloch vector $\vec{\varrho}$ defined in (39.126) and whose evolution is govern by the Hamiltonian (39.129),

$$\hat{H} = \tfrac{1}{2}\mathbf{G}\cdot\sigma \equiv \begin{pmatrix} \mathfrak{Re}\,\Omega \\ \mathfrak{Im}\,\Omega \\ \Delta/2 \end{pmatrix} \begin{pmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \end{pmatrix} \ .$$

Now, we change the parameters regrouped in $\mathbf{G}$ adiabatically. It is easy to see that,

$$E_\pm = \pm R/2 \qquad \text{and} \qquad \nabla_{\mathbf{G}} \hat{H} = \vec{\sigma}/2 \ ,$$

such that,

$$\mathbf{V}_n(\mathbf{r}) = \mathrm{Im} \frac{\langle n_\pm(\mathbf{G})|\nabla_{\mathbf{G}} \hat{H}(\mathbf{G})|n_\mp(\mathbf{G})\rangle \cdot \langle n_\mp(\mathbf{G})|\nabla_{\mathbf{G}} \hat{H}(\mathbf{G})|n_\pm(\mathbf{G})\rangle}{(E_+(\mathbf{G}) - E_-(\mathbf{G})^2} = \pm \frac{\mathbf{G}}{2G^3} \ .$$

The geometric phase accumulated on a closed loop $C = \partial S$ surrounding an area $S = 4\pi\Omega_S$ on the surface of the Bloch sphere is,

$$\gamma_n(C) = \mp \oint_C \frac{dS}{2G^2} = 4\pi \mp \oint_C dR = \mp \frac{\Omega_S(C)}{2}$$

and thus equal to half the enclosed solid angle Ω_S. The Berry phase can be measured in Ramsey experiments, as discussed in Exc. 41.3.3.2.

41.3.1.3 Generalization of the Berry phase according to Aharonov

We will now drop the conditions imposed to the Hamiltonian with regard to its adiabatic behavior and request that the state must be a eigenstate [182]:

$$\hat{H}|\psi(t)\rangle = \imath\hbar|\dot{\psi}(t)\rangle \ . \tag{41.47}$$

A process is cyclic, when there is a τ, such that,

$$|\psi(\tau\rangle = e^{\imath[f(\tau)-f(0)]}|\psi(0)\rangle \ . \tag{41.48}$$

Defining the space of radii by $|\tilde{\psi}(t)\rangle = e^{-\imath f(t)}|\psi(t)\rangle$, we obtain,

$$|\tilde{\psi}(\tau)\rangle = |\tilde{\psi}(0)\rangle \ , \tag{41.49}$$

and from the Schrödinger equation we obtain,

$$f(t) - f(0) = -\tfrac{1}{\hbar}\int_0^t \langle\psi(t)|\hat{H}(t)|\psi(t)\rangle dt + \int_0^t \langle\tilde{\psi}(t)|\imath\tfrac{d}{dt}|\tilde{\psi}(t)\rangle \equiv \delta + \beta \ . \tag{41.50}$$

Therefore, in the space of radii we have a closed curve:

$$\begin{aligned} C : [0,\tau] &\longrightarrow \psi(t) \in \mathcal{H} \\ &\downarrow e^{-\imath f(t)} \\ C' : [0,\tau] &\longrightarrow \tilde{\psi}(t) \in \mathcal{P} \ . \end{aligned} \tag{41.51}$$

The dynamic phase δ can be zeroed by an appropriate choice of $\hat{H}(t)$, but not the topological phase β. β does not depend on $\hat{H}(t)$, but is a geometric property of the curve, which projects $\mathcal{H}$ onto $\mathcal{P}$. In contrast to $e^{\imath\beta}$, the phase β is only determined modulo $2\pi n$.

41.3.2 Aharonov-Bohm effect

A particular case for topological phases is the *Aharonov-Bohm effect*, which we will discuss in the following. The only observables of electromagnetism are the forces of Coulomb and Lorentz which, in the theory of electrodynamics, are described by electric and magnetic fields. Electromagnetic potentials can be introduced to simplify calculations, but they are not observables with a physical reality. In contrast, in quantum mechanics, electromagnetic potentials are more fundamental than electromagnetic fields. This is demonstrated by the Aharonov-Bohm effect.

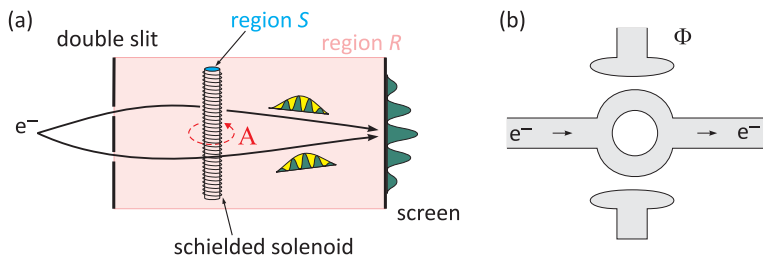

Figure 41.12: (a) Scheme for measuring the Aharonov-Bohm effect. The electrons propagate as wavepackets whose centers-of-mass are not subject to forces, but whose de Broglie waves are phase-shifted by the vector potential. (b) Aharonov-Casher effect: the electrodes Φ do not produce electric fields inside the conductors; even so, one observes constructive or destructive interference at the output of the interferometer, depending on the applied potential.

The idea of this effect is schematized in Fig. 41.12. An electron beam is coherently divided into two arms (e.g. by a double slit) passing both sides of an infinitely extended and perfectly shielded solenoid. In this way the magnetic field $\vec{\mathcal{B}}$ vanishes in the region outside the solenoid, but there must exist nonetheless a potential vector $\mathbf{A}$, because we observe on the screen an interference pattern of the two arms of the electronic interferometer. When pass a current through the solenoid, we observe a displacement of the interference pattern.

41.3.2.1 Aharonov-Bohm effect and gauge transformation

Let R and S be two disconnected spatial regions. Suppose that the electric and magnetic fields are kept zero in region R. Then, it is *classically impossible* to measure some change in the dynamics of a body confined to the region R resulting from a change of the magnetic field confined to the region S. The Aharonov-Bohm effect shows that the *opposite* is true: Electrons in the magnetic field-free region R do sense magnetic field fluxes in a region S, despite the regions R and S having no intersection!

In the classical theory of electromagnetism, in a region of empty space (except for electric charges and electric currents), the electric $\vec{\mathcal{E}}(\mathbf{r},t)$ and magnetic fields $\vec{\mathcal{B}}(\mathbf{r},t)$ are related to the electric charge $\rho(\mathbf{r},t)$ and current densities $\mathbf{j}(\mathbf{r},t)$ according to the *Maxwell equations*. When we know for a spatial region the sources ρ and $\mathbf{j}$ and the

boundary conditions that the fields $\vec{\mathcal{E}}$ and $\vec{\mathcal{B}}$ must fulfill, we can determine the fields as solutions of Maxwell's system of partial differential equations.

In classical electrodynamics, observed from some inertial frame, the electromagnetic force $\mathbf{F}_{\text{em}}$ acting on a point-like body with charge q, at position $\mathbf{r}$, and with velocity $\mathbf{v}$, is given by the Lorentz force:

$$\mathbf{F}_{\text{em}}(\mathbf{r}(t),t) = q\vec{\mathcal{E}}(\mathbf{r}(t),t) + q\mathbf{v}(t)\times\vec{\mathcal{B}}(\mathbf{r}(t),t) \ . \tag{41.52}$$

Electrodynamic theory affirms the existence of two functions $\Phi(\mathbf{r},t)$ and $\mathbf{A}(\mathbf{r},t)$, such that,

$$\vec{\mathcal{B}}(\mathbf{r},t) = \nabla\times\mathbf{A}(\mathbf{r},t) \qquad \text{and} \qquad \vec{\mathcal{E}}(\mathbf{r},t) = -\nabla\Phi(\mathbf{r},t) - \frac{\partial\mathbf{A}(\mathbf{r},t)}{\partial t} \ . \tag{41.53}$$

Thus, we can use the equations (41.53) to rewrite the Maxwell equations.

The so-defined potentials Φ and $\mathbf{A}$ are not unique, but any Φ and $\mathbf{A}$ leading to the same fields $\vec{\mathcal{E}}$ and $\vec{\mathcal{B}}$, and thus to the same physics, are equivalent. We will, however, fix Φ and $\mathbf{A}$ adopting an additional condition that must be obeyed, i.e. we will adopt a particular gauge. For the discussion of the Aharonov-Bohm effect, we will adopt the *Lorentz gauge* defined by,

$$\nabla\cdot\mathbf{A}(\mathbf{r},t) + \frac{1}{c^2}\frac{\partial\Phi(\mathbf{r},t)}{\partial t} = 0 \ , \tag{41.54}$$

where c is the propagation velocity of light in vacuum.

41.3.2.2 Equation for quantum particle exposed to a vector potential A

Assume a particle (without spin) of mass m and charge q, whose wavefunction is confined to a region R (connected by paths). We demand $\Phi = 0$ and $\vec{\mathcal{E}} = 0 = \vec{\mathcal{B}}$, but we let $\mathbf{A}\neq 0$, that is, $\nabla\times\mathbf{A}(\mathbf{r},t) = 0$. Note that along with (41.53) this forces $\mathbf{A}$ to be stationary. According to quantum mechanics the wavefunction Ψ of the particle must obey the following Schrödinger equation:

$$\frac{1}{2m}\left(\frac{\hbar}{\imath}\nabla - q\mathbf{A}(\mathbf{r})\right)^2\Psi(\mathbf{r},t) + V(\mathbf{r})\Psi(\mathbf{r},t) = \imath\hbar\frac{\partial\Psi(\mathbf{r},t)}{\partial t} \ . \tag{41.55}$$

In (41.55) the potential vector $\mathbf{A}$ is present, even if ϕ, $\vec{\mathcal{E}}$, and $\vec{\mathcal{B}}$ are kept zero throughout the region R.

Since the rotation $\mathbf{A}$ vanishes in R, considering that the integral can be calculated for any path contained in R that is deformable to a (arbitrarily chosen) point $O\in R$, we can define the following scalar field:

$$g(\mathbf{r}) \equiv \frac{q}{\hbar}\int_0^{\mathbf{r}}\mathbf{A}(\mathbf{x})\cdot d\mathbf{x} \ . \tag{41.56}$$

From (41.56) we have:

$$\nabla g(\mathbf{r}) = \frac{q}{\hbar}\mathbf{A}(\mathbf{r}) \ . \tag{41.57}$$

Now, we have already shown in Sec. 23.7.4, that the wavefunction

$$\psi(\mathbf{r},t) \equiv e^{-\imath g(\mathbf{r})}\Psi(\mathbf{r},t) \tag{41.58}$$

corresponds to the gauge transform (23.325) and, given the condition (23.324), satisfies the same Schrödinger equation as $\Psi(\mathbf{r}, t)$. We showed this explicitly in Exc. 41.3.3.3. Thus, the presence of a potential vector in the region R, even in the absence of fields, causes a phase shift $e^{\imath g(\mathbf{r})}$ of the wavefunction. An interesting issue studied in Exc. 41.3.3.4 is, whether this implies that the freedom of choice of the gauge field is lost.

Example 295 (*Observation of the Aharonov-Bohm effect*): Imagine an electron beam passing through a double-slit, as shown in Fig. 41.12(a). The electronic wavefunction diffracts through both slits, which produces an interference pattern on a subsequent screen. Now, just after the double-slit, in the shade of the region separating the two slits, we place an ideal infinitely long solenoid traversed on its axis by a constant, however, adjustable flux of magnetic field. The magnetic (and also the electric) field of the solenoid is confined to a region S, and the confinement can be guaranteed, e.g. with layers of shielding materials, including superconductors. On the other hand, the wavefunctions of the electrons are manifestly zero in this S region. In the R region, where the electronic wavefunction may be non-zero, the fields are kept zero. R and S have no overlap, both R and S are *separately* connected by paths.
We will show that the flux of the magnetic field in S can be measured through the electronic dynamics in the region R, although the electron is *never* in the region S, but confined to the field-free region R. This is the Aharonov-Bohm (magnetic) effect.
The field $\vec{\mathcal{B}}$ in the inner region of the solenoid is given by (I is the electric current in the wire, N is the density of windings),

$$\vec{\mathcal{B}}(\mathbf{r}, t) = \mu_0 I N \hat{\mathbf{e}}_z \ .$$

Outside the solenoid, that is, for $\rho > a$, we have,

$$\mathbf{A}(\mathbf{r}, t) = \frac{\Phi_B}{2\pi\rho}\hat{\mathbf{e}}_\phi \ ,$$

where $\Phi_B = \pi a^2 B(0, t)$ is the magnetic field flux $\vec{\mathcal{B}}$ through the cross section of the solenoid.
At a point $\mathbf{r}_{sim}$ of the screen, located in the plane of symmetry of the system, we calculate $g(\mathbf{r}_{sim})$ from Eq. (41.56) for two different paths: both starting at the source and ending at the screen, but one going through the left slit, the other through the right slit:

$$g(\mathbf{r}_{sim}) = \frac{q}{\hbar}\int_0^{\mathbf{r}_{sim}} \mathbf{A}(\mathbf{x}) \cdot d\mathbf{x} = \frac{q\Phi_B}{2\pi\hbar}\int \left(\frac{1}{\rho}\hat{\phi}\right) \cdot (\rho\hat{\phi}d\phi) = \pm\frac{q\Phi_B}{2\hbar} \ .$$

The + sign means, that the integration was done in the sense parallel to $\mathbf{A}$, and thus in the sense of I in the solenoid. The sign - holds for the other integration path. The phase difference, at point $\mathbf{r}_{sim}$, between these two paths will be:

$$\delta = \frac{q\Phi_B}{\hbar} \ .$$

That is, the phase difference (experimentally observable via a shift of the interference pattern) is directly proportional to the magnetic field flux $\vec{\mathcal{B}}$, even though the wavefunction is zero in the region S, where the $\vec{\mathcal{B}}$ field is confined.
Let us also imagine another situation: Instead of an electron source producing

a beam, let us confine an electronic wavefunction on a closed path circling the solenoid at a distance b, but inside the region of R. That is, the electron follows a field line $BA \propto \hat{\mathbf{e}}_\phi$. Then it can be shown, that the flow Φ_B removes the degeneracy of the energy levels of the electron:

$$E_n = \frac{\hbar^2}{2mb}\left(n - \frac{q\Phi_B}{2\pi\hbar}\right)^2 ,$$

with integer, that is, $n = 0, \pm 1, \pm 2, ...$ [387].

The *Aharonov-Bohm phase is a (topological) Berry-phase* [87]. This is shown explicitly in Exc. 41.3.3.5.

41.3.2.3 Generalizations of the Aharonov-Bohm effect

The Aharonov-Bohm effect can be generalized to the internal degrees of freedom of a single atom, that is, from real space to configuration space. Let us imagine a Mach-Zehnder interferometer, where one of the arms crosses a constant homogeneous field region. The corresponding Lorentz force $\mathbf{F} = \int d^3r\ \rho(\mathbf{r})\vec{\mathcal{E}}(\mathbf{r}) + \mathbf{j}(\mathbf{r}) \times \vec{\mathcal{B}}(\mathbf{r})$ vanishes, but the de Broglie wave undergoes a phase shift $\chi = \int \hat{H}_{\text{int}} dt$:

scalar potentials		
$\chi = -\int e\phi dt$	$\nabla\phi = 0$	for e^-
$-\int \mathbf{d} \cdot \vec{\mathcal{E}} dt$	$\nabla \times \vec{\mathcal{E}} = \nabla \cdot \vec{\mathcal{E}} = 0$	Mg, Yb^+
$-\int \vec{\mu} \cdot \vec{\mathcal{B}} dt$	$\nabla \times \vec{\mathcal{B}} = \nabla \cdot \vec{\mathcal{B}} = 0$	n, Yb^+
vector potentials		
$-\oint e\mathbf{A} d\mathbf{r}$	$\nabla \times \mathbf{A} = 0$	e^-, (ABE)
$-\oint d \times \vec{\mathcal{B}} d\mathbf{r}$		?
$-\oint \mu \times \vec{\mathcal{E}} d\mathbf{r}$		n, Ca, (ACE)

Example 296 (*Topological phase in configuration space*): We consider a temporal Ramsey experiment with a single trapped ion by exciting a hyperfine transition. Between the pulses we apply a magnetic field for a time t. The accumulated phase will be $\phi = (\vec{\mu} \cdot \vec{\mathcal{B}}/\hbar)t$. This phase corresponds to the precession of the dipole moment excited by the first Ramsey pulse. The phase can be interpreted in analogy to Aharonov-Bohm effect, considering that 1. the magnetic field is homogeneous, and 2. despite this fact still acts on the spin, not exerting a force, but causing a phase shift.

41.3.3 Exercises

41.3.3.1 Ex: Derivation of the Berry curvature

Derive the expression (41.46) for the Berry curvature.

41.3.3.2 Ex: Measurement of the Berry phase in a two-level system

Discuss how the Berry phase in a two-level system can be measured via a Ramsey experiment.

41.3.3.3 Ex: The Aharonov-Bohm effect as a gauge transform

Show explicitly that the wavefunction transformed by a gauge transformation (41.58) satisfies the Schrödinger equation.

41.3.3.4 Ex: Aharonov-Bohm effect and gauge transformation

The phase of the interference pattern in the Aharonov-Bohm effect is fixed by the magnetic flux through the solenoid. Does that mean, that we lose the freedom of choosing an arbitrary gauge potential?

41.3.3.5 Ex: Aharonov-Bohm effect as a geometric phase

Show that the Aharonov-Bohm effect represents a particular case of a geometric phase.

