$$\int_0^t dt\cdot e^{-\imath(\omega_k-\omega_0)t} \simeq \mathcal{P}\left(\frac{1}{\omega_k+\omega_0}\right) - \imath\mathcal{P}\left(\frac{1}{\omega_k-\omega_0}\right) + \pi\delta(\omega_k-\omega_0) \ . \tag{44.27}$$

The whole expression leads to the exponential kernel, the first two terms are the cosine part, the third term is the sine part. The rotating wave approximation consists in neglecting the first term, i.e. it only concerns the cosine part of the kernel.

Within the RWA we got [5,6],

$$\gamma_{jm} = e^{-\imath \mathbf{k}_0 \cdot (\mathbf{r}_j - \mathbf{r}_m)} \frac{\imath \sin(k_0 |\mathbf{r}_j - \mathbf{r}_m|)}{\imath k_0 |\mathbf{r}_j - \mathbf{r}_m|} \ . \tag{44.28}$$

Without the RWA we would have found [836, 831, 832, 900],

$$\gamma_{jm} = e^{-\imath \mathbf{k}_0 \cdot (\mathbf{r}_j - \mathbf{r}_m)} \frac{e^{\imath k_0 |\mathbf{r}_j - \mathbf{r}_m|}}{\imath k_0 |\mathbf{r}_j - \mathbf{r}_m|} \ . \tag{44.29}$$

An alternative derivation from a Green function approach to the master equation is presented in Sec. 46.3.2 (see Eq. (46.111)).

There has been a controversy between Friedberg and Scully about the role of virtual photons (or *collective Lamb-shift*) [327, 899, 328, 833]. These terms result from counterrotating terms in the rotating wave approximation. Scully assumes timed Dicke states in *infinitely large* clouds and finds the contributions weak. Friedberg does a mode expansion of the cloud and finds that different modes decay at different velocities. This yields time-dependent radiation patterns, which can be temporarily larger in backward direction.

Normally, the RWA is a good approximation, when $\Omega \ll \omega$. Deviations from this approximations lead e.g. to the Bloch-Siegert shift and important corrections for very far-detuned (quasi-electrostatic) optical trapping. The above requirement is not well satisfied for our experiment, since $\Omega_N = \sqrt{N}\Omega \simeq 1..10\,\mathrm{THz}$.

Be $|b_1 b_2 ... a_j ... b_N\rangle$ the state with all atoms in the ground state except atom j being in the excited state. Hence, the cloud's state is simply expressed by the wavefunction,

$$\Psi_{atom}(t) = \sum_{j=1}^{N} \beta_j(t) |b_1 b_2 ... a_j ... b_N\rangle \ . \tag{44.30}$$

For large σ the radiation pressure is independent on the choice of the kernel. In fact we may even set the kernel to 0. For small σ there appears a considerable deviation. Interestingly, the imaginary part of the kernel gets important for higher densities, even when the optical density is maintained, e.g. by compressing the cloud in z-direction. This means that the collective Lamb shift becomes more apparent is small compressed clouds. But we postpone a more thorough discussion to Sec. 44.4.

The analytic expansion into eigenmodes assumes the RWA. Hence, the numerics deviate from the analytics for small σ and large N. Is it possible to generalize the expansion to the exponential kernel (see [900])? The authors also suggest that the scattered radiation be frequency-shifted due to the imaginary part of the kernel. This might be an interesting observable for experiments.

44.1.4.1 Low collective saturation

Note that for low *saturation*, $\alpha(t) = 1$, the first term simply becomes $-\frac{\imath}{2}\Omega_0$. Even though the single atom excitation rate may be small in case of large detuning, the

[5] Note that dipole-dipole interactions are mediated by the exchange of virtual photons. Hence, they are included in the Hamiltonian when the RWA is NOT applied.

[6] Note that Maxwell's equations contain non-RWA terms.

collective Rabi frequency $\sqrt{N}\Omega$ can be large. The presence of many excitations in the cloud means, that higher Dicke states are populated. Then we may expect a complicated many-body dynamics, if decay into other states than the timed Dicke state is possible.

Even though the single atom excitation rate may be small in case of large detuning, the *collective* Rabi frequency $\sqrt{N}\Omega$ can be large. The presence of many excitations in the cloud means, that higher Dicke states are populated. Then we may expect a complicated many-body dynamics, if decay into other states than the timed Dicke state is possible.

The model we use (ground state + first excited state in the times Dicke basis) does not allow more than 1 photon for N atoms. For such a model, neglecting saturation means 'much' less than 1 atom in the excited state, i.e. the probability of having the any atom in the excited state is less than 1. But having N atoms, this means that each atoms should have a excited state population of much less than $1/N$. Including the saturation in the naive way, means that when this term $N\Omega_0^2$ is not negligible, than we will have less atoms in the first excited state of the timed Dicke basis, than if when we would neglect saturation. This is precisely why we call this saturation, we cannot take more atoms away from the ground state, because the system cannot absorb more than one photon. But when this term is not longer negligible, then in a cloud of N atoms, this does not prevent us from taking atoms away from the ground state (we have N atoms which each can take one photon). Either the term is negligible (and we could drop it) or we will try to keep its contribution (even at first order in $N\Omega_0^2$), but then we cannot neglect the possibility of having 2 atoms excited.

44.1.4.2 Steady-state solution

In steady-state the equations of the coupled dipoles model can be solved numerically for an arbitrary (ordered or disordered) cloud of immobile atoms located at positions $\mathbf{r}_j$ illuminated by an electric field.

Assuming scalar light and the validity of the Markov approximation, and furthermore defining $\bar{\beta}_j \equiv \tilde{\beta}_j e^{\imath \mathbf{k}_0 \cdot \mathbf{r}_j}$ and $\bar{\Omega}_0(\mathbf{r}_j) \equiv \Omega_0(\mathbf{r}_j) e^{\imath \mathbf{k}_0 \cdot \mathbf{r}_j}$, and using the exponential kernel,

$$\bar{\gamma}_{jm} = \frac{e^{\imath k_0 |\mathbf{r}_j - \mathbf{r}_m|}}{\imath k_0 |\mathbf{r}_j - \mathbf{r}_m|} \ , \tag{44.31}$$

the Eq. (44.26) for the atomic states reads,

$$\frac{d}{dt}\bar{\beta}_j = \left(\imath\Delta_0 - \frac{\Gamma}{2}\right)\bar{\beta}_j - \frac{\imath\bar{\Omega}_0(\mathbf{r}_j)}{2} - \frac{\Gamma}{2}\sum_{m\neq j}\bar{\gamma}_{jm}\bar{\beta}_m \ . \tag{44.32}$$

Defining the matrix,

$$M_{jm} \equiv (\imath\Delta_0 - \tfrac{\Gamma}{2})\delta_{jm} - \tfrac{\Gamma}{2}(1-\delta_{jm})\bar{\gamma}_{jm} = \begin{pmatrix} \imath\Delta_0 - \frac{\Gamma}{2} & \imath\gamma_{12}\frac{\Gamma}{2} & \cdots \\ \imath\gamma_{21}\frac{\Gamma}{2} & \imath\Delta_0 - \frac{\Gamma}{2} & \\ \vdots & & \ddots \end{pmatrix} \ , \tag{44.33}$$

we can rewrite Eq. (44.34) as,

$$\boxed{\frac{d}{dt}\bar{\beta}_j = \sum_m M_{jm}\bar{\beta}_m - \frac{\imath}{2}\bar{\Omega}_0(\mathbf{r}_j)} \ . \tag{44.34}$$

The steady-state solution of is simply obtained by $\dot{\bar{\beta}}_j = 0$ [198, 148],

$$M_{jm}\bar{\beta}_m(\infty) = \tfrac{\imath}{2}\bar{\Omega}_0(\mathbf{r}_j) \ . \tag{44.35}$$

This equation can now be solved by the dipole moment amplitudes,

$$\boxed{\bar{\beta}_m(\infty) = (M_{jm})^{-1} \ \tfrac{\imath}{2}\bar{\Omega}_0(\mathbf{r}_j)} \ , \tag{44.36}$$

where we use the exponential kernel,

$$\gamma_{jm} = \frac{e^{\imath k_0(|\mathbf{r}_j - \mathbf{r}_m| + \delta_{jm})}}{\imath k_0(|\mathbf{r}_j - \mathbf{r}_m| + \delta_{jm})} \ , \tag{44.37}$$

where the trick with the δ_{jm}-symbol helps to remove divergences for equal atom positions.

In this form the solution is immediately suitable for numerical implementation of the coupled dipoles model, although in practice the number of atoms is limited to $N < 10000$ for ordinary PCs.

44.1.4.3 Limit of dilute clouds

Dilute clouds are characterized by a large interatomic distance $k_0|\mathbf{r}_j - \mathbf{r}_m| \gg 1$. In this case, the non-diagonal elements of the kernel (44.33) quickly vanish, and the equations of motion (44.34) decouple to,

$$\frac{d}{dt}\bar{\beta}_j = \left(\imath\Delta_0 - \frac{\Gamma}{2}\right)\bar{\beta}_j - \frac{\imath}{2}\bar{\Omega}_0(\mathbf{r}_j) \ . \tag{44.38}$$

44.1.4.4 Characterization of the atomic cloud in steady-state

Plot the spacial dependence of the phases of the atomic dipoles, $\phi(\mathbf{r}_j) = \mathfrak{Im}\,(\ln\tilde{\beta}_j)$.

44.1.4.5 Time-dependence

In order to calculate the time-dependence, we reconsider the equation (44.34) for the excitation amplitudes. Its solution is formally given by the sum of the general solution of the homogeneous equation and a particular (e.g. the asymptotic) solution of the inhomogeneous equation,

$$\bar{\beta}_j(t) = e^{M_{jm}t}\bar{\beta}_m(0) + (\mathbb{I} - e^{M_{jm}t})\bar{\beta}_m(\infty) \ . \tag{44.39}$$

Inserting the steady-state solution we finally get,

$$\boxed{\bar{\beta}_j(t) = e^{M_{jm}t}\bar{\beta}_m(0) + (\mathbb{I} - e^{M_{jn}t})M^{-1}_{mn} \ \tfrac{\imath}{2}\bar{\Omega}_0(\mathbf{r}_m)} \ . \tag{44.40}$$

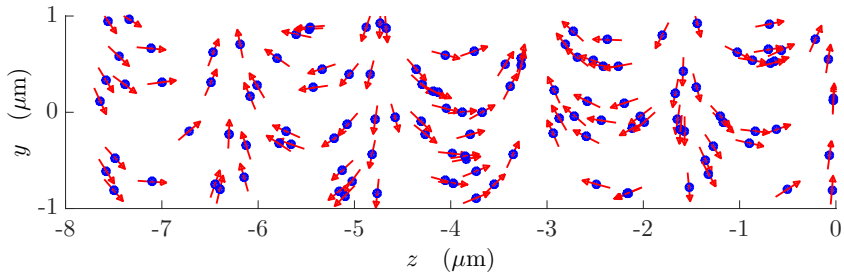

Figure 44.3: Phase delay in the excitation of the atomic dipoles (a) without rescattering ($\gamma_{jm} = 0$) and (b) with rescattering.

44.1.5 Calculation of light scattering in steady-state

To calculate the distribution of scattered light, we start from the Heisenberg equation for the field operator [320],

$$\frac{d\hat{a}_{\mathbf{k}}}{dt} = \frac{1}{\imath\hbar}[\hat{a}_{\mathbf{k}}, \hat{H}] = -\imath g_{\mathbf{k}} e^{\imath(\omega_{\mathbf{k}}-\omega_{\mathrm{a}})t} \sum_{j=1}^{N} \hat{\sigma}_j e^{-\imath\mathbf{k}\cdot\mathbf{r}_j} \ . \tag{44.41}$$

where the fast oscillating term proportional to $e^{\imath(\omega_{\mathbf{k}}+\omega_{\mathrm{a}})t}$ has been neglected. Now,

$$\hat{\mathcal{E}}_{\mathrm{sct}}(\mathbf{r}, t) = \sum_{\mathbf{k}} \mathcal{E}_k \hat{a}_{\mathbf{k}}(t) e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega_k t)} \ , \tag{44.42}$$

where $\mathcal{E}_k = \sqrt{\hbar\omega_k/2\varepsilon_0 V_{\mathrm{ph}}}$. Integrating Eq. (44.41) with $\hat{a}_{\mathbf{k}}(0) = 0$, inserting it in Eq. (44.42), and approximating the sum over the modes $\mathbf{k}$ by an integral, we obtain,

$$\hat{\mathcal{E}}_{\mathrm{sct}}(\mathbf{r}, t) = -\imath \frac{V_{\mathrm{ph}}}{8\pi^3} \sum_{j=1}^{N} \int_0^t dt' \hat{\sigma}_j(t-t') e^{\imath\omega_{\mathrm{a}} t} \int d^3k \ \mathcal{E}_k g_k e^{\imath\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}_j)-\imath ckt'} \ . \tag{44.43}$$

Introducing spherical coordinates, $d^3k = dkk^2 d\phi d\theta \sin\theta$, and integrating the angular part Eq. (44.43) becomes,

$$\begin{aligned} \hat{\mathcal{E}}_{\mathrm{sct}}(\mathbf{r}, t) = -\imath \frac{V_{\mathrm{ph}}}{4\pi^2} \sum_{j=1}^{N} \frac{1}{|\mathbf{r}-\mathbf{r}_j|} \int_0^t dt' \hat{\sigma}_j(t-t') e^{\imath\omega_{\mathrm{a}} t'} \times \\ \times \int dkk\mathcal{E}_k g_k [e^{-\imath ck(t'-|\mathbf{r}'-\mathbf{r}_j|/c)} - e^{-\imath ck(t'+|\mathbf{r}'-\mathbf{r}_j|/c)}] \ . \end{aligned} \tag{44.44}$$

Assuming the radiation spectrum centered around $k \simeq k_0$, we approximate $k\mathcal{E}_k g_k \simeq k_0 \mathcal{E}_{k_0} g_{k_0}$. Then, extending the lower limit of integration of k to $-\infty$, we obtain for $t < |\mathbf{r}-\mathbf{r}_j|/c$ [746, 590],

$$\hat{\mathcal{E}}_{\mathrm{sct}}(\mathbf{r}, t) \simeq -\frac{dk_0^2}{4\pi\varepsilon_0} \sum_{j=1}^{N} \frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}_j|}}{|\mathbf{r}-\mathbf{r}_j|} \hat{\sigma}_j(t - |\mathbf{r}-\mathbf{r}_j|/c) \ . \tag{44.45}$$

where we may neglect the radiation retardation in the limit $t \gg \sigma_R/c$. Using (44.19) and expressing the coupling strength,

$$\hbar g_k = d\mathcal{E}_k \qquad \text{with} \qquad \mathcal{E}_k = \sqrt{\frac{\hbar\omega_k}{2\varepsilon_0 V_{\text{ph}}}} \ , \tag{44.46}$$

we get,

$$\hat{\mathcal{E}}_{\text{sct}}(\mathbf{r},t) \simeq -\frac{\imath\hbar\Gamma}{2d}\sum_{j=1}^{N}\gamma_{oj}(\mathbf{r})\hat{\sigma}_j(t) \ , \tag{44.47}$$

where we defined the abbreviation,

$$\gamma_{oj}(\mathbf{r}) \equiv \frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}_j|}}{\imath k_0|\mathbf{r}-\mathbf{r}_j|} \ . \tag{44.48}$$

When applied on the state of Eq. (44.11), neglecting virtual transitions, it yields $\hat{\mathcal{E}}_{\text{sct}}|\Psi\rangle = \mathcal{E}_{\text{sct}}|g_1,...,g_N\rangle$, where $\mathcal{E}_{\text{sct}}$ is the electric field radiated by the excited atoms. Once the excitation amplitudes $\beta_j(\infty)$ are known, the scattered light field and the total field can easily be calculated via [806],

$$\boxed{\mathcal{E}_{\text{sct}}(\mathbf{r}) = \langle\hat{\mathcal{E}}_{\text{sct}}(\mathbf{r})\rangle = -\frac{\imath\hbar\Gamma}{2d}\sum_{j=1}^{N}\gamma_{oj}(\mathbf{r})\beta_j(\infty) \qquad \text{and} \qquad \mathcal{E}_{tot} = \mathcal{E}_{las} + \mathcal{E}_{\text{sct}}} \ , \tag{44.49}$$

Example 300 (*Light scattering from a Gaussian beam*): Fig. 44.4 shows an example of light scattering from an incident light field parametrized as a Gaussian beam, as shown in (15.270),

$$\mathcal{E}_{las}(\mathbf{r}) = \hat{\epsilon}\mathcal{E}_0\frac{w_0}{w(z)}e^{-r^2/w(z)^2+\imath kz+z\imath kr^2/2R(z)-\imath\varphi(z)} = \hat{\epsilon}\frac{\hbar}{|\mathbf{d}|}\Omega_0(\mathbf{r})e^{\imath\mathbf{k}_0\cdot\mathbf{r}} \ . \tag{44.50}$$

Note that, for the chosen parameters, the result does not depend on the interaction terms. I.e. we can as well set the kernel to 0.

Note, that the phase factor $e^{\imath\mathbf{k}_0\cdot\mathbf{r}}$ can either be attributed to the atomic dipole moments or to the field. Here, $N = 125$ atoms are periodically arranged in a three-dimensional cubic lattice.

44.1.6 Calculation of the steady-state radiation pressure force

Let us now calculate the radiative pressure force exerted by an incident beam of light $\mathbf{k}_0$ on an atom j located at position $\mathbf{r}_j$ inside an atomic cloud, as illustrated in Fig. 44.2,

$$\frac{d\hat{\mathbf{p}}_j}{dt} = \hat{\mathbf{F}}_j = -\nabla_{\mathbf{r}_j}\hat{H} \ . \tag{44.51}$$

Inserting the Hamiltonian in the RWA (44.10),

$$\begin{aligned}\hat{\mathbf{F}}_j &= \imath\hbar\mathbf{k}_0 g_{k_0}\left[\hat{\sigma}_j\hat{a}^\dagger_{\mathbf{k}_0}e^{\imath(\omega_0-\omega_{\text{a}})t-\imath\mathbf{k}_0\cdot\mathbf{r}_j} - h.c.\right] \\ &+ \sum_{\mathbf{k}}\imath\hbar\mathbf{k}g_k\left[\hat{\sigma}_j\hat{a}^\dagger_{\mathbf{k}}e^{\imath(\omega_k-\omega_{\text{a}})t-\imath\mathbf{k}\cdot\mathbf{r}_j} - h.c.\right] \ .\end{aligned} \tag{44.52}$$

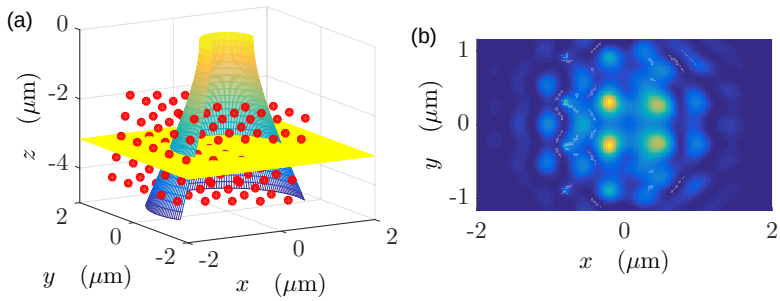

Figure 44.4: (code) (a) Geometry of light scattering from a cubic lattice with lattice constant $d = 100\,\mathrm{nm}$. The light is irradiated from below and is partially reflected. (b) Intensity distribution of scattered light along the yellow plane.

Introducing $\Delta_0 = \omega_0 - \omega_\mathrm{a}$, the expectation value of the force separates in two contribution,

$$\begin{aligned}\langle\hat{\mathbf{F}}_j\rangle \equiv \mathbf{F}_{aj} + \mathbf{F}_{ej} &= \imath\hbar\mathbf{k}_0 g_{k_0}\left[\alpha^*(t)\beta_j(t)e^{\imath\Delta_0 t - \imath\mathbf{k}_0\cdot\mathbf{r}_j} - c.c.\right] \\ &\quad + \sum_{\mathbf{k}} \imath\hbar\mathbf{k} g_k \left[\beta_j(t)\gamma^*_{\mathbf{k}}(t)e^{\imath(\omega_k-\omega_\mathrm{a})t - \imath\mathbf{k}\cdot\mathbf{r}_j} - c.c.\right] \\ &= \imath\hbar\mathbf{k}_0 g_{k_0}[\alpha^*(t)\tilde{\beta}_j(t) - c.c.] \\ &\quad + \sum_{\mathbf{k}} \imath\hbar\mathbf{k} g_k \left[\tilde{\beta}_j(t)e^{-\imath(\omega_0-\omega_k)t + \imath(\mathbf{k}_0-\mathbf{k})\cdot\mathbf{r}_j}\gamma^*_{\mathbf{k}}(t) - c.c.\right] \;,\end{aligned} \tag{44.53}$$

where we reintroduced the abbreviation (44.17). In particular, the term $m = j$ in the sum of $\mathbf{F}_{ej}$ vanishes since $\sum_{\mathbf{k}} \mathbf{k} = 0$. Substituting $\gamma_{\mathbf{k}}$ with equation (44.16),

$$\begin{aligned}\mathbf{F}_{aj} + \mathbf{F}_{ej} &= \imath\hbar\mathbf{k}_0 g_{k_0}[\alpha^*(t)\tilde{\beta}_j(t) - c.c.] \\ &\quad - \sum_{\mathbf{k}} \hbar\mathbf{k} g_k^2 \left[\tilde{\beta}_j(t)e^{-\imath(\omega_0-\omega_k)t + \imath(\mathbf{k}_0-\mathbf{k})\cdot\mathbf{r}_j}\sum_{m=1}^{N} e^{\imath\mathbf{k}\cdot\mathbf{r}_m}\int_0^t e^{-\imath(\omega_k-\omega_\mathrm{a})t'}\tilde{\beta}^*_m(t')dt' - c.c.\right] \\ &= -2\hbar\mathbf{k}_0 g_{k_0}\mathfrak{Im}\left[\alpha^*(t)\tilde{\beta}_j(t)\right] \\ &\quad - \sum_{\mathbf{k}} \hbar\mathbf{k} g_k^2 \sum_{m=1}^{N}\left[\tilde{\beta}_j(t)e^{\imath(\mathbf{k}_0-\mathbf{k})\cdot(\mathbf{r}_j-\mathbf{r}_m)}\int_0^t e^{\imath(\omega_0-\omega_k)(t'-t)}\tilde{\beta}^*_m(t')dt' - c.c.\right] \;,\end{aligned} \tag{44.54}$$

and applying the Markov approximation (44.20),

$$\begin{aligned}\mathbf{F}_{aj} + \mathbf{F}_{ej} &= -2\hbar\mathbf{k}_0 g_{k_0}\mathfrak{Im}\left[\alpha^*(t)\tilde{\beta}_j(t)\right] \\ &\quad - \sum_{\mathbf{k}} \hbar\mathbf{k} g_k^2 \sum_{m=1}^{N}\left[e^{\imath(\mathbf{k}_0-\mathbf{k})\cdot(\mathbf{r}_j-\mathbf{r}_m)}\tfrac{\pi}{c}\delta(k-k_0)\tilde{\beta}_j(t)\tilde{\beta}^*_m(t) - c.c.\right] \;.\end{aligned} \tag{44.55}$$

This is the expression for the force acting on an atom at the position $\mathbf{r}_j$. Knowing the stationary excitation amplitudes $\beta_j(\infty)$ and assuming $\alpha(\infty) \simeq 1$, the radiation pressure force can numerically be calculated. Remembering $\Omega_0 = 2g_{k_0}$ we get for the

absorption force acting on atom j,

$$\mathbf{F}_{aj} = -2\hbar\mathbf{k}_0 g_{k_0} \mathfrak{Im}\, \tilde{\beta}_j(\infty) \ . \tag{44.56}$$

To evaluate the emission force acting on atom j, for every atom m of the sum, we need to average over all possible scattering angles. To do so, we choose a reference frame in which the z-component of $\mathbf{k}$ is directed along $\hat{\mathbf{r}}_{jm} = \frac{\mathbf{r}_j - \mathbf{r}_m}{|\mathbf{r}_j - \mathbf{r}_m|}$, that is,

$$\mathbf{k} = \hat{\mathbf{e}}_{x,jm} k \sin\theta_{jm} \cos\phi_{jm} + \hat{\mathbf{e}}_{y,jm} k \sin\theta_{jm} \sin\phi_{jm} + \hat{\mathbf{r}}_{jm} k \cos\theta_{jm} \ , \tag{44.57}$$

and evaluate the sum over the wavevectors by $\sum_{\mathbf{k}} \to \frac{V_{\rm ph}}{(2\pi)^3} \int d^3k$,

$$\begin{aligned}
\mathbf{F}_{ej} &= -\sum_{m=1}^{N} \tilde{\beta}_j(\infty)\tilde{\beta}_m^*(\infty) \frac{V_{\rm ph}}{(2\pi)^3} \frac{\pi}{c} \int_{\mathbb{R}^3} d\theta_{jm} d\phi_{jm} dk\ \hbar k \begin{pmatrix} \sin\theta_{jm}\cos\phi_{jm} \\ \sin\theta_{jm}\sin\phi_{jm} \\ \cos\theta_{jm} \end{pmatrix} \times \\
&\times g_k^2 [e^{\imath(\mathbf{k}_0 - \mathbf{k})\cdot(\mathbf{r}_j - \mathbf{r}_m)} \delta(k - k_0) k^2 \sin\theta_{jm} - c.c. \\
&= -\hbar k_0 \frac{\Gamma}{8\pi} \sum_{m=1}^{N} e^{\imath\mathbf{k}_0\cdot(\mathbf{r}_j - \mathbf{r}_m)} \tilde{\beta}_j(\infty)\tilde{\beta}_m^*(\infty) \int_0^{\pi}\int_0^{2\pi} d\theta_{jm} d\phi_{jm} \begin{pmatrix} \sin\theta_{jm}\cos\phi_{jm} \\ \sin\theta_{jm}\sin\phi_{jm} \\ \cos\theta_{jm} \end{pmatrix} \times \\
&\times e^{-\imath k\cdot|\mathbf{r}_j - \mathbf{r}_m|\cos\theta_{jm}} \sin\theta_{jm} - c.c. \ .
\end{aligned} \tag{44.58}$$

remembering $\Gamma = \frac{V_{\rm ph}}{\pi c} k_0^2 g_{k_0}^2$ from Eq. (44.19). The integrals over ϕ_{jm} vanishes whereas the integral over θ_{jm} becomes, using,

$$\int_0^{\pi} d\theta \sin\theta \cos\theta e^{-\imath\alpha\cos\theta} = 2\imath \frac{\alpha\cos\alpha - \sin\alpha}{\alpha^2} = -2\imath j_1(\alpha) \ , \tag{44.59}$$

we find,

$$\begin{aligned}
\mathbf{F}_{ej} &= -\hbar k_0 \frac{\Gamma}{4} \sum_{m=1}^{N} e^{\imath\mathbf{k}_0\cdot(\mathbf{r}_j - \mathbf{r}_m)} \tilde{\beta}_j(\infty)\tilde{\beta}_m^*(\infty) \hat{\mathbf{r}}_{jm} \times \\
&\times \int_0^{\pi} \cos\theta_{jm} \sin\theta_{jm} e^{-\imath k|\mathbf{r}_j - \mathbf{r}_m|\cos\theta_{jm}} d\theta_{jm} - c.c. \\
&= \imath\hbar k_0 \frac{\Gamma}{2} \sum_{m=1}^{N} e^{\imath\mathbf{k}_0\cdot(\mathbf{r}_j - \mathbf{r}_m)} \tilde{\beta}_j(\infty)\tilde{\beta}_m^*(\infty) \hat{\mathbf{r}}_{jm} j_1(k|\mathbf{r}_j - \mathbf{r}_m|) - c.c. \\
&= -\imath\hbar k_0 \frac{\Gamma}{2} \sum_{m=1}^{N} \mathbf{f}_{jm} \tilde{\beta}_j(\infty)\tilde{\beta}_m^*(\infty) - c.c. \ ,
\end{aligned} \tag{44.60}$$

where we defined [7],

$$\mathbf{f}_{jm} = -j_1(k|\mathbf{r}_j - \mathbf{r}_m|) e^{\imath\mathbf{k}_0\cdot(\mathbf{r}_j - \mathbf{r}_m)} \hat{\mathbf{r}}_{jm} \ . \tag{44.61}$$

[7] For exploitation in MATLAB we may express the spherical Bessel function by a Bessel function of the first kind: $j_n(x) = \sqrt{\pi/2x} J_{n+1/2}(x)$.

In summary we got,

$$\boxed{\begin{aligned} \mathbf{F}_{aj} &= -\imath\hbar k_0\Omega_0\Im\mathfrak{m}\,\tilde{\beta}_j(\infty) \\ \mathbf{F}_{ej} &= -\imath\hbar k_0\Gamma\sum_{m=1}^{N}\mathbf{f}_{jm}\Im\mathfrak{m}\,[\tilde{\beta}_j(\infty)\tilde{\beta}_m^*(\infty)] \end{aligned}} \;. \tag{44.62}$$

The steady state absorption and the emission part of the radiation pressure force on the *center of mass* of the atomic cloud follow from,

$$\mathbf{F}_{\mathrm{a}} = \frac{1}{N}\sum_j\langle\hat{\mathbf{F}}_{aj}\rangle \qquad \text{and} \qquad \mathbf{F}_e = \frac{1}{N}\sum_j\langle\hat{\mathbf{F}}_{ej}\rangle \;. \tag{44.63}$$

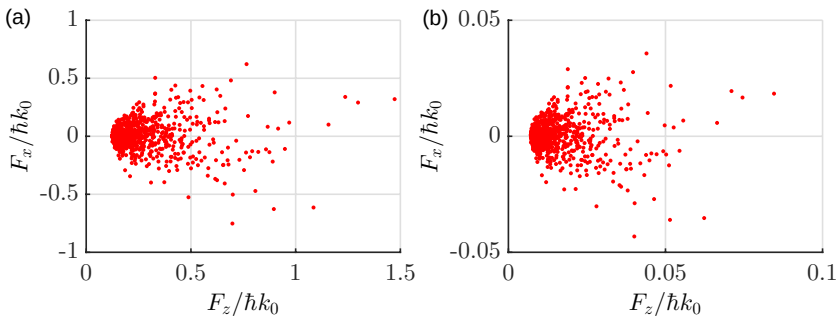

Figure 44.5: (code) Force distribution upon scattering of a photon by an atom of an spherical Gaussian cloud (a) without and (b) with rescattering according to Eqs. (44.63).

As long as the RWA and the Markov approximation are valid and only the lowest Dicke state is considered (no collective saturation), this simulation is supposed to be exact and contains all the physics including, e.g. multiple scattering. Fig. 44.5 shows a comparison of the cases when the off-diagonal components of the kernel (44.37) are present or not. Apparently, the presence of rescattering dramatically spoils the radiation pressure force, a phenomenon that we will extensively study in Secs. 44.1.7 and 44.3 [320, 45, 46, 737, 89, 47].