Chapter 42

Nonlinear optics

The discipline of *nonlinear optics* studies phenomena that occur as a consequence of modifications of the optical properties of materials by the presence of light. Such modifications are appreciable only, when the interacting light is sufficiently intense, i.e. of the order of the interatomic electric field,

$$\mathcal{E}_{\rm at} = \frac{e^2}{4\pi\varepsilon_0 a_B^2} \simeq 5.14 \cdot 10^{11}\,{\rm V/m} \ , \tag{42.1}$$

which explains that nonlinear effects could only be studied properly after the advent of the laser.

In general, light-matter interaction is expressed through the relationship between the polarization induced in the medium, $\mathcal{P}(\omega)$, with the optical light field, $\mathcal{E}(\omega)$. In linear optics this relation can be expressed as,

$$\tilde{\mathcal{P}}(\omega) = \varepsilon_0 \chi(\omega) \tilde{\mathcal{E}}(\omega) \ . \tag{42.2}$$

But in the perturbative regime of non-linear optics this expression must be generalized to a series of powers of the electric field,

$$\tilde{\mathcal{P}}(\omega) = \varepsilon_0 [\chi^{(1)}(\omega)\tilde{\mathcal{E}}(\omega) + \chi^{(2)}(\omega)\tilde{\mathcal{E}}^2(\omega) + \chi^{(3)}(\omega)\tilde{\mathcal{E}}^3(\omega) + ...] \ , \tag{42.3}$$

so that higher order polarization terms, $\mathcal{P}^{(n)}(\omega) = \varepsilon_0 \chi^{(n)} \mathcal{E}^N(\omega)$, are considered. Therefore, the phenomena are non-linear in the sense that they depend non-linearly on the optical field applied to the material. In a more complete treatment, in terms of the optical properties of materials, $\tilde{\mathcal{P}}$ and $\tilde{\mathcal{E}}$ are vector fields and the electric susceptibility is a tensor. However, to simplify the treatment, we consider the fields as scalars and $\chi^{(n)}$ as constants independent of the frequency ω.

Examples of non-linear optical phenomena are: parametric processes of sum and difference frequency generation, as shown in Fig. 42.1, optical parametric oscillation, and the dependence of the refractive index with the optical intensity. Examples of non-parametric processes are: multi-photonic absorption, stimulated Raman scattering, and saturated absorption. In the latter example, the absorption coefficient of the material decreases with increasing light intensity:

$$\alpha = \frac{\alpha_0}{1 + I/I_s} \ . \tag{42.4}$$

Saturated absorption is an example where a perturbative approach is not capable of providing good results, and its most reliable description is given by the approximation of a two-level quantum system.

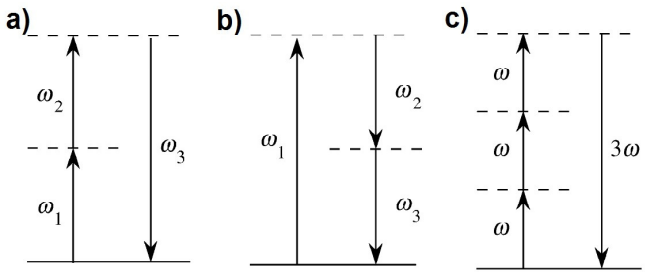

Figure 42.1: Parametric (a) sum and (b) difference frequency generation. (c) Third harmonic generation.

It is also important to emphasize that parametric processes are those, in which the initial and final quantum states of a system are identical. Consequently, the population of an initial state can only be moved to a virtual state, different in energy by ΔE, for a short time lapse limited by Heisenberg's uncertainty principle ($\hbar/\Delta E$). Nonparametric processes are those involving population transfer between real energy levels, eigenstates of the system's Hamiltonian. In terms of the electrical susceptibility of the medium, $\chi^{(n)}$ is a real quantity for parametric and an imaginary one for nonparametric processes.

42.1 The nonlinear optical susceptibility

The description of nonlinear optical phenomena can be approached from a variety of perspectives, most of which are semi-classical in the sense that the matter is treated quantum mechanically, while the electromagnetic radiation is treated classically. One possible description explores the wave nature of the radiation, using Maxwell's equations to describe the generation of new spectral components by the nonlinear terms of the polarization. More generally, this description explains how different frequencies can be coupled through their nonlinear interaction with the material. It can be shown that the electromagnetic wave equation in the nonlinear regime is,

$$\nabla\tilde{\mathcal{E}} - \frac{n^2}{c^2}\frac{\partial^2}{\partial t^2}\tilde{\mathcal{E}} = \frac{1}{\varepsilon_0 c^2}\frac{\partial^2}{\partial t^2}\tilde{\mathcal{P}} \ , \tag{42.5}$$

such that $\tilde{\mathcal{P}} = \tilde{\mathcal{P}}^{(1)} + \tilde{\mathcal{P}}^{(\mathrm{nl})}$. In this view, $\tilde{\mathcal{P}}^{(\mathrm{nl})}$ acts as a source of frequencies, several of that are incident.

Although electromagnetic theory is capable of explaining several aspects of nonlinear optics, it is the quantum description that provides explicit expressions for nonlinear optical susceptibility. There are three main motivations for obtaining quantum expressions:

- They reveal a functional form of the nonlinear optical susceptibility and show how they depend on microscopic parameters of the material, such as transition dipole moments and atomic energy levels.
- They exhibit the intrinsic symmetries of nonlinear susceptibility.

- They can be used to calculate numerically the values of nonlinear susceptibilities.

The numerical predictions of quantum theory for nonlinear optical susceptibilities are particularly accurate in the case of atomic vapors, because the atomic parameters of these are known with sufficient precision for the theory to provide reliable results.

Two quantum mechanical formalisms can be used for the calculation of nonlinear optical susceptibilities. Perturbation theory is used to make predictions on non-resonant systems, i.e. situations where the photon energy is much smaller than the energy separation between two eigenstates of the material. On the other hand, when the interactions are close to resonance, such that it becomes necessary to include relaxation processes, the state-density matrix formalism is used. Although this approach is more complex, it provides better results.

42.1.1 Exercises

42.2 Quantum interference

We have seen earlier that a *dark resonance* in Λ-shaped three-level systems create superposition states between the two stable ground states which allow the adiabatic elimination of the excited state. Dark resonances may be understood as destructively interfering excitation paths at Raman-coherences between inneratomic transitions. Quantum interference is at the origin of various other phenomena which are discussed in the following sections.

42.2.1 Lasing without inversion

The question of the necessity of population inversion to construct a laser has been the subject of debates. Indeed, even an ordinary two-level system may exhibit gain with a small frequency interval [659] known as *Mollow gain*. Lasing without population inversion may also result from a splitting of emission and absorption spectra caused by atomic recoil as in the example of CARL [111].

Various schemes of a *laser without inversion* (LWI) have been proposed. Here is one of them [687]. We will discuss an example in Exc. 42.2.3.1.

42.2.2 Brillouin scattering

Stimulated scattering of phonons is called *stimulated Brillouin scattering* (SBS). Like *Raman-scattering* (SRS) Brillouin-scattering is a limiting factor for the transmission efficiency in optical fibers. It is used in acousto-optic modulators (AOM). While SBS is based on the exchange of phonons between atoms bound in crystals, SRS is based on the exchange of phonons between atoms bound in molecules.

Raman-scattering (in a restricted historical sense) is very common technique of molecular spectroscopy. The process is Rayleigh-scattering at an electronic transition, but towards a different vibrational substate. Brillouin-scattering also involves the motional state of the scatterer, but its center-of-mass motion rather than some internal degree of freedom. It is also related to *polariton scattering* in solids, which produces optical phonons, rather than acoustic phonons.

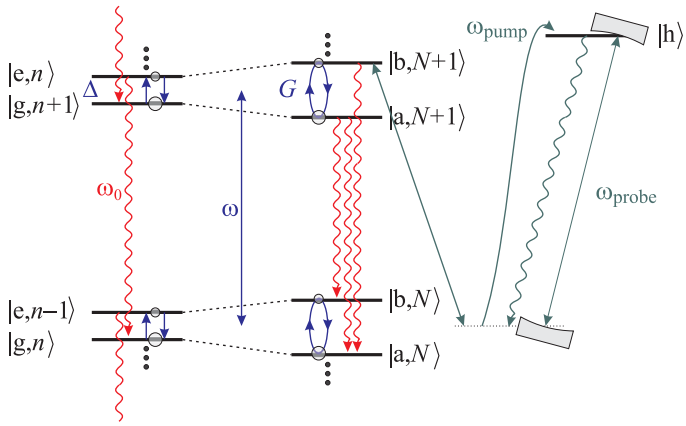

Figure 42.2: Dressed states level scheme for LWI. Quantum interference between two possible Raman transitions (green) leads to a cancellation of the ground state population. When the upper level $|h\rangle$ is incoherently pumped, gain can be reached for a weak probe field. Inserting the atoms in a cavity one can reach lasing [456].

If a strong electromagnetic field (pump laser) is irradiated into a medium (typically a crystal or a fluid) it produces a time-varying *electrostrictive strain*, which can be understood as the reaction force of particles dislocated from their equilibrium position. The strain is quantized into *phonons* and may drive a sound wave. This wave modulates the optical dielectric constant ε and thus create a periodic polarization $\vec{\mathcal{P}}$. This polarization may now interact with the incident electric field (pump laser $\omega_2, \mathbf{k}_2, \vec{\mathcal{E}}_2$). The resulting energy exchange can, under suitable circumstances, lead to simultaneous amplification of a probe wave $(\omega_2, \mathbf{k}_2, \vec{\mathcal{E}}_2)$ and a sound wave $(\omega_s, \mathbf{k}_s, u_s)$.

Let us consider a $1D$ geometry, $\mathbf{k}_j = k_j \hat{\mathbf{e}}_z$ and $\vec{\mathcal{E}}_j = \mathcal{E}_j \hat{\mathbf{e}}_x$. (More general geometries can be considered [997]). The pump field $\mathcal{E}_2(t,z)$ causes a strain $\partial u_s/\partial z$ via longitudinal displacements $u_s(z,t)$ of test volumes. This strain produces a modulation of ε by $\delta\varepsilon = -\gamma \partial u_s/\partial z$, where γ is the strain coefficient (or coupling strength). The modulation of the dielectric constant $\delta\varepsilon$ now modulates the interaction energy $\delta U = -\frac{1}{2}\delta\varepsilon \mathcal{E}_2$, which exerts work $p\partial u_s/\partial z = \delta U$ against the pressure p. The pressure modulation creates a force $F = -\partial p/\partial z = \frac{1}{2}\gamma \partial \mathcal{E}_2^2/\partial z$. We can now set up a Fokker-Planck type force equation,

$$\rho \frac{\partial^2 u_s}{\partial t^2} = \frac{\gamma}{2}\frac{\partial \mathcal{E}_2^2}{\partial z} - \eta \frac{\partial u_s}{\partial t} + T \frac{\partial^2 u_s}{\partial z^2} \ , \tag{42.6}$$

where ρ is the mass density, T the elastic constant and η acoustic dissipation. $v_s \equiv \omega_s/k_s = \sqrt{T/\rho}$ is the free propagation velocity of sound. Simultaneously we know that the light wave propagates like,

$$\frac{\partial^2 \mathcal{E}_j}{\partial z^2} + \mu\varepsilon \frac{\partial^2 \mathcal{E}_j}{\partial t^2} + \mu \frac{\partial^2 \mathcal{P}_{NL,j}}{\partial t^2} \ . \tag{42.7}$$

We insert the ansatz $\mathcal{E}_j(t,z) = \frac{1}{2}\mathcal{E}_{0j}(z) e^{\imath(\omega_j t - k_j z)} + c.c.$ and $u_s(t,z) = \frac{1}{2} u_{0s}(z) e^{\imath(\omega_s t - k_s z)} + c.c.$ first into the above equations. We use the approximations $k_s^2 u_s \gg d^2 u_s/dz^2 \ll$

$k_s du_s/dz$ and $|\partial(\mathcal{E}_2\mathcal{E}_1^*)/\partial z| \ll |k_s\mathcal{E}_2\mathcal{E}_1^*|$ and focus on the real parts. Assuming that the pump field $\mathcal{E}_2$ is undepleted, stimulated Brillouin-scattering is described by the following set of equations,

$$\begin{aligned} \frac{d\mathcal{E}_1^*}{dz} &= -\frac{\alpha}{2}\mathcal{E}_1^* - \frac{\gamma k_1 k_s}{4\varepsilon_1}\mathcal{E}_2^* u_s \\ \frac{du_s}{dz} &= -\frac{\eta}{2\rho v_s}u_s - \frac{\gamma}{8\rho v_s^2}\mathcal{E}_2\mathcal{E}_1^* \ . \end{aligned} \tag{42.8}$$

Here ρ is the mass density, optical losses are described by α, and η is the dissipation constant for phonons. $\varepsilon_1 \approx \varepsilon_0$. The scattering satisfies the *Bragg condition* $\mathbf{k}_2 - \mathbf{k}_1 = \mathbf{k}_s$. The above equations describe *exponential gain* and *threshold behavior* for $\mathcal{E}_1$ and u_s. For backscattering $\mathbf{k}_1\mathbf{k}_2 = -k_1k_2$ the rate of growth for the probe $\mathcal{E}_1$ is influenced by the values of $\mathcal{E}_1$ lying ahead in the direction $\mathbf{k}_1$. This is by virtue of the sound beam propagating in opposite direction to E_1 and provides the positive feedback being at the origin of exponential gain.

The equations are reminiscent to the CARL equations. The difference is the nature of the mediating force field: The CARL force is mediated by photons. The mediation is thus instantaneous. Photons do not require a medium in order to propagate. In contrast, the Brillouin-gain is mediated by phonons. Phonons propagate through a gas by collisions. Sound needs a medium to propagate. In dilute gases where CARL is observed, collisions are totally neglegible. Brillouin-scattering may lead to bunching, which propagates along $\mathbf{k}_s$. But similar to water waves, which do not transport the water molecules, the bunching does not lead to a net transport of atoms.

Just like CARL and the superradiant Rayleigh scattering in BECs SBS can be understood as being mediated by dipole-dipole interactions (i.e. the exchange of real or virtual photons between atoms). In a BECs SBS can be interpreted as phonon-like excitations (smaller momentum transfer) due to dipole-dipole interactions [361], while CARL are particle-like excitations due to dipole-dipole interactions (the nature of scattered particles changes from recoiling atoms to phonons). Note that while ultralow temperatures are necessary, these effects are not base on superfluidity, i.e. binary collisions. Thus the speed of sound is not the Bogolubov sound. The question is whether quantum degeneracy plays a role.

Chapter 43

Atomic motion in force fields

So far –and especially in Sec. 24.7.2– we analyzed the motion of quantum particles in potential landscapes without specifying the physical origin of the potentials. We know the *gravitational force*, which can be derived from the Earth's homogeneous attraction,

$$\mathbf{F} = -\nabla V_{\text{grav}} = -\nabla(mgz) = -gm\hat{\mathbf{e}}_z \ . \tag{43.1}$$

Another fundamental force comes from electromagnetism. We have already studied –mainly in Sec. 33.4– the reaction of the electronic shell in atoms subjected to applied electromagnetic fields.

In contrast, the present chapter is devoted to the motion of the *atomic center-of-mass* subject to forces resulting from interactions with *electromagnetic fields*. We will begin, in the first section, with electromagnetic forces of the Coulomb-Lorentz type acting on charges (e.g. ions), permanent electric dipoles (e.g. polar molecules), or permanent magnetic dipoles (e.g. paramagnetic atoms). Also, more complex situations will be discussed, such as the scattering of light by confined atoms, atoms interacting with optical cavities, and adiabatic potentials.

The second section will entirely be devoted to the forces exerted by light beams, in particular the *radiation pressure* and the *optical dipole force*, which are nowadays widely used in atomic cooling and trapping experiments. We will leave the issue of the application of these forces to Chp. 49 and concentrate here on the (semiclassical or quantum) derivation and the interpretation of the forces. In fact, to understand optical forces acting on atoms, we need to consider their internal degrees of freedom.

Apart from the degrees of freedom related to their center-of-mass motion (kinetic or potential energy), many quantum objects are endowed with internal degrees of freedom, for example, the motion of electrons inside atoms or molecules. In the simplest case, the Hamiltonian of such a system is composed of an outer part, comprising the kinetic and the potential energy, and an inner part counting for the excitation energy $\hbar\omega_0$ of an internal state $|e\rangle$,

$$\hat{H}_{\text{atom}} = \frac{\mathbf{p}^2}{2m} + V(\mathbf{r}) + \hbar\omega_0|e\rangle\langle e| \ . \tag{43.2}$$

The time scale of the electronic motion is usually very rapid compared to the motion of the nucleus, where (almost) the entire mass of the atom is concentrated. Therefore, the external (nuclear) dynamics decouples from the internal (electronic) one, which allows the separation of the total wavefunction in two parts,

$$|\psi\rangle = |\psi\rangle_{\text{ext}}|\psi\rangle_{\text{ele}} \ , \tag{43.3}$$

where for a simple two-level atom, $|\psi(t)\rangle_{\text{ele}} = c_g(t)|g\rangle + c_e(t)|e\rangle$, with the atomic ground state $|g\rangle$ and the excited state $|e\rangle$. The external states are eigenstates of the momentum in the case of a free particle, $|\psi\rangle_{\text{ext}} = |\mathbf{p}\rangle$. For particles confined in a potential the external states are the vibrational eigenstates, $|\psi\rangle_{\text{ext}} = |n\rangle$. The temporal evolutions of the internal and external degrees of freedom are governed by independent Schrödinger equations. For cold atomic clouds the kinetic energy is much smaller than the excitation energy, which allows the separation of the energy scales. That is, the internal degrees of freedom are frozen in the ground state. Many phenomena, for example, Bose-Einstein condensation and the dynamics of condensates are described in this regime.

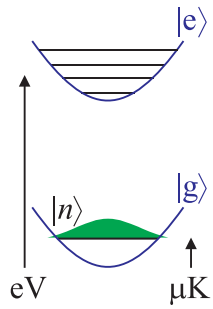

Figure 43.1: The internal degrees of freedom of cold atoms are thermally frozen.

Nevertheless, the fact that it is thermally frozen does not prevent the intentional excitation of the internal degree of freedom by irradiating electromagnetic fields tuned close to resonances and coupling electronic energy levels. In the case of coupling, the external and internal degrees of freedom must both be considered.

43.1 Electromagnetic forces

Obviously, in order to allow for forces acting on the atomic center-of-mass, the atomic Hamiltonian must contain terms depending on the center-of-mass coordinates:

$$\mathbf{F} = -\langle \nabla \hat{H}_{\text{atom:field}} \rangle \ . \tag{43.4}$$

We will see shortly that some of the terms may be dissipative, other conservative.

The impact of electromagnetic fields on the internal dynamics of atoms has already been studied in the Chp. 33. Here, we will focus on the force on the center-of-mass exerted by the gradient of *electromagnetic potentials*, where the Hamiltonian in Eq. (43.4) of a charge interacting with electromagnetic fields is obtained in minimum coupling (33.11) by,

$$\boxed{\hat{H}_{\text{atom:field}} = \frac{1}{2m}(-\imath\hbar\nabla - q\mathbf{A})^2 + q\Phi \simeq \frac{-\hbar^2}{2m}\nabla^2 + \frac{\imath\hbar q}{m}\mathbf{A}\cdot\nabla + q\Phi} \ . \tag{43.5}$$

From this formula we can, in principle, calculate all electromagnetic forces.

The coupling of external and internal degrees of freedom is mediated by the photonic recoil transferred to the atom during absorption and emission processes. That

is, the feature that the interaction with light simultaneously *excites* the atom and exerts a *force* couples the degrees of freedom. This fact manifests itself in the Hamiltonian of the atom interacting with a light field (40.8) by the appearance of terms joining operators acting on different degrees of freedom,

$$\hat{H} = \hbar\omega\hat{a}^\dagger\hat{a} + \hat{H}_{\text{atom:field}} + \hat{H}_{\text{atom}} \qquad (43.6)$$
$$\text{where} \qquad \hat{H}_{\text{atom:field}} = \hbar g(\hat{\mathbf{r}})e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\hat{a}^\dagger\hat{\sigma} + c.c. \ ,$$

where $\hat{\sigma} \equiv |g\rangle\langle e|$ and $\hat{a} \equiv \sum_n \sqrt{n}|n\rangle\langle n+1|$ and $\hbar g(\hat{\mathbf{r}}) \equiv \mathbf{d}_{12} \cdot \vec{\mathcal{E}}_1(\hat{\mathbf{r}})$ is the coupling constant or one-photon *Rabi frequency* derived from (11.10). The Hamiltonian is that of the Jaynes-Cummings model, except that in addition to the field operators $\hat{a}$ and the atom transition operators $\hat{\sigma}$, appears an operator for the position of the atom $\hat{\mathbf{r}}$, whose quantum features we have not taken very seriously so far. It appears in the Rabi frequency and also in the term $e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}$. Now, we must remember, that

$$\mathcal{U}_{\text{rec}} = e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}} = |\mathbf{p} + \hbar\mathbf{k}\rangle\langle\mathbf{p}| \qquad (43.7)$$

is the unitary operator of the photonic recoil in the absorption process introduced in Sec. 23.7.3 and extensively discussed in Sec. 24.6.2. We shall shortly see, that it is precisely this term in the Hamiltonian that gives rise to all phenomena related to light forces on atoms.

The presence of the position operator in the Jaynes-Cummings Hamiltonian introduces a new degree of freedom. With no external potential (that is, the system is invariant to spatial translations), this degree of freedom is simply the atomic center-of-mass momentum, such that the new set of quantum numbers is $|j, n, \mathbf{p}\rangle$. Strictly speaking we have to span the whole Hilbert space by an external product, $\hat{H}_{\text{ele}} \otimes \hat{H}_{\text{field}} \otimes \hat{H}_{\text{ext}}$.

Often a *semi-classical* description treating the light field a classically is sufficient, $\hat{a} \simeq \sqrt{n}$ with n the number of photons. Then the Hamiltonian (43.6) simplifies to,

$$\hat{H}_{\text{atom:field}} = \tfrac{\hbar}{2}\Omega(\hat{\mathbf{r}})e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\hat{\sigma} + c.c. \ , \qquad (43.8)$$

with the Rabi frequency $\Omega(\mathbf{r}) = \sqrt{n}2g(\mathbf{r})$.

43.1.1 Forces on charges and electric dipole moments

As shown in Eq. (33.8), the equations (43.4) and (43.5) (obviously) lead to Coulomb-Lorentz forces on charges and currents.

In atomic optics, the Coulomb-Lorentz force is used, for example, to accelerate or trap ions (see Sec. 49.5) and other electrically charged particles.

Atoms naturally do not exhibit *permanent electric dipole moments*, when they are not subject to external electric fields. In contrast, polar molecules (such as heteronuclear dimers), which have permanent electric dipole moments can have their motion be influenced by inhomogeneous electric fields (see Sec. 49.5.3).

43.1.2 Forces on magnetic dipole moments

Neutral atoms are insensitive to electric fields. But as we have already seen in Chp. 33, the orbital motion of the electrons corresponds to a circular current generating a permanent magnetic dipole moment $\vec{\mu}$, which can interact with external magnetic fields. We have already shown in the calculation (33.15) and (33.19) that the interaction energy (43.5) can be written as,

$$\hat{H}_{\rm magn} = -\vec{\mu}_J \cdot \vec{\mathcal{B}} = -\frac{g_J \mu_{\rm B}}{\hbar} \mathbf{J} \cdot \vec{\mathcal{B}} \longrightarrow -\frac{g_J \mu_{\rm B}}{\hbar} |\mathbf{J}|\, |\vec{\mathcal{B}}| = -g_J \mu_{\rm B} m_J \mathcal{B} \ , \tag{43.9}$$

where the *Landé factor* is given by the formula (33.21),

$$g_J = 1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)} \ . \tag{43.10}$$

Here, $\mathbf{J} = \mathbf{L} + \mathbf{S}$ is the total angular momentum resulting from the coupling of the total angular orbital momentum and the total spin of all electrons. If the atom has a nuclear spin I other than zero, then $\mathbf{F} = \mathbf{J} + \mathbf{I}$ replaces $\mathbf{J}$ in Eq. (43.9), and the g-factor generalizes to (33.35) [1],

$$g_F \simeq g_J \frac{F(F+1) + J(J+1) - I(I+1)}{2F(F+1)} \ . \tag{43.11}$$

In Sec. 33.2 we used the formula (43.9) to calculate the Zeeman shift of internal energy levels. But, according to the formula (43.4), the interaction also generates a force acting on the center-of-mass of atom,

$$\boxed{\mathbf{f} = -g_F \mu_{\rm B} m_F \nabla \mathcal{B}} \ . \tag{43.12}$$

In case of absence of hyperfine structure we simply replace F by J.

Obviously, force is conditioned by the existence of a gradient of the absolute value of the magnetic field. It was first used in the famous *Stern-Gerlach experiment*, which led to the discovery of the electron (see Sec. 25.3.3). In atomic optics (see Sec. 49.4), this force is widely used to create *magnetic traps* for cold atoms. Resolve the Excs. 33.2.7.2, 43.1.4.1, and 43.1.4.2.

43.1.3 Adiabatic potentials

Adiabatic potentials can be used to realize more complicated trapping geometries [199]. To study adiabatic potentials we consider the two-level system $|\frac{1}{2}, \frac{1}{2}\rangle \leftrightarrow |\frac{1}{2}, -\frac{1}{2}\rangle$ coupled by an incident radiation (e.g. a radiofrequency). A generalization to multilevel systems $F > \frac{1}{2}$ is simple. The dressed states Hamiltonian of our two-level system is a 2×2 matrix,

$$\hat{H}_{\rm adiab}(z) = \begin{pmatrix} \frac{1}{2}\mu_{\rm B} g_F \mathcal{B}(z) - \frac{1}{2}\hbar\omega & \frac{1}{2}\hbar\Omega \\ \frac{1}{2}\hbar\Omega & -\frac{1}{2}\mu_{\rm B} g_F \mathcal{B}(z) + \frac{1}{2}\hbar\omega \end{pmatrix} \ . \tag{43.13}$$

[1] Note that the formula only applies to weak fields. For strong fields the Zeeman unfolding changes to the Paschen-Back unfolding of the hyperfine structure.

For simplicity, we assume a one-dimensional geometry, $\mathcal{B} = \mathcal{B}(z)$, but we can easily generalize to three dimensions. The eigenvalues of $\hat{H}$ are,

$$E_{\pm}(z) = \pm\tfrac{1}{2}\sqrt{\hbar^2\Omega^2 + [\mu_{\rm B} g_F \mathcal{B}(z) - \hbar\omega]^2} \ . \tag{43.14}$$

Sufficiently far from resonance, $\hbar\Omega \ll |\mu_{\rm B} g_F \mathcal{B}(z) - \hbar\omega|$, we obtain,

$$E_{\pm}(z) \simeq \pm\tfrac{1}{2}[\mu_{\rm B} g_F \mathcal{B}(z) - \hbar\omega] \pm \frac{\hbar^2\Omega^2}{4[\mu_{\rm B} g_F \mathcal{B}(z) - \hbar\omega]} \ , \tag{43.15}$$

where the second term can be interpreted as the dynamic Stark shift of the energy levels.

To illustrate the influence of the radiofrequency, we calculate the potential energy and the dressed states assuming a linear $1D$ magnetic field gradient $\mathcal{B}(z) \equiv zb$. Fig. 43.2(a) illustrates the radiofrequency coupling and Fig. 43.2(b) the dressed states for two magnetic substates coupled by a radiofrequency. The minimum emerging in

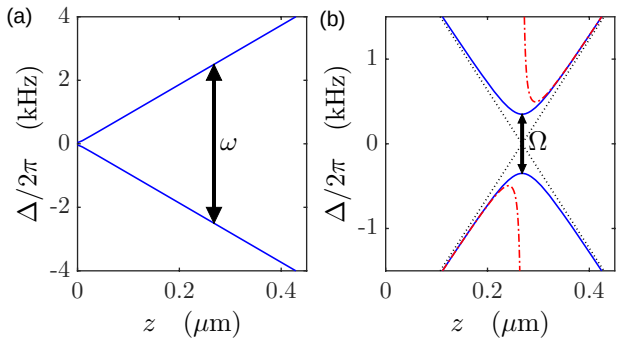

Figure 43.2: (code) (a) Potential energies for a hyperfine structure $F = \frac{1}{2}$ with a g-fator of $g = -\frac{2}{3}$ (as e.g. in the ground state $^2S_{1/2}$ of ^{6}Li). A radiofrequency (arrow) couples the substates $m_F = \pm\frac{1}{2}$. Here, $b = 200\,$G/cm and $\omega = 2\pi \times 5\,$kHz. (b) Uncoupled dressed states (dotted line), coupled dressed states (solid line), and dynamic Stark shifts (dash-dotted) approximated far away from resonance. The Rabi frequency is $\Omega = 2\pi \times 700\,$Hz.

the upper curve of Fig. 43.2(a) may serve as a confinement potential. Using an rf-radiation composed by several frequencies, potential minima can be realized at several distances z. In Exc. 43.1.4.3 we calculate an example.

In the dressed states basis with the Hamiltonian (43.13), the force is calculated from,

$$\mathbf{F}(\mathbf{r}) = \langle\hat{\mathbf{F}}(\mathbf{r})\rangle = -{\rm Tr}_{\rm atom:laser}\ \hat{\rho}\nabla_{\mathbf{r}}\hat{H}_{\rm adiab} = -\sum_{n,j}\langle n,j|\hat{\rho}\nabla_{\mathbf{r}}\hat{H}_{\rm adiab}|j,n\rangle \ . \tag{43.16}$$

We consider only one dimension and disregard the degrees of freedom of the radiation field,

$$F(z) = -{\rm Tr}_{\rm atom:laser}\ \hat{\rho}\partial_z\hat{H}_{\rm adiab} \tag{43.17}$$
$$= -\sum_j \langle j|\hat{\rho}\partial_z\left(\tfrac{\mu_{\rm B} g_F \mathcal{B}}{2}|1\rangle\langle 1| - \tfrac{\hbar\omega}{2}|1\rangle\langle 1| - \tfrac{\mu_{\rm B} g_F \mathcal{B}}{2}|2\rangle\langle 2| + \tfrac{\hbar\omega}{2}|2\rangle\langle 2| + \tfrac{\hbar\Omega}{2}e^{\imath kz}\hat{\sigma}^+ + c.c.\right)|j\rangle \ .$$

Here we neglect any possible position dependence of Ω,

$$F(z) = -\tfrac{1}{2}\mu_{\mathrm{B}} g_F \partial_z \mathcal{B} \sum_j \langle j|\hat{\rho}(|1\rangle\langle 1| - |2\rangle\langle 2|)|j\rangle = -\tfrac{1}{2}\mu_{\mathrm{B}} g_F \partial_z \mathcal{B}(\rho_{11} - \rho_{22}) \ . \quad (43.18)$$

If the atoms enter the coupling area adiabatically, the populations of the adiabatic potentials will only depend on z. This is analogous to the *adiabatic transfer* via adiabatic sweeps or STIRAP pulse sequences. If the atoms are too fast, the populations also depend on history (i.e. the recent trajectory of the atoms), which can result in Landau-Zener transitions to other (possibly untrapped) states.

43.1.4 Exercises

43.1.4.1 Ex: The Stern-Gerlach effect

Consider initially motionless ^{87}Rb atoms trapped in a superposition of two the trappable Zeeman states $|F, m_F\rangle = |2, +2\rangle$ and $|1, -1\rangle$. Suddenly a magnetic gradient of $\partial_z \mathcal{B} = 100\,\mathrm{G/cm}$ is applied for 2 ms. Calculate the spatial separation of the atoms being in either one of the two states after 10 ms of ballistic expansion.

43.1.4.2 Ex: Potential for magnetic trapping

Invent a potential for magnetic confinement.

43.1.4.3 Ex: Adiabatic potentials

An *adiabatic potential* can be used to create more complicated trapping potentials [199]. To study these potentials we consider a system of two Zeeman states $m = \frac{1}{2}$ coupled by a radiofrequency radiation $\hbar\omega$. The dressed states Hamiltonian of our two-level system is a 2×2 matrix,

$$\hat{H} = \begin{pmatrix} \frac{1}{2}\mu_{\mathrm{B}}\mathcal{B} - \frac{1}{2}\hbar\omega & \frac{1}{2}\hbar\Omega \\ \frac{1}{2}\hbar\Omega & -\frac{1}{2}\mu_{\mathrm{B}}\mathcal{B} + \frac{1}{2}\hbar\omega \end{pmatrix} ,$$

defining the energetic zero in the middle between the states. Now, assume that the magnetic field grows linearly along the axis z, $\mathcal{B}(z) = z\partial_z\mathcal{B}$, where $\partial_z\mathcal{B}$ is the gradient. Also assume that the radiofrequency is tuned in resonance with the difference of the energies of the Zeeman states at some distance z_0 such that, $\hbar\omega = \mu_{\mathrm{B}} z_0 \partial_z \mathcal{B}$.
a. Calculate the eigenenergies of the coupled system as a function of z.
b. Expands eigenenergies around the position z_0.
c. What would be the oscillation frequency of the trapped atoms inside the adiabatic potential?
d. Expands the eigenenergies in $\hbar\Omega$ for locations away from resonance.

43.2 Optical forces

Light carries momentum, and the scattering of light by an object produces a force on that object. Although these properties of light are direct consequences of Maxwell's classical theory of electromagnetism, they were only verified in 1933 by *Frisch*, who

observed a very small transverse deviation ($3 \cdot 10^{-5}$ rad) of an atomic sodium beam exposed to the light of a lamp. With the invention of the laser, it became easier to observe the light's mechanical effects, because the more intense and highly directional laser light exerts much larger forces. Although these results sparked the interest in using light forces to control the motion of neutral atoms, the fundamental bases for understanding the physics of light forces were not developed before the late 1970s. Unequivocal experimental demonstrations of cooling and trapping of atoms were not performed before the mid-1980s. In this section we will discuss some fundamental aspects of light forces. Practical schemes used to cool and trap neutral atoms will be presented in Secs. 49.2 and 49.3.

The light force acting on an atom can be of two types: a spontaneous dissipative force and a conservative dipole force. The spontaneous force arises from the recoil experienced by an atom when it absorbs or emits a quantum of light. As we saw in Sec. 23.2.6, when an atom scatters light, the resonant scattering cross section can be written as in Eq. (23.72), $\sigma_{0a} = \frac{g_2}{g_1}\frac{\lambda_0^2}{2\pi}$, where λ_0 is the resonant wavelength. In the optical region of the electromagnetic spectrum the wavelengths of light are of the order of several hundred nanometers, and the resonant cross sections for scattering become very large, ($\sim 10^{-9}\,\mathrm{cm}^2$). Each absorbed photon transfers a quantum of momentum $\hbar k$ to the atom in the direction of propagation. Spontaneous emission following an absorption process occurs in random directions and, hence, averaged over many absorption-emission cycles, it cancels to zero. Consequently, the total spontaneous force acts on the atom in the propagation direction of the light, as shown schematically in the diagram of Fig. 43.3. The saturated photon scattering rate via spontaneous emission (the reciprocal value of the excited state's lifetime) sets the upper limit for the magnitude of the force. This force is called *radiation pressure* force.