44.1.7 The structure coefficient of the 'timed' Dicke state

When a beam of light passes through an atomic cloud, its phase fronts will excite the atomic dipole moments as it traverses the cloud. That is, understanding the beam as a plane wave $e^{\imath(\mathbf{k}_0\cdot\mathbf{r}-\omega t)}$, the dipoles start to oscillate with relative phase delays $e^{\imath\mathbf{k}_0\cdot(\mathbf{r}_j-\mathbf{r}_m)}$ depending on their position along the optical axis $\mathbf{k}_0$. The resulting collective state has been termed *timed Dicke state* [834]. Assuming that this phase delay is the only parameter distinguishing two atoms, we may write with Eq. (44.17),

$$\tilde{\beta}_j(t) = \beta_j(t)e^{\imath(\Delta_0 t-\mathbf{k}_0\cdot\mathbf{r}_j)} \equiv \frac{1}{\sqrt{N}}\beta(t) \;, \tag{44.64}$$

where β is the macroscopic dipole moment. Note, that the fact that $\beta(t)$ does not depend on the atomic position does not imply a continuous density distribution. The atoms are still sitting at their positions $\mathbf{r}_j$; only are their dipole moments synchronized to the incident light wave.

The assumption of a timed Dicke state for the atomic cloud is, nevertheless, an approximation which is not always good [320]. For example, it neglects dispersive phase shifts of the excitation of the atomic dipole moments by the pump laser beam being delayed on its propagation due to its interaction with the atoms. If such phase shifts (and absorption as well) are radially inhomogeneous, this can lead to deformation of the pump laser beam's phase front and thus to lensing. We will discuss this in Exc. 44.1.8.5 and in Sec. 44.3.

44.1.7.1 Structure coefficient for 'timed' Dicke states

We start again with the Eqs. (44.24) inserting the ansatz of *timed Dicke* states,

$$\begin{aligned}\dot{\beta}(t) &= \frac{1}{N}\sum_{j=1}^{N}\dot{\beta}(t) = \frac{1}{\sqrt{N}}\sum_{j=1}^{N}\frac{d}{dt}\tilde{\beta}_j(t) \\ &= \frac{1}{\sqrt{N}}\sum_{j=1}^{N}\left(\imath\Delta_0\tilde{\beta}_j(t) - \imath\frac{\Omega_0}{2}\alpha(t) - \frac{\Gamma}{2}\sum_{m=1}^{N}\gamma_{jm}\tilde{\beta}_m(t)\right) \\ &= \left(\imath\Delta_0 - \frac{\Gamma}{2}Ns_N\right)\beta(t) - \imath\frac{\sqrt{N}\Omega_0}{2}\alpha(t)\ ,\end{aligned} \tag{44.65}$$

where we introduced the abbreviation,

$$s_N \equiv \frac{1}{N}\frac{1}{N}\sum_{j,m=1}^{N}\gamma_{jm}\ . \tag{44.66}$$

Taking the kernel from (44.25), we get,

$$\begin{aligned}s_N &= \frac{1}{N}\frac{2}{\Gamma}\frac{V_{\text{ph}}}{(2\pi)^3}\int_{\mathbb{R}^3} g_k^2\frac{1}{N}\sum_{j,m=1}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot(\mathbf{r}_j-\mathbf{r}_m)}\frac{\pi}{c}\delta(k-k_0)k^2\sin\theta dkd\theta d\phi \\ &= \frac{1}{N}\frac{2}{\Gamma}\frac{V_{\text{ph}}}{(2\pi)^3}\int_0^\infty\int_0^\pi\int_0^{2\pi} g_k^2 N|S_N(k,\theta,\phi)|^2\frac{\pi}{c}\delta(k-k_0)k^2\sin\theta dkd\theta d\phi \\ &= \frac{1}{4\pi}\int_0^\pi\int_0^{2\pi}|S_N(k_0,\theta,\phi)|^2\sin\theta d\theta d\phi\ ,\end{aligned} \tag{44.67}$$

introducing the normalized *structure coefficient*,

$$\boxed{\mathcal{S}_N(\mathbf{k}) \equiv \rho(\mathbf{q}) = \frac{1}{N}\sum_{j=1}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}_j}}\ , \tag{44.68}$$

where $\mathbf{q} = \mathbf{k} - \mathbf{k}_0$ and $\rho(\mathbf{q})$ is the structure coefficient defined in (44.3).

In steady state, $\dot{\beta}(t) = 0$, and disregarding saturation, $\alpha(t) \simeq 1$, the solution of (44.65) reads,

$$\boxed{\beta(\infty) = \frac{\sqrt{N}\Omega_0}{2\Delta_0 + \imath\Gamma N s_N}} \ , \tag{44.69}$$

such that,

$$\begin{aligned} |\beta(\infty)|^2 &= \frac{N\Omega_0^2}{4\Delta_0^2 + N^2\Gamma^2 s_N^2} \\ \mathfrak{Im}\left[\alpha(\infty)\beta^*(\infty)\right] &= \frac{N^{3/2}\Gamma\Omega_0 s_N}{4\Delta_0^2 + N^2\Gamma^2 s_N^2} \ . \end{aligned} \tag{44.70}$$

The time-dependent solution is easily obtained as,

$$\beta(t) = \beta(0)e^{(\imath\Delta_0 - \Gamma N s_n/2)t} + \beta(\infty) \ . \tag{44.71}$$

The evolution of the cloud very much depends on the initial conditions, e.g. $\beta_j(0) = 1$ for the uniformly excited *symmetric state* $\beta_j(0) = e^{\imath\mathbf{k}_0\cdot\mathbf{r}_j}$ for timed Dicke states.

In cylindrical coordinates the structure coefficient can be written,

$$\mathcal{S}(k,\theta,\phi) = \frac{1}{N}\sum_{j=1}^{N} e^{\imath(kx_j \sin\theta\cos\phi + ky_j \sin\theta\cos\phi + (k\cos\theta - k_0)z_j)} \ . \tag{44.72}$$

It basically tells the angular distribution of the scattered light. Fig. 44.6 shows numerical calculations and analytical approximations of the structure factor for various shapes and sizes of the atomic cloud. Obviously, the radiation pattern very much depends on the size of the spherical cloud. For $R < \lambda$ it is isotropic, for $R > \lambda$ scattering mainly occurs in forward direction. Furthermore, if the cloud is ellipsoidal the radiation pattern is shifted into forward direction.

44.1.7.2 Time evolution of radiation modes

We are interested in the power emitted into the solid angle $\Omega_\mathbf{k}$, $P(t) \propto |\gamma_\mathbf{k}(t)|^2$. For timed Dicke state (44.64) we get immediately from the equations of motion,

$$\begin{aligned} \dot{\gamma}_\mathbf{k}(t) &= -\imath g_k e^{\imath\Delta_k t}\sum_{j=1}^{N}\beta_j(t)e^{-\imath\mathbf{k}\cdot\mathbf{r}_j} \\ &= -\imath g_k e^{\imath(\Delta_k - \Delta_0)t}\frac{1}{\sqrt{N}}\beta(t)\sum_{j=1}^{N} e^{\imath(\mathbf{k}_0 - \mathbf{k})\cdot\mathbf{r}_j} = -\imath g_k e^{\imath(\Delta_k - \Delta_0)t}\sqrt{N}\mathcal{S}_N(\mathbf{k}) \ . \end{aligned} \tag{44.73}$$

We see that the time-dependence factorizes from the structure factor, which is the only component containing an angular dependence. The same holds for *symmetric Dicke states* defined by $|\beta_j| = |\beta_m|$.

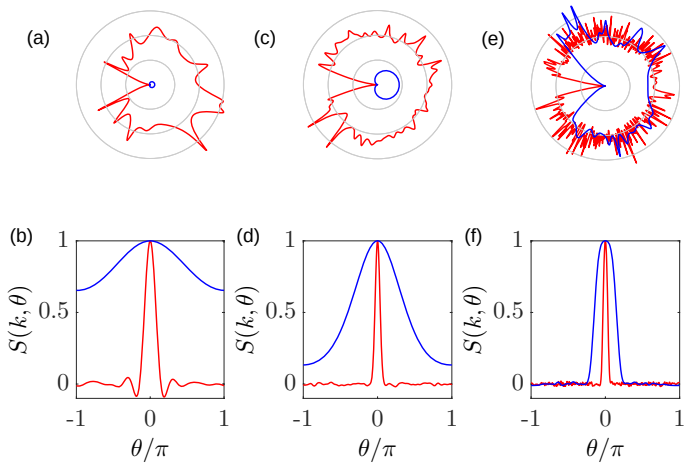

Figure 44.6: (code) Numerical calculation of $\mathcal{S}(k,\theta)$ according to (44.68) for 10^4 atomic positions r_j chosen by a random number generator. For the graphs (a-b) the cloud is *homogeneous and spherical* and has the sizes $R = \lambda$ (red) and $R = 10\lambda$ (blue). For the graphs (c-d) the cloud is *Gaussian and spherical* and has the same sizes as (a-b). For the graphs (d-e) the cloud is *homogeneous and ellipsoidal with aspect ratio* $R_z/R_\rho = 3$ and has the same radial sizes as in (a-b).

44.1.7.3 Light scattering in the 'timed Dicke state'

The scalar electric field scattered by an arbitrary distribution of atoms has been calculated in (44.49). Substituting the stationary timed Dicke state (44.69), we get,

$$\mathcal{E}_{\rm sct}(\mathbf{r}) = -\frac{\imath\hbar\Gamma}{2d}\frac{\sqrt{N}\Omega_0}{2\Delta_0 + \imath\Gamma N s_N}\sum_{j=1}^{N}\frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}_j|}}{\imath k_0|\mathbf{r}-\mathbf{r}_j|} \ . \tag{44.74}$$

Note that the 'timed Dicke' state starts from the assumption of an infinitely extended plane wave incident light field. This excludes situations where the incident beam size is smaller than the cloud's size.

44.1.7.4 Force in the 'timed Dicke state' on a particular atom in a cloud

The time-dependent expressions (44.56) for the forces in the coupled dipoles model can be further evaluated for timed Dicke states (44.64),

$$\begin{aligned}
&\mathbf{F}_{aj} + \mathbf{F}_{ej} \qquad (44.75)\\
&= -\frac{2\hbar\mathbf{k}_0 g_{k_0}}{\sqrt{N}}\Im\mathfrak{m}\,\beta(t) - \sum_{\mathbf{k}}\frac{\hbar\mathbf{k}g_k^2}{N}\sum_{m=1}^{N}\left[e^{\imath(\mathbf{k}_0-\mathbf{k})\cdot(\mathbf{r}_j-\mathbf{r}_m)}\frac{\pi}{c}\delta(k-k_0)|\beta(t)|^2 - c.c.\right]\\
&= -\frac{2\hbar\mathbf{k}_0 g_{k_0}}{\sqrt{N}}\Im\mathfrak{m}\,\beta(t) - \sum_{\mathbf{k}}\hbar\mathbf{k}g_k^2\left[\mathcal{S}_N(\mathbf{k})e^{-\imath(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}_j}\frac{\pi}{c}\delta(k-k_0)|\beta(t)|^2 - c.c.\right] \ .
\end{aligned}$$

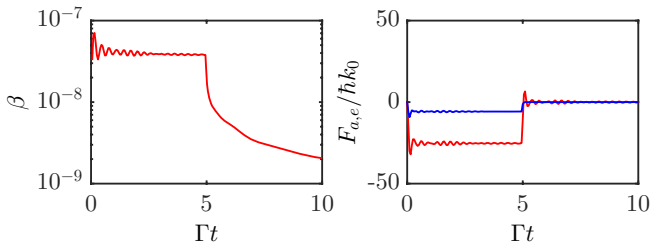

Figure 44.7: (code) Time-dependent of (a) the dipole amplitudes and (b) the forces for $\sigma = 1$, $\Delta_0 = 20\Gamma$, $\Omega_0 = 0.01\Gamma$, and $\eta = 1$.

Evaluating the sum over the wavevectors by $\sum_{\mathbf{k}} \to \frac{V_{\rm ph}}{(2\pi)^3}\int d^3k$,

$$\mathbf{F}_{aj} + \mathbf{F}_{ej} = \frac{-2\hbar\mathbf{k_0} g_{k_0}}{\sqrt{N}} \Im\mathfrak{m}\, \beta(t) \tag{44.76}$$
$$- |\beta(t)|^2 \frac{V_{\rm ph}}{(2\pi)^3} \int_0^\infty \int_0^\pi \int_0^{2\pi} \hbar\mathbf{k} g_k^2 \left[\mathcal{S}_N(k,\theta,\phi) e^{-\imath(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}_j} \frac{\pi}{c}\delta(k-k_0) - c.c.\right] k^2 \sin\theta d\theta d\phi dk \ .$$

Let us consider an atom sitting on axis, $\mathbf{r}_j = 0$, and use cylindrical coordinates, $\mathbf{k}_0 = k_0\hat{\mathbf{e}}_z$ and $\mathbf{k} = \hat{\mathbf{e}}_x k\sin\theta\cos\phi + \hat{\mathbf{e}}_y k\sin\theta\sin\phi + \hat{\mathbf{e}}_z k\cos\theta$, and using the definition (44.19) of Γ,

$$\mathbf{F}_{aj} + \mathbf{F}_{ej} = \frac{-2\hbar k_0 g_{k_0}}{\sqrt{N}} \hat{\mathbf{e}}_z \Im\mathfrak{m}\, \beta(t) \tag{44.77}$$
$$- |\beta(t)|^2 \frac{\Gamma}{8\pi}\hbar k_0 \int_0^\pi \int_0^{2\pi} (\hat{\mathbf{e}}_x \sin\theta\cos\phi + \hat{\mathbf{e}}_y \sin\theta\sin\phi + \hat{\mathbf{e}}_z \cos\theta) \left[\mathcal{S}_N(k,\theta,\phi) - c.c.\right] \sin\theta d\theta d\phi \ .$$

Using the abbreviation,

$$\tilde{f}_N \equiv \frac{1}{4\pi}\int_0^\pi \int_0^{2\pi} \Re\mathfrak{e}\, \mathcal{S}_N(k_0,\theta,\phi) \sin\theta\cos\theta d\theta d\phi \ , \tag{44.78}$$

the z-component becomes,

$$F_{zaj} + F_{zej} = -\frac{2\hbar k_0 g_{k_0}}{\sqrt{N}} \Im\mathfrak{m}\, \beta(t) - |\beta(t)|^2 \Gamma\hbar k_0 \tilde{f}_N \ . \tag{44.79}$$

In steady state and normalizing to the standard radiation pressure,

$$F_{z1j} = \Gamma\hbar k_0 \frac{\Omega_0^2}{4\Delta_0^2 + \Gamma^2} = \hbar k_0 \sigma(\Delta) \frac{I}{\hbar\omega} \ , \tag{44.80}$$

where $\sigma(\Delta_0)$ is the optical cross section and I the intensity of the incident light, we can write,

$$\frac{F_{zaj} + F_{zej}}{F_{z1j}} = \left(-\frac{2\hbar k_0 g_{k_0}}{\sqrt{N}} \Im\mathfrak{m}\, \beta(\infty) - |\beta(\infty)|^2 \Gamma\hbar k_0 \tilde{f}_N\right) \frac{4\Delta_0^2 + \Gamma^2}{\Gamma\hbar k_0 \Omega_0^2} \ . \tag{44.81}$$

Finally, inserting the the expression (44.69) for the dipole moment, we obtain for the timed Dicke state,

$$\boxed{\frac{F_{zaj} + F_{zej}}{F_{z1j}} = \frac{(2\Delta_0/\Gamma)^2 + 1}{(2\Delta_0/\Gamma)^2 + N^2 s_N^2} N(s_N - \tilde{f}_N)} \ , \tag{44.82}$$

using $\Omega_0 = 2g_{k_0}$.

The factors s_N and f_N can be calculated exactly, as will be done in Exc. 44.1.8.6,

$$s_N = \frac{1}{N^2}\sum_{j,m=1}^{N}\frac{\sin(k_0|\mathbf{r}_j-\mathbf{r}_m|)}{k_0|\mathbf{r}_j-\mathbf{r}_m|}\cos[k_0(z_j-z_m)] \tag{44.83}$$

$$f_N = \sqrt{\frac{\pi}{2}}\frac{1}{N^2}\sum_{j,m=1}^{N}\frac{J_{3/2}(k_0|\mathbf{r}_j-\mathbf{r}_m|)}{(k_0|\mathbf{r}_j-\mathbf{r}_m|)^{3/2}}k_0(z_j-z_m)\sin[k_0(z_j-z_m)] \ .$$

However, this is only practicable for atom numbers small enough for numerical simulations. For larger atom number we may use the analytic expressions including the disorder term [90].

44.1.7.5 Force on the center of mass of the cloud

The force acting on the center of mass of the atomic cloud is given by the average of the forces (44.76) sensed by particular atoms,

$$\begin{aligned}\mathbf{F}_\mathrm{a}+\mathbf{F}_e &= \frac{1}{N}\sum_{j=1}^{N}(\mathbf{F}_{aj}+\mathbf{F}_{ej}) \qquad (44.84)\\ &= -\frac{2\hbar\mathbf{k_0}g_{k_0}}{\sqrt{N}}\mathfrak{Im}\,\beta(t)\\ &\quad -|\beta(t)|^2\frac{V_\mathrm{ph}}{(2\pi)^3}\int_{\mathbb{R}^3}\hbar\mathbf{k}g_k^2\left[\mathcal{S}_N(k,\theta,\phi)\frac{1}{N}\sum_{j=1}^{N}e^{-\imath(\mathbf{k}-\mathbf{k}_0)\cdot\mathbf{r}_j}\frac{\pi}{c}\delta(k-k_0)-c.c.\right]k^2\sin\theta d\theta d\phi dk\\ &= \frac{-2\hbar\mathbf{k_0}}{\sqrt{N}}g_{k_0}\mathfrak{Im}\,\beta(t)-|\beta(t)|^2\frac{V_\mathrm{ph}}{(2\pi)^3}\int_{\mathbb{R}^3}\hbar\mathbf{k}g_k^2 2|\mathcal{S}_N(k,\theta,\phi)|^2\frac{\pi}{c}\delta(k-k_0)k^2\sin\theta d\theta d\phi dk \ .\end{aligned}$$

Using cylindrical coordinates, $\mathbf{k}_0 = k_0\hat{\mathbf{e}}_z$ and $\mathbf{k} = \hat{\mathbf{e}}_x k\sin\theta\cos\phi + \hat{\mathbf{e}}_y k\sin\theta\sin\phi + \hat{\mathbf{e}}_z k\cos\theta$, and the definition of Γ,

$$\begin{aligned}\mathbf{F}_\mathrm{a}+\mathbf{F}_e &= \frac{-2\hbar k_0}{\sqrt{N}}\hat{\mathbf{e}}_z g_{k_0}\mathfrak{Im}\,\beta(t) \qquad (44.85)\\ &\quad -|\beta(t)|^2\frac{\Gamma}{8\pi}\hbar k_0\int_0^\pi\int_0^{2\pi}(\hat{\mathbf{e}}_x\sin\theta\cos\phi+\hat{\mathbf{e}}_y\sin\theta\sin\phi+\hat{\mathbf{e}}_z\cos\theta)\,2|\mathcal{S}_N(k,\theta,\phi)|^2\sin\theta d\theta d\phi \ .\end{aligned}$$

Using the abbreviation,

$$f_N \equiv \frac{1}{4\pi}\int_0^\pi\int_0^{2\pi}|\mathcal{S}_N(k_0,\theta,\phi)|^2\sin\theta\cos\theta d\theta d\phi \ , \tag{44.86}$$

we get for the z-component an analogous formula to (44.79),

$$\begin{aligned}F_{za}+F_{ze} &= \frac{-2\hbar k_0 g_{k_0}}{\sqrt{N}}\mathfrak{Im}\,\beta(t)-|\beta(t)|^2\frac{\Gamma}{8\pi}\hbar k_0\int_0^\pi\int_0^{2\pi}2|\mathcal{S}_N(k,\theta,\phi)|^2\sin\theta\cos\theta d\theta d\phi\\ &= -\frac{2\hbar k_0 g_{k_0}}{\sqrt{N}}\mathfrak{Im}\,\beta(t)-|\beta(t)|^2\Gamma\hbar k_0 f_N \ . \qquad (44.87)\end{aligned}$$

In steady state and normalizing again to the standard radiation pressure (44.80),

$$\frac{F_{za}+F_{ze}}{F_{z1}} = \left(-\frac{2\hbar k_0 g_{k_0}}{\sqrt{N}}\mathfrak{Im}\,\beta(\infty)-|\beta(\infty)|^2\Gamma\hbar k_0 f_N\right)\frac{4\Delta_0^2+\Gamma^2}{\Gamma\hbar k_0\Omega_0^2} \ . \tag{44.88}$$

Finally, inserting the the expression (44.69) for the dipole moment, we obtain for the timed Dicke state,

$$\boxed{\frac{F_{za}+F_{ze}}{F_{z1}} = \frac{(2\Delta_0/\Gamma)^2+1}{(2\Delta_0/\Gamma)^2+N^2 s_N^2} N(s_N - f_N)} \,, \tag{44.89}$$

using $\Omega_0 = 2g_{k_0}$. Inserting the expressions (44.67) for s_N and (44.86) for f_N, we may also write,

$$\frac{F_{0a}+F_{0e}}{F_{z1}} = \frac{(2\Delta_0/\Gamma)^2+1}{(2\Delta_0/\Gamma)^2+N^2 s_N^2} N \frac{1}{4\pi} \int_0^\pi \int_0^{2\pi} |\mathcal{S}_N(k,\theta,\phi)|^2 (1-\cos\theta)\sin\theta d\theta d\phi \,. \tag{44.90}$$

Let us assume in the following that the scattering of every single photon can be treated independently [832]. In particular, the density distribution may change between two scattering events. The force is something like the first moment of the structure factor. This makes it so adapted to measure fluctuation-induced deviations from the structure coefficient [8].

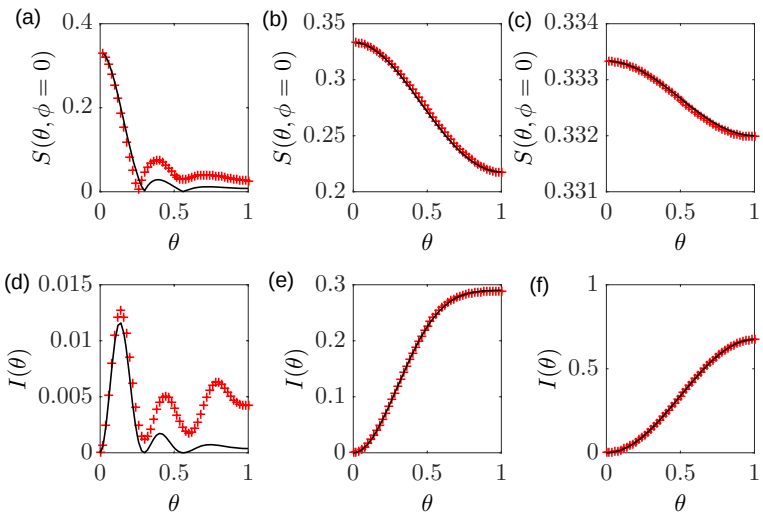

Figure 44.8: (code) (a-c) Calculation of the structure coefficient $|\mathcal{S}(k=k_0,\theta,\phi=0)|^2$ for an isotropic homogeneous density distribution. (d-f) Calculation of the force $I(\theta) = \int_0^{2\pi} |\mathcal{S}(k=k_0,\theta,\phi)|^2(1-\cos\theta)d\phi$. The red curves show numerical calculations based on (44.68), the green curves show analytical calculations according to (44.119). (a,d) $k_0R = 1$ and $N = 100$. (b,e) $k_0R = 5$ and $N = 100$. (c,f) $k_0R = 5$ and $N = 1000$.

We want to compare this force to the force acting on a cloud of N uncorrelated scatterers, i.e. atoms receiving recoil from the pump photons but reemitting isotrop-

[8] Insert a clarifying discussion of what we said in the EPDJ and what we did not: We said there is a collective effect coming from the structure factor of the cloud. We did NOT say that interatomic interactions are essential...!

ically,

$$\langle F_{\rm unc,z}\rangle = \frac{V_{\rm ph}}{(2\pi)^3}\sigma(\Delta)\frac{I}{\hbar\omega}\hbar k_0\int_0^\infty\int_0^\pi\int_0^{2\pi}|\mathcal{S}_N(k,\theta,\phi)|^2k^2\sin\theta d\theta d\phi dk\ . \tag{44.91}$$

For such a cloud the structure coefficient is $\mathcal{S}_N = N^{-1/2}$. Note that this is unlike N atoms in the Dicke limit, where $\mathcal{S}_N = 1$.

A dense homogeneous cloud with $\mathcal{S}_N(\mathbf{k}) \propto \delta^3(\mathbf{k}_0 - \mathbf{k})$ does not scatter light and experiences no force, $\langle F_{\rm hom}\rangle = 0$. This is however not true any more in the limit of small extended clouds, where fluctuations introduce disorder. This can be shown by simulating a random atomic distribution $\mathbf{r}_j$ and integrating the resulting force over all possible $\mathbf{k}$. For simplicity we assume a very sharp momentum distribution, $|\mathbf{k}| = |\mathbf{k}_0|$ or $\frac{V_{\rm ph}}{2\pi^2}\int_0^\infty k^2dk = 1$,

$$\langle F_z\rangle = \sigma(\Delta)\frac{I}{\hbar\omega}k_0(s_N - f_N)\ . \tag{44.92}$$

Finally to compare with experiment we evaluate the ratio,

$$\frac{\langle F_z\rangle}{\langle F_{\rm unc,z}\rangle} = 1 - \frac{f_N}{s_N}\ . \tag{44.93}$$

We describe the cloud as being made of two fractions: An isotropically scattering fraction of $N_0 = \sqrt{N}$ disordered atoms, whose structure factor is $\mathcal{S}_{\rm iso}(\mathbf{k}) = 1$, and a forward scattering homogeneous cloud with structure factor $\mathcal{S}_{\rm hom}(\mathbf{k}) = \delta_{\mathbf{k}_0,\mathbf{k}}$. The surface integration of the total structure factor,

$$\mathcal{S}_N(\mathbf{k}) = \frac{N_0}{N}\mathcal{S}_{\rm iso}(\mathbf{k}) + \frac{N-N_0}{N}\mathcal{S}_{\rm hom}(\mathbf{k}) = \frac{N_0}{N} + \frac{N-N_0}{N}\delta_{\mathbf{k}_0,\mathbf{k}} \simeq \frac{N_0}{N} \tag{44.94}$$

yields the same N-dependence of the force,

$$\frac{\langle F_z\rangle}{\langle F_{\rm iso,z}\rangle} = \frac{1}{4\pi N^2}\int_0^\pi\int_0^{2\pi}|\sqrt{N}|^2(1-\cos\theta)\sin\theta d\theta d\phi = \frac{1}{N}\ . \tag{44.95}$$

The interpretation is the following. In the experimentally realized situation, we are very far in the large cloud limit completely dominated by forward scattering, which means that *if the cloud were homogeneous no radiation pressure force should be expected* at all. However diffuse scattering from disordered atoms (or fluctuations) disturbs the forward scattering. It is this scattering which gives rise to radiation pressure.

There is an interesting analogy: Diffuse scattering not only inhibits forward scattering in homogeneous clouds, but also coherent backscattering from ordered structures. E.g. in optical lattices [859] it disturbs the detection of photonic band gaps. In an optical lattice the atoms are in the Dicke limit and do not absorb photonic recoil. Hence, no displacement due to radiation pressure is expected. However, diffuse scattering is observed as absorptive features in the spectra [92, 859].

The Bragg scattering is expressed by a periodic structure factor. A widely used approach to describe the impact of disordered atoms in lattices is to divide the cloud into a perfectly ordered part with density nf_{DW} and isotropically scattering part with density $n(1-f_{DW})$ [859]. The factor f_{DW} is known as Debye-Waller factor. In Exc. 44.1.8.7 we try an alternative traetment of radiation pressure based on a Monte-Carlo simulation.

44.1.7.6 Cooperative scattering and single photon superradiance

A non-isotropic structure factor scattering light into a specific direction of space (e.g. the Bragg angle) at a rate scaling like N^α with $\alpha > 1$ needs several 'cooperating' particles. In this sense cooperation only means, that the particles be arranged in space in a particular way, i.e. in a lattice or in a particular bulk shape like a homogeneous sphere or a Gaussian cigar-shaped density distribution. It also immediately becomes clear that disorder ought to play a major role. However, cooperation goes further, since cooperative scattering can be observed in spontaneous emission of an atomic cloud being excited by just a single photon. Single-photon superradiance is the topic of the following sections.

For now let us state that a non-isotropic structure factor results in collective scattering. The density distribution (which is the Fourier transform of the structure factor) can adopt two extremes: A periodic lattice results in backscattering into specific directions, a homogeneous clouds shows nothing but forward scattering. Both situations are never perfectly realized, but are subject to density fluctuations (Debye-Waller factor in a lattice, radiation pressure in a homogeneous cloud).

A single photon on its trip through an atomic cloud successively excites the atomic dipole moment thus establishing a phase relation between potential radiators [284, 901, 833, 902]. One could think that the scattering process localizes atom and photon, i.e. only one atom scatters. However, we don't know which atom scatters, and this introduces a correlation of the dipole moments along the propagation direction of the light beam.

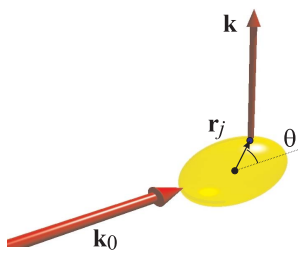

Figure 44.9: Scattering of a photon by an atom of an ellipsoidal cloud.

While normally the radiation rate of a dilute cloud is $\propto N$, in the presence of coherent interactions it scales as $\propto N^2$. Coherent interactions are not conditioned to overlapping space functions of the atoms, i.e. it is not compulsory that the density be $n^{-1/3} > \lambda$. For example, scattering from ordered structures also scales as $\propto N^2$ [497]. However, the scattering will be dramatically different if $n^{-1/3} < \lambda$.

Spontaneous emission radiation pattern from uncorrelated scatterers only depend on the relative orientation of $\hat{\sigma}$ and $\vec{\mathcal{B}}$, but not on the $\mathbf{k}$-vector of the incident light. This also holds for Dicke superradiance in the small cloud limit, but not for large clouds. Here forward scattering dominates.

We have seen in this section that, despite its simplicity, the coupled dipoles model has a large range of applications. It allows for a deeper understanding of known classical phenomena and, as we will study in Excs. 46.2.4.9 to 46.2.4.2 and in forthcoming sections, it allows to unravel new effects.

44.1.8 Exercises

44.1.8.1 Ex: Structure coefficient of a linear array

a. Based on the definition (44.1) compute the structure factor of a linear array of point-like scatterers.
b. Based on the definition (44.2) compute the structure factor of a linear array of 10 Gaussian density distributions.

44.1.8.2 Ex: Structure factor of a cloud

a. Based on the definition (44.1) compute the structure coefficient of (i) a slit, (ii) a pinhole, and (iii) a homogeneous spherical cloud.
b. Based on the definition (44.3) compute the structure coefficient of a homogeneous spherical cloud.

44.1.8.3 Ex: Structure coefficient and Snell's law

Calculate the structure coefficient for a light beam passing through a plane interface between two dielectrics.

44.1.8.4 Ex: Validity of Markov approximation

a. Calculate the single-atom scattering rate for a rubidium cloud of $N = 10^6$ atoms driven with $P = 100\,\mathrm{mW}$ laser power focused into a waist of $w_0 = 100\,\mu\mathrm{m}$ and detuned by $\Delta = (2\pi)\ 100\,\mathrm{GHz}$ from the D_2-line at $780\,\mathrm{nm}$ [148].
b. Assume for the cloud a homogeneous spherical density distribution with radius $R = 250/k_0$. Based on Ref. [901] estimate whether the Markov approximation is valid.

44.1.8.5 Ex: Lensing by a dense atomic cloud with the coupled dipoles model

Simulate the pump laser phase shift and lensing by a small dense cloud by the coupled dipoles model for red and blue detuning. Discuss the influence of rescattering by removing artificially the off-diagonal terms from the scattering kernel. Discuss whether lensing is observed within the timed Dicke approximation.

44.1.8.6 Ex: Exact calculation of projected structure coefficients

Calculated the integrals (44.66), (44.78), and (44.86).

44.1.8.7 Ex: Monte-Carlo simulation of cooperative radiation pressure

In a regime of negligible interatomic interaction single photons are scattered by individual atoms, which thereby receive the entire photonic recoil. That is, the acceleration occurs in quantized steps, which can be easily resolved in experiments [464, 857] with Bose-Einstein condensates. In the absence of collective effects, we generally observe halo-shaped momentum distributions. Because of the recoil received upon absorption, the halos are centered at $\hbar k$, and since the emission is generally isotropic,

they have a radius of $\hbar k$. On the other hand, as we have seen earlier, cooperative effects can suppression radiation pressure. In the following we try a different approach based on a Monte-Carlo simulation with a Langevin force.
This approach starts from the idea that it is possible to simulate the radiation pressure without explicit calculation of the force by treating the scattering process as a Langevin force. The simulation describes the scattering of single photons by individual atoms. Cooperativity is included 1. in the scattering rate, which is *influenced by collective effects*, 2. by weighing the probability for the direction (θ, ϕ) into which the photons are scattered with the structure factor. The enhancement of the collective scattering rate corresponds to the rate of absorption part of the radiation pressure, [9,10]

$$\gamma_c = \gamma_R \frac{F_{\mathrm{c,abs}}}{F_{\mathrm{1,abs}}} = \sigma_{\mathrm{opt}}(\Delta_0) \frac{I}{\hbar\omega} \cdot \frac{4\Delta_0^2 + \Gamma^2}{4\Delta_0^2 + N^2\Gamma^2 s_N^2} N \ ,$$

where $s_N = N^{-1} + (2\sigma)^{-2}$. The structure factor is numerically calculated for a randomly distributed cloud.

44.1.8.8 Ex: Super- and subradiance with two atoms

Super- and subradiance have been observed in two ion crystals [745, 254]. In this exercise, we study this system in the framework of the coupled dipoles model.
a. Calculate the structure coefficient of this system.
b. Write down the equations of motion (44.26) and solve them in steady-state.

44.1.8.9 Ex: Signatures of subradiance

Super- and subradiance are contained in the coupled dipoles model. Try to identify the presence of subradiant states via a reduced decay rate of $\beta(t)$ starting from the timed Dicke state.

44.1.8.10 Ex: Other applications of the coupled dipoles model

Discuss whether the coupled dipoles model can be extended to provide a microscopic description of gaseous metamaterials (negative refractive index) and the Goos-Hänchen, Imbert-Fedorov, Spin-Hall, and *Ewald-Oseen effects*, and interference with a LO. Is it possible to check Ewald-Oseen's theorem in media with negative refractive index?

[9] Note that in reality the scattering of a photon converts the scattering atom into a coherent superposition of directions into which the atom might have scattered. This is of course not described by the simulation.

[10] Although the atomic motion is frozen, it is not correct to say that the external degree of freedom is not involved in the collective dynamics, since the spatial atomic distribution shapes the structure factor.

44.2 Coupled dipoles model with real atoms

44.2.1 Limitations of the classical vectorial Green function

The vectorial Green function (ED) correctly describes the interaction between point-like classical oscillating dipoles at all inter-dipolar distances R [174]. It contains terms oscillating with kR, where k is the wavenumber of the radiation, and scaling with the distances as $1/R$, $1/R^2$, and $1/R^3$. Although the Green function ignores any internal structure of the dipoles, it has been successfully used within the coupled dipoles model (CDM) to describe the coupling between atoms interacting with each other by exchanging radiation near an atomic transition.

In reality, however, the internal atomic structure consists of electronic orbitals which react to the presence of other atoms via van der Waals forces and by forming adiabatic molecular potentials causing frequency shifts of the atomic resonances at small interatomic distances. Moreover, the molecular potentials resulting from interatomic forces develop a rich ro-vibrational structure, which contributes to the complexity of the collision process in the presence of light. The ro-vibrational spectra may even reach into the molecular decay widths. That is, there are bound states at energies below the dissociation limits smaller than Γ. At sufficiently high densities the vibrational levels of excited state potentials may add a resonance structure causing red-blue asymmetries e.g. in transmission spectra.

The calculation of molecular potentials is a difficult task [962]. At long range the molecular potentials have terms proportional to $1/R^6$, $1/R^8$, and $1/R^{10}$. However, the vibrational level structure also depends on the shape of the potential at short range. In the case of cold collisions the atoms do not penetrate deeply into the adiabatic potentials, which then may be modeled by a generic shape whose few parameters are adjusted for coincidence between the vibrational level structure and experimental data. Experimentally, the ro-vibrational structure is revealed by photoassociation spectroscopy [962]. For introductory literature on cold binary collisions in a light field see f.ex. [962, 495].

Even in the absence of radiation, colliding atoms exert forces on each other. However, if the primary focus is the transport of light through the atomic cloud, we may at first neglect the force induced by the molecular potentials and concentrate on level shifts.

At long range resonant dipole interaction scaling as R^{-3} will dominate the atomic collision dynamics in the presence of light. It mainly depends on the radiative decay width and only weakly on short range features of the molecular potentials. Thus, as a first step in understanding how the existence of atomic degrees of freedom can be incorporated into the CDM, we may concentrate on this interaction.

Here, we want to study all this for dense ^{88}Sr (and ^{172}Yb) clouds. In Sec. 44.2.2 we recapitulate the molecular level structure, and in Sec. 44.2.4 we look more closely at the vectorial Green tensor.

44.2.1.1 Delocalized atoms

If one wants to understand the interaction of light with dense clouds of atoms, the assumption of classical motionless atoms is somewhat paradox: If the atoms stand still, they have an infinite de Broglie wavelength; that is, they 'sense' the presence of all

other atoms. Even if Sr atoms are as hot as 1 μK the thermal de Broglie wavelength is about $\lambda_{therm} = 200\,\text{nm}$, which corresponds to a density of $\lambda_{therm}^{-3} = 10^{14}\,\text{cm}^{-3}$. Atomic clouds with this temperature and density approach unit phase space density.

Even if we disregard wavefunction symmetrization issues and quantum statistics, by the fact that the atoms are delocalized, their interaction with light is modulated with the Frank-Condon overlap of their wavefunctions.

44.2.2 Molecular level structure

The low-lying adiabatic potentials of Sr_2 dimers have been determined through ab initio calculations [119] and photoassociation measurements [903, 682]. We find to find reliable data on the strontium-88 ground state potential $X^1\Sigma_g^+$ connecting to the $^1S_0{+}^1S_0$ collisional channel and the excited state potentials $A^1\Pi_g$, $A^1\Pi_u$, and $A^1\Sigma_g^+$ connecting to the $^1S_0{+}^1P_1$ collisional channel.

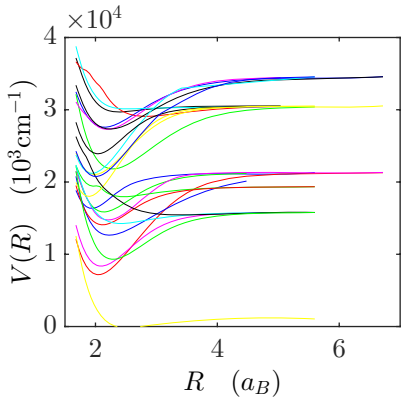

Figure 44.10: Sr_2 potentials connecting to $^1S_0{+}^1S_0$ and $^1S_0{+}^1P_1$.

Fig. 44.10 shows the excited state potential spaghetti found in [903]. The potentials which are relevant for our Sr1 experiment need to be identified. The ground state potential is given in [881, 231].

44.2.2.1 $^{88}Sr_2$ ground state potential $X^1\Sigma_g^+$

The $X^1\Sigma_g^+$ potential has been determined via two-color photoassociation spectrocopy [881],

$$V_{X^1\Sigma_g^+}(R) = \begin{cases} A + \frac{B}{R^n} & \text{for} \quad R < R_i \\ T_m + \sum_i a_i x^i & \\ -\frac{C_6}{R^6} - \frac{C_8}{R^8} - \frac{C_{10}}{R^{10}} & \text{for} \quad R > R_o \end{cases} \tag{44.96}$$

where $x \equiv (R - R_m)/(R + bR_m)$ and $v_{last} = 62, J = 0$ and $R_{rot} = 100a_B$.

44.2.2.2 $^{88}\mathrm{Sr}_2$ excited state potential $(2)^1\Sigma_u^+$

The $(2)^1\Sigma_u^+$ long-range potential at large internuclear distances,

$$V_{^1\Sigma_u^+}(R) = D - \frac{C_3}{R^3} + \frac{\hbar^2[J(J+1)+2]}{2\mu R^2} \tag{44.97}$$

with the reduced mass $\mu = m_{Sr}/2$, the transition wavelength $\lambda = 460.73\,\mathrm{nm}$, the decay width $\Gamma = (2\pi)\ 30.5\,\mathrm{MHz}$, and the resonant dipole interaction coefficient

$$C_3 \simeq \frac{3\hbar\Gamma}{2k^3} = 18.5013\,\mathrm{a.\,u.}\ , \tag{44.98}$$

which can be obtained from the Green function in the limit of small distances, $kR \ll 1$.

$X^1\Sigma_g^+$	$hc \times \mathrm{cm}^{-1}\,\mathbf{r}A^{\,n}$	a.u. [881]	a.u. [231]
C_6	1.4955×10^7	3103.5	3103
C_8	5.1175×10^8	3.7926×10^5	3.792×10^5
C_{10}	2.495×10^{10}	6.6034×10^7	4.215×10^7
$(2)^1\Sigma_u^+$			
C_3	5.9712×10^5	18.3609	
C_6	-5.1541×10^7	-10696	
C_8	8.9977×10^8	6.6682×10^5	

Table 44.1: For the transformation between SI units and a.u. see Sec. 28.1.2.

Example 301 (*Ytterbium potentials*): The $^{174}\mathrm{Yb}_2$ potentials are characterized by $\Gamma = (2\pi)\ 29.128\,\mathrm{MHz}$ and $\lambda = 399\,\mathrm{nm}$ [905, 922, 296, 518].

44.2.2.3 Vibrational levels and wavefunctions

Once the relevant potentials are known, we need to calculate their vibrational structure. To this end we probably need to fit the potentials with analytic functions, calculate the vibrational levels using the Fourier grid method [616, 279, 878], and check that the results coincides with photoassociation spetra such as the ones obtained in [682, 743, 1001, 881, 231]. An example of a Fourier grid calculation is shown in Fig. 44.11(a).

The Fourier grid calculations also deliver the vibrational radial wavefuntions. Collisional wavefunctions can be obtained by solving the radial Schrödinger equation, see red curve in Fig. 44.11.

Note, that in Fig. 44.11 the Fourier grid method yields good results for the$X^1\Sigma_g^+$ ground state potential, which is relatively shallow and short ranged, yielding 63 bound states. This is not the case for the $(2)^1\Sigma_u^+$ excited state potentials, which extends to huge range and supports hundreds of bound states. Here, an adapted Fourier grid method must be employed [529].

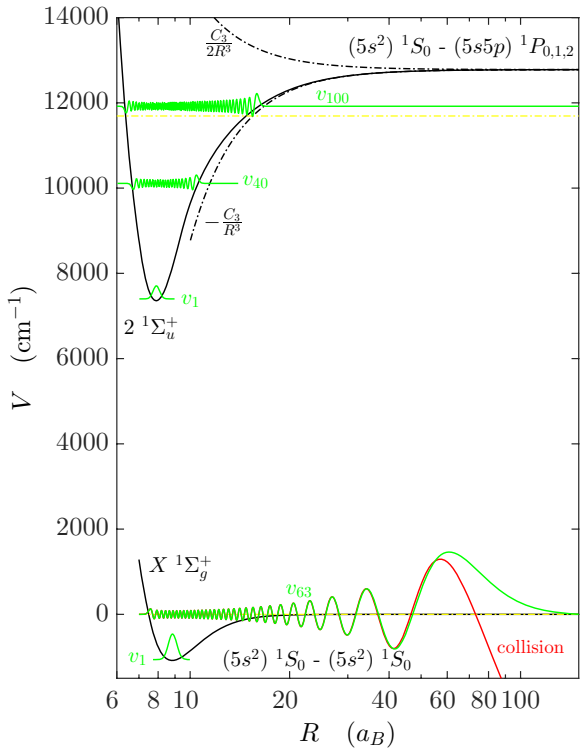

Figure 44.11: Fourier grid calculation for the states $X^1\Sigma_g^+$ and $(2)^1\Sigma_u^+$. Potentials (black) and vibrational structure. The dash-dotted potential only accounts for the C_3 long range force. The red wavefunction is the collisional channel at $T = 0$. The green wavefunctions are vibrational states, the depth in the potential corresponds to the eigenenergies, the indicated vibrational quantum number v' is counted from the dissociation limit.

44.2.3 Photoassociation

To calculate the interaction strength, as we will show below, we must evaluate the Franck-Condon overlap between the collisional ground state wavefunction and resonant repulsive or near-resonant vibrational excited state wavefunctions. In the context of the CDM we are predominantly interested in small light detunings. In this case, only very long range wavefunction play a role, which are dominated by long range van der Waals forces. We may therefore neglect the short range potential and set,

$$V_g(R) = -\frac{C_6}{R^6} \qquad \text{and} \qquad \pm\frac{C_3}{R^3}\ , \tag{44.99}$$

and only consider the highest bound states.

44.2.3.1 The LeRoy-Bernstein method

The LeRoy-Bernstein method allows us to estimate the highest bound levels. It only applies near the dissociation limit, where the semi-classical formula of quantization is

valid,

$$v + \tfrac{1}{2} = \sqrt{\frac{8m_{\rm red}}{\hbar^2}} \int_0^{R_t} dR \sqrt{E(v) - V(R)} \ . \tag{44.100}$$

Inserting the potential (44.112) we get,

$$E(v^*) = -E_{loc} \left(\sqrt{2\pi} \frac{(n-2)\Gamma\left(1+\frac{1}{n}\right)}{2\Gamma\left(\frac{1}{2}+\frac{1}{n}\right)} v^* \right)^{2n/(n-2)} \ , \tag{44.101}$$

where $v^* = v_D - v$ is a number counting the vibrational levels from the top to the bottom starting at the dissociation limit and E_{loc} is the localization energy calculated in (44.114),

$$E_{loc} = -\frac{8\hbar^6}{m^3 C_3^2} \ . \tag{44.102}$$

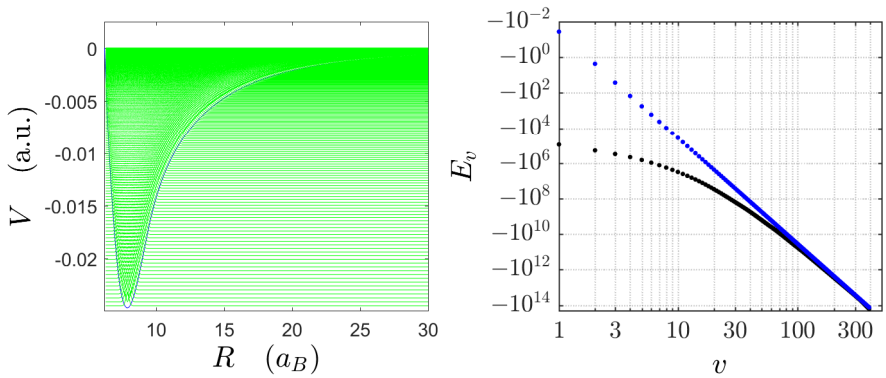

Figure 44.12: (a) Vibrational states of the $(2)\Sigma_u^+$ potential of Yb_2 dimers obtained by the mapped Fourier grid method [529]. (b) Energies of the highest vibrational states as a function of the vibrational quantum number v^* obtained by the LeRoy-Bernstein method. The states inside the red box have been measured [905].

Fig. 44.13 shows a comparison of the vibrational states bound via the Fourier grid method (green dots) and the LeRoy-Bernstein formula (blue dots). Although the coincidence should be good at low v' the contrary is observed. The reason is a failure of the Fourier grid method at extremely long range.

44.2.3.2 Long range wavefunctions

44.2.3.3 Optical cross sections

Calculate optical cross sections at all relative velocities.

44.2.3.4 PA spectra

Calculate PA spectra as a function of temperature.

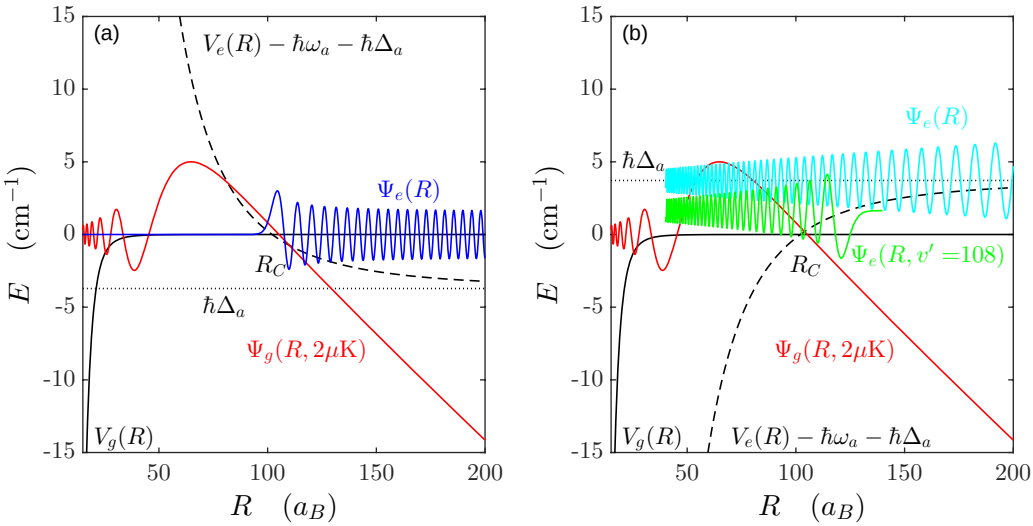

Figure 44.13: Collisional and vibrational wavefunctions in C_6 ground state and C_3 excited state potentials [495] in the presence of (a) blue and (b) red-detuned light ($C_6 = 1500\,\mathrm{a.\,u.}$, $C_3 = 18\,\mathrm{a.\,u.}$, $\Delta_\mathrm{a} = (2\pi)\ 700\,\mathrm{GHz}$). The colored curves denote (red) the wavefunction of two atoms colliding on their ground state with a velocity corresponding to $2\,\mu\mathrm{K}$, (blue) a wavefunction repelled from the excited state potential, (cyan) an unbound wavefunction of the excited state potential, and (green) a vibrational wavefunction of the excited state potential.

44.2.4 Generalization of the CDM

Discuss whether this can be treated in a generalized Green function or in a generalized CDM.

Discuss similarities with Rydberg dressing/blockade?

44.2.4.1 Hamiltonian for the CDM

The many-body Hamiltonian and the Lindbladian read,

$$\hat{H} = \tfrac{1}{2}\sum_j \left[\Omega(\mathbf{r}_j)\hat{\sigma}_j^+ + h.c.\right] - \sum_{i,j} \Delta_{ji}\hat{\sigma}_j^+\hat{\sigma}_i^- \tag{44.103}$$

$$\mathcal{L}^\dagger[\hat{A}] = \tfrac{1}{2}\sum_{i,j}\Gamma_{ij}(2\hat{\sigma}_i^+\hat{A}\hat{\sigma}_j^- - \hat{\sigma}_i^+\hat{\sigma}_j^-\hat{A} - \hat{A}\hat{\sigma}_i^+\hat{\sigma}_j^-)\ .$$

How to include van der Waals forces [703]?

44.2.4.2 Exclusion volume

At short distances the CDM is wrong, because the inner degrees of freedom come into play. In the past the problem has been avoided by introducing an 'exclusion volume', i.e. a volume determined by an interatomic distance which are simply discarded from the analysis. The radius was typically set to $r_{min} = n^{-1/3}/\pi \approx 73\,\mathrm{nm} = 1400 a_B$.

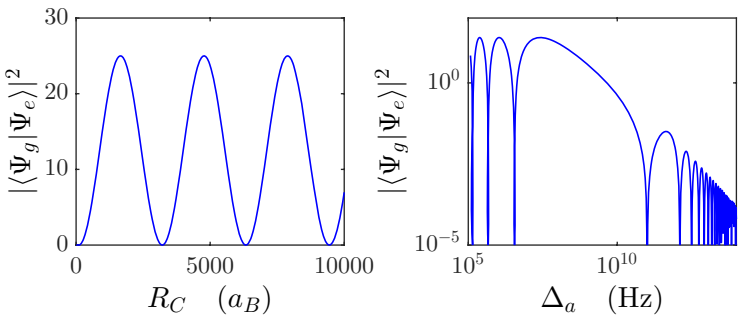

Figure 44.14: [495].

44.2.5 Green tensor for parallel classical dipoles

The Purcell factor allows us to calculate the modification of the decay rate in the presence of a Green tensor. Assuming that the interacting dipoles are parallel, $\hat{\mathbf{e}}_d = \hat{\mathbf{e}}'_d$, we have,

$$\begin{aligned}\Gamma_{ij} &= 3\lambda\Gamma^{(0)}\hat{\mathbf{e}}_d^* \,\mathfrak{Im}\,\mathcal{G}(\mathbf{r}_i,\mathbf{r}_j,\omega)\,\hat{\mathbf{e}}_d \\ &= \tfrac{3}{2}\Gamma^{(0)}\left[(1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\frac{\sin kR}{kR}\right. \\ &\quad \left.+(1-3(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\left(\frac{\cos kR}{k^2R^2}-\frac{\sin kR}{k^3R^3}\right)\right] ,\end{aligned} \tag{44.104}$$

where $\mathbf{R} \equiv \mathbf{r}_i - \mathbf{r}_j$.

Similarly, the Lamb shift can be calculated,

$$\begin{aligned}\Delta_{ij} &= -\tfrac{3}{2}\lambda\Gamma^{(0)}\hat{\mathbf{e}}_d^* \,\mathfrak{Re}\,\mathcal{G}(\mathbf{r}_i,\mathbf{r}_j,\omega)\,\hat{\mathbf{e}}_d \\ &= \tfrac{3}{4}\Gamma^{(0)}\left[(1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\frac{\cos kR}{kR}\right. \\ &\quad \left.-(1-3(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\left(\frac{\sin kR}{k^2R^2}+\frac{\cos kR}{k^3R^3}\right)\right] .\end{aligned} \tag{44.105}$$

At long distances, $kR > 1$, the results (44.104) and (44.105) simplify to,

$$\begin{aligned}\Delta_{ij} &\simeq -\tfrac{3}{4}\Gamma^{(0)}[1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2]\frac{\cos kR}{kR} \\ \Gamma_{ij}^{(b)} &\simeq \tfrac{3}{2}\Gamma^{(0)}[1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2]\frac{\sin kR}{kR} .\end{aligned} \tag{44.106}$$

And since the radiatively induced dipoles are perpendicular to their distance, $\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R$,

$$\begin{aligned}\Delta_{ij} &\simeq -\tfrac{3}{4}\Gamma^{(0)}\frac{\cos kR}{kR} \\ \Gamma_{ij}^{(b)} &\simeq \tfrac{3}{2}\Gamma^{(0)}\frac{\sin kR}{kR} ,\end{aligned} \tag{44.107}$$

we recover the scalar model. Obviously, at very long distances, $kR \gg 1$, $\Delta_{ij} \to 0 \leftarrow \Gamma_{ij}$.

At small distances, $kR \ll 1$, the results (44.104) and (44.105) simplify to,

$$\begin{aligned} \Delta_{ij} &= -\tfrac{3}{4}\Gamma^{(0)} \frac{3(\hat{\mathbf{e}}_d \cdot \hat{\mathbf{e}}_R)^2 - 1}{k^3 R^3} \\ \Gamma_{ij} &= \tfrac{3}{2}\Gamma^{(0)} \frac{1 - (\hat{\mathbf{e}}_d \cdot \hat{\mathbf{e}}_R)^2}{kR} \ . \end{aligned} \tag{44.108}$$

and assuming interaction between induced dipoles the same formula becomes,

$$\Delta_{ij} \simeq \frac{C_3}{R^3} \begin{cases} -1 & \text{for} \quad \hat{\mathbf{e}}_d = \hat{\mathbf{e}}_R \\ \frac{1}{2} & \text{for} \quad \hat{\mathbf{e}}_d \perp \hat{\mathbf{e}}_R \end{cases} \tag{44.109}$$

with the abbreviation,

$$C_3 = \frac{3\Gamma}{2k^3} \ . \tag{44.110}$$

44.2.5.1 Van der Waals C_3 coefficient

Hence, the C_3 coefficient of van der Waals resonant dipole interaction is obtained directly from the vectorial Green tensor. This indicates that the corresponding long range potential,

$$V_{lr}(R) = -\frac{C_3}{R^3} \tag{44.111}$$

results from a reorientation of the atomic dipoles due to molecular forces [173] p. 56. This effect is (probably) accounted for in the CDM at short distances, $kR < 100 a_B \approx 5 \cdot 10^{-9}$.

44.2.5.2 Estimation of the localization energy

One consequence of Heisenberg's uncertainty relation is that a certain localization energy is always required to localize a particle. The zero-point energy of the harmonic oscillator is an example: If the potential is shallower than this energy, it will not be capable of localizing a particle.

As another example, let us consider the attractive potential,

$$V = -\frac{C_n}{R^n} \ . \tag{44.112}$$

The space available for the particle is limited between the classical turning point, which for a given energy is $R_t = (C_n/|E|)^{1/n}$. The momentum corresponding to this energy is $k_t = (2m_{\text{red}}|E|/\hbar^2)^{1/2}$. Heisenberg's uncertainty relation requires,

$$k_t R_t > \pi \ , \tag{44.113}$$

that is, at least half of the wavelength must fit within the potential (between 0 and R_t) at the height of the bound state. Therefore,

$$\boxed{|E| > E_{loc} \equiv \left(\frac{\pi\hbar^2}{2m_{\text{red}}}\right)^{1/(1-2/n)} C_n^{1/(1-n/2)}} \ . \tag{44.114}$$

For a Coulomb potential, with $n = 1$ and $C_1 = e^2/4\pi\varepsilon_0$, we obtain the energy of the ground state of the hydrogen atom,

$$E > E_1 = -\frac{e^2}{4\pi\varepsilon_0 2a_B}\frac{4}{\pi^2} \ , \tag{44.115}$$

apart from a numerical factor. Note that the condition $k_t R_t > 2n$ yields the correct Bohr energies, $E = E_1/m^2$.

For $n = 2$, we do not get a condition for the energy. For the Casimir-Polder potential, $n = 3$ and $C_3 = 3\hbar\Gamma/2k^3$, we obtain,

$$E < -\frac{\pi^6\hbar^6}{8m_{\rm red}^3 C_3^2} = \frac{(\pi\hbar k)^6}{2m_{\rm red}^3(3\hbar\Gamma)^2} \ . \tag{44.116}$$

This means that, in contrast to the Coulomb potential, in order to minimize the momentum-position uncertainty, the binding energy must be *lower* than a certain limit.

44.2.6 Exercises

44.3 Continuous density distributions and Mie scattering

In the last sections we developed the coupled dipoles model describing light scattering from ensembles of individual microscopic particles by a set of equations of motion, in the simplest case, one for every atomic dipole. This limits the number of atoms that can be considered in numerical simulations to a few 1000. On the other hand, most cold atom experiments nowadays are performed with 10^5 to 10^9 atoms. The following section are devoted to introducing concepts and approximations allowing us to understand light scattering from large atomic clouds.

The main step will consist in an approximation called smooth or *continuous density approximation*, where the discrete distribution of point-like scatterers is replaced by an inhomogeneous but smooth continuous density distribution characterized by a refraction index field $n_{\rm rfr}(\mathbf{r})$. The interaction of this density distribution with light is then treated in the framework of Maxwell's equations, i.e. inhomogeneities are treated as macroscopic boundary conditions to the electromagnetic fields. In the following we will term this regime as *Mie scattering*.

At first sight Rayleigh scattering from point-like particles and Mie scattering from extended objects are quite different phenomena. Rayleigh scattering exhibits resonances due to the internal structure of the particles, e.g. an atom. Mie scattering shows resonances induced by the boundary conditions the scattering objects impose to the field. On the other hand, from a microscopic viewpoint, any extended object (e.g. a dielectric sphere) is nothing but an assembly of microscopic scattering particles. The question we need to study is then whether a description of the diffraction from this object as the sum of the radiation patterns scattered from the individual constituent particles is correct; or in how far the graininess of the cloud's density distribution and cooperative effects arising from the interaction *between* the individual particles play a role [148].

Interesting phenomena are expected in the transition regime between the limits of a dense bunch of individual scatterers and macroscopic dielectric objects. One of them is a strong modification of the radiation pressure force [198], which can conveniently be studied with atomic ensembles. The reason is that, in the smooth density approximation, the cloud can be understood as a macroscopic object characterized by a refraction index, which can be tuned over huge ranges by changing the cloud's density and volume, or by tuning the frequency of the incident light exploiting the existence of atomic resonances. We will see in the following that it is possible to study radiation pressure with cold atoms in the Rayleigh-Debye-Gans limit of small phase-shifts, as well as in the Mie limit of large phase shifts [45]. Despite the absence of sharp boundaries for the atomic cloud, we predict the occurrence of Mie resonances, which could be detected experimentally [46].