The *dipolar gradient force* can be easily understood by considering light as a classical wave. It is simply the time-averaged force resulting from the interaction of the transition dipole –induced by the oscillating electric field of the light– with the gradient of the electric field amplitude. The strength of this gradient can be controlled, e.g. by focusing the light beam. By tuning the optical frequency below or above an atomic transition, we can control the sign of the force acting on the atom: Tuning the light below resonance attracts the atom to the center of the light beam, tuning it above resonance repels it. The dipole force is a stimulated process without energy exchange between the field and the atom. Photons are absorbed in one light mode and reappear by stimulated emission in another one. However, conservation of momentum requires that the change in the propagation direction of the scattered photons from an initial mode to a final mode leaves the atom with a recoil. Contrary to spontaneous force, there is, in principle, no upper limit for the magnitude of the dipole force, since it is a function of the field gradient only and the detuning.

Within the theory of electromagnetism we calculate radiative forces on charges via *Maxwell's stress tensor* [2]. The interaction of radiation with atoms having internal degrees of freedom exhibiting resonances can be treated qualitatively by the *Lorentz*

[2] See script on *Electrodynamics* (2023), Sec. 6.2.3.

model [3].

In the following, we will show quantitative semi-classical and quantum calculations: The force of a light beam on an atom can be calculated in many different ways, each emphasizing a slightly different aspect: From the classical Lorentz force exerted on an atom by electromagnetic fields we can derive a semi-classical Fokker-Planck equation [887]. In Sec. 43.2.1 we will derive the two contributions (dipole force and radiative pressure) within a semi-classical theory [370]. Wineland *et al.* [976] chose as starting point the cross section for an elementary scattering process (Sec. 43.2.3). Dalibard *et al.* [219] developed a quantum theory using the dressed states representation (Sec. 43.2.2). And Cirac *et al.* [176] showed an approach based on the master equation (Sec. 43.2.3).

43.2.1 The dipolar gradient force and the radiation pressure force

To compute the forces of light on an atom, we describe the atom as a two-level system: A fundamental level $|1\rangle$ and an excited level $|2\rangle$ decaying to the fundamental level with the rate Γ. The energy difference between the levels is $\omega_0 \equiv E_2 - E_1$. The light with frequency ω is derived from a laser beam, which can be detuned from the atomic transition, $\Delta \equiv \omega - \omega_0$. To describe the interaction, we consider the part (43.8) of the total Hamiltonian describing the interaction [219]. Using the semi-classical density operator $\hat{\rho}$ [4], we can calculate the force that the light field exerts on the atom,

$$\begin{aligned}
\mathbf{F}(\mathbf{r}) = \langle \hat{\mathbf{F}}(\mathbf{r}) \rangle &= -\mathrm{Trat}\ \hat{\rho} \nabla_{\mathbf{r}} \hat{H}_{\text{atom:field}} \\
&= -\tfrac{1}{2}\hbar \sum\nolimits_j \langle j|\hat{\rho}|\nabla_{\mathbf{r}} \left(\Omega(\mathbf{r}) e^{\imath \mathbf{k}\cdot\mathbf{r} - \imath\Delta t}|2\rangle\langle 1| + \Omega(\mathbf{r}) e^{-\imath \mathbf{k}\mathbf{r} + \imath\Delta t}|1\rangle\langle 2|\right)|j\rangle \\
&= -\tfrac{1}{2}\hbar \nabla_{\mathbf{r}} \Omega(\mathbf{r}) \left(\langle 1|\hat{\rho} e^{\imath \mathbf{k}\cdot\mathbf{r} - \imath\Delta t}|2\rangle + \langle 2|\hat{\rho} e^{-\imath \mathbf{k}\cdot\mathbf{r} + \imath\Delta t}|1\rangle\right) \\
&\quad - \tfrac{\imath}{2}\hbar \mathbf{k} \Omega(\mathbf{r}) \left(\langle 1|\hat{\rho} e^{\imath \mathbf{k}\cdot\mathbf{r} - \imath\Delta t}|2\rangle - \langle 2|\hat{\rho} e^{-\imath \mathbf{k}\cdot\mathbf{r} + \imath\Delta t}|1\rangle\right) \ .
\end{aligned} \tag{43.19}$$

Now, we let the atom be at the position $\mathbf{r} = 0$,

$$\mathbf{F}(\mathbf{0}) = -\tfrac{1}{2}\hbar \nabla_{\mathbf{r}} \Omega(\mathbf{0})(\rho_{12} e^{-\imath\Delta t} + \rho_{21} e^{\imath\Delta t}) - \tfrac{\imath}{2}\hbar \mathbf{k} \Omega(\mathbf{0})(\rho_{12} e^{-\imath\Delta t} - \rho_{21} e^{\imath\Delta t}) \ . \tag{43.20}$$

The quantities $\rho_{12} \equiv \langle 1|\hat{\rho}|2\rangle = \rho_{21}^*$ are the coherences, which develop in a two-level system excited by a laser beam. Inserting the stationary solutions of the Bloch equations (39.151),

$$\rho_{22} = \frac{\Omega^2}{4\Delta^2 + 2\Omega^2 + \Gamma^2} \qquad \text{and} \qquad \rho_{12} = \frac{(2\Delta - \imath\Gamma)\Omega}{4\Delta^2 + 2\Omega^2 + \Gamma^2} e^{-\imath\Delta t} \ . \tag{43.21}$$

we obtain

$$\mathbf{F}(\mathbf{0}) = -\tfrac{1}{2}\hbar \frac{4\Delta\Omega}{4\Delta^2 + 2\Omega^2 + \Gamma^2} \nabla_{\mathbf{r}} \Omega + \hbar \mathbf{k} \frac{\Gamma\Omega^2}{4\Delta^2 + 2\Omega^2 + \Gamma^2} \ . \tag{43.22}$$

[3] See script on *Electrodynamics* (2023), Sec. 7.2.4.

[4] Treating the motional and the optical degrees of freedom as classical the density operator only contains the atomic excitation.

With the definition of the cross section, $\sigma_a(\Delta) = \sigma_{a0}\frac{\Gamma^2}{4\Delta^2+2\Omega^2+\Gamma^2}$,

$$\mathbf{F}(\mathbf{0}) = -\tfrac{1}{2}\hbar\Delta\nabla_{\mathbf{r}}\ln\left(1+\frac{2\Omega^2}{4\Delta^2+\Gamma^2}\right) + \hbar\mathbf{k}\frac{\Omega^2}{\Gamma}\frac{\sigma_a(\Delta)}{\sigma_{a0}} \ . \tag{43.23}$$

The resonant cross section for a 'classical' transition is $\sigma_{a0} = 3\lambda^2/2\pi$.

Apparently, the force comprises two contributions. The *dipolar gradient force* can be derived from a potential. It is proportional to the intensity gradient and can be interpreted as resulting from absorption processes immediately followed by self-stimulated emission. Near resonance it is dispersive. Far from resonance it can be approximated by,

$$\boxed{\mathbf{F}_{\rm dp} = \nabla_{\mathbf{r}}\frac{-\hbar\Delta\Omega^2}{4\Delta^2+\Gamma^2} \overset{|\Delta|\gg\Gamma}{\longrightarrow} -\nabla_{\mathbf{r}}\frac{\hbar\Omega^2}{4\Delta} \ .} \tag{43.24}$$

The *radiation pressure* force is dissipative. Close to resonance it is absorbing. It is proportional to the phase gradient and the only force exerted by plane waves. It can be interpreted as resulting from absorption processes followed by spontaneous emission. With $\Omega^2 = \sigma_{a0}\Gamma I/\hbar\omega$ we get a formula,

$$\boxed{\mathbf{F}_{\rm rp} = \hbar\mathbf{k}\frac{I}{\hbar\omega}\sigma_a(\Delta) = \hbar\mathbf{k}\gamma_{\rm sct}} \ , \tag{43.25}$$

which describes the force as a product of the number of photons in the incident beam, $I/\hbar\omega$, the absorption cross section, $\sigma_a(\Delta)$, and the recoil momentum per photon, $\hbar k$. $\gamma_{\rm sct}$ is the scattering rate. Fig. 43.3(a) illustrates the radiation pressure force.

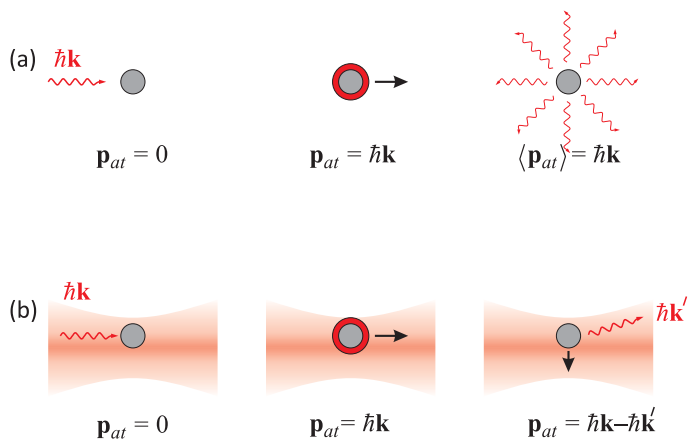

Figure 43.3: (a) Upon absorption of a photon an initially resting atom receives a recoil momentum kick $\hbar k$. As the re-emission is isotropic, averaged over many absorption-emission cycles, the net force is only given by the absorption process. (b) The dipole force may be interpreted as a coherent redistribution of photons between spatial modes of a focused light beam.

The dipole gradient force (and the associated potential) is often used to spatially confine atoms, and the radiation pressure force is often used to cool them down. Note

that we still need to correct Eqs. (43.24) and (43.25) to take into account the square of the average over the possible spatial orientations of the transition matrix element $d_{12}/3$. As illustrated in Fig. 43.3(b), the dipole force may be interpreted as being due to coherent redistribution of photons between partial spatial modes of a non-uniform (e.g. focused) light beam. The orientation of the force depends on the sign of the detuning and can be understood in terms of the Lorentz model treating the atom as classical radiator (see Sec. 15.2.4).

The saturation parameter,

$$s = \frac{\frac{1}{2}\Omega^2}{\Delta^2 + \frac{1}{4}\Gamma^2} \ , \tag{43.26}$$

allows to write the dipolar gradient force and the radiative pressure force as,

$$\mathbf{F}_{\rm dp} = -\frac{\hbar\Delta}{6}\frac{1}{1+s}\nabla s = \frac{\hbar\Delta}{6}\nabla \ln[1+s] \qquad \text{and} \qquad \mathbf{F}_{\rm rp} = \frac{\hbar\mathbf{k}\Gamma}{6}\frac{s}{1+s} \ . \tag{43.27}$$

Eq. (43.27) shows that the radiation pressure force 'saturates' as s increases, and is therefore limited by the spontaneous emission rate. The saturation parameter essentially describes the relative importance of terms appearing in the denominator of the line profile function for the light forces. The spontaneous emission rate is an intrinsic property of the atom, proportional to the square of the atomic transition dipole moment, whereas the square of the Rabi frequency is a function of the incident laser intensity. If $s \ll 1$, the spontaneous emission is fast compared to any stimulated process, and the light field is said to be weak. If $s \gg 1$, the Rabi oscillation is fast compared to spontaneous emission and the field is considered as strong. The line profile factor indicates a 'power broadening' by saturation of a factor of $\sqrt{2}$. Note that the dipolar gradient force and potential, Eqs. (43.27), do not saturate when the intensity of the light field is increased. Usually $\mathbf{F}_{\rm dp}$ and $U_{\rm dp}$ are used to manipulate and trap atoms in a laser beam tuned far away from resonance in order to avoid absorption.

Often, the transition moment can be oriented using circularly polarized light. In this case, all previous expressions for $\mathbf{F}_{\rm dp}$, $\mathbf{F}_{\rm rp}$, and $U_{\rm dp}$ should be multiplied by 3. From now on we will abandon the average over the orientations and only use d_{12}^2 for the square of the transition dipole moment. Solve Excs. 43.2.5.1 and 43.2.5.2.

43.2.2 Semiclassical calculation of dipole force and radiative pressure

In quantum mechanics we calculate the force from the Heisenberg equation [370],

$$\hat{\mathbf{F}} = \frac{d}{dt}\hat{\mathbf{p}} = \frac{\imath}{\hbar}[\hat{H}, \hat{\mathbf{p}}] = -\nabla_{\mathbf{r}}\hat{H}_{\rm atom:field} \ . \tag{43.28}$$

Thus, the force is given by the gradient of the interaction energy between the atom and the light field. Within the dipole approximation the interaction energy is given by $\mathbf{d}\cdot\vec{\mathcal{E}}(\mathbf{r})$. The force is now,

$$\begin{aligned}\mathbf{F}(\mathbf{r}) = \langle\hat{\mathbf{F}}(\mathbf{r})\rangle = \langle\nabla_{\mathbf{r}}[\mathbf{d}\cdot\vec{\mathcal{E}}(\mathbf{r})]\rangle &= \langle(\mathbf{d}\cdot\nabla_{\mathbf{r}})\vec{\mathcal{E}}(\mathbf{r})\rangle - \langle\mathbf{d}\times(\nabla_{\mathbf{r}}\times\vec{\mathcal{E}}(\mathbf{r}))\rangle \\ &\equiv \mathbf{F}_{\rm C}(\mathbf{r}) + \mathbf{F}_{\rm L}(\mathbf{r}) \ .\end{aligned} \tag{43.29}$$

The first contribution can be interpreted as the Coulomb force acting on the electron performing rapid oscillations at the position $\mathbf{r}(t) = \mathbf{r}_0 + e^{-1}\vec{\mathcal{P}}(\mathbf{r}_0, t)$. The second term is the time-averaged Lorentz force acting on the oscillating electric dipolar moment [427, 430, 428],

$$\mathbf{F}_{\mathrm{C}} = e\langle\vec{\mathcal{E}}\rangle \qquad \text{and} \qquad \mathbf{F}_{\mathrm{L}} = -\langle\mathbf{d}\times\partial_t\vec{\mathcal{B}}\rangle = \langle\partial_t\mathbf{d}\times\vec{\mathcal{B}}\rangle \ . \tag{43.30}$$

The relation between the light-induced electric dipole moment and the polarizability, $\mathbf{d} = \alpha(\vec{\mathcal{E}})\vec{\mathcal{E}}$, where $\alpha_{\nu\nu} \equiv \alpha_\nu + \imath\beta_\nu$ and $\mathcal{E}_\nu \equiv \sqrt{I_\nu}e^{\imath\psi_\nu}$, becomes,

$$\mathbf{F} = \sum_{\nu=1}^{3}\alpha_\nu\nabla I_\nu + 2\sum_{\nu=1}^{3}\beta_\nu I_\nu\nabla\psi_\nu \ . \tag{43.31}$$

43.2.3 Force exerted by a quantized radiation field

Photons carry one unit of momentum $\mathbf{p} = \hbar\mathbf{k}$, which they transfer to the atom during an absorption or emission process. That is, the light exerts a recoil on the atoms. Spontaneous emission couples to all radiative modes of the electromagnetic vacuum, $\hat{H}_{\mathrm{cm:vacuum}} = \sum_j \hat{H}_{\mathrm{cm:laser}}(\mathbf{k}_j)$. We can trace over these variables and only keep those of the atom and the laser. Following Cirac *et al.* [976, 176], the randomness of the recoil by spontaneous emission is accounted for by,

$$\hat{\rho} \to \int_{4\pi\mathbb{R}^2} S(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}}\hat{\rho}e^{-\imath\mathbf{k}\cdot\mathbf{r}}d\Omega \ , \tag{43.32}$$

such that the *Lindblad operator* becomes,

$$\begin{aligned}\mathcal{L}_{\mathrm{atom}}\hat{\rho} &= -\Gamma\{\hat{\sigma}^\dagger\hat{\sigma}\hat{\rho}(t) - \tfrac{3}{4\pi}\int S(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}}\hat{\sigma}\hat{\rho}(t)\hat{\sigma}^\dagger e^{-\imath\mathbf{k}\cdot\mathbf{r}}d\Omega + \hat{\rho}(t)\hat{\sigma}^\dagger\hat{\sigma}\} \\ \mathcal{L}_{\mathrm{cavity}}\hat{\rho} &= -\kappa\{\hat{a}^\dagger\hat{a}\hat{\rho}(t) - 2\hat{a}\rho(t)\hat{a}^\dagger + \hat{\rho}(t)\hat{a}^\dagger\hat{a}\} \ ,\end{aligned} \tag{43.33}$$

where $e^{\pm\imath\mathbf{k}\cdot\mathbf{r}} = \sum_{\mathbf{p}}|\mathbf{p}\mp\imath\mathbf{k}\cdot\mathbf{r}\rangle\langle\mathbf{p}|$ and $S(\mathbf{r}) = \frac{1}{2}\left(1 + (\frac{\mathbf{k}\cdot\mathbf{r}}{kr})^2\right)$ and $d\Omega = d\varphi d\cos\vartheta$. From this they calculate the force and establish a *Fokker-Planck equation* for the *Wigner function*.

43.2.4 Refraction of atoms by light and of light by atoms

Non-resonant light acts on the external degrees of freedom of atoms by a *phase shift of the Broglie wave*, $\exp\left[\imath\hbar^{-1}\int U(\mathbf{r},t)dt\right]$, and simultaneously on the internal degrees of freedom by a *dynamic Stark shift* or *light shift* of the energy levels by the value of $U(\mathbf{r})$. The Bloch vector defined by,

$$\rho \equiv \begin{pmatrix} \frac{1}{\sqrt{2}}c_g c_e^* \\ \frac{1}{\sqrt{2}}c_g^* c_e \\ |c_e|^2 - |c_g|^2 \end{pmatrix} \tag{43.34}$$

describes, under the influence of the dispersive interaction, a precession around the polar axis. This was discussed in Exc. 39.7.3.9. The Stark shift causes a rotation of

$\hbar^{-1}U(\mathbf{r})t$. Simultaneously, the atom is subjected to a force, which corresponds to the gradient of the potential $-\nabla U(\mathbf{r})$, as illustrated in Fig. 43.4(a). We see that the phase shifts of the Broglie wave and the Bloch vector are equal. Finally, the light mode phase is also shifted by the same amount in an effect called *refraction*. That is, the internal, external, and optical degrees of freedom are entangled.