44.3.1 Continuous density approximation

In light scattering experiments, disorder (or granularity) plays a role when the number of atoms projected onto a cross section perpendicular to the incident beam is small enough so that a light mode focused down to the diffraction limit (that is $\sim \lambda^2$) would be able to resolve and count the atoms. In other words, the stochastic fluctuations induced by the random positions of the atoms can be neglected when the total number of atoms N is larger than the number of modes $\sim \sigma^2$ that fit into the cloud's cross section, i.e. when the optical density is $b_0 = 3N/\sigma^2 \gg 1$. Under this hypothesis, the differential equation (44.26) for $\tilde{\beta}_j$ can be simplified by replacing the discrete sum over atom positions by an integral over a density distribution $\rho(\mathbf{r})$,

$$\boxed{\sum_{j=1}^{N} \to \int \rho(\mathbf{r}')d^3r' \qquad \text{and} \qquad \tilde{\beta}_j(t) \to \tilde{\beta}(\mathbf{r}', t)} \,. \tag{44.117}$$

For example, the smoothed structure coefficient reads,

$$\mathcal{S}(\mathbf{k}) = \frac{1}{N}\sum_{j=1}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)\mathbf{r}_j} = \frac{1}{N}\int d^3r' \; \rho(\mathbf{r}')e^{\imath(\mathbf{k}-\mathbf{k}_0)\mathbf{r}'} \,. \tag{44.118}$$

In the Exc. 44.3.5.1 we calculate the structure coefficients for a homogeneous spherical cloud of radius R and for a Gaussian ellipsoidal cloud with the *rms*-width $\sigma_{\rho,z}$:

$$\begin{aligned} \mathcal{S}_{\text{homog.sphere}}(\mathbf{k}) &= \tfrac{3}{q^3R^3}(\sin qR - qR\cos qR) \\ \mathcal{S}_{\text{gauss.ellipse}}(\mathbf{k}) &= e^{-\frac{1}{2}k^2\sigma_\rho^2\sin^2\theta - \frac{1}{2}\sigma_z^2(k\cos\theta - k_0)^2} \,. \end{aligned} \tag{44.119}$$

The simulated structure factor (red curve in Figs. 44.15) agrees well with the analytical expression (green curve). Since small clouds have a larger fluctuations, the fact that the total force is a sum of intensities rather than amplitudes leads to a finite value at large scattering angles θ.

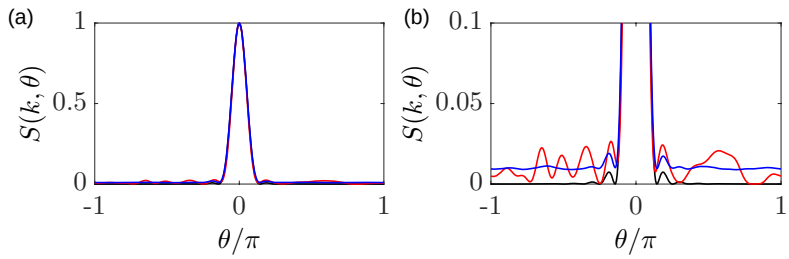

Figure 44.15: (code) (a) The red curve shows a calculation of the structure factor: $|\mathcal{S}(k = k_0, \theta, \phi = 0)|^2$ for 200 atoms randomly distributed in a homogeneous spherical cloud of size $R = 10/k_0$. The blue curve shows an average over 500 realizations of such a cloud according to $\sum_{m=1}^{200} |\mathcal{S}(k, \theta, \phi = 0)|^2$. The black curve is an analytical calculation according to Eq. (44.119) [901]. (b) Same curves as in (a) but with a stretched y-axis.

In the continuous limit defined by (44.117) for the equations of motion (44.32) [11],

$$\dot{\tilde{\beta}}(\mathbf{r},t) = \imath\left(\Delta_0 + \imath\frac{\Gamma}{2}\right)\tilde{\beta}(\mathbf{r},t) - \frac{\imath}{2}\Omega_0 - \frac{\Gamma}{2}\int d^3r'\rho(\mathbf{r}')\frac{\sin(k_0|\mathbf{r}-\mathbf{r}'|)}{k_0|\mathbf{r}-\mathbf{r}'|}\tilde{\beta}(\mathbf{r}',t)e^{-\imath\mathbf{k}_0\cdot(\mathbf{r}-\mathbf{r}')} . \tag{44.120}$$

Transforming back to $\beta_j \equiv \tilde{\beta}e^{\imath\mathbf{k}_0\cdot\mathbf{r}}$, we obtain the fundamental equation for the dipolar excitation field,

$$\boxed{\dot{\beta}(\mathbf{r},t) = \imath\left(\Delta_0 + \imath\frac{\Gamma}{2}\right)\beta(\mathbf{r},t) - \frac{\imath\Omega_0}{2}e^{\imath\mathbf{k}_0\cdot\mathbf{r}} - \frac{\Gamma}{2}\int d^3r'\rho(\mathbf{r}')\frac{\sin(k_0|\mathbf{r}-\mathbf{r}'|)}{k_0|\mathbf{r}-\mathbf{r}'|}\beta(\mathbf{r}',t)} . \tag{44.121}$$

Example 302 (*Connection between coupled dipoles model and Helmholtz equation*): The steady-state solution of (44.121) can also be obtained from the *Helmholtz equation* of Maxwell's theory [320, 45, 46], as shown in Sec. 16.3.2,

$$\boxed{[\nabla^2 + k_0^2 n_{\rm rfr}^2(\mathbf{r})]\beta(\mathbf{r}) = 0 \qquad \text{defining} \qquad n_{\rm rfr}^2(\mathbf{r}) \equiv 1 - \frac{4\pi\rho(\mathbf{r})}{k_0^3(2\Delta_0/\Gamma + \imath)}} . \tag{44.122}$$

44.3.2 Simulations of the time evolution

We start from the second equation (44.18),

$$\dot{\tilde{\beta}}_j(t) = \imath\Delta_0\tilde{\beta}_j(t) - \frac{\Omega_0^2}{4}\sum_{m=1}^{N}\int_0^t \tilde{\beta}_m(t')dt' \tag{44.123}$$
$$- \sum_{\mathbf{k}} g_k^2 \sum_{m=1}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)(\mathbf{r}_j-\mathbf{r}_m)}\int_0^t e^{-\imath(\omega_k-\omega_0)(t-t')}\tilde{\beta}_m(t')dt' .$$

[11] Note that the 'timed Dicke' assumption (44.64) has not been used here.

Substituting the timed Dicke state (44.64),

$$\dot{\beta}(t) = \frac{1}{N}\sum_{j=1}^{N}\dot{\beta}(t) = \frac{1}{\sqrt{N}}\sum_{j=1}^{N}\dot{\tilde{\beta}}_j(t) \tag{44.124}$$
$$= \imath\Delta_0\beta(t) - \frac{N\Omega_0^2}{4}\int_0^t \beta(t')dt' - \frac{V_{\rm ph}}{(2\pi)^3}\int d^3k\; g_k^2 N^2|\mathcal{S}(\mathbf{k})|^2\int_0^t e^{-\imath(\omega_k-\omega_0)(t-t')}\frac{\tilde{\beta}_m(t')}{\sqrt{N}}dt' \;,$$

where we used $\sum_{m=1}^{N} e^{\imath(\mathbf{k}-\mathbf{k}_0)(\mathbf{r}_j-\mathbf{r}_m)} = N^2|\mathcal{S}(\mathbf{k})|^2$ from Eq. (44.67). Finally, at resonance and low saturation we may neglect the first two terms,

$$\dot{\beta}(t) = -N\frac{V_{\rm ph}}{(2\pi)^3}\int_{\mathbb{R}} d^3k\int_0^t dt'\; g_k^2\beta(t')e^{\imath(\nu_k-\omega)(t-t')}|\mathcal{S}(\mathbf{k})|^2 \tag{44.125}$$
$$= -N\frac{V_{\rm ph}}{(2\pi)^3}\int_0^t dt'\;\beta(t')\int_0^\infty\int_0^\pi g_k^2 e^{\imath(\nu_k-\omega)(t-t')}|\mathcal{S}(k,\theta)|^2 2\pi k^2\sin\theta d\theta dk$$
$$= -N\frac{V_{\rm ph}}{(2\pi)^3}g_k^2\int_0^t dt'\;\beta(t')\int_0^\infty e^{\imath(\nu_k-\omega)(t-t')}k^2 I(k)dk = -\Omega_N^2\int_0^t dt'\;\beta(t')G(t-t') \;,$$

with the collective Rabi frequency $\Omega_N = \sqrt{N}g_k$ and the surface integrated structure factor,

$$I(k) = \int_0^{2\pi}\int_0^\pi |\mathcal{S}(k,\theta,\phi)|^2\sin\theta d\theta d\phi \;, \tag{44.126}$$

and

$$G(\tau) = \frac{V_{\rm ph}}{(2\pi)^3}e^{-\imath\omega\tau}\int_0^\infty e^{\imath ck\tau}k^2 I(k)dk \;, \tag{44.127}$$

with $\omega = ck_0$ and $\nu_k = ck$. The integral $I(k)$ has been solved by Nicola for an ellipsoidal Gaussian density distribution. It is quite close to,

$$I(k) \simeq I(k_0) \simeq \sqrt{\frac{\pi}{2}}\frac{1}{k\sigma_z}e^{F^2/2}[1-\mathrm{erf}\,(F/\sqrt{2})] \;, \tag{44.128}$$

with the Fresnel number $F = k\sigma_r^2/\sigma_z$.

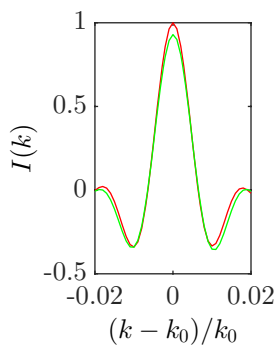

Figure 44.16: (code) Averaging of the structure factor over the whole k-space.

44.3.2.1 Analytical method

To evaluate the above integro-differential equation, we use the rule for differentiating integrals with variable boundaries,

$$\frac{\partial}{\partial t}\int_{\phi(t)}^{\psi(t)} f(x,t)dx = \int_{\phi(t)}^{\psi(t)} \frac{\partial f(x,t)}{\partial t}dx + f(\psi(t),t)\psi'(t) - f(\phi(t),t)\phi'(t) \ , \quad (44.129)$$

it is easy to show,

$$\frac{\partial}{\partial t}\int_0^t f(t')G(t-t')dt' = f(t)G(0) + \int_0^t f(t')\dot{G}(t-t')dt' \quad (44.130)$$

and to thusly evaluate the integral until $\frac{\partial^n}{\partial t^n}G(t-t')$ gets smooth enough to be neglected.

44.3.2.2 Numerical method

We can directly solve the integro-differential equation numerically using,

$$G(\tau) = \left[1 + \frac{3c}{4R}\tau - \frac{c^3}{16R^3}\tau^3\right]\Theta(3R - c\tau) \ , \quad (44.131)$$

for a homogeneous spherical cloud and,

$$G(\tau) = \frac{k\sigma_r^2}{k\sigma_r^2 + ic\tau}e^{-(c\tau/\sigma_z)^2/2} \ , \quad (44.132)$$

for an ellipsoidal Gaussian cloud. The iteration is done via,

$$\beta(t+dt) = \beta(t) - dt\ \Omega_N^2 \int_0^t \beta(t')G(t-t')dt' \ . \quad (44.133)$$

The discretization is done via,

$$t_{m+1} = t_m + dt \quad (44.134)$$
$$\beta_{m+1} = \beta_m - dt\ Ng_k^2 \sum_{m'=1}^{m} \beta_{m'}G(t_m - t_{m'})dt \ .$$

With the solution of the integro-differential equation $\beta(t)$, we can calculate the probability that atoms are excited [901] [12],

$$P(t) = |\beta(t)|^2 = \sum_j |\beta_j(t)|^2 = \int d^3r|\beta(t,\mathbf{r})|^2 \ . \quad (44.135)$$

[12]Compare to Jaynes-Cummings model in a CQED environment: A single photon is coherently exchanged between the cavity and the atomic excitation, we get Rabi oscillations. Here, the atomic cloud is the cavity.
We know that the Mollow triplet in the dressed states picture gives rive to an oscillating decay curve resembling that of Fig. 44.17. Does this curve also have an interpretation in terms of collective dressed states?

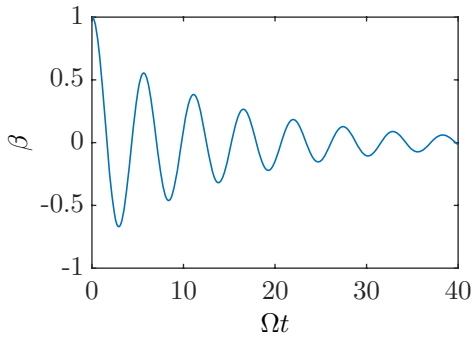

Figure 44.17: (code) Calculation of the time evolution of β for a homogeneous spherical cloud. The parameters are $\lambda \simeq 780\,\text{nm}$ and $c/\Omega \simeq 30\,\text{cm}$ with $\Omega = \sqrt{N} g_k$ for typically $g_k \simeq 1\,\text{MHz}$ and $N \simeq 10^6$.

Example 303 (*Solutions for a homogeneous spherical cloud*): For a homogeneous spherical cloud, we find three regimes characterized by the size of the cloud compared to the two length scales λ and c/Ω:

$$\beta(t) = \beta(0) \begin{cases} e^{-N\Gamma t} & \text{for} \quad R < \lambda \ll c/\Omega \\ e^{-27N\Gamma t/8(k_0 R)^2} & \text{for} \quad \lambda < R \ll c/\Omega \\ \cos \Omega t e^{-3ct/8R} & \text{for} \quad \lambda \ll c/\Omega < R \end{cases} .$$

44.3.2.3 Complete numerical simulation

In order to be independent from initial conditions, we generate a random distribution $\mathbf{r}_{j'}$ and solve the differential equation,

$$\dot{\beta}_j(t) = -N g_k^2 \int_0^t dt' \, \frac{V_{\text{ph}}}{(2\pi)^3} \int d^3k \, \frac{1}{N} \sum_{j'=1}^{N} \beta_{j'}(t') e^{\imath(\nu_k - \omega)(t-t') + \imath \mathbf{k}(\mathbf{r}_j - \mathbf{r}_{j'})} \ . \tag{44.136}$$

We propagate the amplitudes in time via,

$$\beta_j(t+dt) = \beta_j(t) - dt g_k^2 \frac{V_{\text{ph}}}{(2\pi)^3} \int_0^t dt' \, \sum_{j'=1}^{N} \beta_{j'}(t') \int_0^\infty k^2 e^{\imath(ck-\omega)(t-t')} I_{jj'}(k) dk \ , \tag{44.137}$$

where $I_{jj'}(k) \equiv \int_0^\pi \int_0^{2\pi} e^{\imath k \left[(x_j - x_{j'}) \sin\theta \cos\phi + (y_j - y_{j'}) \sin\theta \sin\phi + (z_j - z_{j'}) \cos\theta\right]} \sin\theta d\theta d\phi$, and discretize via,

$$t_{m+1} = t_m + dt \tag{44.138}$$

$$\beta_j(t_{m+1}) = \beta_j(t_m) - dt^2 g_k^2 \sum_{m'=1}^{m} \sum_{j'=1}^{N} \beta_{j'}(t_{m'}) G_{jj'}(t_m - t_{m'}) \ ,$$

with $G_{jj'}(t_m - t_{m'}) = \frac{V_{\text{ph}}}{(2\pi)^3} \int_0^\infty k^2 e^{\imath(ck-\omega)(t_m - t_{m'})} I_{jj'}(k) dk$.

44.3.3 Radiation pressure force in macro- and microscopic scattering

As mentioned at the beginning of this section, scattering of light by an extended object such as an atomic ensemble or a dielectric sphere is fundamentally different from scattering at a point-like scatterer such as a single atom. On one hand, the finite size of the object leads to Mie scattering. On the other hand, the spatial distribution of the scatterers rules the degree of cooperativity. Homogeneous and periodic distributions tend to scatter cooperatively, whereas disorder suppresses cooperativity. In an atomic cloud, the amount of disorder can be tuned via the optical density seen by the incident light, and its role can be studied via the radiation pressure exerted by the light on the atomic cloud. We present an analytic expression for the radiation pressure valid for any numbers of atoms and arbitrary density distributions, which interpolates between the regimes of dominating disorder and dominating cooperativity. Furthermore, we present first experimental signatures of radiation pressure reduction due to cooperative scattering.

The radiation pressure exerted by a plane wave laser beam with frequency ω_0 and wave vector $\mathbf{k}_0 = k_0\hat{\mathbf{e}}_z$ on a single two-level atom with resonance frequency $\omega_\mathrm{a} = \omega_0 - \Delta_0$ is correctly described by the standard formula (44.80). Generalization to scattering by atomic ensembles and extended objects is only possible, if a number of effects is explicitly taken into account. The most important ones are named in the following. a. *Cooperativity* and b. *disorder*: Cooperativity is the tendency of atoms located in the same area of space, forming regular structures or being forced by the mode structure of the environment (e.g. optical cavities) to scatter light synchronously into the same direction, as in the case of Dicke superradiance. While homogeneously or periodically distributed atoms concentrate the scattered light in specific solid angles by forward or Bragg scattering, randomly distributed atoms do not cooperate and scatter light isotropically. In this respect, cooperativity and disorder are antagonists. c. *Mie scattering and refraction*: The finite volume and the shape of the cloud represent an inhomogeneity at which light is scattered in a global way. As long as the optical density is low, the pump mode depletion is mainly due to the fact, that the atomic cloud distorts the phase front of the incident light. For high optical density, scattering is predominantly absorptive. d. *Multiple scattering* and e. *resonance fluorescence*: Near resonance, multiple scattering leads to radiation trapping. Even off-resonance, inelastic scattering pumps resonant photons into the atomic cloud, which have a high probability to be reabsorbed. Taking account of all these effects, the real radiation pressure can differ by orders of magnitude from the naive prediction of the above formula.

For smooth density distributions F_c is only limited by Mie scattering at the inhomogeneity represented by the *finite extend* of the atomic cloud [198]. The radiation pressure depends on the number of atoms N in the volume, and the scaling $F_c(N)$ depends on the pump laser detuning and the radial cross section of the cloud. But small scale inhomogeneity *within the cloud*, i.e. disorder, can play an eminent role for collective scattering. This is the case, when the number of atoms is beyond a critical value, which mainly depends on the volume and shape of the cloud. In the following we will derive an analytic expression for the radiation pressure as a function of atom number, which interpolates between the regimes of dominating disorder (single-atom

Rayleigh scattering) and dominating cooperativity (pure Mie scattering).

On the other hand, we point out, that we do not consider multiple scattering in our treatment. This is a good assumption far from resonance, where the scattering is predominantly Rayleigh scattering and inelastic scattering can safely be disregarded. In contrast, our extensions of single to multi-atom scattering are not valid near resonance.

The radiation pressure provides sensitive signatures for the impact of cooperativity and disorder. We describe an experiment measuring the displacement of cold atoms confined in a far-off resonance dipole trap and interpret our observations in terms of collective scattering.

44.3.3.1 Radiation pressure for timed Dicke states

As a first approach we will calculate the radiation pressure for a timed Dicke state from Eq. (44.89) by explicit analytical integration of the surface-integrated structure factors s_∞ and f_∞ in the smooth density limit (44.117) for an ellipsoidal Gaussian smooth density distribution, as shown in Exc. 44.3.5.2. In the spherical case,

$$\rho(\mathbf{r}) = \rho_0 e^{-r^2/2\bar{r}^2} \qquad \text{with} \qquad \rho_0 = \frac{N}{(2\pi)^{3/2}\bar{r}^3} \ , \tag{44.139}$$

and introducing $\sigma \equiv k\bar{r}$, we get,

$$\begin{aligned} s_\infty &= \frac{1-e^{-4\sigma^2}}{4\sigma^2} \overset{\sigma\gg 1}{\longrightarrow} \frac{1}{4\sigma^2} \\ f_\infty &= \frac{1}{4\sigma^2}\left[1-\frac{1}{2\sigma^2}+\left(1+\frac{1}{2\sigma^2}\right)e^{-4\sigma^2}\right] \overset{\sigma\gg 1}{\longrightarrow} s_\infty - 2s_\infty^2 \ . \end{aligned} \tag{44.140}$$

Hence,

$$\boxed{\frac{F_{za}+F_{ze}}{F_{z1}} = \frac{(2\Delta_0/\Gamma)^2+1}{(2\Delta_0/\Gamma)^2+N^2 s_\infty^2} N(s_\infty - f_\infty)} \ . \tag{44.141}$$

Note that the radiation pressure calculated from Eq. (44.141) also holds for elongated ellipsoidal Gaussian clouds characterized by an aspect ratio $\eta > 1$, even though the expressions for the surface-integrated structure factors become more complicated.

It is revealing to compare the smooth density expressions (44.141) with numerical simulations based on randomly generated atomic distributions from which the structure factor is directly from the sum (44.68). Interestingly, we find in certain parameter regimes (in particular at low atom numbers) considerable deviations between s_N, f_N and s_∞, f_∞ and consequently between the numerical simulations and the analytic calculations of the radiation pressure. We attribute these deviations to disorder in the atomic cloud, which is not seen in the smooth density limit, but naturally incorporated in the numerical approach.

By comparison to numerical simulations [black solid lines and blue circles in Figs. 44.18(a)] we found that the surface-integrated structure factors in the presence of disorder are well described by [90],

$$s_N = \frac{1}{N} + s_\infty \qquad \text{and} \qquad f_N = f_\infty \ . \tag{44.142}$$

44.3.3.2 Cooperativity versus disorder

We expect disorder to play a dominant role, when the coarse graininess, which is related to the average distance between two atoms, $|\mathbf{r}_i - \mathbf{r}_j|$, can be resolved by the incident light. For the *absorption process*, this means that disorder gets important, when the number of spatial modes supported by the pump laser in a radial cross section of the atomic cloud,

$$N_{ca} = s_\infty^{-1} \simeq 4\sigma^2 \ , \tag{44.143}$$

(for voluminous clouds) surpasses the number of atoms, $N < N_{ca}$. This is just the case, when the mean resonant optical density (for a ray passing through the center of the cloud $x = y = 0$) is larger than 1,

$$b_0 = \int_{-\infty}^{\infty} dz \ \rho(z)\sigma_{\rm opt} = \frac{3N}{\sigma^2} = \frac{12N}{N_{ca}} > 1 \ , \tag{44.144}$$

where $\sigma_{\rm opt} = \frac{3\lambda^2}{2\pi}$ is the resonant optical cross section and $\rho(\mathbf{r})$ the spherical Gaussian density distribution (44.139). For the *scattering process*, the number of modes available for the reemitted light also counts. Hence, the critical number of atoms that can be resolved by light scattering is larger than N_{ca}:

$$N_{ce} = (s_\infty - f_\infty)^{-1} \simeq \tfrac{1}{2}(2\sigma)^4 = \tfrac{1}{2} N_{ca} \cdot \sigma^2 \ . \tag{44.145}$$

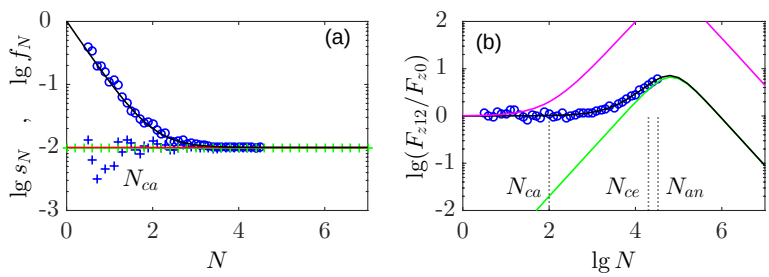

Figure 44.18: (code) (a) Numerical evaluation of s_N (blue circles) and f_N (blue crosses) [148]. Analytical calculation of s_N (black solid line) according to Eq. (44.142). Smooth density limit of s_∞ (red solid line) and f_∞ (green crosses). The cloud is assumed spherical, $\eta = 1$, and Gaussian with size $\sigma = 5$. (b) Numerical evaluation (blue circles) of the corresponding force ratio as a function of atom number N for $\Delta_0 = (2\pi)\ 2\,\text{GHz}$ and small collective saturation, $\sqrt{N}\Omega_0 \ll \Delta_0$. Analytical calculation in the smooth density limit (green solid line) and according to Eq. (44.147) (black solid line). The magenta line traces the radiation pressure force resulting from pump photon absorption only.

In order to simplify the discussion, we neglect saturation, $\Omega_0 \to 0$. Using $\Delta_0 \gg \Gamma$ and defining a third characteristic atom number,

$$N_{cr} = \frac{2\Delta_0}{\Gamma s_\infty} \ , \tag{44.146}$$

Eq. (44.141) can be written,

$$\frac{F_c}{F_1} \simeq \frac{1 + N/N_{ce}}{1 + (N/N_{cr})^2} \ . \tag{44.147}$$

In the limit of very large detunings, $\Delta_0/\Gamma \gg \sigma^2 \gg 1$, the three introduced characteristic atom numbers introduced in Eqs. (44.143), (44.145) and (44.146) satisfy $N_{ca} < N_{ce} < N_{cr}$, and we obtain the N-dependence of the radiation pressure depicted in Fig. 44.18.

In the regime $N < N_{ca}$, radiation pressure is dominated by the absorption process, $s_N \gg f_N$, because the emission is isotropic. The absorption radiation pressure exerted on a hypothetical smooth density distribution occupying the same volume as the atomic cloud [green line in Fig. 44.18] is dramatically reduced with respect to the single-atom radiation pressure (cyan dash-dotted line). However, disorder suppresses cooperativity and increases the radiation pressure up to the single-atom value. The novelty as compared to Ref. [832] is the fact that cooperativity and disorder not only influence the collective emission of a photon by an atomic cloud, but also the collective *absorption* of a photon from a pump laser beam.

Neglecting the photon reemission at higher atom numbers would result in an increase of radiation pressure in the regime $N_{ca} < N < N_{ce}$ (magenta line). However, in this regime, the emission process becomes increasingly important, $s_N \simeq f_N$, because the emission changes its radiation pattern from isotropic to forward scattering. Consequently, the radiation pressure is reduced with respect to its purely absorptive component. This regime is still ruled by disorder, so that the critical atom number for the impact of disorder on the absorption process, N_{ca}, has no impact. It does not even show up in the formula (44.147).

In the regime $N_{ce} < N < N_{cr}$, disorder steps back and cooperativity wins, so that the radiation pressure approaches the smooth density limit. Since in this regime, the smooth density radiation pressure depends on atom number like $\propto N$, as already shown in Ref. [198], we observe an increase of the radiation pressure beyond the single-atom value. This is only possible, because the collective enhancement of absorption (magenta line) rises as fast with N, as the collective enhancement of emission.

For even higher atom numbers, $N_{cr} < N$, the radiation pressure dramatically alters its N-dependency from $\propto N$ to $\propto N^{-1}$. This change of behavior is *not* caused by the interplay of cooperativity and disorder, but can be understood within the framework of Mie scattering, as discussed in the next section.

44.3.3.3 Rayleigh-Debye-Gans versus Mie scattering

Radiation pressure is observed in many experiments, as it is the basis for optical cooling techniques (like magneto-optical traps) and limits the efficiency of resonant absorption imaging of cold atoms, because their acceleration leads to considerable Doppler-shifts. However, as stated before, the impact of disorder on radiation pressure can only be seen for large optical densities, $b \gg 1$, which may partially explain, why this effect has not been observed until two experiments explicitly searched for it [90, 76] (see Fig. 44.19).

Depending on the parameter regime chosen, the measurements exhibited in Fig. 44.19 present data for reduced or enhanced radiation pressure for larger N. As explained

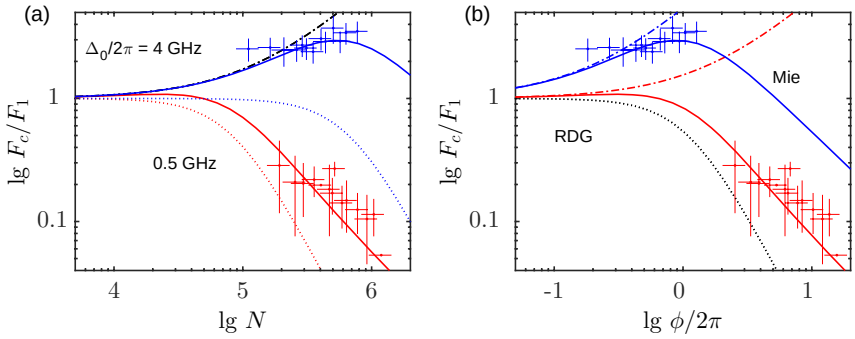

Figure 44.19: (code) (a) Double-logarithmic plot of the measured (symbols) and calculated (lines) N dependence of the radiation pressure force. The red symbols and lines correspond to the detuning $\Delta_0 = (2\pi)\ 0.5\,\mathrm{GHz}$ and the intensity $I_0 = 95\,\mathrm{mW/cm^2}$. For the blue symbols and lines, $\Delta_0 = (2\pi)4\,\mathrm{GHz}$ and $I_0 = 730\,\mathrm{mW/cm^2}$. The red (bottom) and blue (top) solid lines show calculations based on the full expression (44.141) without adjustable parameters. The red (bottom) and blue (top) dotted lines represent just the fraction of expression (44.141). The dash-dotted lines representing just the parentheses coincide for both values of Δ_0. (b) Same data as (a), but plotted as a function of the push beam phase shift φ. In this diagram the dotted lines representing the fraction coincide for both values of Δ_0 [76].

above, the reduction is understood as microscopic Rayleigh scattering at disordered atoms together with superradiant acceleration of the decay, while the enhancement is observed when the bulk cloud becomes so small and dense that it turns into an inhomogeneous dielectric sphere refracting and lensing incident light by macroscopic Mie scattering.

The question then remains why the radiation pressure, with increasing N, after an initial rise the drops again. To answer this question we must have a look at the phase shift induced in the pumjp light by the cloud's refraction index.. From calculations done in Secs. 15.2.4, 23.2.7 and 49.6.1 we know that (below saturation) the optical density b and the phase shift φ are linked to the refraction index n_{rfr} and the optical scattering cross section σ_{opt} via,

$$\frac{\imath b}{2} + \varphi = \frac{\omega}{c}\int_{-\infty}^{\infty}[n_{\mathrm{rfr}}(\mathbf{r}) - 1]dz = \left(\imath - \frac{2\Delta_0}{\Gamma}\right)\sigma_{\mathrm{opt}}(\Delta_0)\int_{-\infty}^{\infty}\rho(\mathbf{r})dz \tag{44.148}$$

$$\text{where}\quad \sigma_{\mathrm{opt}}(\Delta_0) = \frac{2\pi}{k^2}\frac{\Gamma^2}{4\Delta_0^2 + \Gamma^2} \qquad \text{and} \qquad n_{\mathrm{rfr}}(\mathbf{r}) - 1 = -\frac{4\pi\rho(\mathbf{r})}{k_0^3(2\Delta_0/\Gamma + \imath)}\ ,$$

such that,

$$\boxed{b = -\sigma_{\mathrm{opt}}(\Delta_0)\int_{-\infty}^{\infty}\rho(\mathbf{r})dz = b_0\frac{\Gamma^2}{4\Delta_0^2 + \Gamma^2} \qquad \text{and} \qquad \varphi = \frac{2\Delta_0}{\Gamma}b}\ . \tag{44.149}$$

Estimating coarsely $k\int_{-\infty}^{\infty}[n_{\mathrm{rfr}}(\mathbf{r}) - 1]dz \simeq \sigma[n_{\mathrm{rfr}}(\mathbf{r}) - 1]$, where $\sigma \equiv k\bar{r}$, we may simplify,

$$\frac{\imath b}{2} + \varphi = \sigma[n_{\mathrm{rfr}}(\mathbf{r}) - 1]\ . \tag{44.150}$$

At high atom numbers (i.e. in the smooth density limit), the dependency of the radiation pressure on atom number (44.147) exhibits a maximum at N_{cr}. For an atomic cloud with density n and the resonant optical density b_0, the characteristic atom number can be expressed in terms of the phase shift φ experienced by the pump laser beam on its path across the cloud. Absorption losses for the pump beam (e.g. resonance fluorescence, whose differential cross section contributes $\sigma_{\rm opt}$ to the total scattering cross section [590]) is completely negligible at large detunings. Only elastic Rayleigh scattering occurs, which in the smooth density limit of Mie scattering becomes pure *diffraction* (real part of the refraction index). We can than understand the atomic cloud as a non-absorbing dielectric sphere with a Gaussian index of refraction.

Rewriting Eq. (44.147) in terms of the refraction index,

$$\frac{F_c}{F_1} \simeq \frac{N}{1+(2\varphi)^2}\frac{2}{(2\sigma)^4} \ , \tag{44.151}$$

we see that, as long as $\varphi < \frac{1}{2}$, the force increases linearly like $\propto N$. The proportionality comes from the perfect (in the sense of not spoiled by disorder) cooperative enhancement of the scattering rate in the smooth density limit. The enhancement is only limited by the finite size σ of the cloud, which is accounted for in the second fraction. This regime, characterized by [13],

$$\sigma[n_{\rm rfr}(\mathbf{r})-1] \ll 1 \tag{44.152}$$

is termed the *Rayleigh-Debye-Gans regime*.

For larger phase shifts, $\varphi > \frac{1}{2}$, refraction more and more distorts the wavefront of the pump beam, which spoils the pump mode depletion and hence reduces radiation pressure. Consequently, the radiation pressure decreases again like N^{-1}. This is the *Mie regime* of scattering. The maximum is thus a pure diffraction effect, a so-called Mie resonance. It corresponds to the $n_{\rm rfr}$, where the Rayleigh-Debye-Gans scattering approximation looses its validity according to (44.152). In Excs. 44.3.5.3 and 44.3.5.4 we study Mie and Rayleigh-Debye-Gans scattering, and in 44.3.5.5 we discuss the question is whether recoil is imparted to individual atoms or to the center-of-mass of the whole cloud.

In the limit of the approximations made, our formula correctly describes the radiation pressure force on extended objects. These objects can either be ensembles of scatterers like homogeneous, ordered or disordered atomic clouds of arbitrary shapes and volumes, or macroscopic objects like dielectric spheres. The formula thus represents a bridge between microscopic Rayleigh scattering and macroscopic Mie scattering. At very low atom numbers, the atomic cloud basically represents a randomly distributed bunch of scatterers, whose intrinsic disorder spoils cooperativity. The radiation pressure is then well described by the single-atom value. At large atom numbers, the atomic cloud forms a smooth density distribution characterized by an almost perfect a cooperativity, which is only limited by Mie scattering.

[13] Note the necessity of another condition $[n_{\rm rfr}(\mathbf{r})-1] \ll 1$ termed Born approximation, which demands that the incident wave be not appreciably reflected.

44.3.3.4 Light scattering in the continuous density approximation

The scalar electric field scattered by an arbitrary distribution of atoms has been calculated in (44.49). In the continuous density approximation (44.117), we get,

$$\vec{\mathcal{E}}_{\rm sct}(\mathbf{r}) = -\frac{\imath\hbar\Gamma}{2d}\sum_{j=1}^{N}\frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}_j|}}{\imath k_0|\mathbf{r}-\mathbf{r}_j|}\beta_j(\infty) \to -\frac{\imath\hbar\Gamma}{2d}\int d^3r'\rho(\mathbf{r}')\frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}'|}}{\imath k_0|\mathbf{r}-\mathbf{r}'|}\beta(\mathbf{r}',\infty) \ . \tag{44.153}$$

In particular, for a timed Dicke state,

$$\begin{aligned}\vec{\mathcal{E}}_{\rm sct}(\mathbf{r}) &= -\frac{\imath\hbar\Gamma}{2d}\frac{\sqrt{N}\Omega_0}{2\Delta_0+\imath\Gamma N s_N}\sum_{j=1}^{N}\frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}_j|}}{\imath k_0|\mathbf{r}-\mathbf{r}_j|} \\ &\to -\frac{\imath\hbar\Gamma}{2d}\frac{\sqrt{N}\Omega_0}{2\Delta_0+\imath\Gamma(1+Ns_\infty)}\int d^3r'\rho(\mathbf{r}')\frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}'|}}{\imath k_0|\mathbf{r}-\mathbf{r}'|} \ .\end{aligned} \tag{44.154}$$

44.3.4 Spherical harmonics expansion and generalized timed Dicke state

The results derived in (44.141) assumed the cloud to be in a timed Dicke state. As we have seen in Exc. 44.1.8.5, timed Dicke states do not account for pump laser phase shifts induced by the cloud's refraction index. The timed Dicke states might work well for homogeneous cylinders, but not for ellipsoidal clouds, which we assume in our analytical treatments. Therefore, a better approach consists in expanding the cloud into spherical harmonics. Under the assumption that the cloud is radially symmetric, $\rho(\mathbf{r}) = \rho(r)$, we get [320],

$$\beta(r,\theta,t) = \sum_{n=0}^{\infty}\sqrt{\frac{2n+1}{4\pi}}\alpha_n(t)j_n(k_0r)P_n(\cos\theta)e^{-\imath k_0 r\cos\theta} \ , \tag{44.155}$$

where the coefficients α_n are the solutions of,

$$\dot{\alpha}_n = \left[\imath\Delta_0 - \frac{\Gamma}{2}(1+\lambda_n)\right]\left[\alpha_n - \alpha_n(\infty)\right] \ , \tag{44.156}$$

In steady state,

$$\alpha_n(\infty) = \frac{2\imath^n\sqrt{\pi(2n+1)}\Omega_0}{2\Delta_0+\imath\Gamma(1+\lambda_n)} \ , \tag{44.157}$$

where,

$$\lambda_n \equiv 4\pi\int_0^\infty dr\rho(r)j_n^2(k_0r) \tag{44.158}$$

is the decay rate of eigenmode n.

Inserting this into the steady-state solution (44.121) and integrating over the volume,

$$\begin{aligned}\langle\beta_\infty\rangle &\equiv \frac{2\pi}{N}\int_0^{2\pi}d\theta\sin\theta\int_0^\infty dr^2\rho(r)\beta(r,\theta) = \frac{\Omega_0}{N}\sum_{n=0}^{\infty}\frac{(2n+1)\lambda_n}{2\Delta_0+\imath\Gamma(1+\lambda_n)} \\ \langle|\beta_\infty|^2\rangle &\equiv \frac{2\pi}{N}\int_0^{2\pi}d\theta\sin\theta\int_0^\infty dr^2\rho(r)|\beta(r,\theta)|^2 = \frac{\Omega_0^2}{N}\sum_{n=0}^{\infty}\frac{(2n+1)\lambda_n}{4\Delta_0^2+\Gamma^2(1+\lambda_n)^2} \ .\end{aligned} \tag{44.159}$$

Example 304 (*Spherical harmonics expansion for a Gaussian density distribution*): The density distribution determines the coefficients λ_n. For a Gaussian distribution $n(r) = N/[(2\pi)^{3/2}\sigma_R^3]e^{-r^2/2\sigma_R^2}$ using the sine kernel,

$$\lambda_n = N\sqrt{\frac{\pi}{2}}\frac{e^{-\sigma^2}}{\sigma}I_{n+1/2}(\sigma^2) \ .$$

For a homogeneous sphere, $n(r) = n_0$, of radius $\sigma = k_0 R$, using the sine kernel [[900], Eq. (18)],

$$\lambda_n = \frac{3N}{2}[j_n^2(\sigma) - j_{n-1}(\sigma)j_{n+1}(\sigma)] \ .$$

44.3.4.1 Expansion of the radiation pressure forces

This allows us to calculate the forces,

$$F_{\mathrm{a}} = -\hbar k_0 \Omega_0 \Gamma \Im\mathfrak{m}\,\langle\beta_\infty\rangle \tag{44.160}$$

$$F_e = -\hbar k_0 \Omega_0^2 \Gamma \sum_{n=0}^{\infty} \frac{2(n+1)\lambda_n\lambda_{n+1}[4\Delta_0^2 + \Gamma^2(1+\lambda_n)(1+\lambda_{n+1})]}{[4\Delta_0^2 + \Gamma^2(1+\lambda_n)(1+\lambda_{n+1})]^2 + 4\Delta^2\Gamma^2(\lambda_{n+1}-\lambda_n)^2} \ .$$

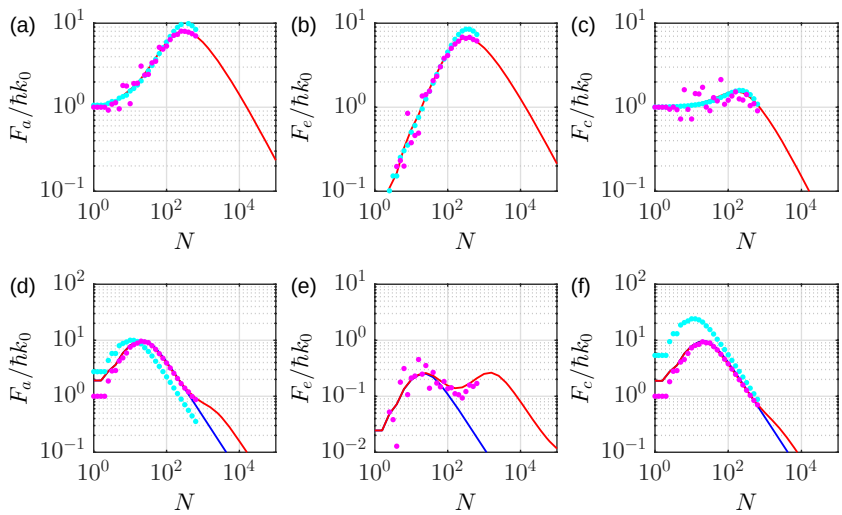

Figure 44.20: (code) (a) Absorption, (b) emission, and (c) total force for a Gaussian cloud with the following parameters: $\sigma = 2$, $\Delta_0 = 10\Gamma$, $\Omega_0 = 0.001\Gamma$, and $\eta = 1$. The magenta dots show a fully numerical calculation for a randomly generated cloud according to formula (44.63). The red lines show a calculation according to the complete formula (44.160). The cyan dots show a calculation assuming timed Dicke states according to (44.82) via numerical calculation of the structure factor according to (44.83) for the same randomly generated cloud as for the full simulation. The blue lines are obtained within the timed Dicke state approximation with structure factors estimated from formula (44.141). (d-f) Same as (a-c) but with $\sigma = 0.2$.

As seen in Fig. 44.20, the results obtained via the complete analytical formula (44.160) coincide with the fully numerical simulations according to formula (44.63). But both disagree with analytical and numerical results obtained within the timed Dicke state approximation.

It is possible to approximate the Bessel function $I_{n+1/2}(\sigma^2)$ and to obtain analytical solutions. The new formula works for $\sigma \gg 1$ and $\eta = 1$ [320],

$$F_{\mathrm{a}} = \frac{\Omega_0^2}{\Gamma}\frac{\sigma^2}{N}\ln\left(1+\frac{N^2\Gamma^2 s_N}{\sigma^2(4\Delta_0^2+\Gamma^2)}\right) = \frac{\Omega_0^2}{4N\Gamma s_\infty}\ln\left(1+\frac{4N^2\Gamma^2 s_\infty s_N}{4\Delta_0^2+\Gamma^2}\right) \tag{44.161}$$

$$F_e = -F_{\mathrm{a}} + \frac{\Omega_0^2}{\Delta_0}\frac{\sigma^2}{N}\arctan\frac{\Delta\Gamma N}{\sigma^2\left(4\Delta_0^2+\Gamma^2+\frac{\Gamma^2 N}{2\sigma^2}\right)} = \frac{\Omega_0^2}{4N\Delta_0 s_\infty}\arctan\frac{4\Delta_0\Gamma N s_\infty}{4\Delta_0^2+\Gamma^2+2\Gamma^2 N s_\infty}$$

$$b_0 = \frac{3N}{\sigma^2}$$

$$s_N = \frac{1}{N} + s_\infty = \frac{1}{N} + \frac{1}{(2\sigma)^2}\ .$$

44.3.4.2 Expansion of the scattered radiation intensity

The incident electric field is ...

The radiated electric field $\hat{\vec{\mathcal{E}}}^{(+)}(\mathbf{r},t)|\psi\rangle$ where $\hat{\vec{\mathcal{E}}}^{(+)}(\mathbf{r},t) = \sum_{\mathbf{k}} \varepsilon_{\mathbf{k}}\hat{a}_{\mathbf{k}} e^{\imath\mathbf{k}\cdot\mathbf{r}-\imath\omega_k t}$,

$$\begin{aligned}\hat{\vec{\mathcal{E}}}^{(+)}(\mathbf{r},t)|\psi\rangle &= \sum_{\mathbf{k}} \varepsilon_{\mathbf{k}}\gamma_{\mathbf{k}}(t) e^{\imath\mathbf{k}\cdot\mathbf{r}-\imath\omega_k t}|0\rangle|1\rangle_{\mathbf{k}} \\ &= -\imath\frac{V_{\mathrm{ph}} g_{k_0}\varepsilon_{k_0}k_0}{4\pi c\sqrt{N}} e^{-\imath\omega_0 t}\sum_{j=1}^{N}\beta_j(t)e^{\imath\mathbf{k}_0\cdot\mathbf{r}_j}\frac{e^{\imath k_0|\mathbf{r}-\mathbf{r}_j|}-e^{-\imath k_0|\mathbf{r}-\mathbf{r}_j|}}{|\mathbf{r}-\mathbf{r}_j|}\ .\end{aligned} \tag{44.162}$$

We neglect the second term, which describes an incoming wave and go to smooth densities. We expand into spherical harmonics and obtain,

$$\hat{\vec{\mathcal{E}}}^{(+)}(\mathbf{r},t)|\psi\rangle = e^{-\imath\omega_0 t}\sum_{n=0}^{\infty}\frac{V_{\mathrm{ph}} g_{k_0}\varepsilon_{k_0}}{c\sqrt{N}}\frac{\lambda_n}{2\Delta_0+\imath\Gamma(1+\lambda_n)}\Omega_0(2n+1)\imath^n h_n^{(1)}(k_0 r)P_n(\cos\theta)\ . \tag{44.163}$$

44.3.4.3 Mie resonances

It is an interesting question whether the maxima found in the curves of Fig. 44.20 can be associated with Mie resonances [106, 868, 81]. To show this we need to apply the formalism of Mie scattering to atomic clouds with the smooth density approximation, where it is described by a continuous refraction index, as studied in Ref. [45]. The Mie formalism had been developed for homogeneous spheres, which can be dielectric or absorptive. For more general refractive index distribution the formalism gets quickly cumbersome [14]. Also Mie resonances are generally though of being conditioned to the existence of sharp boundaries.

The results of Ref. [45] surprisingly show that Mie resonances are expected for parabolic distributions of atoms, as is the case for example for Bose-Einstein condensates in the Thomas-Fermi limit. However, the spectra of Mie resonances exhibit

[14] There is a treatment for parabolic radial variations [506].

much less structure. This is understood by the fact that 'whispering galery' Mie resonances may live on the surface of a sphere whose refraction index drops quadratically to zero, while cavity type Mie resonances may not.

44.3.5 Exercises

44.3.5.1 Ex: Structure coefficient of a homogeneous spherical and of a Gaussian ellipsoidal cloud

a. Calculate the structure coefficient of a homogeneous spherical cloud of radius R, and discuss the limits $qR < 1$ and $qR < 1$. Plot the structure coefficient as a function of θ for various radii R.
b. Calculate the structure coefficient of an ellipsoidal Gaussian cloud having the *rms*-widths σ_z and σ_r, and discuss the limits $qR < 1$ and $qR < 1$. Plot the structure coefficient as a function of θ for various aspect ratios σ_z/σ_ρ.

44.3.5.2 Ex: Force coefficients of a homogeneous spherical and of a Gaussian ellipsoidal cloud

a. Calculate the force coefficients s_N, $\tilde{f}_N$, and f_N from the Eqs. (44.66), Eqs. (44.78), and Eqs. (44.86), respectively, for a homogeneous spherical cloud of radius R.
b. Repeat the calculation of (a) for an ellipsoidal Gaussian cloud having the *rms*-widths σ_z and σ_r.

44.3.5.3 Ex: RDG and Mie

Estimate whether it is possible to distinguish Rayleigh-Debye-Gans scattering from Mie scattering in strontium spectra.

44.3.5.4 Ex: Mie scattering from absorbing spheres

Calculate the force on a homogeneous dielectric sphere as a function of the absorptive and dispersive part of the refraction index [506].

44.3.5.5 Ex: Momentum halos and heating, is the recoil cooperative?

Discuss the question is whether recoil is imparted to individual atoms or to the center-of-mass of the whole cloud.

44.4 Scattering from disordered and dense clouds

44.4.0.1 Vectorial light

The procedure can be generalized to the vectorial case [856, 855, 625], where we get a similar steady-state solution as in (44.37),

$$\boxed{\vec{\beta}_j = (M_{jm})^{-1}\ \hat{\epsilon}\ \tfrac{\imath}{2}\Omega_0(\mathbf{r}_m)}\ , \tag{44.164}$$

only that the dipole moment amplitudes and the incident light field are now considered as vectors. The expression for the matrix M_{jm} is the same as in (44.36). However, the vectorial kernel must be calculated in a different way. Using the abbreviations,

$$\mathbf{r}_{jm} = \mathbf{r}_j - \mathbf{r}_m \quad , \quad r_{jm} = |\mathbf{r}_j - \mathbf{r}_m| + \delta_{jm} \quad , \quad c_{jm} = \frac{\imath}{k_0 r_{jm}} - \frac{1}{(k_0 r_{jm})^2} \ , \tag{44.165}$$

the new vectorial kernel can be written,

$$\gamma^{(3)}_{jm} = \frac{3\gamma_{jm}}{2} \ \frac{(1+c_{jm}) r_{jm}^2 \delta_{mn} - (1+3c_{jm}) \mathbf{r}_{jm} \mathbf{r}_{jm}^{\mathsf{T}}}{r_{jm}^2} \ . \tag{44.166}$$

The steady-state scattered light field and the total field are now,

$$\vec{\mathcal{E}}_{\text{sct}}(\mathbf{r}) = -\frac{\imath\Gamma}{2} \sum_{j=1}^{N} \frac{3\gamma_{oj}(\mathbf{r})}{2} \ \frac{(1+c_{oj}(\mathbf{r})) k_0^2 |\mathbf{r}-\mathbf{r}_j|^2 \vec{\beta}_j - (1+3c_{oj}(\mathbf{r}))[(\mathbf{r}-\mathbf{r}_j)\cdot\vec{\beta}_j](\mathbf{r}-\mathbf{r}_j)}{|\mathbf{r}-\mathbf{r}_j|^2} \ . \tag{44.167}$$

A movie can be assisted at (watch movie).

44.4.0.2 Coherent backscattering

Shining coherent light on a homogeneous cloud, we expect no coherent scattering (exception made of multiple-atom scattering in backward direction, CBS and of fluctuations like speckle patterns). Like radiation trapping, *coherent backscattering* (CBS) is a manifestation of interference in multiple scattering. Just like photon echoes it is *not* due to interatomic correlations. While in radiation trapping this leads to an energy storage inside the atomic cloud connected to destructive interference of the radiation emitted to the cloud's outside, when the coherent beam is reflected at a diffuse scattered, one observes *speckle patterns*. This holds as well for laser light reflection as for atomic wave reflections at a rough surface. See also (watch talk).

The coherent backscattering is an effect of constructive interference between two light scattering paths having the exact time-reversed single scattering sequence,

$$I = \left| \sum_j \vec{\mathcal{E}}_j e^{\imath\varphi_j} \right|^2 = \sum_j \left| \vec{\mathcal{E}}_j \right|^2 + \sum_{j\neq k} \vec{\mathcal{E}}_j \vec{\mathcal{E}}_k^* e^{\imath(\varphi_j - \varphi_k)} \ . \tag{44.168}$$

Only the second term makes speckles. However, the atomic motion smoothes out the speckle pattern in all directions. Only in the presence of correlations in the atomic positions they do not. E.g. in crystals or in the backscattering directions. Therefore, the constructive interference depends strongly on the backscattering angle ϑ. Fast atomic motion internal excitations can dynamically break the time-reversal symmetry of the scattering path, esp. when the laser is close to resonance and the phase delay per scattering process is long. Coherent backscattering is a weak form of *Anderson localization* (also strong localization) of light.

44.4.1 Exercises

44.4.1.1 Ex: The green flash

Discuss whether the '*green flash*' at sunset could be due to *superradiant extinction*. It can last seconds because refraction sweeps the ray through the spectrum (see the

movie *Le rayon vert* by Éric Rohmer).

44.4.1.2 Ex: Faraday effect with vectorial kernel in the coupled dipoles model

Try to simulate the pump laser phase shift and lensing by a small dense cloud by the coupled dipoles model for red and blue detuning. Discuss the influence of rescattering.

44.5 Scattering from periodic structures and photonic bands

Long-range spatial ordering can have a dramatic influence on the propagation of light and the cooperativity of scattering, as we have already pointed out in the introduction of the structure factor in Sec. 44.1.1. This is true for the scattering of electronic waves in crystals. But atomic gases can also be arranged in periodic luminous potentials generated by dipolar forces (introduced in Sec. 43.2.2) exerted by counterpropagating laser beams. Such potentials, called *optical lattices*, can be realized with various geometries in 1, 2 or 3 dimensions.

Periodic structures are usually probed by Bragg scattering. This procedure can be applied to atoms ordered in optical lattices [92, 960, 858, 860]: A test beam with wavevector $\mathbf{k}_{\mathrm{brg}}$ and intensity I_{brg} is irradiated into the atomic cloud, and the power P_s of the first-order reflected beam by Bragg is detected under a solid angle Ω_{s}. Bragg diffraction is an interference effect of radiation patterns emitted by Rayleigh scattering from periodically aligned point-like antennas, the interference being constructive in only specified directions.

For optically dilute lattices, where multiple reflections can be neglected, the imaginary part of the atomic response is sufficient to describe Bragg reflection. For optically dense lattices, multiple reflections between consecutive atomic layers lead to interference phenomena between reflected and transmitted light fields and cause the emergence of frequency bands, inside which the propagation of light waves through the cloud is prohibited. These bands are known as *forbidden photonic bands*.

Photonic bands in optical lattices are interesting for several reasons:

1. They may facilitate the study of the phenomenon of Anderson localization. In fact, Anderson location of light in atomic gases requires very high densities or very large optical cross sections. Now, it is expected that, if the disorder is realized within periodic structures near the Bragg condition, the high density requirement is dramatically relaxed.

2. They modify the local density of states in a way to suppress spontaneous emission.

3. In optical lattices, unlike other systems, the scattering is very weak except when the light is tuned close to atomic resonances. Consequently, the expected forbidden bands are very narrow. This bears the advantage that we can adjust the optical density and tune the photon energy and the Bragg angle (i.e. the

quasi-momentum) independently, which facilitates the mapping of the dispersion relation.

4. Crystals are always hampered by defects in the periodicity [525]. In latest-generation photonic crystals, the typical distance over which coherent light turns diffuse is limited to less than 20 μm. This limitation plays no role in optical lattices, where the delocalized photons rigorously guarantee perfect long-range order, even though the Debye-Waller factor may introduce local disorder.

Spectra of photonic bands in atomic clouds were detected experimentally [821] in one-dimensional structures. Most of the above mentioned effects require omnidirectional photonic bands, but this is technically very difficult, mainly because of the narrow linewidth of the atomic transitions. We will develop this point in the course of this section. We also mention the prediction of forbidden photon bands in Bose condensates [620].

A presentation on this subject is available here (watch talk).

44.5.1 Bragg scattering

44.5.1.1 The reciprocal lattice

Let us consider a periodic *direct lattice* in real three-dimensional space whose elementary cells are located at positions,

$$\mathbf{R_n} = n_1\mathbf{a}_1 + n_2\mathbf{a}_2 + n_3\mathbf{a}_3 \ , \tag{44.169}$$

where $\mathbf{n} = (n_1, n_2, n_3)$ with $n_j \in \mathbb{Z}$ and $\mathbf{a}_j$ are linearly independent vectors describing the distance of two adjacent elementary cells [206]. Functions extended over the lattice, e.g. density distributions, are then supposed to be periodic,

$$n(\mathbf{r}) = n(\mathbf{r} + \mathbf{R_n}) \ , \tag{44.170}$$

such that they can be expanded in Fourier series similarly as we did for the introduction of the Bloch waves in Sec. 26.1,

$$n(\mathbf{r}) = \tfrac{1}{V}\sum_{\mathbf{m}} \rho_{\mathbf{m}} e^{\imath \mathbf{G_m}\cdot\mathbf{r}} \ , \tag{44.171}$$

where $\mathbf{m} = (m_1, m_2, m_3)$ with $m_j \in \mathbb{Z}$. The Fourier coefficients are [15],

$$\rho_{\mathbf{m}} = \int_0^{a_1}\int_0^{a_2}\int_0^{a_3} n(\mathbf{r}) e^{-2\pi\imath(m_1x/a_1+m_2y/a_2+m_3z/a_3)} dxdydz = \int_0^1 n(\tilde{\mathbf{r}}) e^{2\pi\imath\mathbf{m}\cdot\tilde{\mathbf{r}}} d^3\tilde{r} \ . \tag{44.172}$$

The condition (44.170) then yields,

$$n(\mathbf{r}) = \tfrac{1}{V}\sum_{\mathbf{m}} \rho_{\mathbf{m}} e^{\imath \mathbf{G_m}\cdot\mathbf{r}} = \tfrac{1}{V}\sum_{\mathbf{m}} \rho_{\mathbf{m}} e^{\imath \mathbf{G_m}\cdot\mathbf{r}} e^{\imath \mathbf{G_m}\cdot\mathbf{R_n}} = n(\mathbf{r} + \mathbf{R_n}) \ , \tag{44.173}$$

from which we conclude that the vectors $\mathbf{G_n}$ of the reciprocal lattice must satisfy,

$$\tfrac{1}{2\pi}\mathbf{G_m}\cdot\mathbf{R_n} \in \mathbb{Z} \ . \tag{44.174}$$

[15] In crystallography $\rho_{\mathbf{m}}$ is called *structure factor*, but it is not to be confused with the structure factor defined in (44.5).

Example 305 (*The reciprocal lattice in crystallography*): In three dimensions the reciprocal lattice can be constructed by,

$$\mathbf{G_m} = m_1\mathbf{b}_1 + m_2\mathbf{b}_2 + m_3\mathbf{b}_3 \tag{44.175}$$
$$\text{with} \quad \mathbf{b}_1 \equiv \frac{\mathbf{a}_2 \times \mathbf{a}_3}{V} \quad , \quad \mathbf{b}_2 \equiv \frac{\mathbf{a}_3 \times \mathbf{a}}{V} \quad , \quad \mathbf{b}_3 \equiv \frac{\mathbf{a}_1 \times \mathbf{a}_2}{V}$$
$$\text{and} \quad V \equiv \mathbf{a}_1 \cdot (\mathbf{a}_2 \times \mathbf{a}_3) \ .$$

Knowing the density $n_1(\mathbf{r})$ within a single cell, which is often the case when the overlap between the density distributions of adjacent cells is negligible, we can write the global density distribution as,

$$\boxed{n(\mathbf{r}) = n_1(\mathbf{r}) \star \sum_{\mathbf{m}} \delta^{(3)}(\mathbf{r} - \mathbf{R_m})} \ . \tag{44.176}$$

Example 306 (*Elementary cell with Gaussian distribution*): With the ansatz $n_1(\mathbf{r}) = n_0 e^{-r^2/2\bar{r}^2}$, such that $\int n_1(\mathbf{r}) d^3r = n_0(2\pi)^{3/2}\bar{r}^3 = N_1$,

$$\begin{aligned}\rho(\Delta\mathbf{k}) &= \sum_m e^{\imath m \Delta\mathbf{k}\cdot\mathbf{R}} \int_V n_1(\mathbf{r}) e^{\imath\Delta\mathbf{k}\cdot\mathbf{r}} d^3\mathbf{r} \\ &= \frac{1 - e^{\imath N_s \Delta k R}}{1 - e^{\imath \Delta k R}} \times n_0 \int_V e^{-x^2/2\bar{r}^2} e^{-y^2/2\bar{r}^2} e^{-z^2/2\bar{r}^2} e^{\imath\Delta\mathbf{k}\cdot\mathbf{r}} d^3\mathbf{r} \\ &\approx N_s \delta(\Delta k - 2\pi/R) n_0 (2\pi)^{3/2}\bar{r}^3 e^{-6\Delta k^2 \bar{r}^2} = N\delta(\Delta k - 2\pi/R) e^{-6\Delta k_x^2 \bar{r}^2} \ .\end{aligned} \tag{44.177}$$

44.5.1.2 Impact of disorder in one-dimensional lattices

A wave be incident on a lattice in the direction $\mathbf{k}_0$ and scattered into the direction $\mathbf{k}_s \equiv \mathbf{k}_0 + \Delta\mathbf{k}$. The *structure coefficient* $\rho_{\mathbf{m}}$ describes the amplitude of radiation field scattered by the lattice,

$$\rho_{\mathbf{m}} = \int_V \rho(\mathbf{r}) e^{\imath\Delta\mathbf{k}\cdot\mathbf{r}} d^3\mathbf{r} \ . \tag{44.178}$$

Let the density distribution be,

$$n(\mathbf{r}) = \sum_j \rho_j(\mathbf{r}) \star \delta^{(3)}(\mathbf{r} - \mathbf{r}_j) = n_1(\mathbf{r}) \star \sum_j \delta(\mathbf{r} - j\hat{\mathbf{e}}_z \tfrac{\lambda_{\text{dip}}}{2}) \ , \tag{44.179}$$

that is, for perfect periodicity, introducing the density distribution of a unit cell and a $1D$ lattice.