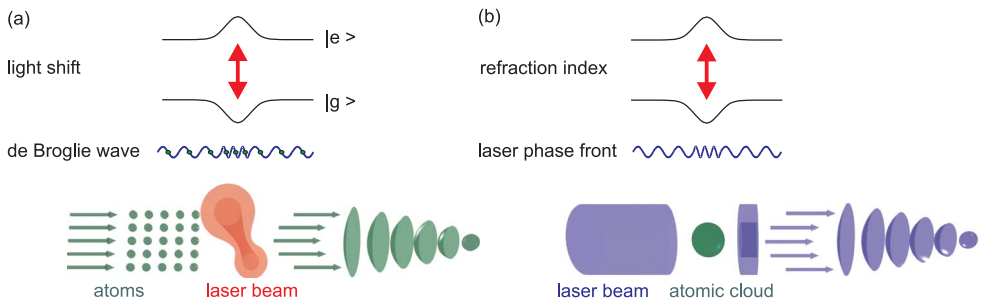

Figure 43.4: Diagram (a) shows product states and dressed states for blue detuning. Note that the population is in the upper level and that the atom is subject to a repulsive weak field seeking force when it enters the laser beam. Diagram (b) is similar, but for red detuning. The population is in the lower level and the atom is subject to an attractive high field seeking force.

This fact has a practical use in atomic interferometers, because it is often easier to detect an interference of internal excitation states rather than of Broglie waves. Because of the entanglement, it is sufficient to measure *one* interference pattern to know the *other one*.

By local variations of the potential $U(\mathbf{r})$, e.g. induced by a focused laser beam, it is possible to manipulate a Broglie wavefront in the same way that, in classical optics, we manipulate the wavefront of a light beam by lenses or other objects, such as for instance, the refractive index represented by an atomic cloud near resonance, as illustrated in Fig. 43.4(b).

The orientation of the force depends on the light frequency as compared to the resonant frequency. The dipolar force attracts the atom to regions where the light field is strong, when the frequency is tuned below ω_0, and it attracts the atom to regions of weak fields, when tuned above ω_0. Integration over the relevant spatial coordinates results in an effective potential or barrier to the atom. The qualitative behavior of the dipolar potential and its effect on the motion of atoms is easily visualized in the dressed states picture. Fig. 43.5 shows what happens when an atom enters a well defined region of an optical field, for example a focused laser beam.

Outside the atom-dipole coupling zone the expression $\hbar\Omega$ is despicable and the 'dressed states' are just the atom-field product states. When the atom enters the field, this expression becomes nonzero and the atom-field states combine to produce a set of dressed states. The energy levels of the product states 'repel' each other and approach the dressed states levels. Assuming that the laser is sufficiently detuned to maintain the absorption rate negligible, the population remains in the ground state. We see that blue (red) detuning leads to a repulsive (attractive) potential for atoms remaining in the grounded state. In addition, since $\hbar\Omega$ is directly proportional to the

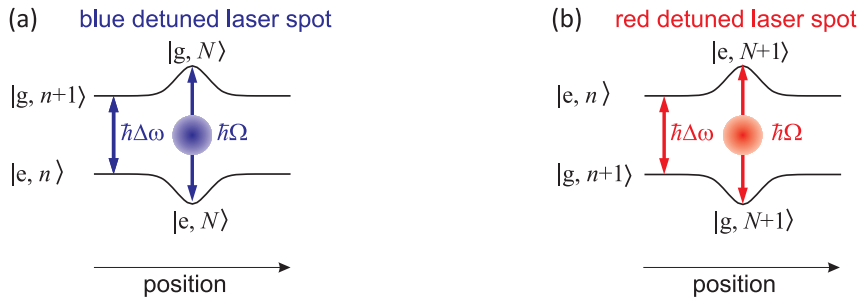

Figure 43.5: Analogy between light optics and atomic optics.

root of the laser intensity, an increase in that intensity (optical power per unit area) obviously amplifies the force on the atom ($\mathbf{F} \simeq \nabla_R \Omega$).

43.2.5 Exercises

43.2.5.1 Ex: Dipole force for large detunings

Verify that in the limit of large detunings the dipole potential Eq. (43.23) tends to $\longrightarrow \frac{\Omega^2}{4\Delta}$.

43.2.5.2 Ex: Radiation pressure

Calculate the radiation pressure force exerted on a strontium atom by a laser beam in plane wave geometry ($I = 100\,\mathrm{mW/cm^2}$) tuned (i) at resonance and (ii) $\Delta/2\pi = -50\,\mathrm{MHz}$ below the resonance at $461\,\mathrm{nm}$ ($\Gamma/2\pi = 30.5\,\mathrm{MHz}$).

43.2.5.3 Ex: lin-lin standing wave

Calculate the electric field of two counter-propagating linearly polarized laser beams of equal intensities,

$$\vec{\mathcal{E}}_{\mathrm{lat}}(\mathbf{r},t) = \tfrac{1}{2} \sum_{\mathbf{k}=\pm k\hat{\mathbf{e}}_z} \mathcal{E}_0 \vec{\varepsilon}_{\mathbf{k}} e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega_{\mathbf{k}}t+\phi_{\mathbf{k}})} + c.c. \ ,$$

but different polarizations in the spherical basis.

43.2.5.4 Ex: Sub-lattices

Consider two laser standing wave laser beams crossing each other under an angle of 90°,

$$\vec{\mathcal{E}}_1 = \vec{\varepsilon}_1 e^{\imath(kx-\omega t)} \qquad \text{and} \qquad \vec{\mathcal{E}}_2 = \vec{\varepsilon}_2 e^{\imath(ky-\omega t)} \ ,$$

with arbitrary elliptical polarizations $\vec{\varepsilon}_i$ and study the scalar light-shift potential,

$$U_s = -\frac{\alpha_s}{4}|\vec{\mathcal{E}}|^2 \ ,$$

as well as the vector light-shift potential,

$$U_v = \vec{\mathcal{B}}_{eff} \cdot \mathbf{F} \qquad \text{where} \qquad \vec{\mathcal{B}}_{eff} = \imath \alpha_v \vec{\varepsilon}^* \times \vec{\varepsilon}$$

in the xy-plane. α_v is the vector part of the atomic polarizability and $\vec{\mathcal{B}}_{eff}$ an effective magnetic field [252, 563, 20].

43.3 Photonic recoil on free and confined atoms

A trap confining the atomic motion can dramatically modify the way in which they interact with light [5]. For instance, a trapping potential may alter the scattering rate, the scattering angle, and the transfer of photonic recoil. However, *potentials do not exist* in microscopic reality, not more than friction forces do. What exists, as we learn in electrodynamics, are *electromagnetic fields* exerting Coulomb and Lorentz forces. When we write down the Hamiltonian $\hat{H} = \mathbf{p}^2/2m + V(\mathbf{r})$ in quantum mechanics, we already make an important approximation, because the potential $V(\mathbf{r})$ is an artifact obtained by tracing over all those degrees of freedom, which are necessary to generate a force field that can be approximated by a conservative potential.

In the great majority of situations, the approximation is very good. Problems may however arise, when the momentum conservation comes into play, which is the case e.g. of light scattering from ultracold atoms being accelerated by the photonic recoil and shifting the scattered light via the Doppler effect. We then have to address the issue of photonic recoil conserving (or not) the momentum.

Let us begin with a recapitulation of the classical picture of the scattering process applying the rules of energy and momentum conservation to the elastic collision between a free atom and a photon. This process is known as *Compton scattering*.

43.3.1 Recoil- and Doppler-shift in classical mechanics

In classical mechanics we speak of *elastic scattering* when no energy is transferred to internal degrees of freedom of the collision partners, so that *kinetic* energy and momentum stay conserved. This concept can be transferred to quantum particles (e.g. atoms) and photons. In elastic Compton scattering, if the atoms keep their initial internal excitation, the law of momentum conservation requires the transfer of photonic momentum to the scattering atom which, consequently, changes its kinetic energy. To compensate for this kinetic energy change, the frequency of the scattered light must change in order to preserve the total energy, as illustrated in Fig. 43.6(b).

We will calculate in the following the frequency distribution of the light scattered by an atom as a function of its initial velocity $\mathbf{p}_1$, of the frequency ω_1 of the incident light and of the scattering angle, that is, the angle between the modes $\mathbf{k}_1$ and $\mathbf{k}_2$. We begin by writing the laws of conservation of energy and momentum,

$$\begin{aligned} \hbar\mathbf{k}_1 + \mathbf{p}_1 &= \hbar\mathbf{k}_2 + \mathbf{p}_2 \\ \hbar\omega_1 + \frac{p_1^2}{2m} &= \hbar\omega_2 + \frac{p_2^2}{2m} \ . \end{aligned} \tag{43.35}$$

[5] The interaction also depends on other parameters, such as the geometry of the confinement potential and on cooperative effects (bosonic stimulation), but this will be discussed later.

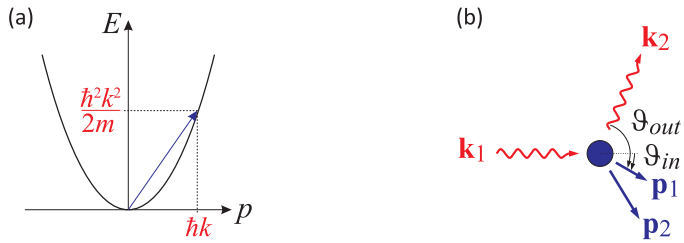

Figure 43.6: (a) Kicking an atom along its dispersion relation. (b) Scheme of the Compton-scattering of light.

Eliminating $\mathbf{p}_2$ from the second equations, we obtain,

$$\hbar\omega_1 - \frac{\hbar^2 k_1^2}{2m} - \frac{\hbar\mathbf{k}_1\cdot\mathbf{p}_1}{m} = \hbar\omega_2 + \frac{\hbar^2 k_2^2}{2m} - \frac{(\hbar\mathbf{k}_1+\mathbf{p}_1)\cdot\hbar\mathbf{k}_2}{m} \ . \tag{43.36}$$

The photonic recoils of the incident and of the scattered light are almost equal,

$$\omega_{\rm rec} \equiv \frac{\hbar k_1^2}{2m} \simeq \frac{\hbar k_2^2}{2m} \ , \tag{43.37}$$

such we can approximate,

$$\omega_2 = \omega_1 \frac{1 - \frac{\hbar\omega_1}{mc^2} - \frac{p_1}{mc}\cos\sphericalangle(k_1,p_1)}{1 - \frac{\hbar\omega_1}{mc^2}\cos\sphericalangle(k_1,k_2) - \frac{p_1}{mc}\cos\sphericalangle(p_1,k_2)} \ , \tag{43.38}$$

using $\omega_1 = ck_1$, or also,

$$\omega_2 - \omega_1 = \omega_1 \frac{\frac{\hbar\omega_1}{mc^2}\left[-1+\cos(\vartheta_{in}-\vartheta_{out})\right] + \frac{p_1}{mc}(\cos\vartheta_{out}+\cos\vartheta_{in})}{1 - \frac{\hbar\omega_1}{mc^2}\cos(\vartheta_{in}-\vartheta_{out}) - \frac{p_1}{mc}\cos\vartheta_{out}} \ , \tag{43.39}$$

where we call the angles $\vartheta_{in} = \sphericalangle(k_1,p_1)$, $\vartheta_{out} = \sphericalangle(k_2,p_1)$, and $\vartheta = \vartheta_{in} - \vartheta_{out} = \sphericalangle(k_1,k_2)$. For non-relativistic velocities, the denominator is approximately 1:

$$\boxed{\omega_2 - \omega_1 = 2\omega_{\rm rec}(-1+\cos\vartheta) + k_1 v_1(\cos\vartheta_{out}+\cos\vartheta_{in})} \ , \tag{43.40}$$

with $\mathbf{p}_1 = m\mathbf{v}_1$. The first term describes the recoil shift and the second term the Doppler shift.

The second term vanishes for initially at resting atoms, $\mathbf{p}_1 = 0$, and Eq. (43.40) simplifies to,

$$\omega_2 - \omega_1 = 2\omega_{\rm rec}(-1+\cos\vartheta) \ . \tag{43.41}$$

It also vanishes for atoms which have no velocity component in the scattering plane spanned by the wavevectors $\mathbf{k}_1$ and $\mathbf{k}_2$, that is $\vartheta_{out} = 180^\circ - \vartheta_{in}$ [6], for which case we get the maximum recoil shift,

$$\omega_2 - \omega_1 = -4\omega_{\rm rec} \ . \tag{43.42}$$

[6] This situation is often realized in Bragg scattering from optical lattices [858, 860, 859].

The recoil shift is a consequence of momentum conservation.

The recoil shift is typically on the order of $\omega_2 - \omega_1 \approx (2\pi)$ 10 kHz, which in many situations is negligible (e.g. when we deal with thermal atomic clouds), such that we can consider the scattering as elastic., i.e. the first term can be disregarded. Considering, for simplicity, only backscattering, $\cos\vartheta_{out} = \cos\vartheta_{in} = 1$, then Eq. (43.40) simplifies to,

$$\omega_2 - \omega_1 = 2k_1 v_1 \ . \tag{43.43}$$

Obviously, the frequency shift depends on the initial velocity through the Doppler shift $k_1 v_1$. In a thermal gas, the velocities are distributed according to the Maxwell-Boltzmann distribution. Therefore, Rayleigh scattering of light off a cloud of free thermal atoms is subject to Doppler broadening [7].

43.3.2 Kicking a free atom

A conceptual difficulty arises from the incompatibility of scattering picture (generally described in homogeneous space with momentum conservation) and the trapping picture (when it is described in inhomogeneous space without momentum conservation). The difficulty can be avoided by separating the processes into a 'kick' followed by a harmonic oscillation, for which we have to calculate the time-dependence of the states and the observables. We will leave the discussion of such a scattering process to 43.3.3 and for the time being just focus on the time evolution of a harmonic oscillator that just received a kick.

By a 'kicking' an atom we denote a change of momentum within an arbitrarily short amount of time. The shorter the kick-time the larger is, according to Heisenberg's uncertainty relation, the spectrum of possible kinetic energies that can be reached by the kick (see Sec. 27.4.3). However, the spectrum is restricted by the free-particle dispersion relation, as illustrated in Fig. 43.6(a).

The kick is not a realistic physical concept, as it corresponds to an infinitely strong and infinitely short force [8]. In a microscopic scattering process it assumes an infinitely heavy collision partner, while we are more interested in photon scattering. Consequently, in this case the spectrum of reachable energies is determined by the frequency of the photon *and* the free-particle dispersion relation. We will now turn our attention to the (Compton-)scattering of light by free atoms.

43.3.3 (In-)elastic light scattering from a single weakly or strongly confined atom

We mentioned in the last subsection that a scattering process is elastic when none of the collision partners changes its internal excitation energy. The situation becomes, however, more complex when one of the collision partners is confined in a potential, as we will show in the following.

[7] This Doppler broadening is explored e.g. in RIR spectroscopy, where the momentum distribution in p_1 reveals as a frequency distribution $\Delta\omega = \omega_2 - \omega_1$ of Bragg-scattered light, which can be measured by beating with an irradiated idler mode, which can be chosen as being identical to $\mathbf{k}_2$.

[8] which is what allows us to write down a potential

43.3.3.1 Cooperativity in light scattering

In light scattering *cooperativity* means *breaking of the isotropic symmetry* for the angular distribution of scattered modes. In this sense, the anisotropic scattering from an atom confined in an anisotropic trap is cooperative. But there are other cooperative scattering effects messing with isotropy and shaping the density-of-states, like the Purcell effect in the presence of an optical cavity or a photonic band gap concentrating optical modes in a specific solid angles [422]. Another cooperative effect, which is observed in the presence of other atoms, has to do with bosonic stimulation by the optical output mode (as in Bragg scattering [858, 860, 859]) or the momentum sidemode (as in stimulated matter wave 4WM). These effects, which all need to be considered in calculations of the static structure factor ruling the scattering of light, are often strong enough to hide the role of an anisotropic trapping potential. In the following subsections we will disregard all these effects and concentrate on a *single trapped atom*.

The simple picture of Compton scattering presented in Sec. 43.3.1 holds for *free atoms*, whose dynamics is totally understood in terms of their internal electronic excitation ($\hat{H}_{\rm ele}$), the kinetic energy of their center-of-mass ($\hat{H}_{\rm cm} = \frac{\mathbf{p}^2}{2m}$), the radiation field ($\hat{H}_{\rm rad}$) (which may be treated classically under the circumstances discussed here), and the coupling ($\hat{H}_{\rm int}$) of all three degrees of freedom,

$$\hat{H}_{free} = \hat{H}_{\rm ele} + \hat{H}_{\rm cm} + \hat{H}_{\rm rad} + \hat{H}_{\rm int} \ . \tag{43.44}$$

Transition probabilities are readily calculated using Fermi's Golden rule, because the density-of-states distributions for the final radiation modes receiving the scattered photons (photonic density-of-states) and the recoil modes receiving the scattered atoms (phononic density-of-states) are white, that is, without resonances, and isotropic.

In the presence of an imposed trapping potential, an additional term appears in the Hamiltonian, which has the capacity of dramatically changing the scattering features,

$$\hat{H}_{\rm cm} = \frac{\mathbf{p}^2}{2m} + \hat{V}_{\rm trp}(\mathbf{r}) \ . \tag{43.45}$$

The confining potential may or may not depend on the internal state of the atom. For ions in a Paul trap it does not depend, but for atoms in magnetic traps it usually depends,

$$\begin{aligned} \hat{H}_{\rm atom} &= |g\rangle \hat{H}_{{\rm cm},g} \langle g| + |e\rangle (\hat{H}_{{\rm cm},e} + \hbar\omega_0) \langle e| \\ \hat{H}_{{\rm cm},j} &= \frac{\hat{p}^2}{2m} + V_j(\mathbf{r}) \ , \end{aligned} \tag{43.46}$$

where ω_0 is the frequency of the atomic transition. In the following, however, we will treat potentials that are independent of the internal atomic state.

43.3.3.2 Resolved sideband regime

As discussed in Sec. 39.5.5, incident light is absorbed by an atom harmonically oscillating in a trap with frequency $\omega_{\rm trp}$ on a spectrum of discrete sidebands separated

by $\omega_{\rm trp}$ with amplitudes given by $J_n(kv_0/\omega_{\rm trp})$. The modulation index $kv_0/\omega_{\rm trp} = kx_0 = 2\pi x_0/\lambda$ corresponds to the Lamb-Dicke parameter. When the modulation amplitude is within the so-called *Lamb-Dicke regime*, $kv_0 \ll \omega_{\rm trp}$, the first sidebands become smaller than the carrier, $J_1(kv_0/\omega_{\rm trp}) < J_0(kv_0/\omega_{\rm trp})$ and, therefore, do not contribute to the Doppler width of the frequency distribution. That is, the linear Doppler effect vanishes.

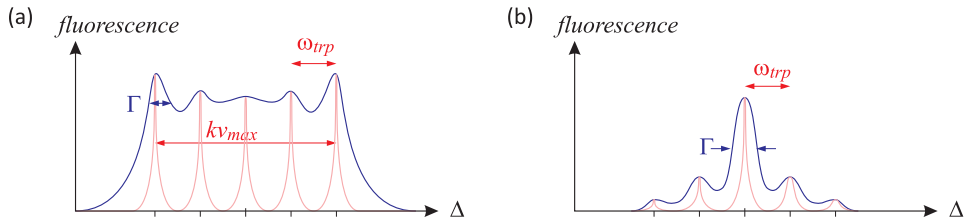

Figure 43.7: Absorption profile in the regimes of (a) weak binding ($\eta > 1$) for the cases of and unresolved sidebands (blue curve) and resolved sidebands (red curve), and (b) strong binding (Lamb-Dicke regime $\eta < 1$) for the same cases as in (a).

The relative size of the characteristic frequencies $\omega_{\rm rec}$, $\omega_{\rm trp}$, and Γ define characteristic regimes, as illustrated in the table.

confinement		sidebands	
weak	$\eta > 1$	unresolved	$\frac{\omega_{\rm trp}}{\Gamma} < 1$
strong	$\eta < 1$	resolved	$\frac{\omega_{\rm trp}}{\Gamma} > 1$

43.3.3.3 The Mößbauer effect

The role of photonic recoil in the scattering of light by confined atoms has been unraveled by *Mößbauer*, who performed scattering experiments of γ-photons on a ^{57}Fe crystal on a narrow transition of this isotope at 14 keV (0.086 nm). The linewidth of this transition, $\Gamma \approx (2\pi)\ 1\,\text{MHz}$, is much narrower than the recoil-shift, $\omega_{\rm rec} \approx (2\pi)\ 500\,\text{MHz} \gg \Gamma$, so that we should expect the scattered light to be considerably recoil-shifted and Doppler-broadened. In fact, the recoil-shift should be so large, that scattered photons cannot be reabsorbed by other atoms on this transition being at rest. This is *not* what Mößbauer observed in his experiments. He found that scattered photons can be reused for subsequent scattering, which means that the scattering must be elastic.

The explanation for this unexpected observation is that, if the nucleus is embedded in a crystal, the vibrational frequencies, which are even higher than the photonic recoil frequency, $\omega_{\rm trp} \approx 2\pi \cdot 3\,\text{THz}$, are unreachable. That is to say, we are in the *resolved sidebands Lamb-Dicke regime*, $\omega_{\rm trp} \gg \omega_{\rm rec} \gg \Gamma$. Here, the phonons corresponding to the vibrations cannot be excited, so that the recoil momentum must be absorbed by the whole lattice, whose entire mass is so large, that the photon frequency is not recoil-shifted by the scattering process. Hence, the first-order *Doppler effect* is avoided and the measured width of the transition is just the natural linewidth. Furthermore,

the atom remains in the same vibrational state of their localizing potential. This is the *Mößbauer effect*.

	γ for ^{57}Fe	optical for ^{172}Yb$^+$
photon energy	$\approx 14\,\text{keV} \quad \approx 4\times 10^{18}\,\text{Hz}$	$\approx 3\,\text{eV} \quad \approx 640\,\text{THz}$
recoil	$\approx 2\,\text{meV} \quad \approx 500\,\text{MHz} \quad \approx 10^{-10}$	$\approx 20\,\text{peV} \quad \approx 5\,\text{kHz} \quad \approx 10^{-11}$
linewidth	$\approx 5\,\text{neV} \quad \approx 1\,\text{MHz} \quad \approx 2\times 10^{-13}$	$\approx 5\,\text{feV} \quad \approx 1\,\text{Hz} \quad \approx 2\times 10^{-15}$
lattice vibrations	$\approx 10\,\text{meV} \quad \approx 3\,\text{THz}$	$\approx 3\,\text{neV} \quad \approx 1\,\text{MHz}$

Table 43.1: Comparison of γ-radiation and the optical regime.

A similar effect can be observed with trapped atoms driven on very narrow transitions, as we will discuss in the following.

43.3.3.4 Coupling of internal and external motion by photonic recoil, tracing over the internal excitation

When discussing the transfer of momentum to a harmonic oscillator in 24.6.2, we did not say how the momentum shift could be realized in practice. As we have seen in the example of the Mößbauer effect, a possible way is via the photonic recoil received on a light scattering process. The coupling of the relevant degrees of freedom of the system induced by the absorption of a photon by an atom is accounted for by an additional interaction term $\hat{H}_{\text{int}}$ in the Hamiltonian. The relevant degrees of freedom are the electronic orbital $|i\rangle$, the vibrational state $|n\rangle$, and the number of photons $|N\rangle$ in the light mode, assumed to be a plane wave $\vec{\mathcal{E}}(\mathbf{r},t) = E_0\hat{\mathbf{e}}_y e^{\imath k_z z - \imath\omega t}$. Neglecting the quantum nature of the light, we will disregard this degree of freedom in the following. Assuming that the trapping potential is the same for all electronic orbitals, as in (43.46), the total state can be expressed as a product state, $|n,i\rangle \equiv |i\rangle\otimes|n\rangle$. The interaction Hamiltonian,

$$\hat{H}_{\text{int}} = \frac{\hbar\Omega}{2}(e^{\imath k\hat{z}}\hat{a}|e\rangle\langle g| + e^{-\imath k\hat{z}}\hat{a}^\dagger|g\rangle\langle e|) - |e\rangle\hbar\omega\langle e| \ , \tag{43.47}$$

couples the dynamics on the internal transition, given by the Rabi frequency $\hbar\Omega \equiv \langle e|d_y|g\rangle\mathcal{E}_0$, with the absorption (or stimulated emission) of a photon $\hat{a}$, and the transfer of a recoil momentum. The last term comes from the transformation into the interaction picture [9]. With this our total Hamiltonian (43.46) becomes,

$$\boxed{\hat{H} = \hbar\omega_{\text{trp}}(\hat{b}^\dagger\hat{b} + \tfrac{1}{2}) + |e\rangle\hbar(\omega_0-\omega)\langle e| + \tfrac{\hbar\Omega}{2}(e^{\imath k\hat{z}}|e\rangle\langle g| + e^{-\imath k\hat{z}}|g\rangle\langle e|)} \ . \tag{43.48}$$

So, vibrational states are only coupled via electronic transitions,

$$\langle n,g|\hat{H}_{\text{int}}|0,g\rangle = 0 \qquad \text{and} \qquad \langle n,e|\hat{H}_{\text{int}}|0,g\rangle = \tfrac{1}{2}\hbar\Omega\langle n,e|e^{\imath k\hat{z}}|0,g\rangle \ . \tag{43.49}$$

[9] Note, that this Hamiltonian cannot be used to describe spontaneous emission. To do so, we need to allow for 3D systems and decay modes,

$$\hat{H} = \hbar\omega_{\text{trp}}(|\mathbf{n}\rangle\langle\mathbf{n}| + \tfrac{1}{2}) + \hbar(\omega_0-\omega)|e\rangle\langle e| + \tfrac{\hbar\Omega}{2}(e^{-\imath\mathbf{k}_i\cdot\hat{\mathbf{r}}}\hat{\sigma}^\dagger\hat{a}_{\mathbf{k}_i} + c.c.) + \hbar g\sum_{\mathbf{k}_f}(e^{\imath\mathbf{k}_f\cdot\hat{\mathbf{r}}}\hat{\sigma}\hat{a}^\dagger_{\mathbf{k}_f} + c.c.) \ .$$

Hence, we have to span the complete Hilbert space of all operators like $\hat{\sigma}^\dagger = \sum_n |n\rangle\langle n| \otimes |e\rangle\langle g|$.

We can expand the system's state into,

$$|\psi(t)\rangle = \sum_{n=0}^{\infty} (c_{n,g}|n,g\rangle + c_{n,e}|n,e\rangle \ , \tag{43.50}$$

and insert it together with the Hamiltonian (43.48) into the Schrödinger equation. Projecting onto the states $\langle n,g|$ and $\langle n,e|$, we easily derive the following equations of motion,

$$\boxed{\begin{aligned} \frac{dc_{n,g}}{dt} &= -\imath\omega_{\rm trp}(n+\tfrac{1}{2})c_{n,g} - \frac{\imath\Omega}{2}\sum_{m=0}^{\infty} c_{m,e}\langle n|e^{-\imath k\hat{z}}|m\rangle \\ \frac{dc_{n,e}}{dt} &= -\imath\omega_{\rm trp}(n+\tfrac{1}{2})c_{n,e} - \imath(\omega_0-\omega)c_{n,e} - \frac{\imath\Omega}{2}\sum_{m=0}^{\infty} c_{m,g}\langle n|e^{\imath k\hat{z}}|m\rangle \end{aligned}} \ . \tag{43.51}$$

The fact that only terms proportional to $\langle n|e^{ik\hat{z}}|m\rangle$ contribute can be understood in terms of the *Franck-Condon overlap* between the vibrational states to be coupled. And the fact that the energy of the harmonic oscillator, and thus the effective detuning $\Delta_n \equiv \omega - \omega_0 - \omega_{\rm trp}(n+\frac{1}{2})$, depend on the vibrational state couples the internal and the external dynamics.

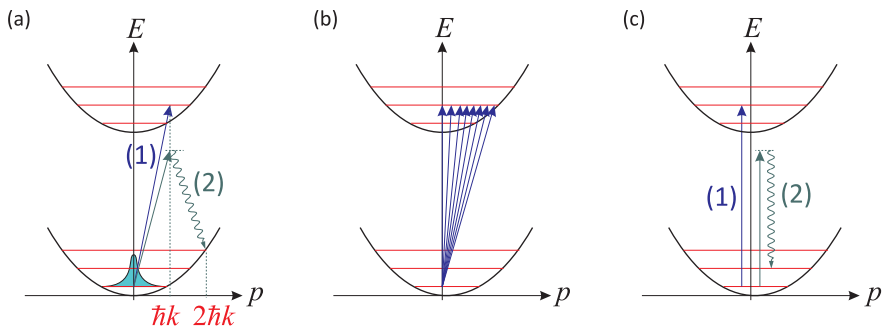

Figure 43.8: (a) Absorption (1) and Rayleigh scattering (2) in a weakly confining trap, where the momentum must stay conserved. (b) Illustration of the regime $\omega_{\rm rec} > \Gamma$, where the atom moves during the absorption process. (c) Absorption and Rayleigh scattering in a strongly confining trap.

Nevertheless, the off-diagonal coupling elements only contain the degrees of freedom of the harmonic oscillator.

43.3.3.5 Momentum kick by photonic recoil

We said earlier that a momentum kick can drive an atom from the vibrational ground state $|0\rangle$ into a coherent superposition of states $|\alpha\rangle$, except when the Lamb-Dicke parameter is very small. When the kick is realized via photonic recoil, e.g. when an

electronically excited atom decays to the ground state, the frequency of the emitted photon depends on the final vibrational state of the atom. That is we expect a coherent superposition of light frequencies, which in the limit $\eta > 1$ generates a *Doppler broadening* and in the limit $\eta < 1$ stays unshifted as for *elastic scattering*.

Let us now consider a single confined atom and address the question of the absorption probability. In first-order perturbation, using the Hamiltonian (43.48), the transition rate for absorption of a photon incident in z-direction is given by Fermi's Golden Rule,

$$\begin{aligned}\frac{1}{\tau} &= \frac{d}{dt}|\langle n,e|e^{\imath\hat{H}t/\hbar}|0,g\rangle|^2 \simeq \frac{2\pi}{\hbar^2}|\langle n,e|\hat{H}|0,g\rangle|^2 \\ &= \frac{2\pi}{\hbar^2}|\langle n,e|\tfrac{\hbar\Omega}{2}(e^{\imath k\hat{z}}\hat{\sigma}^\dagger + e^{-\imath k\hat{z}}\hat{\sigma})|0,g\rangle|^2 = \frac{\pi\Omega^2}{2}|\langle n,e|e^{\imath k\hat{z}}|0,e\rangle|^2 \ .\end{aligned} \tag{43.52}$$

Obviously, it is thus sufficient to calculate $\langle n|e^{ik\hat{z}}|0\rangle$, i.e. we can trace over the internal degrees of freedom. Using our previous results (24.152), we find with $\alpha = -ika_{\rm trp}/\sqrt{2}$,

$$\boxed{\frac{1}{\tau} = \frac{\pi\Omega^2}{2}|\langle n|\alpha\rangle|^2 = \frac{\pi\Omega^2}{2}e^{-|\alpha|^2}\frac{|\alpha^n|^2}{n!}} \ . \tag{43.53}$$

The interpretation of this result is that the absorption of a photon by an atom in state $|0,g\rangle$ transfers recoil by *leaving the vibrational state of the atom in a coherent superposition state*. Inversely, for the emission process from state $|0,e\rangle$ within the Lamb-Dicke regime, most of the time we will encounter the emitted photon at the resonance frequency ω_0, and rarely at $\omega_0 - \omega_{\rm trp}$. In any case, energy conservation is satisfied, since,

$$\begin{aligned}&\sum_n n\hbar\omega_{\rm trp}\langle n|\alpha\rangle\langle\alpha|n\rangle = \sum_n n\hbar\omega_{\rm trp}e^{-|\alpha|^2}\frac{|\alpha|^{2n}}{n!} \quad = \hbar\omega_{\rm trp}|\alpha|^2\sum_n ne^{-|\alpha|^2}\frac{|\alpha|^{2n-2}}{(n-1)!} \\ &= \frac{\hbar^2k^2}{2m}\langle\alpha|\alpha\rangle = \hbar\omega_{\rm rec} \ .\end{aligned} \tag{43.54}$$

Thus energy and momentum conservation are automatically satisfied by the way the kick is implemented.

43.3.3.6 A single anisotropically trapped atom in first-order perturbation

Let us now consider a single atom (e.g. a trapped ion) confined in an 3-dimensional anisotropic trap (e.g. strong confinement in one and weak confinement in the other direction) and address the question, whether the scattering will be anisotropic, as well. We generalize the problem to three dimensions by allowing for quantized vibrational states in three dimensions, $\hat{\sigma}^\dagger = \sum_{\mathbf{n}}|\mathbf{n}\rangle\langle\mathbf{n}| \otimes |e\rangle\langle g|$ with $|\mathbf{n}\rangle = |n_x, n_y, n_z\rangle$.

In first-order perturbation, using the Hamiltonian (43.48), the transition rate for absorption or emission is given by Fermi's Golden Rule,

$$\begin{aligned}\frac{1}{\tau} &= \frac{d}{dt}|\langle \mathbf{n},e|e^{\imath\hat{H}t/\hbar}|\mathbf{0},g\rangle|^2 \simeq \frac{2\pi}{\hbar^2}|\langle \mathbf{n},e|\tfrac{\hbar\Omega}{2}(e^{\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\hat{\sigma}^\dagger + e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}\hat{\sigma})|\mathbf{0},g\rangle|^2 \\ &= \frac{\pi\Omega^2}{2}|\langle n_x,e|e^{\imath k\hat{x}}|0,e\rangle\langle n_y,e|e^{\imath k\hat{y}}|0,e\rangle\langle n_z,e|e^{\imath k\hat{z}}|0,e\rangle|^2 \ .\end{aligned} \tag{43.55}$$

Obviously, it is thus sufficient to calculate $\langle n_j|e^{\imath k\hat{z}}|0\rangle$, i.e. we can trace over the internal degrees of freedom. Using our previous results (24.152), we find with $\alpha_j = -\imath k_j a_{\text{trp,j}}/\sqrt{2}$,

$$\boxed{\frac{1}{\tau} = \frac{\pi\Omega^2}{2}|\langle n_x|\alpha_x\rangle\langle n_y|\alpha_y\rangle\langle n_z|\alpha_z\rangle|^2 = \frac{\pi\Omega^2}{2}e^{-|\alpha_x|^2-|\alpha_y|^2-|\alpha_z|^2}\frac{|\alpha_x^{n_x}\alpha_y^{n_y}\alpha_z^{n_z}|^2}{n_x!n_y!n_z!}}\,.$$

In Exc. 43.3.4.1 we calculate and illustrate the transition matrix elements $\langle\mathbf{0}|e^{\imath k\hat{z}}|0\rangle$ and $\langle\mathbf{n}|e^{\imath k\hat{z}}|0\rangle$.