The *Debye-Waller factor* describes the diffusion of the density over the sites of the lattice due to the thermal motion,

$$\begin{aligned}\overline{\rho_{\mathbf{m}}} &= \int_V n_1(\mathbf{r}) e^{\imath\Delta\mathbf{k}\cdot\mathbf{r}} d^3r \sum_j \overline{e^{\imath(j\hat{\mathbf{e}}_z\lambda_{\text{dip}}/2 + \mathbf{u})\Delta\mathbf{k}}} \\ &= f_i \sum_j \overline{e^{\imath(j\hat{\mathbf{e}}_z\lambda_{\text{dip}}/2 + \mathbf{u})\Delta\mathbf{k}}} = \rho_{\mathbf{m}} \overline{e^{\imath\mathbf{u}\Delta\mathbf{k}}} \ ,\end{aligned} \tag{44.180}$$

with

$$\overline{e^{\imath \mathbf{u}\Delta\mathbf{k}}} \approx e^{-|\mathbf{G}|^2\overline{u^2}/6} \ . \tag{44.181}$$

Example 307 (*Optical lattice*): The exponential distribution $e^{-6\Delta k_x^2 \bar{r}^2}$ is called Debye-Waller factor and describes the smearing out of the population over the lattice due to the thermal motion of the atoms. The δ-function sets the wavevector of emitted light. That is, the power of light is only emitted in particular directions given by the Bragg condition. Here, the solid angle $\Delta\Omega_\mathrm{s}$ does not depend on the thermal distribution (as long as the atoms are within the Lamb-Dicke regime), but on the lattice size, which determines the goodness of the approximation of the Airy function (the sum in the above equation) by a Dirac δ-function. The width of the Airy function for a lattice of size w_0 is approximately $\Delta k = 2\sqrt{3}/w_0$. With this the solid angle is,

$$\Delta\Omega_s = \frac{12}{k^2 w_0^2} \ . \tag{44.182}$$

We can also estimate the solid angle from the diameter d of the Gaussian beam at a distance x away from a scattering medium of size w_0,

$$d = w_0\sqrt{1+\left(\frac{\lambda x}{\pi w_0^2}\right)^2} \tag{44.183}$$

$$\Delta\Omega_s = \frac{\pi d^2}{x^2} = \frac{\lambda^2}{\pi w_0^2} = \frac{4\pi}{k^2 w_0^2} \ .$$

The power scattered into this solid angle is,

$$P_s = |A_s|^2 F^2 \Delta\Omega_\mathrm{s} = |A_s|^2 e^{-2W} N^2 \Delta\Omega_\mathrm{s} \ . \tag{44.184}$$

It depends quadratically on the number of atoms. Strictly speaking, the derivation only applies to perfectly ordered lattices, i.e. all the lattice sites are equally occupied. Defects lead to diffuse scattering, i.e. a background of isotropically distributed power at the expense of Bragg scattering. The sharpness of the Bragg radiation distribution remains intact.

We parametrize the density in an optical $1D$ lattice as follows:

$$n_l(\mathbf{r}) = n_0 e^{(-x^2-y^2)/2\sigma_r^2} e^{-z^2/2\sigma_z^2} \tag{44.185}$$

$$n_\mathrm{a}(\mathbf{r}) = \sum_{m=1}^{N_s} \delta(\mathbf{r} - md\hat{\mathbf{e}}_z) \star n_l(\mathbf{r}) = \sum_{m=1}^{N_s} n_l(\mathbf{r} - md\hat{\mathbf{e}}_z) \ .$$

We will show in Exc. 44.5.5.1, that the structure factor is then,

$$\boxed{\mathcal{S}_{\mathbf{k}_0}(\mathbf{k}) = \frac{n_0}{N}\frac{1-e^{\imath N_s d q_z}}{e^{-\imath d q_z}-1} e^{-q_x^2\sigma_r^2/2} e^{-q_y^2\sigma_r^2/2} e^{-q_z^2\sigma_z^2/2}} \ . \tag{44.186}$$

In Exc. 44.5.5.2 we derive the structure factor in spherical coordinates.

Some comments are needed:

1. The structure factor treatment assumes low optical density, which is not necessarily guaranteed when the laser is tuned close to a resonance [858].

2. As the structure factor is independent of the laser detuning, it will not reveal any spectral structure, such as a band-gap or dip due to diffuse scattering. Also, absorption is not incorporated into the model.

44.5.1.3 The structure factor and the Bragg condition

The reciprocal space, obtained by Fourier transformation of the periodic density distribution, also adopts the shape of a periodic lattice. The Bragg condition requires that the difference between the incident and emitted wavevectors, $\Delta\mathbf{k} \equiv \mathbf{k}_s - \mathbf{k}_i$, matches a vector of the reciprocal lattice, $\mathbf{r}_j = j\mathbf{G}$. The Bragg condition is thus automatically incorporated into the structure factor (44.191).

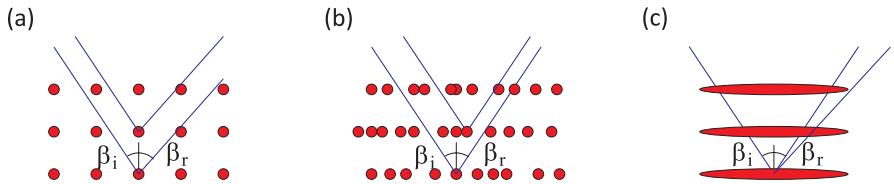

Figure 44.21: Several Bragg lattices.

With the lattice constant $d = \frac{1}{2}\lambda_{\rm dip}$ the interference is constructive when the difference of the paths of two beams reflected by different layers is a multiple of the wavelength,

$$\tfrac{1}{2}\lambda_{\rm dip}\cos\beta_i + \tfrac{1}{2}\lambda_{\rm dip}\cos\beta_s = \lambda \ . \tag{44.187}$$

This is illustrated in Fig. 44.21(a). If the transverse distribution can be considered as homogeneous, as shown in Fig. 44.21(b), we have as second condition,

$$\beta_i = -\beta_s \ . \tag{44.188}$$

That is, the angles of incidence and reflection must be the same, as if we were dealing with a dielectric mirror. In contrast, if the transverse extent of the atomic layers gets smaller (until converging to the limit of a one-dimensional chain of point-scatterers, $\mathbf{G} \equiv 2k_{\rm dip}\hat{\mathbf{e}}_z$), we return to the condition (44.187). In intermediate situations, illustrated in Fig. 44.21(c), and for $\lambda_{\rm dip}\cos\beta_i \neq \lambda$ the reflection angle does not follow any of the relations (44.187) and (44.188).

44.5.1.4 Incoherent background

A finite size or defects in the periodic ordering of the atoms may lead to an isotropic background of Rayleigh-scattered light,

$$\frac{dP_s}{d\Omega_{\rm s}} = |A_s|^2\left[e^{-2W}|F|^2 + N_1N(1-e^{-2W})\right] \ . \tag{44.189}$$

The amount of photons scattered into the *same solid angle* as the one of Bragg scattering is typically for $1D$ lattices,

$$\frac{(1-e^{-2W})N_1N}{e^{-2W}|F|^2} = (e^{2W}-1)\frac{N_1}{N} \approx 0.002 \ . \tag{44.190}$$

However, if we compare the total amount of coherently Bragg-scattered light, we obtain,

$$\frac{(1-e^{-2W})N_1N}{e^{-2W}|F|^2}\frac{4\pi}{d\Omega_{\rm s}} \approx 2500 \ . \tag{44.191}$$

44.5.2 Scattering and transfer matrices

For one-dimensional optical lattices, that is, when the atoms are trapped in a potential dipole generated by a stationary light wave, we may consider applying the transfer matrix formalism developed in Secs. 15.1.7 and 24.3. The premisses of this model are the homogeneity and the infinite extent of the cloud in a direction transverse to the optical axis.

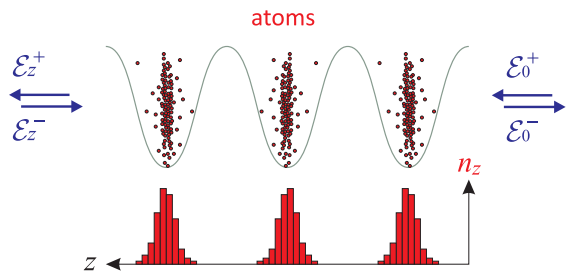

Figure 44.22: Scheme for transfer matrices calculations on $1D$-lattices.

With the notation introduced in Fig. 44.22 we find the equations relating the incident electric fields with the transmitted and reflected ones. If the $\mathcal{T}$-matrix and the $\mathcal{S}$-matrix are defined by [253],

$$\boxed{\begin{pmatrix}\mathcal{E}_z^+\\ \mathcal{E}_0^-\end{pmatrix} = \mathcal{S}\begin{pmatrix}\mathcal{E}_0^+\\ \mathcal{E}_z^-\end{pmatrix} \qquad \text{and} \qquad \begin{pmatrix}\mathcal{E}_z^+\\ \mathcal{E}_z^-\end{pmatrix} = \mathcal{T}\begin{pmatrix}\mathcal{E}_0^+\\ \mathcal{E}_0^-\end{pmatrix}}\ , \tag{44.192}$$

they are connected by,

$$\mathcal{S} = \begin{pmatrix}S_{11} & S_{12}\\ S_{21} & S_{22}\end{pmatrix} = \begin{pmatrix}T_{11} - \frac{T_{12}T_{21}}{T_{22}} & \frac{T_{12}}{T_{22}}\\ -\frac{T_{21}}{T_{22}} & \frac{1}{T_{22}}\end{pmatrix} \tag{44.193}$$

$$\text{and} \qquad \mathcal{T} = \begin{pmatrix}T_{11} & T_{12}\\ T_{21} & T_{22}\end{pmatrix} = \begin{pmatrix}S_{11} - \frac{S_{12}S_{21}}{S_{22}} & \frac{S_{12}}{S_{22}}\\ -\frac{S_{21}}{S_{22}} & \frac{1}{S_{22}}\end{pmatrix}\ .$$

Depending on the boundary conditions the $\mathcal{S}$ and $\mathcal{T}$-matrices can have very different shapes. For example, for classical beam splitters we require *energy conservation* (see Sec. 55.1.1), while for atomic scatterers we require *reciprocity*, meaning that the $\mathcal{S}$ shall not depend on the direction of incidence. On the other hand, energy does not need to be conserved, since it may be dissipated via spontaneous emission.

44.5.2.1 Transfer matrices for propagation in free space

Propagation in free space along the optical axis by a distance d is described by the matrices,

$$\boxed{\mathcal{S}_d = \begin{pmatrix}e^{\imath kd} & 0\\ 0 & e^{\imath kd}\end{pmatrix} \quad , \quad \mathcal{T}_d = \begin{pmatrix}e^{\imath kd} & 0\\ 0 & e^{-\imath kd}\end{pmatrix}}\ . \tag{44.194}$$

The determinants are,

$$\det \mathcal{S}_d = e^{2\imath kd} \neq 1 = \det \mathcal{T}_d\ , \tag{44.195}$$

which shows that only the $\mathcal{T}$-matrix is unitary.

If the incident beam hits the cloud under an angle, $\mathbf{k}\cdot\mathbf{d} = kd\cos\theta = k_z d$, the $\mathcal{T}$-matrix must be generalized [16],

$$\mathcal{T}_d = \begin{pmatrix} e^{\imath\mathbf{k}\cdot\mathbf{d}} & 0 \\ 0 & e^{-\imath\mathbf{k}\cdot\mathbf{d}} \end{pmatrix} . \tag{44.197}$$

44.5.2.2 Transfer matrices for beam splitters

Beam splitters are described by the matrices,

$$\boxed{\mathcal{S}_{\rm bs} = \begin{pmatrix} t_{\rm bs} & -r_{\rm bs} \\ r_{\rm bs} & t_{\rm bs} \end{pmatrix} \quad , \quad \mathcal{T}_{\rm bs} = \begin{pmatrix} t_{\rm bs} + \frac{r_{\rm bs}^2}{t_{\rm bs}} & -\frac{r_{\rm bs}}{t_{\rm bs}} \\ -\frac{r_{\rm bs}}{t_{\rm bs}} & \frac{1}{t_{\rm bs}} \end{pmatrix} = \begin{pmatrix} 1 & -\frac{r_{\rm bs}}{t_{\rm bs}} \\ -\frac{r_{\rm bs}}{t_{\rm bs}} & \frac{1}{t_{\rm bs}} \end{pmatrix}} , \tag{44.198}$$

where the beam splitter transmissity $t_{\rm bs}$ and reflectivity $r_{\rm bs}$ are real numbers. These matrices satisfy the energy conservation condition,

$$\begin{aligned} 1 &= |S_{11}|^2 + |S_{21}|^2 = |t_{\rm bs}|^2 + |r_{\rm bs}|^2 = |S_{12}|^2 + |S_{22}|^2 \\ 0 &= S_{11}S_{12}^* + S_{21}S_{22}^* . \end{aligned} \tag{44.199}$$

Also,

$$\det \mathcal{S}_{\rm bs} = t_{\rm bs}^2 + r_{\rm bs}^2 = 1 = \det \mathcal{T}_{\rm bs} . \tag{44.200}$$

44.5.2.3 Transfer matrices for atomic scatterers

Atomic scatterers are described by the matrices,

$$\boxed{\mathcal{S}_{\rm at} = \begin{pmatrix} t_{\rm at} & r_{\rm at} \\ r_{\rm at} & t_{\rm at} \end{pmatrix} \quad , \quad \mathcal{T}_{\rm at} = \begin{pmatrix} t_{\rm at} - \frac{r_{\rm at}^2}{t_{\rm at}} & \frac{r_{\rm at}}{t_{\rm at}} \\ -\frac{r_{\rm at}}{t_{\rm at}} & \frac{1}{t_{\rm at}} \end{pmatrix}} . \tag{44.201}$$

Note, that t and r may be complex numbers.

For the $\mathcal{S}$-matrix we find,

$$\mathbb{I} = \mathcal{S}_{\rm at}^\dagger \mathcal{S}_{\rm at} = \begin{pmatrix} |t_{\rm at}|^2 + |r_{\rm at}|^2 & t_{\rm at}^* r_{\rm at} + r_{\rm at}^* t_{\rm at} \\ t_{\rm at}^* r_{\rm at} + r_{\rm at}^* t_{\rm at} & |t_{\rm at}|^2 + |r_{\rm at}|^2 \end{pmatrix} . \tag{44.202}$$

Apparently, the $\mathcal{S}$-matrix does not describe a unitary transform unlike the $\mathcal{T}$-matrix, for which we find that by construction,

$$\det \mathcal{S}_{\rm at} = t_{\rm at}^2 - r_{\rm at}^2 \neq 1 = \det \mathcal{T}_{\rm at} . \tag{44.203}$$

To evaluate the components of the scattering matrices, we calculate the reflection coefficient β of a classical polarizable sample from the microscopic polarizability

[16] Furthermore, as shown in [253] Eq. (A10), the single-atom reflection coefficient must be generalized by replacing,

$$\beta \to \frac{\beta}{2}(\cos^{-1}\theta + \cos\theta) . \tag{44.196}$$

However, for $\theta < 60°$ the correction is small.

(15.123) and the optical density (depth) of a thin layer, $n\,\delta z\,\sigma_0$, where σ_0 is the resonant optical cross section,

$$\beta = n\frac{k_{\rm brg}\,\delta z}{2}\frac{\alpha_{\rm pol}}{\varepsilon_0} = \frac{n\,\delta z}{2}\frac{6\pi}{k_{\rm brg}^2}\frac{-1}{\imath + 2\Delta_{\rm brg}/\Gamma} = \frac{n\,\delta z\,\sigma_0}{2}\frac{-1}{\imath + 2\Delta_{\rm brg}/\Gamma}\ . \tag{44.204}$$

We remember that the polarizability is linked to the macroscopic susceptibility $\chi_e = n\alpha_{\rm pol}/\varepsilon_0$ [17]. The reflection and transmission coefficients are now,

$$\boxed{r_{\rm at} = \frac{\imath\beta}{1-\imath\beta} \qquad \text{and} \qquad t_{\rm at} = \frac{1}{1-\imath\beta}}\ . \tag{44.205}$$

Example 308 (*Absorption and spontaneous emission*): The real part of both coefficients is associated to amplitude and the imaginary part to phase,

$$\mathfrak{Re}\,t_{\rm at} = \frac{1}{1+\beta^2} = 1 + \mathfrak{Re}\,r_{\rm at} \quad , \quad \mathfrak{Im}\,r_{\rm at} = \frac{\beta}{1+\beta^2} = \mathfrak{Im}\,t_{\rm at}\ . \tag{44.206}$$

Let us also recalculate the quantities (44.202),

$$|\det \mathcal{S}_{\rm at}| = |t_{\rm at}^2 - r_{\rm at}^2| = \left|\frac{1+\imath\beta}{1-\imath\beta}\right| \stackrel{?}{=} 1 \tag{44.207}$$

$$|t_{\rm at}|^2 + |r_{\rm at}|^2 = \frac{1+\beta\beta^*}{1-\imath\beta+\imath\beta^*+\beta\beta^*} \stackrel{?}{=} 1$$

$$r_{\rm at}t_{\rm at}^* + r_{\rm at}^* t_{\rm at} = \frac{\imath\beta - \imath\beta^*}{1-\imath\beta+\imath\beta^*+\beta\beta^*} \stackrel{?}{=} 0\ .$$

This means that the $\mathcal{S}$-matrix is not unitary, unless the imaginary part of the β-coefficient vanishes. A look at the expression (44.204) tells us, that this comes down to neglecting spontaneous emission, which only is a good assumption far away from resonance,

$$\beta \stackrel{\Delta_{\rm brg}\gg\Gamma}{\longrightarrow} \frac{n\,\delta z\,\sigma_0}{2}\frac{2\Delta_{\rm brg}/\Gamma}{1+4\Delta_{\rm brg}^2/\Gamma^2} \simeq \frac{n\,\delta z\,\sigma_0\Gamma}{4\Delta_{\rm brg}}\ . \tag{44.208}$$

On the other hand, the fact that the $\mathcal{T}$-matrix is always unitary makes a good choice for theoretical calculations.

With the substitution (44.205) we get for the scattering and the transfer matrices,

$$\boxed{\mathcal{S}_\beta = \frac{1}{1-\imath\beta}\begin{pmatrix}1 & \imath\beta\\ \imath\beta & 1\end{pmatrix} \qquad \text{and} \qquad \mathcal{T}_\beta = \begin{pmatrix}1+\imath\beta & \imath\beta\\ -\imath\beta & 1-\imath\beta\end{pmatrix}}\ . \tag{44.209}$$

We note that the employed model is classical, since we describe the gas by a sequence of layers, each characterized by a refractive index. Applying the transfer matrix model, we calculate how the incident and reflected light fields transform from one layer to another. The intrinsically 1D model allows to calculate the reflection, transmission, and absorption by the atomic lattice as a function of the incident laser frequency.

[17] Note the analogy to the calculation (45.34) made for the reflection coefficient of an atom in a cavity in Sec. 45.1.2,

$$\beta = \frac{k}{\pi w^2}\frac{\alpha_{\rm pol}}{\varepsilon_0} = \frac{6}{k^2w^2}\frac{-1}{2\Delta/\Gamma+\imath} = \frac{\sigma_0}{\pi w^2}\frac{-1}{2\Delta/\Gamma+\imath}\ .$$

44.5.2.4 Concatenating transfer matrices

Transfer matrices for propagation through a structure, such as the passage through an interface between media with different reflective indices or absorption by a homogeneous atomic gas, are obtained by concatenating the matrices. For example, the propagation of the incident beam through the layer, such that the transfer matrix for passing the beam through an atomic layer is,

$$\mathcal{T} = \mathcal{T}_\beta \, \mathcal{T}_d \ . \tag{44.210}$$

For a periodic structure with N_s identical layers we must obviously concatenate the matrices like $\mathcal{T}^{N_s}$.

The reflection coefficient is obtained from the $\mathcal{S}$-matrix,

$$\begin{pmatrix} \mathcal{E}_z^+ \\ \mathcal{E}_0^- \end{pmatrix} = \mathcal{S} \begin{pmatrix} \mathcal{E}_0^+ \\ \mathcal{E}_z^- \end{pmatrix} = \begin{pmatrix} T_{11} - \frac{T_{12}T_{21}}{T_{22}} & \frac{T_{12}}{T_{22}} \\ -\frac{T_{21}}{T_{22}} & \frac{1}{T_{22}} \end{pmatrix} \begin{pmatrix} \mathcal{E}_0^+ \\ \mathcal{E}_z^- \end{pmatrix} \ . \tag{44.211}$$

If no beam enters the structure form the reverse side, $\mathcal{E}_z^- = 0$,

$$\begin{pmatrix} \mathcal{E}_z^+ \\ \mathcal{E}_0^- \end{pmatrix} \longrightarrow \begin{pmatrix} \left(T_{11} - \frac{T_{12}T_{21}}{T_{22}}\right) \mathcal{E}_0^+ \\ -\frac{T_{21}}{T_{22}} \mathcal{E}_0^+ \end{pmatrix} \ . \tag{44.212}$$

Hence, the total reflectivity and transmissivity of the structure are,

$$\boxed{t \equiv \frac{\mathcal{E}_z^+}{\mathcal{E}_0^+} = T_{11} - \frac{T_{12}T_{21}}{T_{22}}} \quad , \quad r \equiv \frac{\mathcal{E}_0^-}{\mathcal{E}_0^+} = -\frac{T_{21}}{T_{22}} \ . \tag{44.213}$$

and can be evaluated numerically or analytically [253].

44.5.2.5 Intensity distribution and within a structure

The transfer matrix formalism outlined in Sec. 44.5.2 not only allows to calculate the overall reflectivity of a structure, but also the local intensity $I \propto |\mathcal{E}_\mathrm{a}^+ + \mathcal{E}_\mathrm{a}^-|^2$ at a point $z = a$ inside a structure assumed to extend between an input at $z = 0$ and an output at $z = b$ of the optical axis [859]. To calculate this intensity, we first derive the scattering matrix for the total structure,

$$\begin{pmatrix} \mathcal{E}_b^+ \\ \mathcal{E}_b^- \end{pmatrix} = \mathcal{T} \begin{pmatrix} \mathcal{E}_0^+ \\ \mathcal{E}_0^- \end{pmatrix} \qquad \Longleftrightarrow \qquad \begin{pmatrix} \mathcal{E}_b^+ \\ \mathcal{E}_0^- \end{pmatrix} = \mathcal{S} \begin{pmatrix} \mathcal{E}_0^+ \\ \mathcal{E}_b^- \end{pmatrix} \ , \tag{44.214}$$

and then set up the transfer matrix $\mathcal{T}^{(a)}$ from $z = 0$ to $z = a$ with $0 < a < b$ and obtain the intensity as,

$$\begin{pmatrix} \mathcal{E}_\mathrm{a}^+ \\ \mathcal{E}_\mathrm{a}^- \end{pmatrix} = \mathcal{T}^{(a)} \begin{pmatrix} \mathcal{E}_0^+ \\ \mathcal{E}_0^- \end{pmatrix} = \mathcal{T}^{(a)} \begin{pmatrix} \mathcal{E}_0^+ \\ 0 \end{pmatrix} + \mathcal{T}^{(a)} \begin{pmatrix} 0 \\ \mathcal{E}_0^- \end{pmatrix} = \mathcal{X}^{(a)} \begin{pmatrix} \mathcal{E}_0^+ \\ \mathcal{E}_b^- \end{pmatrix} \ , \tag{44.215}$$

defining

$$\mathcal{X}^{(a)} \equiv \mathcal{T}^{(a)} \left[\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \mathcal{S} \right] \ . \tag{44.216}$$

In the last step we used (44.211) and exploited the boundary condition that, $\mathcal{E}_0^+$ being preset, there is no reflection of light behind the structure. Explicitly,

$$\begin{pmatrix} \mathcal{E}_{\rm a}^+ \\ \mathcal{E}_{\rm a}^- \end{pmatrix} = \mathcal{T}^{(a)} \begin{pmatrix} 1 \\ -\mathcal{T}_{21}/\mathcal{T}_{22} \end{pmatrix} \mathcal{E}_0^+ \ . \tag{44.217}$$

The sum gives,

$$\boxed{\mathcal{E}_{\rm a}^+ + \mathcal{E}_{\rm a}^- = \left(\mathcal{T}_{11}^{(a)} + \mathcal{T}_{21}^{(a)} - \frac{\mathcal{T}_{21}}{\mathcal{T}_{22}} (\mathcal{T}_{12}^{(a)} + \mathcal{T}_{22}^{(a)}) \right) \mathcal{E}_0^+} \ . \tag{44.218}$$

Fig. 44.23 shows as an example the intensity distribution inside an optical lattice.

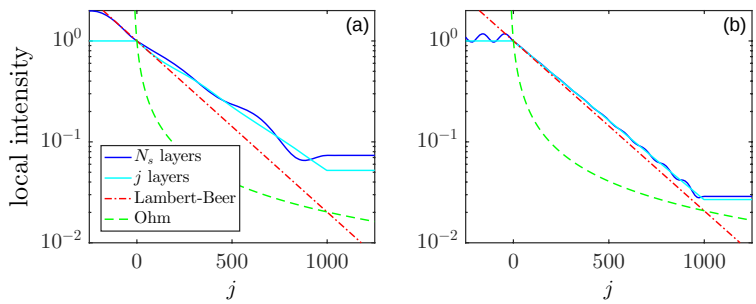

Figure 44.23: (code) The intensity decreases exponentially over a infinite lattice. For a finite lattice (here $N_s = 1000$), the intensity approaches a constant value at the end of the lattice. The graphs show in solid blue the intensity evaluated at each lattice site, in dash-dotted red the exponential decay due to absorption in a homogeneous cloud (Lambert-Beer law), in dashed green the hyperbolic decay following Ohm's law (calibrated to Lambert Beer's law), in cyan the transmission at the end of a lattice of j layers. The parameters are $\Delta_{\rm a} = \Gamma/2$, average density $n = 10^{11}$ cm^{-3}, and for panel (a) $\Delta_{\rm lat} = 5 \cdot 10^8 \Gamma$ while for panel (b) $\Delta_{\rm lat} = 5 \cdot 10^8 \Gamma$.

44.5.2.6 Transfer matrices for optical cavities

The transfer matrix formalism can be applied to obtain the transmission and reflection spectra of optical cavities (see Exc. 15.3.7.19). It can be extended to ring cavities and, in the presence of (non-saturated) atoms interacting with the cavity, it correctly describes normal mode splitting [202].

44.5.3 Transfer matrices for optical lattices

A particularly interesting application if the transfer matrix formalism are optical lattices, which we will treat in the following.

44.5.3.1 Limit of optically dilute clouds

For optically dilute clouds, $r \ll 1$, we expect standard Bragg scattering. The atomic transfer matrix (44.209) can be approximated by,

$$\mathcal{T}_\beta = \begin{pmatrix} 1 & \imath\beta \\ -\imath\beta & 1 \end{pmatrix} , \tag{44.219}$$

so that we find for the single-layer and transfer matrix,

$$\boxed{\mathcal{T} = \mathcal{T}_\beta \mathcal{T}_d \simeq \begin{pmatrix} e^{\imath k_z d} & \imath\beta e^{-\imath k_z d} \\ -\imath\beta e^{\imath k_z d} & e^{-\imath k_z d} \end{pmatrix}} . \tag{44.220}$$

Near the Bragg angle we have $\cos\theta \simeq \cos\theta_{\rm brg} = \lambda_{\rm sp}/\lambda_{\rm dip}$ and near resonance we have $2\pi/k = \lambda \simeq \lambda_{\rm sp}$, so that, with $d = \lambda_{\rm dip}/2$, we obtain $k_z d \simeq \pi$ and,

$$\mathcal{T}^{N_s} \simeq \begin{pmatrix} e^{\imath\pi} & \imath\beta e^{-\imath\pi} \\ -\imath\beta e^{\imath\pi} & e^{-\imath\pi} \end{pmatrix}^{N_s} = \begin{pmatrix} -1 & -\imath\beta \\ \imath\beta & -1 \end{pmatrix}^{N_s} = (-1)^{N_s} \begin{pmatrix} 1 & N_s\imath\beta \\ -N_s\imath\beta & 1 \end{pmatrix} , \tag{44.221}$$

which we will verify in Exc. 44.5.5.3. The total reflectivity being $r_{N_s} \simeq N_s\imath\beta$, we get the reflection,

$$|r_{N_s}|^2 \simeq \frac{N_s^2 \beta_{\rm sp}^2 \Gamma_{\rm sp}^2}{4\Delta^2 + \Gamma_{\rm sp}^2} . \tag{44.222}$$

Thus, the profile of the reflection curve is Lorentzian.

Example 309 (*Estimation of the reflectivity in the dilute cloud limit*): In resonance we estimate for typical experimental values $N_s = 1000$, $n = 10^{17}\,{\rm cm}^3$, $\lambda_{\rm dip} = 797\,{\rm nm}$, and $\Lambda_{\rm brg} = 422\,{\rm nm}$,

$$|r_{N_s}| = N_s \frac{nd\sigma_{\rm sp}}{2} = N_s n \lambda_{\rm dip} \frac{3\lambda_{\rm sp}^2}{8\pi} \approx 1.7 .$$

The high reflectivity is not physical, which shows that the assumption of optically diluted clouds is not necessarily satisfied in experimentally achievable parameter regimes. On the contrary we can expect to reach regimes, where the clouds are optically so dense, that photonic bands can be expected. That is, if the goal is to detect a band gap, it helps to have (1) many layers filled with atoms, (2) high atomic densities per layer.