43.3.3.7 A single anisotropically trapped atom in second-order perturbation

To understand Rayleigh scattering, we need to go to second perturbation order summing over all intermediate vibrational states according to the Kramers-Heisenberg formula,

$$\begin{aligned}
\frac{d\sigma}{d\Omega} &= \frac{d}{dt}|\langle\mathbf{n},g,\mathbf{k}_f|e^{\imath\hat{H}t/\hbar}|\mathbf{0},g,\mathbf{k}_i\rangle|^2 \simeq \frac{2\pi}{\hbar^2}|\langle\mathbf{n},g,\mathbf{k}_f|\sum_{\mathbf{m}}\frac{\hat{H}^{(1)}|\mathbf{m},e\rangle\langle\mathbf{m},e|\hat{H}^{(1)}}{\omega_i-\omega_m}|\mathbf{0},g,\mathbf{k}_i\rangle|^2\\
&= \frac{\pi\hbar^2\Omega^4}{8}\left|\sum_{\mathbf{m}}\frac{\langle\mathbf{n},\mathbf{k}_f|e^{-\imath\mathbf{q}\cdot\hat{\mathbf{r}}}|\mathbf{m}\rangle\langle\mathbf{m}|e^{\imath\mathbf{q}\cdot\hat{\mathbf{r}}}|\mathbf{0},\mathbf{k}_i\rangle}{E_i/\hbar+(0\omega_x+0\omega_y+0\omega_z+\frac{3}{2})-E_m/\hbar-(m_x\omega_x+m_y\omega_y+m_z\omega_z+\frac{3}{2})}\right|^2\\
&= \frac{\pi\hbar^2\Omega^4}{8}\left|\sum_{m_x,m_y,m_z}\frac{\langle n_x,n_y,n_z|e^{-i\mathbf{k}_f\cdot\hat{\mathbf{r}}}|m_x,m_y,m_z\rangle\langle m_x,m_y,m_z|e^{\imath\mathbf{k}_i\cdot\hat{\mathbf{r}}}|0,0,0\rangle}{(E_i-E_m)/\hbar-m_x\omega_x-m_y\omega_y-m_z\omega_z}\right|^2\\
&= \frac{\pi\hbar^2\Omega^4}{8}\left|\sum_{m_x,m_y,m_z}\prod_{j=x,y,z}\frac{\langle n_j|e^{-ik_{jf}r_j}|m_j\rangle\langle m_j|e^{ik_{ji}\mathbf{r}_j}|0\rangle}{(E_i-E_m)/\hbar-m_x\omega_{mx}-m_y\omega_{my}-m_z\omega_{mz}}\right|^2.
\end{aligned}\tag{43.56}$$

The transition matrix elements can be calculated via (24.157). This expression represents (in the same time) the *dynamic structure factor* of the single trapped atom.

Example 297 (*Axial incidence*): Let us consider the particular case of Rayleigh scattering from the ground state of light incident in the direction $\mathbf{k}_i \equiv k_{iz}\hat{\mathbf{e}}_z$. We can then simplify,

$$\begin{aligned}
\frac{d\sigma}{d\Omega} &= \frac{\pi\hbar^2\Omega^4}{8}\left|\sum_{m_z}\frac{\langle 0|e^{-\imath k_{xf}\hat{x}}|0\rangle\langle 0|e^{-\imath k_{yf}\hat{y}}|0\rangle\langle 0|e^{-\imath k_{zf}\hat{z}}|m_z\rangle\langle m_z|e^{\imath k_{zi}\hat{z}}|0\rangle}{-m_z\omega_{\text{trp}}}\right|^2\\
&= \frac{\pi\hbar^2\Omega^4}{8}e^{-|\alpha_{fx}|^2-|\alpha_{fy}|^2-|\alpha_{fz}|^2-|\alpha_{iz}|^2}\left|\sum_{m_z}\frac{1}{(E_m-E_i)/\hbar-m_z\omega_{\text{trp,z}}}\frac{\alpha_{fz}^{m_z}\alpha_{iz}^{m_z}}{m_z!}\right|^2\\
&= \frac{\pi\hbar^2\Omega^4}{8}e^{-(\mathbf{k}_f\cdot\mathbf{a}_{\text{trp}})^2/2-(\mathbf{k}_i\cdot\mathbf{a}_{\text{trp}})^2/2}\left|\sum_{m_z}\frac{1}{(E_m-E_i)/\hbar-m_z\omega_{\text{trp,z}}}\frac{(-\frac{1}{2}k_{fz}k_{iz}a_{\text{trp,z}}^2)^{m_z}}{m_z!}\right|^2,
\end{aligned}$$

where $\mathbf{a}_{\text{trp}} \equiv (a_{\text{trp,x}}\ a_{\text{trp,y}}\ a_{\text{trp,z}})$. Looking into scattering into transverse direction, $\mathbf{k}_{f,z} = 0$, we get,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\perp} = \frac{\pi\hbar^4\Omega^4}{8|E_m - E_i|^2} e^{-\mathbf{k}_{fx}^2 a_{\text{trp,x}}^2/2 - \mathbf{k}_{fy}^2 a_{\text{trp,y}}^2/2 - \mathbf{k}_{iz}^2 a_{\text{trp,z}}^2/2} .$$

Looking into backscattering, $\mathbf{k}_{f,z} = -\mathbf{k}_{i,z}$,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\parallel} = \frac{\pi\hbar^2\Omega^4}{8} e^{-\mathbf{k}_i a_{\text{trp,z}})^2} \left| \sum_{m_z} \frac{1}{(E_m - E_i)/\hbar - m_z\omega_{\text{trp,z}}} \frac{(-\frac{1}{2}k_{iz}^2 a_{\text{trp,z}}^2)^{m_z}}{m_z!} \right|^2 .$$

we expect a spectrum with vibrational resonances.

43.3.4 Exercises

43.3.4.1 Ex: Transition elements in anisotropic harmonic traps

a. Calculate and illustrate $\langle \mathbf{0}|e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}|\mathbf{0}\rangle$ for an anisotropic trap with cylindrical symmetry.
b. Calculate $\langle \mathbf{n}|e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}|\mathbf{0}\rangle$ and $\sum_{n_x,n_y,n_z} \langle \mathbf{n}|e^{-\imath\mathbf{k}\cdot\hat{\mathbf{r}}}|\mathbf{0}\rangle$.

43.3.4.2 Ex: Periodicity of a lattice

Calculate $e^{\imath a\hat{p}} e^{2\imath k\hat{z}} e^{-\imath a\hat{p}}$.

43.3.4.3 Ex: Energy commutators

Calculate the commutator between the kinetic and the potential energy for (a) a harmonic oscillator and (b) a standing wave dipolar potential.

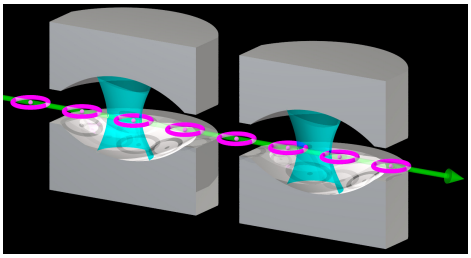
Part IX

Collective Scattering of Light and Correlations

Preface to the part *Collective Scattering of Light and Correlations*



In Chp. 39 we discussed the interaction of light with individual atoms. In the practice of spectroscopy, however, we often work with ensembles of scatterers. Depending on their *spatial distribution* (e.g. disordered, quasi-continuous, periodic), their *motion* (hot gas or cold cloud), the possible existence of *correlations* between them, the presence of *boundary conditions* (e.g., free space, cavities, or photon bands), and finally, in case of degenerate quantum gases, of a possible *bosonic stimulation* of the scattering process, we expect new collective effects.

In chapter 45 we will discuss several examples, in particular, localization effects induced by disorder, super- and subradiance, Bragg scattering, and the formation of forbidden photonic bands in periodic lattices. Chp. 45 is devoted to the impact of optical cavities on scattering. In Chp. 46 we discuss effects resulting from correlations between many atoms. In Chp. 47 we turn our attention to quantum information. Finally, phenomena leading to self-organization, such as the collective atomic recoil laser, will be discussed in Chp. 48.

Chapter 44

Cooperativity in light scattering

This chapter starts with introducing as the main theoretical tools the *structure factor* and the *coupled dipoles model*. In Sec. 44.1 we will derive the formalism and learn, how to employ it to calculate, e.g. the spatial distribution of light scattered by an atomic cloud and the radiation pressure force on the atoms focusing on situations, where interatomic interactions induced by the incident light can be neglected. In Sec. 44.3 we will, disregarding the atomic's cloud graininess and disorder, introduce the *smooth density approximation* and compare it to macroscopic Mie scattering. In Sec. 44.4 we will focus on cooperative effects inducing collective lineshifts and broadenings, such as the Lorentz-Lorenz and the Lamb shift. We will also discuss disorder-induced localization effects, super- and subradiance. In Sec. 44.3 we investigate Bragg scattering, i.e. scattering from periodically ordered atoms, and finally in Sec. 45.1 we study scattering from correlated atoms.

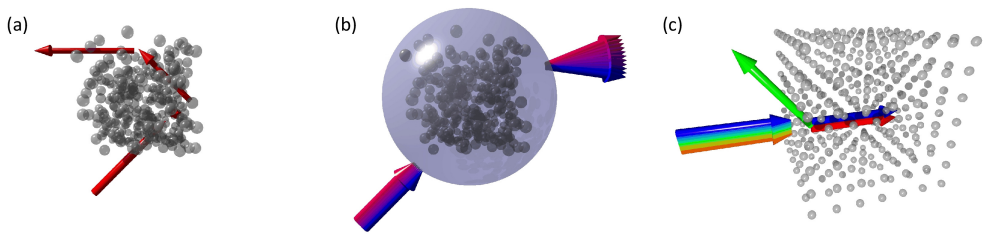


Figure 44.1: (a) Artist's view of multiple scattering of a photon through a dilute cloud. (b) Atomic cloud as a bulk object characterized by a refraction index $n(\mathbf{r})$. (c) Illustration of a photonic band in an optical lattice.

44.1 Theoretical tools and models

As mentioned above, the process of light scattering by an atomic cloud depends on several factors, many of which can be summarized by a quantity called the *structure factor*. This structure factor, obtained in perturbation theory, describes the probability for the light to be scattered into a particular direction as a function of the

properties of the atomic cloud (spatial distribution, motion, etc.). The quantity is well suited for dealing with stationary situations.

On the other hand we have at our disposal a microscopic theory called the *coupled dipole model*. In this model we treat every individual atom as a dipole, which interacts with all other atoms by rescattering the incident light. The resolution of the Schrödinger equation allows, several approximations having been made, to calculate the dynamics of the system.

44.1.1 The structure factor and definition of cooperativity

One way of characterizing the scattering process is by structure factor. The *static structure factor* is the normalized response of a system to a perturbation with the wave vector $\mathbf{q}$. It can be understood as the final density of states for the atom after the scattering process. In contrast, the *dynamic structure factor* also considers the final density of states for the emitted or scattered photon. That is, on one hand, the frequency and momentum of the photon must satisfy the Bragg condition. On the other hand, the density of available states can also be structured, for example, when the scattering process takes place inside a cavity.

In lowest-order perturbation theory (Fermi's Golden Rule) we get the general expressions [511],

$$\boxed{\frac{d\sigma}{d\Omega_{\mathrm{s}}d\omega} = \left(\frac{d\sigma}{d\Omega_{\mathrm{s}}}\right)_1 S(\mathbf{q},\omega)}\,, \tag{44.1}$$

that is, the effective scattering cross section is reduced to the effective Rayleigh scattering cross section by an isolated atom times a geometric term called *dynamic structure factor*,

$$\boxed{S(\mathbf{q},\omega) \equiv \tfrac{1}{2\pi}\int dt e^{\imath\omega t}\langle\hat{\rho}(\mathbf{q},t)\hat{\rho}^\dagger(\mathbf{q},0)\rangle}\,, \tag{44.2}$$

where,

$$\hat{\rho}(\mathbf{q},t) = \int_V \hat{n}(\mathbf{r},t)e^{\imath\mathbf{q}\cdot\mathbf{r}}d^3r \tag{44.3}$$

is Fourier transform of the atomic density. Thus, $S(\mathbf{q},\omega)$ is the Fourier transform of the density-density correlation function. On the other hand, $\int e^{\imath\omega t}d\omega = 2\pi\delta(t)$, and we calculate the *static structure factor*,

$$\boxed{S(\mathbf{q}) \equiv \int S(\mathbf{q},\omega)d\omega = \langle\hat{\rho}(\mathbf{q},0)\hat{\rho}^\dagger(\mathbf{q},0)\rangle}\,. \tag{44.4}$$

In the equations (44.2) and (44.3) we have written the quantities $\hat{\rho}(\mathbf{q},t)$ and $\hat{n}(\mathbf{r},t)$ as operators, in order to allow for the possibility, that the atomic ensemble is a quantum gas, i.e. a Bose-Einstein condensate characterized by a single wavefunction $\hat{\psi}(\mathbf{r},t)$ normalized to the density distribution, $\hat{\rho}(\mathbf{r},t) = \hat{\psi}^\dagger(\mathbf{r},t)\hat{\psi}(\mathbf{r},t)$. We shall return to this subject in Sec. 52.1.1. In the following, we will restrict ourselves to atoms localized in space with well-defined velocities and calculate the structure factor (i) for disordered clouds of atoms excited by the passage of a photon in Sec. 44.1.6 and (ii) for Bragg scattering by optical lattices in Sec. 44.5. In these cases, we find in the

literature often another definition of the structure factor as the expectation value of the Fourier transform of the atomic density,

$$\mathcal{S}(\mathbf{q}) = \langle \hat{\rho}(\mathbf{q}) \rangle \ , \tag{44.5}$$

Thus, it describes the amplitude of the electric field of the scattered radiation. In order to avoid confusion we will call this quantity *structure coefficient* and denote it by a calligraphic $\mathcal{S}$. We study the structure factor for various atomic density distributions in Excs. 44.1.8.1 to 44.1.8.3.

Example 298 (*Structure factor of a discrete cloud*): In case of discrete clouds, $n(\mathbf{r},t) = \sum_j \delta^{(3)}(\mathbf{r}-\mathbf{r}_j)$, we can disregard the quantum nature of the operators. The relationship (44.3) immediately gives,

$$\rho(\mathbf{q},t) = \sum_j e^{\imath \mathbf{q}\cdot\mathbf{r}_j(t)} \tag{44.6}$$

and the relationship (44.2),

$$S(\mathbf{q},\omega) = \frac{1}{2\pi}\int dt e^{\imath\omega t}\rho(\mathbf{q},t)\rho^*(\mathbf{q},0) = \frac{1}{2\pi}\int dt e^{\imath\omega t}\sum_{j,k} e^{\imath\mathbf{q}\cdot[\mathbf{r}_j(t)-\mathbf{r}_k(0)]} \ . \tag{44.7}$$

Assuming atoms fixed in space, $\mathbf{r}_j(t) = \mathbf{r}_j$,

$$S(\mathbf{q},\omega) = \sum_{j,k} e^{\imath\mathbf{q}\cdot(\mathbf{r}_j-\mathbf{r}_k)}\delta(\omega) \ . \tag{44.8}$$

That is, without recoil the light must be scattered elastically.

The notion of *cooperativity* is fundamental for any problem involving scattering of radiation and, depending on the specific area of physics, is called by many different names, such as Purcell factor, cavity-to-free-space scattering ratio, or phase matching condition. Here, we will regard cooperativity as any ***deviation of the structure factor from isotropy***. For example, Bragg scattering and optical cavities are highly cooperative, because they favor scattering in particular directions [1].

44.1.2 The scalar coupled dipoles model

In the following, we develop the coupled dipoles model, within which we define the structure factor for light scattering by a cloud of scatterers making the following assumptions:

- The light is (mostly) treated as a scalar field. That is, we disregard effects due to the polarization of light and assume two-level atoms. Generalizations are shown in Sec. 44.6.4 [855, 625].
- Atoms are supposed to be fixed in space. That is, we disregard the Doppler shift of moving atoms and the photonic recoil. Therefore, it will suffice to consider the static structure factor.

[1] Note that cooperativity does not request the atoms to interact and exists in the single scattering regime. In the multiple scattering regime other forms of collective phenomena, such as collective Lamb shifts emerge, as we will see later on.

- Atoms are initially uncorrelated and not degenerate. That means that we neglect effects such as bosonic stimulation or Fermi blocking [2].

Be ω_0 the frequency of the incident light, $\omega_{\rm a}$ the frequency of the atomic resonance, and ω the frequency of the scattered light. The Hamiltonian is nothing more than the generalization of (40.106) to several assumed atoms located at the positions r_j,

$$\boxed{\begin{aligned}\hat{H} &= \sum_{j=1}^{N}\hbar g_{\mathbf{k}_0}(\hat{\sigma}_j e^{-\imath\omega_{\rm a}t}+\hat{\sigma}_j^\dagger e^{\imath\omega_{\rm a}t})(\hat{a}_{\mathbf{k}_0}^\dagger e^{\imath\omega_0 t-\imath\mathbf{k}_0\cdot\mathbf{r}_j}+\hat{a}_{\mathbf{k}_0}e^{-\imath\omega_0 t+\imath\mathbf{k}_0\cdot\mathbf{r}_j})\\ &+ \sum_{\mathbf{k}}\sum_{j=1}^{N}\hbar g_{\mathbf{k}}(\hat{\sigma}_j e^{-\imath\omega_{\rm a}t}+\hat{\sigma}_j^\dagger e^{\imath\omega_{\rm a}t})(\hat{a}_{\mathbf{k}}^\dagger e^{\imath\omega_k t-\imath\mathbf{k}\cdot\mathbf{r}_j}+\hat{a}_{\mathbf{k}}e^{-\imath\omega_k t+\imath\mathbf{k}\cdot\mathbf{r}_j})\end{aligned}} \quad . \tag{44.9}$$

Here, $\Omega_0 = 2g_{k_0}\sqrt{n_0}$ is the Rabi frequency of the interaction between an atom and the incident light (which is treated as a classical field with n_0 photons), $\hat{\sigma}_j$ is the deexcitation operator for the j-th atom, $\hat{a}_{\mathbf{k}}$ is the photon annihilation operator, and $g_k = d\sqrt{\omega/(\hbar\varepsilon_0 V_{\rm ph})}$ describes the coupling between the atom and the vacuum modes the volume of which is $V_{\rm ph}$. The j-th atom has its lower and upper states denoted by $|g_j\rangle$ and $|e_j\rangle$, respectively. That is, we treat the atoms as simple two-level systems. We also assume that all atoms are excited by the same unperturbed incident laser beam, thus neglecting their dephasing along the laser path or induced by near-field effects (which could arise for large spatial densities).