44.5.3.2 Limit of optically dense clouds

In order to obtain analytical expressions in the regime of dense clouds, we write the transfer matrix for a single layer, using the expressions (44.209) and (44.211), as follows [253],

$$\boxed{\mathcal{T} = \mathcal{T}_\beta \mathcal{T}_d = \begin{pmatrix} (1+\imath\beta)e^{\imath\mathbf{k}\cdot\mathbf{d}} & \imath\beta e^{-\imath\mathbf{k}\cdot\mathbf{d}} \\ -\imath\beta e^{\imath\mathbf{k}\cdot\mathbf{d}} & (1-\imath\beta)e^{-\imath\mathbf{k}\cdot\mathbf{d}} \end{pmatrix}} . \tag{44.223}$$

Given that $\det\mathcal{T} = 1$, the matrix represents a unitary transformation and the eigenvalues can be cast into the form $e^{\pm\imath\phi}$. Letting,

$$\cos\Theta \equiv \tfrac{1}{2}{\rm Tr}\ \mathcal{T} = \cos k_z d - \beta \sin k_z d , \tag{44.224}$$

we can write the matrix,

$$\mathcal{T} = \mathbb{I}\cos\Theta + \imath A \sin\Theta = e^{\imath\Theta A} \tag{44.225}$$

with

$$A = \frac{1}{\sin\Theta}\begin{pmatrix} \beta\cos k_z d + \sin k_z d & \beta e^{-\imath k_z d} \\ -\beta e^{\imath k_z d} & -\beta\cos k_z d - \sin k_z d \end{pmatrix} \tag{44.226}$$

The eigenvectors of $\mathcal{T}$, and therefore of each power of $\mathcal{T}$, are *Bloch states of the periodic lattice*. We verify in Exc. 44.5.5.4, that the following relationships are satisfied,

$$\mathrm{Tr}\ A = 0 \quad , \quad A^2 = 1 \quad , \quad \det A = 1\ . \tag{44.227}$$

The eigenvalues of $A\sin\Theta$ are $\lambda_A \pm 1$. The eigenvalues of the transfer matrix are,

$$\begin{aligned} \lambda &= \cos k_z d - \beta\sin k_z d \pm \imath\sqrt{1-(\cos k_z d - \beta\sin k_z d)^2} = \cos\Theta \pm \imath\sin\Theta \\ &= e^{\pm\imath\arccos(\cos k_z d - \beta\sin k_z d)} = e^{\pm\imath\Theta}\ . \end{aligned} \tag{44.228}$$

This decomposition allows us to calculate the transfer matrix for a succession of N_s layers. We get,

$$\begin{aligned} \mathcal{T}^{N_s} &= e^{\imath N_s\Theta A} = \mathbb{I}\cos(N_s\Theta) + \imath A\sin(N_s\Theta) \\ &= \mathbb{I}\cos\left[N_s\arccos(\cos k_z d - \zeta\sin k_z d)\right] + \imath A\sin\left[N_s\arccos(\cos k_z d - \zeta\sin k_z d)\right]\ , \end{aligned} \tag{44.229}$$

which gives us the reflection coefficient,

$$\begin{aligned} r_\mu &= \frac{(\mathcal{T}^{N_s})_{12}}{(\mathcal{T}^{N_s})_{22}} = \frac{\imath\sin(\mu\Theta)\mathcal{T}_{12}}{\cos(N_s\Theta) + \imath\sin(\mu\Theta)\mathcal{T}_{22}} \\ &= \frac{-\imath\beta e^{\imath k_z d}}{\sin\Theta\cot(N_s\Theta) - \imath\sin k_z d - \imath\beta\cos k_z d}\ . \end{aligned} \tag{44.230}$$

This is the final result. Near the Bragg angle, $\cos\Theta \simeq 1$, we have,

$$\begin{aligned} r_{N_s} &= \frac{\imath\beta}{\sin\Theta\cot(N_s\Theta) - \imath\beta} \simeq \frac{\imath N_s\zeta}{1 - \imath N_s\beta} \\ |r_{N_s}|^2 &\simeq \frac{N_s^2\beta_{\rm sp}^2\Gamma_{\rm sp}^2}{4\Delta^2 + (1+n\beta_{\rm sp}^2)\Gamma_{\rm sp}^2}\ . \end{aligned} \tag{44.231}$$

The intensity reflection profile, therefore, is a Lorentzian also in the limit of thick clouds. The additional condition for the occurrence of prohibited photonic bands is a large number of atomic layers, $N_s \gg 1$. We note that the model is an extension of the *Kronig-Penney model* introduced in Sec. 26.1.3.

44.5.3.3 Application of transfer matrices to real $1D$ optical lattices

The analytical treatment shown in the previous sections does not take account of possible lattice imperfections, since the atomic layers are assumed to be identical, infinitely thin, immobile and located at fixed periodic distances. Realistic optical lattices are different for several reasons:

1. Atomic clouds are not perfectly localized in ultra-thin layers, but distributed in a Gaussian way as a function of the cloud's temperature. The Debye-Waller factor (44.180) describes the impact of this distribution on the Bragg model.

2. The atoms are in thermal motion causing an inhomogeneous Doppler shift and are affected by the photonic recoil received in each scattering process. This causes a broadening of the reflection profiles and decreases the interference capability.

3. The number of atoms per layer may vary. Also, the global extent of the cloud is not infinite, that is, we have N_s layers filled with atoms with a gradual decrease at the confines of the cloud.

4. The atoms trapped in the optical potential are subjected to a dynamic Stark shift [18] causing an inhomogeneous broadening of the atomic transition as well.

5. The periodicity of the lattice is slightly modified because the refractive index experienced by the laser beams creating the dipole potential locally depends on the atomic density concentrated in the lattice's anti-nodes. The consequence is a local decrease of the lattice constant d [19].

All of the aforementioned imperfections may be included in a numerical treatment of the transfer matrices. For this we subdivide the atomic cloud into sufficiently thin sublayers, as shown in Fig. 44.22. Each sublayer, being characterized by its own 2D atomic density and its own shift from resonance, is described by an individual transfer matrix. The matrices are concatenated, and the reflection profile is computed, as shown in the expression (44.213) [859]. Fig. 44.24 shows a numerical calculation of a photonic band in a rubidium optical lattice. The experimental variables are the incidence angle θ of the probe laser and its tuning Δ from a transition $\lambda_{\rm sp}$. Δ determines σ and β via the polarizability (44.193) [20] and thus governs the propagation of light inside the layers. θ determines $k_z d$ and thus probes the periodicity *between* the layers.

Depending on the atomic density we can identify different behaviors [21]:

1. At the limit of thin lattices, we do not expect multiple scattering. The absorptive (imaginary) part of polarizability dominates, $\beta \approx \mathfrak{Im}\,\beta$. Thus, the reflection coefficient is almost real, $re^{\imath\phi} \approx |r|$, the phase shifts are negligible, the profile of the reflection spectrum is symmetric. In this scheme, the interference of the radiation patterns of individual atoms is destructive in all directions, except

[18] Or 'light-shift', see Exc. 39.4.4.13.

[19] More correctly: If between $\lambda_{\rm dip}$ and λ_{D1} a photonic band were created for the laser beams that produce the optical lattice [253, 959], these beams would be reflected without being able to penetrate the lattice. In fact, the periodicity changes in such a way, that the frequency of the beams is at the edge of the band gap. Deutsch *et al.* [253] showed that a self-consistent solution gives the modified lattice constant,

$$d' = \frac{\lambda_{\rm dip}}{2}\left[1 + \frac{\phi_{\rm dip}}{\pi}(1 - {\rm sign}\Delta_{\rm dip})\right] ,$$

where $\phi_{\rm dip} = \arctan\left(-\frac{\Delta_{\rm dip}}{\Gamma} nd\ \sigma_{D1}(\Delta_{\rm dip})\right)$.

[20] Δ also enters $k_z d$, but so weakly, that we can despise this dependence.

[21] The densities are assumed to be sufficiently low to eliminate collective effects such as, for example, superradiance.

under the Bragg angle. There are losses caused by scattering in non-paraxial modes. They are also due to elastic Rayleigh scattering but, because of the finite Debye-Waller factor, the radiation becomes diffuse and incoherent.

2. At the limit of thick lattices, we have multiple scattering. The (real) dispersive part of the polarizability is $\beta \approx \mathfrak{Re}\,\beta$. Thus, absorption is suppressed, we observe large phase shifts and the reflection spectrum profile is asymmetric. Multiple beam interference gives rise to global scattering.

Physically, the set parameters consistent of the quasi-momentum and the energy of the Bloch wave, (Θ, Δ), is more relevant because it allows analyzing the *dispersion relation* [22]. We observe the existence of energies Δ, where the real part of the quasi-momentum vanishes (modulo π). The 3D representation in Fig. 44.24(e) illustrates the occurrence of an *avoided crossing* due to the band gap at the edge of the Brillouin zone.

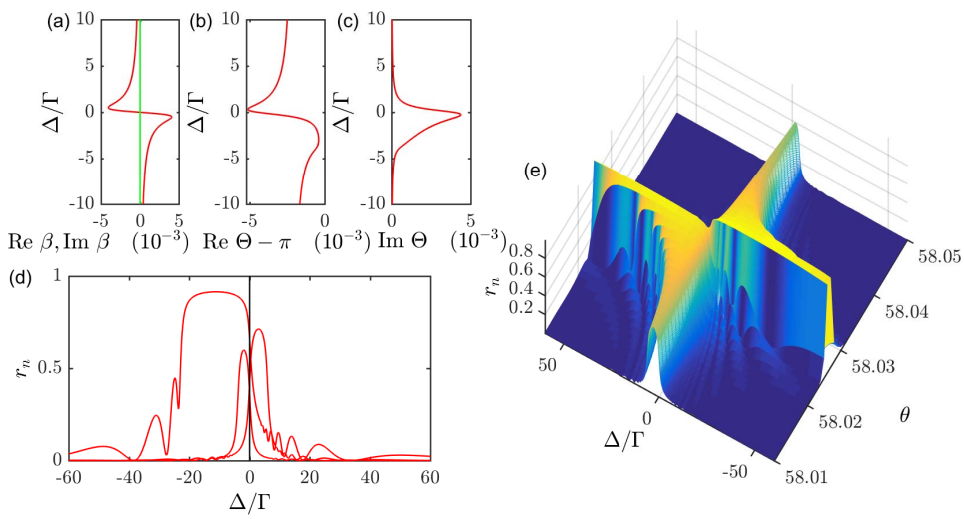

Figure 44.24: (code) Numerical calculation of a photonic band in a 1D optical lattice (wavelength $\Lambda_{\rm dip} = 797$ nm) far-tuned from the rubidium D1 transition ($\lambda_{D1} = 795\,$nm). The probe laser exciting the Bragg resonance is tuned close to the rubidium resonance at $\lambda_{\rm sp} = 422$ nm. We assume atomic densities of $n = 4 \cdot 10^{11}\,$cm^{-3} and $N_s = 40000$ atomic layers. (a) Real and imaginary parts of the reflection index ($\propto$ polarizability) as a function of detuning Δ. (b,c) Real and imaginary parts of the quasi-momentum (x-axis) as a function of the detuning Δ. (d,e) 2D and 3D representation of the reflection coefficient.

In fact, Bragg resonances can be understood in reciprocal space as reflections at the edges of the Brillouin zone. Through the angle of incidence of the injected light beam, we adjust the quasi-momentum. The frequency of the light beam determines the energy. The forbidden photonic bands are caused by the formation of an energetic gap in the dispersion relation induced by the interaction of the atoms with the optical lattice.

[22] We note, that Θ via the relation (44.224) of the angle of incidence θ, but only weakly of the energy Δ.

44.5.3.4 LDOS and the suppression of spontaneous emission in forbidden photonic bands

The *local density of states* (LDOS) in a photonic band can be evaluated from [933, 354],

$$N(\omega) = 2\omega \sum_{\mathbf{k}} \delta(\omega^2 - \omega_{\mathbf{k}}^2) \ . \tag{44.232}$$

William found out:

$$k_{\text{eff}} = \frac{d\phi}{dz} \ , \tag{44.233}$$

with $\phi = \arctan(\mathfrak{Im}\,\mathcal{E}/\mathfrak{Re}\,\mathcal{E})$. The $\mathcal{E}$-field between two layers can be calculated using transfer matrices. The density of the states is given as the derivative of the inverse function of the dispersion relation:

$$N(\omega) = \frac{dk_{\text{eff}}(\omega)}{d\omega} \ . \tag{44.234}$$

The decrease in the LDOS is equivalent to the suppression of spontaneous emission [23], that is, an excited atom located inside the lattice will not be able to emit its photon. This is the condition for a forbidden photonic band to be *omnidirectional*. Omnidirectional bands need three-dimensional lattices. Nevertheless, the reduction of the spontaneous emission rate has already been observed in [422, 980], which can be interpreted as $1D$ photonic crystals.

44.5.3.5 Impurities

The formalism allows for the calculation of the impact of localized defects in numerical simulations. For example, it is instructive to look at the intensity profile along the structure in the presence of a localized lattice defect. In Fig. 44.25(c) we observe an intensity peak located at the 100-th atomic layer, exactly where the defect was introduced. This peak corresponds to a localized evanescent wave. Photons can not propagate freely through the lattice: they prefer to tunnel between lattice defects the rather than propagate by radiation.

The curves (a-b) of Fig. 44.25 illustrate how an empty photonic band fills up with localized states with well-defined energies when noise is added to the periodicity of the lattice. This situation is similar to that in semi-conductors doped by donor and acceptor states.

44.5.4 Photonic bands in the Bloch and the coupled dipoles models

The transfer matrix model is limited in several respects:

1. Firstly, being intrinsically 1D, the model does not apply to 2D or 3D lattices.
2. Also, it does not incorporate the possibility of transverse disorder or effects linked to the finite transverse extension of the atomic layers, for example, the limitation of the number of layers participating in multiple reflection ('walk-off') [860] or the impact of an imperfect mode matching [858].

[23] For the same reason, resonant dipole-dipole interactions are suppressed [547].

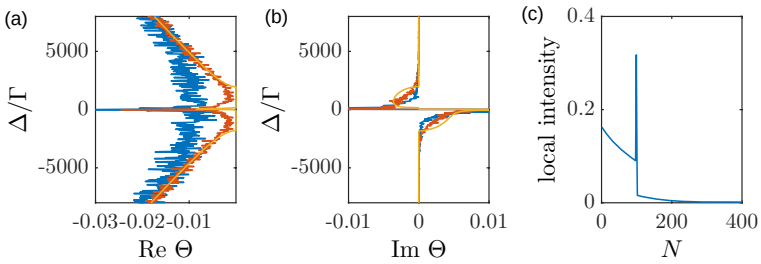

Figure 44.25: (code) (a,b) Dispersion relation as in Fig. 44.24, but in the presence of randomly distributed defects. (c) Intensity profile along the lattice with a defect located in the 100^{esima} atomic layer.

In contrast, the coupled dipoles model offers several advantages. An optical lattice is, after all, nothing more than a periodically ordered diluted sample of atoms. Hence, we can apply the coupled dipoles model introduced in Sec. 44.1.2 [807, 806]. The advantages of this model are its applicability to 3D systems and finite and disordered lattices. It also allows the inclusion of all kinds of inhomogeneities such as, for example, the spatial intensity distribution of a focused incident laser, or the deviation of the laser beam penetrating an atomic cloud due to refraction. On the other hand, the model only lends itself to heavy numerical simulations, limiting it to some 10000 atoms.

44.5.4.1 The Bloch model and forbidden electronic bands

The *Bloch model* is another model to describe 3D periodic systems [28]. It was introduced in Chp. 26 for 1D optical lattices. Its disadvantages are that it supposes infinite lattices and the absence of defects.

The Bloch model is commonly used to describe the scattering of electron waves in a solid, where the band gap originates from the Coulomb interaction of the electron with the atoms of the solid crystal. In contrast, in photonic crystals, the modes with high (low) frequency ω concentrate their energy in spatial regions with low (high) dielectric index ϵ. Close to geometric (Mie) resonances this causes a repulsion in the density distribution of photonic states, and the opening of a gap separating high frequency bands (air bands) from low frequency bands.

In optical lattices the photons interact with the atomic resonances. Photons and electrons are distinguished by their different dispersion relations and by the fact that electronic waves are scalar and photonic waves are vectorial. The electrons of a crystal are bound to an energy surface and follow the lines of the dispersion relation without leaving the metal. In contrast, photons are usually injected into the structure, which gives an additional degree of freedom. Therefore, any point in the phase diagram can be reached and the dispersion relation only informs, where at which point the transmission is stronger.

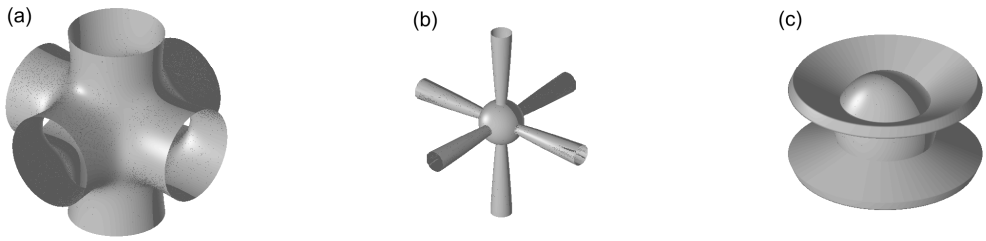

Figure 44.26: Attempt of an artistic illustration of the isoenergetic surfaces for electrons in a metal (left), photons in a 3D optical lattice (center), and photons in a 1D optical lattice (right). The interaction of atoms with the lattice is much weaker than the interaction of electrons with the metal, except close to resonances. Therefore, photonic bands are much narrower than electronic bands.

Table 44.2: Comparison between band gaps photonic crystals and metals.

	photonic crystal	metal
lattice structure	atoms in a stationary wave	atoms in a crystal
particles	photons	electrons in a metal
equations of motion	Maxwell	Schrödinger
dispersion relation	$\hbar k/c$	$\hbar k^2/2m$
tune	Bragg angle and frequency	voltage
band gap origin	$\mathfrak{Im}\,\alpha$ absorption by atoms	e^- interacting with the atomic nuclei
band gap width	$< \omega_0 - \omega_{\text{dip}}$	interaction energy

44.5.5 Exercises

44.5.5.1 Ex: Structure coefficient of a 1D lattice

Calculate the structure coefficient of the density distribution (44.185) and the square $|S_{\mathbf{k}_0}(\mathbf{k})|^2$.

44.5.5.2 Ex: Structure coefficient in spherical coordinates

Write the structure coefficient (44.185) in spherical coordinates.

44.5.5.3 Ex: Reflection in the dilute cloud limit

Verify the calculation (44.229).

44.5.5.4 Ex: Reflection in the dense cloud limit

Verify the representation (44.225).

44.5.5.5 Ex: Photonic band spectra

Plot the 1D-photonic band gap spectrum in a standing wave as a function of Δ_{pr} and n.

44.5.5.6 Ex: Intensity drop inside photonic bands

Plot the intensity of the probe on its passage through the 1D optical lattice.

44.5.5.7 Ex: Intensity drop inside photonic bands in the presence of disorder

Simulate the intensity of the probe on its passage through the 1D optical lattice inthe presence of disorder.

44.5.5.8 Ex: Photonic bands with sidebands

Plot the intensity of the probe on its passage through the 1D optical lattice as a function of detuning in the presence of modulation sidebands.

44.5.5.9 Ex: Photonic bands versus absorption

Compare the signatures of band gaps with absorption.

44.5.5.10 Ex: Structure of a diamond lattice

A geometric configuration of point-like scatterers that can exhibit a broad omnidirectional photonic bandgap is the one of a diamond lattice [181, 812, 28]. In this exercise we will study such a diamond-shaped lattice.
a. Produce a geometric representation of the primitive cell and a Wigner-Seitz cell.
b. Study the optical lattice generated by the following configuration of incident lasers,

$$\mathbf{k}_0 = \frac{\pi}{a}(0,-2,-1) \quad , \quad \mathbf{k}_1 = \frac{\pi}{a}(2,0,1) \quad , \quad \mathbf{k}_2 = \frac{\pi}{a}(0,2,-1) \quad , \quad \mathbf{k}_3 = \frac{\pi}{a}(-2,0,1)$$

with $k_{laser} = \omega_{laser}/c = \sqrt{5}\pi/a$.
c. Calculate the forbidden band according to [181, 812, 28].

Chapter 45

Individual atoms in optical cavities

So far we have considered the coherent dynamics between atoms and radiation fields in free space, and we extended the theory to take into account the dissipative coupling to the electromagnetic vacuum by spontaneous emission and atomic motion. The vacuum represents a homogeneous and isotropic reservoir characterized by a continuous white energy spectrum. The situation changes completely when we place the atom inside an optical cavity which breaks the translational and rotational symmetries and imprints a resonance structure into the density of photonic states. Obviously, the cavity will profoundly change the atomic coupling to the electromagnetic vacuum, and hence the way in which the atom reacts to incident light, as much with respect to light scattering as with respect to optical forces.

In this chapter we analyze the coupled dynamics of atoms interacting with the optical field modes of a cavity pumped by incident laser beams. We first concentrate in Sec. 38.2 on empty cavities. Then in Sec. 45.1 we turn our attention to the impact of atoms on the cavity dynamics, in particular its transmission spectrum. Cooperative and collective effects that may be induced by cavities will be discussed in Chps. 47 and 48.

45.1 Interaction of a cavity with one atom

In Sec. 40.1 we have shown how to describe the dynamics of a *single two-level atom* driven by a quantized electromagnetic field and embedded in an electromagnetic vacuum under the assumption that the driving field be a plane wave and the vacuum be isotropic. In the following, we want to relax these conditions. We generalize Eq. (37.7) replacing the plane wave $e^{\imath\mathbf{k}\cdot\mathbf{r}}$ by a mode function $u_{\mathbf{k}}(\mathbf{r})$ and allowing the coupling constant (40.8) $g_{\mathbf{k}}$ to depend on $\mathbf{k}$. Such a situation corresponds to placing the atom inside an optical cavity whose macroscopic boundary conditions create a cooperative environment for the atom. We note that the role of the cavity can be understood as generating mirror images with which the atom interacts. Furthermore, both the atomic excitation and the radiation fields may decay. On the other hand, we restrict to non-interacting atoms, that is, free atoms or atoms trapped in external potentials that only interact with each other via re-scattering of an incident radiation field, i.e. no collisions and no properties requiring symmetrization of their wavefunctions.

In Sec. 45.1.1 we study a single atom in a cooperative environment (e.g. a cavity).

In particular, we will find that spontaneous emission is affected by the presence of a cavity. A wider discussion of scattering from correlated atoms and of how cavities can generate correlations is postponed to Sec. 46.1. Then, in Sec. 45.1.2 we will introduce some parameters characterizing the interaction between atoms and cavities. In particular, we will relate the important notions of the *cooperativity* of several atoms and the structure factor for light scattering introduced in 44.1.1 with the cavity-to-free space scattering ratio, the finesse and the density-of-states of a cavity, simply by pointing out that a cavity multiplies the number of atoms interacting with a light mode by the number of its mirror images. In Secs. 45.1.3, 45.1.4, and 45.1.6 we study the Hamiltonian governing the dynamics of a cavity mode interacting with a single immobile atom emphasizing the phenomenon of normal mode splitting. In Sec. 45.1.5 we simplify the equations of motion by adiabatically eliminating the internal atomic degree of freedom. Finally, in Secs. 45.1.7 and 45.1.8 we study the impact of the atomic center-of-mass degree of freedom (position and velocity) on the dynamics of the cavity fields. The discussion of backaction of the cavity fields on the atomic motion is postponed to Chp. 48.

45.1.1 Spontaneous emission in a cooperative environment

45.1.1.1 Atoms in a cooperative environment

The quantization of the electromagnetic field has been presented in Sec. 37.1.1 for the case of plane wave radiation modes. In the following, we want to generalize the treatment to arbitrary field modes characterized by mode functions $\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r})$ labeled by a wavevector and a polarization. These are classical vector functions satisfying the vector Helmholtz equation and the transversality condition,

$$[\nabla^2 + k_\lambda^2]\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r}) = 0 \qquad \text{and} \qquad \nabla \cdot \mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r}) = 0 \ , \tag{45.1}$$

with $k_\lambda = \omega_{\mathbf{k}\lambda}/c$ [650]. These classical functions are chosen to form an orthonormal set,

$$\int_V \mathbf{u}^*_{\mathbf{k}\lambda}(\mathbf{r}) \cdot \mathbf{u}_{\mathbf{k}'\lambda'}(\mathbf{r}) d^3r = \delta_{\mathbf{k}\mathbf{k}'}\delta_{\lambda,\lambda'} \ . \tag{45.2}$$

In free space, the plane wave approximation is generally good,

$$\mathbf{u}^{\text{free}}_{\mathbf{k}\lambda}(\mathbf{r}) = \frac{\vec{\epsilon}_\lambda}{\sqrt{V}} e^{\imath \mathbf{k}\cdot\mathbf{r}} \ , \tag{45.3}$$

where $\vec{\epsilon}_{\mathbf{k}\lambda}$ is a polarization vector such that $\mathbf{k}\cdot\vec{\epsilon}_{\mathbf{k}\lambda} = 0$ and V is the photon quantization volume.

Let us now rewrite the quantized transverse vector potential of the radiation field (37.7) as,

$$\boxed{\hat{\mathbf{A}}(\mathbf{r},t) = \sum_{\mathbf{k}\lambda} \sqrt{\frac{\hbar}{2\omega_{\mathbf{k}\lambda}\varepsilon_0}}[\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r})\hat{a}_{\mathbf{k}\lambda}(t) + \mathbf{u}^*_{\mathbf{k}\lambda}(\mathbf{r})\hat{a}^\dagger_{\mathbf{k}\lambda}(t)]} \ . \tag{45.4}$$

The quantum properties of the electric and magnetic field operators are determined by the bosonic annihilation and creation operators, $\hat{a}_{\mathbf{k}\lambda}(t)$ and $\hat{a}^\dagger_{\mathbf{k}\lambda}(t)$, respectively, with usual commutation relations: $[\hat{a}_{\mathbf{k}\lambda}(t), \hat{a}_{\mathbf{k}'\lambda'}(t)] = 0$ and $[\hat{a}_{\mathbf{k}\lambda}(t), \hat{a}^\dagger_{\mathbf{k}'\lambda'}(t)] = \delta_{\mathbf{k}\mathbf{k}'}\delta_{\lambda\lambda'}$.

For weak-coupling between the atoms and the field, one has the contributions to the Hamiltonian,

$$\boxed{\begin{aligned} \hat{H}_{atom} &= \hbar\omega_0\hat{\sigma}^z \\ \hat{H}_{field} &= \sum_{\mathbf{k}} \hbar\omega_{\mathbf{k}}[\hat{a}^\dagger_{\mathbf{k}\lambda}(t)\hat{a}_{\mathbf{k}\lambda}(t) + \tfrac{1}{2}] \\ \hat{H}_{atom:field} &= -\imath\hbar\sum_{\mathbf{k},\lambda}(\hat{\sigma}^+ + \hat{\sigma}^-)[g_{\mathbf{k}\lambda}(\mathbf{r})\hat{a}_{\mathbf{k}\lambda} - g^*_{\mathbf{k}\lambda}(\mathbf{r})\hat{a}^\dagger_{\mathbf{k}\lambda}] \end{aligned}} \quad , \tag{45.5}$$

and,

$$g_{\mathbf{k}\lambda}(\mathbf{r}) \equiv \sqrt{\frac{\omega_{\mathbf{k}}}{2\varepsilon_0\hbar}}\mathbf{d}\cdot\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r}) \tag{45.6}$$

is a complex function associated with the coupling strength between the atom and the field.

By solving the Heisenberg equations of motion for the atomic and field operators within the Born and Markov approximations (or using the procedure leading to the expression (40.118)), one obtains the spontaneous emission rate on a transition $|e\rangle \to |g\rangle$ of frequency ω_0:

$$\Gamma(\mathbf{r}) = 2\pi\sum_{\mathbf{k},\lambda}|g_{\mathbf{k}\lambda}(\mathbf{r})|^2\delta(\omega_{\mathbf{k}} - \omega_0) \ . \tag{45.7}$$

which is the same result obtained by the Weisskopf-Wigner theory [650]. To evaluate the sum we need go to a continuous k-space via,

$$\sum_{\mathbf{k},\lambda} \longrightarrow \lim_{V\to\infty}\sum_{\lambda}\frac{V}{8\pi^3}\int d^3k \ . \tag{45.8}$$

Hence, in free space, inserting the mode function (45.3),

$$\begin{aligned} \Gamma(\mathbf{r}) &= \frac{\pi\omega_0}{\varepsilon_0\hbar}\sum_{\mathbf{k},\lambda}|\mathbf{d}\cdot\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r})|^2\delta(\omega_{\mathbf{k}} - \omega_0) \\ &= \frac{\hbar\omega_0}{8\pi^2\varepsilon_0\hbar^2}\lim_{V\to\infty}\sum_{\lambda}\int d^3k\ |\mathbf{d}\cdot\vec{\epsilon}_{\mathbf{k}\lambda}|^2\delta(\omega_{\mathbf{k}} - \omega_0) \\ &= \lim_{V\to\infty}\sum_{\lambda}\int\frac{|\mathbf{d}\cdot\vec{\epsilon}_{\mathbf{k}\lambda}|^2\vec{\mathcal{E}}^2_{\mathbf{k}}}{\hbar^2}2\pi\delta(\omega_{\mathbf{k}} - \omega_0)\frac{V}{8\pi^3 c}k^2 d\Omega_{\mathbf{k}}d\omega_{\mathbf{k}} \ . \end{aligned} \tag{45.9}$$

Obviously, in free space the decay rate does not depend on position. Plugging in the density of states for free space (23.53) and (39.23), we finally get,

$$\Gamma = \sum_{\lambda}\int\frac{|\mathbf{d}\cdot\vec{\epsilon}_{\mathbf{k}\lambda}|^2\vec{\mathcal{E}}^2_{\mathbf{k}}}{\hbar^2}2\pi\delta(\omega_{\mathbf{k}} - \omega_0)\rho(\omega_{\mathbf{k}}, \mathbf{k})d\Omega_{\mathbf{k}}d\omega_{\mathbf{k}} \ , \tag{45.10}$$

where the density of states can now be arbitrarily shaped by the presence of boundary conditions, such as optical cavities or dielectric or metallic surfaces.

45.1.1.2 Modification of the natural linewidth by cavities

The *cooperativity parameter* of a cavity is defined as the rate at which an atom emits into the volume of a cavity mode normalized to the rate at which it would scatter into free space,

$$\boxed{\Upsilon \equiv \frac{\Gamma_{\rm cav}}{\Gamma_{\rm free}}} \ . \tag{45.11}$$

In a cavity, spontaneous emission is strongly modified [422, 423, 424]. An atom interacting with a cavity will spontaneously emit into the cavity mode at an increased (reduced) rate, depending on whether the cavity is resonant or out of resonance. The natural width due to spontaneous decay and the line shift are calculated by integration over the coupling force between the atom and every available field mode [see (45.9)],

$$\boxed{\begin{aligned} \Gamma &= \iint \frac{|\mathbf{d}_{eg}\cdot\vec{\epsilon}_{\mathbf{k}}|^2|\vec{\mathcal{E}}_{\mathbf{k}}|^2}{\hbar^2} 2\pi\delta(\omega_0-\omega_{\mathbf{k}})\rho(\omega_{\mathbf{k}},\mathbf{k})d\Omega_{\mathbf{k}}d\omega_{\mathbf{k}} \\ \Delta\omega &= \sum_i \iint \frac{|\mathbf{d}_{ei}\cdot\vec{\epsilon}_{\mathbf{k}}|^2|\vec{\mathcal{E}}_{\mathbf{k}}|^2}{\hbar^2}\frac{1}{\omega_{ei}-\omega_{\mathbf{k}}}\rho(\omega_{\mathbf{k}},\mathbf{k})d\Omega_{\mathbf{k}}d\omega_{\mathbf{k}} \end{aligned}} \ , \tag{45.12}$$

with the field amplitude per photon, $|\vec{\mathcal{E}}_{\mathbf{k}}| = \sqrt{\hbar\omega_{\mathbf{k}}/2\varepsilon_0 V}$, derived in (38.74), and the index i running over all internal atomic states. These formulas are simply applications of second-order perturbation theory (27.16) and of Fermi's golden rule (27.111) for transition probabilities both weighed with dynamic structure factor of the cavity.