Within the *rotating wave approximation* RWA the Hamiltonian simplifies to,

$$\begin{aligned}\hat{H} &= \hbar\sum_{j=1}^{N}[g_{k_0}\hat{\sigma}_j\hat{a}_{\mathbf{k}_0}^\dagger e^{\imath(\omega_0-\omega_{\rm a})t-\imath\mathbf{k}_0\cdot\mathbf{r}_j}+h.c.]\\ &+\hbar\sum_{j=1}^{N}\sum_{\mathbf{k}}[g_k\hat{\sigma}_j\hat{a}_{\mathbf{k}}^\dagger e^{\imath(\omega_k-\omega_{\rm a})t-\imath\mathbf{k}\cdot\mathbf{r}_j}+h.c.]\ .\end{aligned} \tag{44.10}$$

The RWA only considers energy-conserving terms in single-photon processes. But this is an artifact from the field quantization. Energy conservation can be warranted by considering multi-photon virtual processes, which as a whole, conserve energy. These terms appear in the full Hamiltonian, but are neglected in the RWA. While the RWA often is a good assumption in single atom quantum optics, this is frequently not the case for collective scattering. Here, we adopt the RWA to a simplify the subsequent solution of the Schrödinger equation, but we will need to generalize the results obtained a posteriori, as shown in the discussion of Sec. 44.1.4.

We call $|0\rangle_{\rm a} = |g_1,..,g_N\rangle$ the atomic ground state, $|j\rangle_{\rm a} = |g_1,..,e_j,..,g_N\rangle$ the state where only the atom j is excited, and we assume that the system is in a the

[2] Spontaneous emission by an atom in a Fermi gas of temperature $T = 0$ can not occur if the photon wave vector is inside the Fermi lake, $q < k_F$.

superposition of states described by [3],

$$|\Psi(t)\rangle = \alpha(t)|0\rangle_{\rm a}|n_0\rangle_{\mathbf{k}_0}|0\rangle_{\mathbf{k}} + \sum_{j=1}^{N}\beta_j(t)|j\rangle_{\rm a}|n_0-1\rangle_{\mathbf{k}_0}|0\rangle_{\mathbf{k}} + \sum_{\mathbf{k}}\gamma_{\mathbf{k}}(t)|0\rangle_{\rm a}|n_0-1\rangle_{\mathbf{k}_0}|1\rangle_{\mathbf{k}} \ . \tag{44.11}$$

With this ansatz we imply that at every instant of time, there can be at most only one excitation in the atomic cloud. The temporal evolution of the amplitudes is obtained by inserting the Hamiltonian and the ansatz into the Schrödinger equation, $\imath\hbar\partial_t|\Psi(t)\rangle = \hat{H}|\Psi(t)\rangle$. Once the evolution of the amplitudes is calculated, we can determine the observables of the system, such as the radiative pressure force or the amplitudes of the scattered radiation fields or the fields inside the cloud.

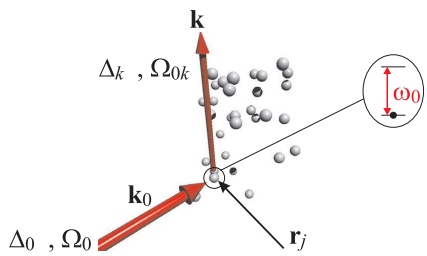

Figure 44.2: Scheme of the interaction of a light beam with a sample of atoms.

Example 299 (*Interaction Hamiltonian in the rotating frame*): The Hamiltonian in the rotating wave approximation is,

$$\hat{H} = \hbar g\left(\hat{\sigma}e^{-\imath\omega_{\rm a}t} + \hat{\sigma}^\dagger e^{\imath\omega_{\rm a}t}\right)\left(\hat{a}^\dagger e^{\imath\omega_0 t} + \hat{a}e^{-\imath\omega_0 t}\right) \simeq \hbar g\left(\hat{\sigma}\hat{a}^\dagger e^{\imath\Delta_0 t} + \hat{\sigma}^\dagger\hat{a}e^{-\imath\Delta_0 t}\right) \ .$$

For the Pauli matrices we have the following rules,

$$[\hat{\sigma}_z,\hat{\sigma}] = -\hat{\sigma} \qquad \text{and} \qquad [\hat{\sigma}_z,\hat{\sigma}^\dagger] = \hat{\sigma}^\dagger \ ,$$

such that,

$$\begin{aligned}
[\hat{\sigma}_z,\hat{H}] &= \hbar g\left(-e^{\imath\Delta_0 t}\hat{a}^\dagger\hat{\sigma} + e^{-\imath\Delta_0 t}\hat{a}\hat{\sigma}^\dagger\right)\\
[\hat{\sigma}_z,[\hat{\sigma}_z,\hat{H}]] &= \hbar g\left(e^{\imath\Delta_0 t}\hat{a}^\dagger\hat{\sigma} + e^{-\imath\Delta_0 t}\hat{a}\hat{\sigma}^\dagger\right) = \hat{H}\\
[\hat{\sigma}_z,[...[\hat{\sigma}_z,\hat{H}]]...] &= \hbar g\left[(-1)^n e^{\imath\Delta_0 t}\hat{a}^\dagger\hat{\sigma} + e^{-\imath\Delta_0 t}\hat{a}\hat{\sigma}^\dagger\right] \ .
\end{aligned}$$

[3] This ansatz is well adapted to situations where the RWA holds. Otherwise, additional counter-rotating terms must be included [320].

Using the Baker-Haussdorff formula,

$$
\begin{aligned}
e^{\imath\omega_0 t\hat{\sigma}_z}\hat{H}e^{-\imath\omega_0 t\hat{\sigma}_z} &= \hat{H} + [\imath\omega_0 t\hat{\sigma}_z, \hat{H}] + \tfrac{1}{2!}[\imath\omega_0 t\hat{\sigma}_z, [\imath\omega_0 t\hat{\sigma}_z, \hat{H}]] + ... \\
&= \hbar g \sum_{n=0}^{\infty} \tfrac{(\imath\omega_0 t)^n}{n!} \left[(-1)^n e^{\imath\Delta_0 t}\hat{a}^\dagger\hat{\sigma} + e^{-\imath\Delta_0 t}\hat{a}\hat{\sigma}^\dagger\right] \\
&= \hbar g e^{\imath\Delta_0 t}\hat{a}^\dagger\hat{\sigma}\sum_{n=0}^{\infty}\tfrac{(-\imath\omega_0 t)^n}{n!} + \hbar g e^{-\imath\Delta_0 t}\hat{a}\hat{\sigma}^\dagger\sum_{n=0}^{\infty}\tfrac{(\imath\omega_0 t)^n}{n!} \\
&= \hbar g\left(e^{-\imath\omega_{\mathrm{a}} t}\hat{a}^\dagger\hat{\sigma} + e^{\imath\omega_{\mathrm{a}} t}\hat{a}\hat{\sigma}^\dagger\right) \ .
\end{aligned}
$$

44.1.2.1 Temporal evolution of the amplitudes

The time evolution of the amplitudes is obtained by inserting the Hamiltonian $\hat{H}$ and the ansatz $|\Psi(t)\rangle$ into the Schrödinger equation,

$$
\frac{\partial}{\partial t}|\Psi(t)\rangle = -\frac{\imath}{\hbar}\hat{H}|\Psi(t)\rangle \ . \tag{44.12}
$$

one obtains with $\Omega_0 = 2g_{k_0}\sqrt{n_0}$,

$$
\begin{aligned}
\dot{\alpha}(t) &= -\imath\tfrac{\Omega_0}{2}e^{\imath\Delta_0 t}\sum_{j=1}^{N}\beta_j(t)e^{-\imath\mathbf{k}_0\cdot\mathbf{r}_j} \\
\dot{\beta}_j(t) &= -\imath\tfrac{\Omega_0}{2}\alpha(t)e^{-\imath\Delta_0 t+\imath\mathbf{k}_0\cdot\mathbf{r}_j} - \sum_{\mathbf{k}}\imath g_k\gamma_{\mathbf{k}}(t)e^{-\imath\Delta_k t+\imath\mathbf{k}\cdot\mathbf{r}_j} \\
\dot{\gamma}_{\mathbf{k}}(t) &= -\imath g_k e^{\imath\Delta_k t}\sum_{j=1}^{N}\beta_j(t)e^{-\imath\mathbf{k}\cdot\mathbf{r}_j} \ .
\end{aligned} \tag{44.13}
$$

We set the initial conditions,

$$
\alpha(0) = 1 \quad , \quad \beta_j(t) = 0 \quad , \quad \gamma_{\mathbf{k}}(t) = 0 \ . \tag{44.14}
$$

For low excitation rate, we can set $\alpha(t) \simeq 1$. Integrating the third equation,

$$
\gamma_{\mathbf{k}}(t) = -\imath g_k\sum_{j=1}^{N}e^{-\imath\mathbf{k}\cdot\mathbf{r}_j}\int_0^t e^{\imath\Delta_k t'}\beta_j(t')dt' \ , \tag{44.15}
$$

and substituting it into the second equation,

$$
\dot{\beta}_j(t) = -\imath\tfrac{\Omega_0}{2}\alpha(t)e^{-\imath\Delta_0 t+\imath\mathbf{k}_0\cdot\mathbf{r}_j} - \sum_{\mathbf{k}}g_k^2\sum_{m=1}^{N}e^{\imath\mathbf{k}\cdot(\mathbf{r}_j-\mathbf{r}_m)}\int_0^t e^{\imath\Delta_k(t'-t)}\beta_m(t')dt' \ . \tag{44.16}
$$

44.1.3 The Markov approximation

For small systems, $R < \lambda$, we can make use of the Markov approximation, which holds when the collective decay time $t_{decay} < R/c$. Larger systems persist memory effects, which may lead to (Rabi) *collective Rabi oscillations*. In the Markov approximation given by $\beta_j(t') \simeq \beta_j(t)$ the integro-differential equation (which is equivalent to a differential equation of arbitrarily high order) reduces to a simple first order differential equation. Defining [4],

$$\beta_j \equiv \tilde{\beta}_j e^{-\imath\Delta_0 t + \imath \mathbf{k}_0\cdot\mathbf{r}_j} \ , \tag{44.17}$$

we obtain,

$$\frac{d}{dt}\alpha(t) = -\imath\frac{\Omega_0}{2}\sum_{j=1}^{N}\tilde{\beta}_j(t) \tag{44.18}$$

$$\begin{aligned}\frac{d}{dt}\tilde{\beta}_j(t) &= \imath\Delta_0\tilde{\beta}_j(t) - \frac{\Omega_0^2}{4}\sum_{m=1}^{N}\int_0^t \tilde{\beta}_m(t')dt' \\ &\quad - \sum_{\mathbf{k}} g_k^2 \sum_{m=1}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot(\mathbf{r}_j-\mathbf{r}_m)}\int_0^t e^{-\imath(\omega_k-\omega_0)t''}\tilde{\beta}_m(t-t'')dt'' \ ,\end{aligned}$$

where we substituted $t'' \equiv t - t'$ in the last integral. Now, using the Markov approximation $\tilde{\beta}_m(t-t'') \simeq \tilde{\beta}_m(t)$, with $\lim_{t\to\infty}\int_0^t e^{-\imath(\omega_k-\omega_0)t'}dt' = \pi\delta(\omega_k-\omega_0)$, and with the rate of spontaneous emission,

$$\boxed{\Gamma \equiv \frac{V_{\rm ph}}{\pi c}k_0^2 g_{k_0}^2} \ , \tag{44.19}$$

the third term becomes for the case $m = j$,

$$\begin{aligned}\sum_{\mathbf{k}} g_k^2\int_0^t e^{-\imath(\omega_k-\omega_0)t''}\tilde{\beta}_j(t-t'')dt'' &\simeq \sum_{\mathbf{k}} g_k^2\tilde{\beta}_j(t)\pi\delta(\omega_k-\omega_0) \\ &= \frac{V_{\rm ph}}{(2\pi)^3}\tilde{\beta}_j(t)\int g_k^2\pi\delta(\omega_k-\omega_0)d^3k = \frac{V_{\rm ph}}{(2\pi)^3}\tilde{\beta}_j(t)4\pi g_{k_0}^2\pi k_0^2\frac{1}{c} = \frac{\Gamma}{2}\tilde{\beta}_j(t) \ .\end{aligned} \tag{44.20}$$

The third term becomes for the case $m \neq j$, evaluating the sum over the wavevectors by $\sum_{\mathbf{k}} \to \frac{V_{\rm ph}}{(2\pi)^3}\int d^3k$,

$$\begin{aligned}&\sum_{\mathbf{k}} g_k^2\sum_{m\neq j}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot(\mathbf{r}_j-\mathbf{r}_m)}\int_0^t e^{-\imath(\omega_k-\omega_0)t''}\tilde{\beta}_m(t-t'')dt'' \\ &\simeq \sum_{\mathbf{k}} g_k^2\sum_{m\neq j}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot(\mathbf{r}_j-\mathbf{r}_m)}\tilde{\beta}_m(t)\pi\delta(\omega_k-\omega_0) \\ &= \frac{V_{\rm ph}}{(2\pi)^3}\sum_{m\neq j}^{N}\tilde{\beta}_m(t)\int g_k^2 e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot(\mathbf{r}_j-\mathbf{r}_m)}\pi\delta(\omega_k-\omega_0)d^3k = \frac{\Gamma}{2}\sum_{m\neq j}^{N}\gamma_{jm}\tilde{\beta}_m(t) \ ,\end{aligned} \tag{44.21}$$

[4] Later on we will be particularly interested in so-called *timed Dicke states* characterized by $\tilde{\beta}_j = \tilde{\beta}$ independent on j.

with

$$\gamma_{jm} \equiv \frac{2}{\Gamma}\frac{V_{\rm ph}}{(2\pi)^3}\int_0^\infty\int_0^\pi\int_0^{2\pi} g_k^2 e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot(\mathbf{r}_j-\mathbf{r}_m)}\frac{\pi}{c}\delta(k-k_0)k^2\sin\theta dk d\theta d\phi \ . \tag{44.22}$$

Finally,

$$\frac{d}{dt}\tilde{\beta}_j(t) = \imath\Delta_0\tilde{\beta}_j(t) - \frac{\Omega_0^2}{4}\sum_{m=1}^N\int_0^t\tilde{\beta}_m(t')dt' - \frac{\Gamma}{2}\sum_{m=1}^N\gamma_{jm}\tilde{\beta}_m(t) \ , \tag{44.23}$$

or

$$\frac{d}{dt}\alpha(t) = -\imath\frac{\Omega_0}{2}\sum_{j=1}^N\tilde{\beta}_j(t) \tag{44.24}$$

$$\frac{d}{dt}\tilde{\beta}_j(t) = \imath\Delta_0\tilde{\beta}_j(t) - \imath\frac{\Omega_0}{2}\alpha(t) - \frac{\Gamma}{2}\sum_{m=1}^N\gamma_{jm}\tilde{\beta}_m(t) \ .$$

This means that the problem is reduced to finding the γ_{jm}. Continuing the evaluation of Eq. (44.22),

$$\begin{aligned}\gamma_{jm} &= \frac{1}{\Gamma}g_k^2\frac{V_{\rm ph}}{4\pi^2 c}e^{-\imath\mathbf{k}_0\cdot(\mathbf{r}_j-\mathbf{r}_m)}\int_0^\infty\int_0^{2\pi}\int_{-1}^1 e^{\imath k|\mathbf{r}_j-\mathbf{r}_m|\cos\theta}d\cos\theta d\phi\delta(k-k_0)k^2dk \\ &= \frac{1}{\Gamma}g_k^2\frac{V_{\rm ph}}{\pi c}e^{-\imath\mathbf{k}_0\cdot(\mathbf{r}_j-\mathbf{r}_m)}\int_0^\infty\frac{\sin k|\mathbf{r}_j-\mathbf{r}_m|}{k|\mathbf{r}_j-\mathbf{r}_m|}\delta(k-k_0)k^2dk \\ &= e^{-\imath\mathbf{k}_0\cdot(\mathbf{r}_j-\mathbf{r}_m)}\frac{\sin k_0|\mathbf{r}_j-\mathbf{r}_m|}{k_0|\mathbf{r}_j-\mathbf{r}_m|} \ .\end{aligned} \tag{44.25}$$

Isolating the self-decaying term and assuming low saturation, $\alpha(t) = 1$, we get,

$$\boxed{\dot{\tilde{\beta}}_j = \left(\imath\Delta_0 - \frac{\Gamma}{2}\right)\tilde{\beta}_j - \frac{\imath\Omega_0}{2} - \frac{\Gamma}{2}\sum_{m\neq j}\gamma_{jm}\tilde{\beta}_m} \ . \tag{44.26}$$

In Exc. 44.1.8.4 we will analyze the validity of the Markov approximation for typical cold atoms experiments.

44.1.4 General solution with exponential kernel, validity of the RWA

The RWA is valid for $\max(\Omega, \Gamma_n) \ll \omega$,