We use the number of modes per unit of frequency range and per unit of solid angle in free space derived in (38.82) (ρ/V is the density of states),

$$\rho_{\rm free}(\omega_{\mathbf{k}}) = \frac{V\omega_{\mathbf{k}}^2}{(2\pi)^3c^3} \ . \tag{45.13}$$

Setting $\theta_{\mathbf{k}}$ as the angle between the atomic dipole moment and the cavity axis (which is not in place, yet, as we are still in free space), $\mathbf{d}\cdot\hat{\epsilon}_{\mathbf{k}} = d\cos\alpha_{\mathbf{k}} = d\cos(90^\circ-\theta_{\mathbf{k}}) = d\sin\theta_{\mathbf{k}}$,

$$\begin{aligned} \Gamma_{\rm free} &= \int \frac{d^2\sin^2\theta_{\mathbf{k}}}{\hbar^2}\frac{\hbar\omega_0}{2\varepsilon_0 V}2\pi\frac{V\omega_0^2}{(2\pi)^3c^3}\sin\theta d\theta d\phi \\ &= \frac{d^2k^3}{4\pi\varepsilon_0\hbar}\int_0^\pi \sin^3\theta d\theta = \frac{d^2k^3}{3\pi\varepsilon_0\hbar} \ . \end{aligned} \tag{45.14}$$

Since the integration covers the whole solid angle of space 4π and the free space is isotropic, there is no preferred orientation, and we can perform the integration setting $\theta \equiv \theta_{\mathbf{k}}$. The result coincides with earlier calculations (39.46).

Now, we put the cavity in place, but tune it off resonance, such that no photons can be emitted into the solid angle covered by the cavity. That is, in the presence of the cavity, the solid angle of free space into which photons can be emitted is restricted. We repeat the calculation (45.14), but now we are not free to choose the axis of the coordinate system arbitrarily. Instead, we we assume that $\theta_{\mathbf{k}}(\theta,\phi) \simeq const$ over the

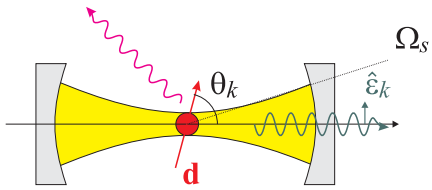

Figure 45.1: Illustration of cooperativity in a cavity. An excited atom can decay by emitting light into a cavity mode or into free space. Note that the cavity is not pumped directly by an incident laser beam.

small solid angle covered by the cavity, $\theta, \phi \in \Omega_{\rm cav}$,

$$\begin{aligned}\Gamma_{{\rm free}\notin{\rm cav}} &= \int_{\hat{\mathbf{e}}_k\notin{\rm cav}} \frac{d^2\sin^2\theta_k}{\hbar^2}\frac{\hbar\omega_0}{2\varepsilon_0 V}2\pi\frac{V\omega_0^2}{(2\pi)^3c^3}\sin\theta d\theta d\phi \\ &\simeq \Gamma_{\rm free} - \frac{d^2k^3\sin^2\theta_{\mathbf{k}}}{8\pi^2\varepsilon_0\hbar}\int_{\hat{\mathbf{e}}_k\in{\rm cav}}\sin\theta d\theta d\phi = \Gamma_{\rm free}\left(1-\frac{3}{8\pi}\Omega_{\rm cav}\sin^2\theta_{\mathbf{k}}\right) .\end{aligned} \tag{45.15}$$

Finally, we study the situation, when the cavity is in place but now tuned on resonance. Then the density of states in the photon emission directions $\mathbf{k}\in$ cavity is modulated by the Airy function (38.83),

$$\rho_{\rm cav}(\omega_{\mathbf{k}},\mathbf{k}) = \rho_{\rm free}(\omega_{\mathbf{k}})\mathfrak{L}(\omega_{\mathbf{k}}) . \tag{45.16}$$

That is, photons can be emitted into the cavity mode with increased probability. Once again we repeat the calculation (45.14), but now inserting the density of states of the cavity,

$$\begin{aligned}\Gamma_{\rm cav} &= \int_{\hat{\mathbf{e}}_k\in{\rm cav}} \frac{d^2\sin^2\theta_{\mathbf{k}}}{\hbar^2}\frac{\hbar\omega_0}{2\varepsilon_0 V}2\pi\mathfrak{L}(\omega_0)\frac{V\omega_0^2}{(2\pi)^3c^3}\sin\theta d\theta d\phi \\ &\simeq \frac{d^2k^3\sin^2\theta_{\mathbf{k}}}{8\pi^2\varepsilon_0\hbar}\mathfrak{L}(\omega_0)\int_{\hat{\mathbf{e}}_k\in{\rm cav}}\sin\theta d\theta d\phi = \Gamma_{\rm free}\mathfrak{L}(\omega_0)\frac{3}{8\pi}\Omega_{\rm cav}\sin^2\theta_{\mathbf{k}} ,\end{aligned} \tag{45.17}$$

where, in the last step, we substituted the free space decay rate (45.14). An analogous calculation for the *cooperative Lamb shift* $\Delta\omega_{\rm cav}$ is left to the Exc. 45.1.11.1:

$$\boxed{\begin{aligned}\Gamma_{\rm cav} &= \Gamma_{\rm free}\tfrac{3}{8\pi}\Omega_{\rm cav}\sin^2\theta_{\mathbf{k}}\mathfrak{L}(\omega_0) \\ \Delta\omega_{\rm cav} &= \Gamma_{\rm free}\tfrac{3}{32\pi}\Omega_{\rm cav}\sin^2\theta_{\mathbf{k}}\tfrac{\mathfrak{L}'(\omega_0)}{\mathfrak{L}(\omega_0)}2\delta_{\rm fsr}\end{aligned}} . \tag{45.18}$$

The quantities $\Gamma_{\rm cav}$ and $\Gamma_{free\in cav}$ are scattering rates into complementary solid angles. Now, the total spontaneous emission rate, which determines the lifetime of the radiating excited state and the spectral width of the transition is simply the sum of the partial scattering rates,

$$\begin{aligned}\Gamma &= \Gamma_{free\notin cav} + \Gamma_{\rm cav} \\ &= \Gamma_{\rm free}\left(1-\tfrac{3}{8\pi}\Omega_{\rm cav}\right)\sin^2\theta_{\mathbf{k}} + \Gamma_{\rm free}\mathfrak{L}(\omega_0)\tfrac{3}{8\pi}\Omega_{\rm cav}\sin^2\theta_{\mathbf{k}} \\ &= \Gamma_{\rm free}\left[1+(\mathfrak{L}(\omega_0)-1)\tfrac{3}{8\pi}\Omega_{\rm cav}\right]\sin^2\theta_{\mathbf{k}} .\end{aligned} \tag{45.19}$$

Assuming for simplicity, $\theta_{\mathbf{k}} = \pi/2$, we find the extremes of the spontaneous emission rate, Γ_{enh} and Γ_{inh}, when the cavity is on or off resonance. With a resonant high finesse cavity the emission is obtained via $kL \to 0$,

$$\Gamma_{enh} = \Gamma_{\text{free}} \left[1 + \left(\sqrt{1 + \left(\tfrac{2F}{\pi}\right)^2} - 1 \right) \tfrac{3}{8\pi} \Omega_{\text{cav}} \right] \simeq \Gamma_{\text{free}} \left(1 + \tfrac{3}{4\pi^2} F \Omega_{\text{cav}} \right) \ . \tag{45.20}$$

assuming high finesse, $F \gg 1$. With a non-resonant cavity, the emission is obtained via $kL \to \pi/2$,

$$\Gamma_{inh} = \Gamma_{\text{free}} \left[1 + \left(\frac{1}{\sqrt{1 + \left(\tfrac{2F}{\pi}\right)^2}} - 1 \right) \tfrac{3}{8\pi} \Omega_{\text{cav}} \right] \simeq \Gamma_{\text{free}} \left(1 - \tfrac{3}{8\pi} \Omega_{\text{cav}} \right) \ . \tag{45.21}$$

For a small solid angle, we can expect a big increase of the scattering into the cavity, but without noticeable inhibition of the total decay, $\Gamma_{inh} \simeq \Gamma_{\text{free}}$.

If the atoms are saturated by an incident laser, they scatter light into the cavity at a rate (apart from a factor $\frac{1}{2}$),

$$\Gamma_{\text{cav}} = \Gamma_{\text{free}} \mathfrak{L}(\omega_0) \tfrac{3}{8\pi} \Omega_{\text{cav}} \ . \tag{45.22}$$

Without cavity the emission into the same solid angle is obtained via $F \to 0$,

$$\Gamma_{free \in cav} = \Gamma_{\text{free}} \tfrac{3}{8\pi} \Omega_{\text{cav}} \ . \tag{45.23}$$

The scattering will fill the cavity with photons, until the leakage equalizes the pumping. When the balance is reached, Γ_{cav} will also be the rate at which photons are emitted by the cavity mode. We calculate an example in Exc. 45.1.11.2.

45.1.1.3 Purcell factor for confocal and concentric cavities

Using the solid angle of a confocal cavity (38.89), the cooperativity parameter is,

$$\Upsilon \simeq \frac{3F}{4\pi^2} \Omega_{\text{cav}} = \frac{3F}{4\pi^2} \frac{8\pi b^2}{L^2} \ , \tag{45.24}$$

where b is the clear aperture of the cavity mirrors. That is,

$$\boxed{\Upsilon = \frac{F}{\pi} \frac{6b^2}{L^2} \ .} \tag{45.25}$$

45.1.1.4 Purcell factor for the TEM_{00} cavity mode

With the solid angle (38.95) calculated for a this TEM_{00} cavity mode we calculate the *cooperativity parameter*,

$$\begin{aligned} \Upsilon \equiv \frac{\Gamma_{\text{cav}}}{\Gamma_{\text{free}}} &= \mathfrak{L}(\omega_0) \tfrac{3}{8\pi} \Omega_{\text{cav}} = \sqrt{1 + \left(\frac{2F}{\pi}\right)^2} \frac{3}{8\pi} \Omega_{\text{cav}} \\ &\simeq \frac{3F}{4\pi^2} \Omega_{\text{cav}} = \frac{\Gamma_{enh}}{\Gamma_{\text{free}}} - 1 = \frac{3F}{4\pi^2} \frac{8\pi}{k^2 w_0^2} \ , \end{aligned} \tag{45.26}$$

that is,

$$\boxed{\Upsilon = \frac{F}{\pi}\frac{6}{k^2 w_0^2}} \ , \tag{45.27}$$

which is also called *Purcell factor*.

Now, exploiting the relationships (38.95), (45.27), and (38.68),

$$\Omega_{\rm cav} = \frac{8\pi}{k^2 w_0^2} \quad , \quad \Upsilon = \frac{F}{\pi}\frac{6}{k^2 w_0^2} \quad , \quad \frac{F}{\pi} = \frac{\delta_{\rm fsr}}{\kappa} \ , \tag{45.28}$$

and defining a new quantity,

$$g^2 = \tfrac{1}{4}\Upsilon\kappa\Gamma_{\rm free} \ , \tag{45.29}$$

which we will call the atom-field coupling strength, we may rewrite the prefactor $\Gamma_{\rm free}\frac{3}{8\pi}\Omega_{\rm cav}$ for the case of Gaussian cavity modes,

$$\Gamma_{\rm free}\frac{3}{8\pi}\Omega_{\rm cav} = \frac{g^2}{2\delta_{\rm fsr}} \ . \tag{45.30}$$

Close to a cavity resonance, $kL = \omega/2\delta_{\rm fsr} = (\omega_c + \Delta_{\rm c})/2\delta_{\rm fsr} = 2\pi N + \Delta_{\rm c}/2\delta_{\rm fsr}$, the sine appearing in the Airy function (38.83) may be expanded $\sin kL = \sin \Delta_{\rm c}/2\delta_{\rm fsr} \simeq \Delta_{\rm c}/2\delta_{\rm fsr}$. Furthermore, assuming a high finesse, $F \gg 1$, the Airy function simplifies to,

$$\mathfrak{L}(\omega_0) = \frac{\sqrt{1+(2F/\pi)^2}}{1+(2F/\pi)^2\sin^2\frac{\omega}{2\delta_{\rm fsr}}} \simeq \frac{2F/\pi}{1+\Delta_{\rm a}^2/\kappa^2} \ . \tag{45.31}$$

Inserting this into the formulae (45.18), where we set $\theta_{\mathbf{k}} = \frac{\pi}{2}$,

$$\boxed{\begin{array}{rcl} \Gamma_{\rm cav} & \simeq & \frac{g^2\kappa}{\Delta_{\rm c}^2+\kappa^2} \\ \Delta\omega_{\rm cav} & \simeq & \frac{-2g^2\Delta_{\rm c}}{\Delta_{\rm c}^2+\kappa^2} \end{array}} \ . \tag{45.32}$$

Obviously, the atom-field coupling strength g plays a central role in the modification of the emission spectra of atoms interaction with cavities. Therefore, we will have to study this quantity more deeply in the next sections.

Example 310 (*Cooperativity of non-degenerate and confocal cavities*): For example, for a non-degenerate linear cavity with finesse $F = 110000$ and waist $w_0 = 50\,\mu$m at 689 nm, the cooperativity is relatively weak, $\Upsilon \simeq 1$. Still, at this cooperativity, half of the spontaneously emitted photons go into a tiny solid angle represented by the cavity. Confocal or concentric cavities may present more favorable geometries [422, 423, 424]. With $N_0 = 10^4$ saturated strontium atoms, the light power scattered into the cavity is $P_j = 20$ fW. Estimation the cavity transmission by $T \simeq \pi/F$, we expect that a number of $T\frac{P_{\rm cav}}{\hbar\omega} = 10^7\,{\rm s}^{-1}$ photons can be detected by a photodetector recording the photon number leaking out of the cavity.

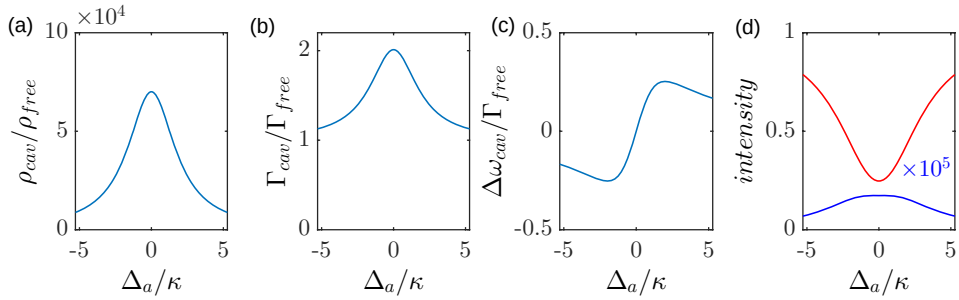

Figure 45.2: (code) Spontaneous emission on the strontium atom cooling transition ($\lambda = 689\,\mathrm{nm}$, $\Gamma = (2\pi)\ 7.6\,\mathrm{kHz}$) in a $L = 3.6\,\mathrm{cm}$ long cavity with $F = 110000$ and $w_0 = 50\,\mu\mathrm{m}$. (a) Cooperativity $\mathfrak{L}(\omega)$ from Eq. (38.83) as a function of the detuning of the cavity. (b) Linewidth Γ_{cav} from (45.18)(ii) and (c) frequency shift of the strontium transition from Eq. (45.18)(ii). (d) Spontaneous emission into the cavity (blue) and into the open space (red).

45.1.2 Characterization of the atom-field coupling

In Sec. 38.3.1 we started introducing a number of quantities characterizing empty cavities. We will now pursue this task including their interaction with atoms. In particular, we will introduce three important quantities allowing us to measure the degree of quantization of the system: the cooperativity Υ, the saturation parameter s, and the cavity resolution r.

45.1.2.1 The atomic dipole moment

As usual, the interaction strength of an atom with a light field is measured by the atom-field coupling constant, which is precisely HALF the single photon Rabi frequency. Using relationships derived in Sec. 38.3.1 and the expression (39.41) for the atomic dipole moment d, we find,

$$g \equiv \frac{d\mathcal{E}_1(0)}{\hbar} = \sqrt{\frac{3\pi\Gamma\omega}{2k^3 V_{\mathrm{m}}}} = \sqrt{\frac{6\Gamma\delta_{\mathrm{fsr}}}{k^2 w^2}}\ , \tag{45.33}$$

where $\mathcal{E}_1(0)$ the electric field produced by a single photon inside the cavity mode volume $V_{\mathrm{m}} = \frac{\pi}{2} L w_0^2$ calculated in (38.71), δ_{fsr} the free spectral range calculated in (38.67), and Γ is the spontaneous decay rate. See also (watch talk).

45.1.2.2 Single atom reflection coefficient

Based on the complex atomic polarizability (15.123),

$$\frac{\alpha_{\mathrm{pol}}}{\varepsilon_0} \simeq \frac{6\pi}{k^3}\frac{-1}{\imath + 2\Delta/\Gamma}\ , \tag{45.34}$$

the *single atom reflection coefficient* is defined as,

$$\beta_\Delta = \frac{k}{\pi w^2}\frac{\alpha_{\mathrm{pol}}}{\varepsilon_0} = \frac{6}{k^2 w^2}\frac{-1}{\imath + 2\Delta/\Gamma}\ , \tag{45.35}$$

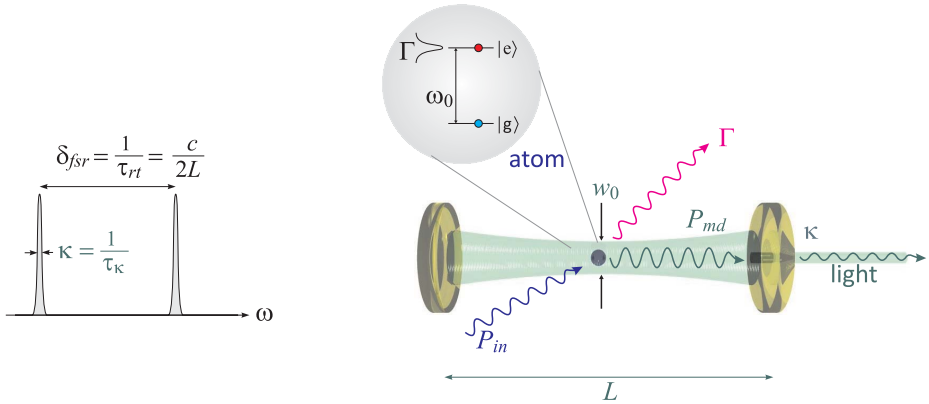

Figure 45.3: Relevant parameters for an atom interacting with a cavity.

where $\Delta_\mathrm{a} = \omega - \omega_0$. The resonant reflection coefficient can be interpreted in terms of a phase shift that depends on the matching between the resonant optical cross-section of the atom, $\sigma_0 = 3\lambda^2/2\pi$, and the cross section of the optical mode,

$$-\imath\beta_0 = \frac{\sigma_0}{\pi w^2} = \frac{6}{k^2 w^2} = \frac{2g^2}{\delta_\mathrm{fsr}\Gamma} \ . \tag{45.36}$$

The total reflection coefficient multiplied with the free spectral range of the cavity,

$$\delta_\mathrm{fsr}\beta_\Delta = \frac{6\delta_\mathrm{fsr}}{k^2 w^2}\frac{-1}{\imath + 2\Delta/\Gamma} = g^2\frac{\Delta - \imath\Gamma/2}{\Delta^2 + \Gamma^2/4} = U_0 - \imath\gamma_0 = U_\gamma \ , \tag{45.37}$$

is just the *single-photon light-shift* combined with the single-photon Rayleigh scattering rate.

Using the dipole moment $d = \sqrt{3\pi\varepsilon_0\hbar\Gamma/k^3}$ and defining the electric field amplitude per photon $\mathcal{E}_1$ by the photon number n, the power P, and the intensity $I = \varepsilon_0 c n_\mathrm{ph}\mathcal{E}_1^2 = 2P/\pi w^2$, we calculate for the single-photon Rabi frequency (or atom-field coupling strength),

$$g = \frac{d\mathcal{E}_1}{\hbar} = \sqrt{\frac{1}{\hbar^2}\frac{3\pi\varepsilon_0\hbar\Gamma}{k^3}\frac{I}{\varepsilon_0 c n_\mathrm{ph}}} = \sqrt{\frac{1}{\hbar^2}\frac{3\pi\varepsilon_0\hbar\Gamma}{k^3}\frac{1}{\varepsilon_0 c n_\mathrm{ph}}\frac{2P}{\pi w^2}} = \sqrt{\frac{6}{k^2 w^2}\Gamma\frac{P}{n_\mathrm{ph}\hbar\omega}} \ . \tag{45.38}$$

Far from resonance, the single-photon light shift (or atom-atom coupling strength) is,

$$U_0 = \frac{g^2}{|\Delta_\mathrm{a}|} = \frac{6}{k^2 w^2}\frac{\Gamma}{|\Delta_\mathrm{a}|}\frac{P}{n_\mathrm{ph}\hbar\omega} = \beta_\Delta\frac{P}{n_\mathrm{ph}\hbar\omega} \ , \tag{45.39}$$

and the single-photon Rayleigh scattering rate,

$$\gamma_0 = \frac{g^2\Gamma}{\Delta_\mathrm{a}^2} = \frac{6}{k^2 w^2}\frac{\Gamma^2}{\Delta_\mathrm{a}^2}\frac{P}{n_\mathrm{ph}\hbar\omega} \ . \tag{45.40}$$

In a cavity the flux $\delta_\mathrm{fsr} = P/n_\mathrm{ph}\hbar\omega$ is just the photon round trip rate (or free spectral range). $1/\delta_\mathrm{fsr}$ is the time a photon interacts with an atom. In free space,

this does not make sense to me, because I don't know how define the mode volume. I can however consider the interaction of a photon with an extended sample of length L. In this case, a photon interacts with the sample for the time L/c, so that,

$$U_0 = \frac{g^2}{|\Delta_\mathrm{a}|} = \frac{6}{k^2 w^2}\frac{\Gamma}{|\Delta_\mathrm{a}|}\frac{c}{L} = \beta_\Delta \frac{c}{L} \ , \tag{45.41}$$

and

$$\gamma_0 = \frac{g^2\Gamma}{\Delta_\mathrm{a}^2} = \frac{6}{k^2 w^2}\frac{\Gamma^2}{\Delta_\mathrm{a}^2}\frac{c}{L} \ . \tag{45.42}$$

This means, we can use the CARL equations derived for a ring cavity also in free space by just substituting $\kappa = \delta_\mathrm{fsr} = c/L$, where L is now not the cavity but the sample length.

45.1.2.3 Collective cooperativity

The frequency shift accumulated during a round trip in the cavity, $\delta_\mathrm{fsr}\beta_0$, becomes noticeable, when it exceeds the linewidth of the cavity κ. From this condition, we obtain the optical depth for a single passage through the atomic sample multiplied by the finesse of the cavity, which is precisely the *cooperativity parameter*,

$$\boxed{\Upsilon \equiv \frac{\delta_\mathrm{fsr}\beta_0}{\kappa} = \frac{F}{\pi}\frac{6}{k^2 w^2} = \frac{4g^2}{\kappa\Gamma}} \ . \tag{45.43}$$

The sensitivity to the atom number can be measured in terms of a *critical atom number* N_crt, which the system can resolve,

$$N_\mathrm{crt} = \frac{4\pi}{F\beta_0} = \frac{1}{\Upsilon} \ . \tag{45.44}$$

While the strong coupling regime of the CQED requires $\Upsilon > 1$ with a single atom, collective cooperativity is reached with N atoms if $N\Upsilon > 1$ [127, 191]. In this case, the atomic ensemble couples to the mode like a single 'super-atom', the coupling force being magnified to $g_N = g_1\sqrt{N}$. We have already obtained this result within the Jaynes-Cummings model for two indistinguishable atoms coupling to the same light mode and forming a *Dicke state* (see Sec. 46.1.1).

45.1.2.4 Optical density

Lambert-Beer's law relates the amplitude of the field transmitted to the incident [see also Eq. (49.133)],

$$\frac{\mathcal{E}_\mathrm{t}}{\mathcal{E}_0} = \exp\left[\imath\sigma(\Delta_\mathrm{a})\left(\frac{\imath}{2} - \frac{\Delta_\mathrm{a}}{\Gamma}\right)\int_{-\infty}^{\infty} n(\mathbf{r})dz\right] = e^{-b/2}e^{\imath\varphi} \ . \tag{45.45}$$

I.e. the field is shifted by an amount φ and absorbed by an amount b. The exponent (called optical density) can be rewritten, if we assume a number of N atoms homogeneously distributed over a cylinder with length L and radius $\bar{r} = w_0$. Using with

(23.72),

$$b = OD(\Delta_\mathrm{a}) = -2\imath\sigma(\Delta_\mathrm{a})\left(\frac{\imath}{2} - \frac{\Delta_\mathrm{a}}{\Gamma}\right)\int_{-\infty}^{\infty} n(\mathbf{r})dz \tag{45.46}$$
$$= -\imath\frac{g_2}{g_1}\frac{\lambda^2}{2\pi}\frac{\frac{1}{2}\Gamma^2}{\Delta_\mathrm{a}^2 + \frac{1}{4}\Gamma^2}\left(\frac{\imath}{2} - \frac{\Delta_a}{\Gamma}\right)\int_{-\infty}^{\infty}\frac{N}{\frac{\pi}{2}w_0^2 L}dz = \frac{12N}{\pi k^2 w_0^2}\frac{1}{1 - 2\imath\Delta_\mathrm{a}/\Gamma} \ .$$

Hence, the optical density is nothing else than the collective cooperativity divided by the finesse,

$$\boxed{OD(0) = \frac{12N}{\pi k^2 w_0^2} = \frac{4g_N^2}{\pi\delta_\mathrm{fsr}\Gamma} = \frac{\kappa\Upsilon_N}{\pi\delta_\mathrm{fsr}} = \frac{\Upsilon_N}{F}} \ . \tag{45.47}$$

45.1.2.5 Saturation parameter in cavities

The *saturation parameter* for a single photon is given by,

$$\boxed{s = \frac{2\Omega_1^2}{\Gamma^2} = \frac{8g^2}{\Gamma^2}} \ , \tag{45.48}$$

where Ω_1 is the single photon Rabi frequency. Therefore, the number of photons needed to saturate an atomic transition is,

$$n_\mathrm{sat} = \frac{1}{s} \ . \tag{45.49}$$

We see, that there is a *symmetry* between Υ and s, that is, between N_crt and n_sat. The regime $N\Upsilon > 1$ denotes the collective behavior of N atoms in the same way as $n_\mathrm{sat} > 1$ indicates saturation. While Υ depends only on the phase matching between the atomic antenna and the cavity, s also depends on the cavity mode volume and the natural decay rate.

45.1.2.6 Cavity resolution parameter

Comparing the photonic recoil, which is given by,

$$\omega_\mathrm{rec} = \frac{\hbar k^2}{2m} \ , \tag{45.50}$$

with the resolution power of a cavity κ, we can define the *resolution parameter*,

$$\boxed{r \equiv \frac{\omega_\mathrm{rec}}{\kappa}} \ . \tag{45.51}$$

With the three parameters defined in Eqs. (45.43), (45.48), and (45.51) we are able to measure the degree of quantization of the degrees of freedom involved in the matter-light interaction in a cavity. The cooperativity Υ measures the resolvability of single atoms in the atomic cloud, which depends on the phase matching between the atomic antenna (i.e. its optical cross section) and the focus of the optical mode. The saturation parameter s measures the resolvability of single photons in the cavity.

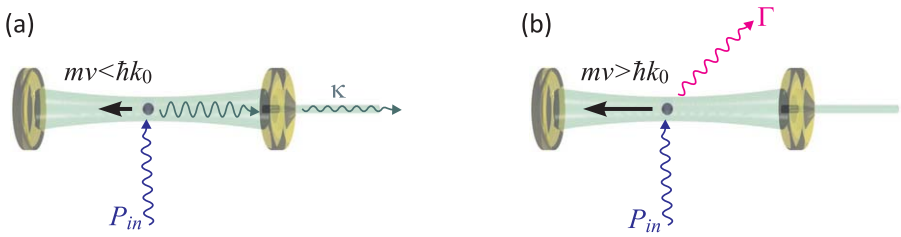

Figure 45.4: (a) If the recoil-induced Doppler shift of the atom moving along the cavity axis is smaller than the cavity linewidth, the light is preferentially scattered into the cavity mode. (b) Else it is scattered outside the mode.

And the cavity resolution parameter r measures the resolvability of the Doppler-shift due to the atomic center-of-mass motion caused by the absorption of a single photon. If one wants to operate in an environment, where all degrees of freedom involved in the atom-light interactions are fully quantized, the atoms need to be placed into a cavity whose characteristic quantities are all large, $\Upsilon, s, r \gg 1$.

In Exc. 45.1.11.3 we compare the coupling force and other characteristic parameters for various combinations of atomic species and optical cavities. In Exc. 45.1.11.4 we calculate the number of photons in a cavity pumped in or out of resonance.

45.1.3 Jaynes-Cummings model for one or two radiation modes

To study the dynamics of the coupled atom-cavity system, we consider the Jaynes-Cummings Hamiltonian (40.18) (or (45.5)), for a more concrete situation. That is, we allow for optical pumping and decay of internal states with the rates R and Γ, respectively, and we allow for inhomogeneous (however, mostly one-dimensional) mode functions $g(z) = ge^{\imath kz}$. On the other hand, we stick to a single atom (or N uncorrelated atoms), we disregard polarization and multi-mode excitation, and we will explicitly consider and compare two well distinct cases, linear and ring cavities.

45.1.3.1 Linear and ring cavities

From the Heisenberg equations with the Hamiltonian (45.5),

$$\boxed{\begin{aligned} \hat{H}_{\text{atom}} &= -\Delta_{\text{a}}\hat{\sigma}^{+}\hat{\sigma}^{-} \\ \hat{H}_{\text{cav}} &= -\Delta_{\text{c}}\hat{a}^{\dagger}\hat{a} \\ \hat{H}_{\text{atom:cav}} &= g(z)\hat{a}^{\dagger}\hat{\sigma}^{-} + h.c. \\ \hat{H}_{\text{laser:cav}} &= -\imath\eta(\hat{a} - \hat{a}^{\dagger}) \end{aligned}} \quad . \tag{45.52}$$

The Hamiltonian for a single motionless atom interacting with two cavity modes $|+\rangle$ and $|-\rangle$ (we may, for instance, consider the counterpropagating modes of a ring

cavity) reads,

$$\boxed{\begin{aligned} \hat{H}_{\text{atom}} &= -\Delta_{\text{a}}\hat{\sigma}^{+}\hat{\sigma}^{-} \\ \hat{H}_{\text{cav}} &= -\Delta_{+}\hat{a}_{+}^{\dagger}\hat{a}_{+} - \Delta_{-}\hat{a}_{-}^{\dagger}\hat{a}_{-} \\ \hat{H}_{\text{atom:cav}} &= g(z)\hat{a}_{+}^{\dagger}\hat{\sigma}^{-} + h.c. + g(z)\hat{a}_{-}^{\dagger}\hat{\sigma}^{-} + h.c. \\ \hat{H}_{\text{laser:cav}} &= -\imath\eta_{+}(\hat{a}_{+} - \hat{a}_{+}^{\dagger}) - \imath\eta_{-}(\hat{a}_{-} - \hat{a}_{-}^{\dagger}) \end{aligned}} \ . \tag{45.53}$$

45.1.3.2 Time-evolution of an atom in a ring cavity

The coupling of the atom to the cavities $g(z)$ will, in general, depend on the atomic position. For simplicity let us, however, consider uniform and identical coupling, $g_{+}(z) = g_{-}(z) = g$, and furthermore assume that both cavities be on resonance, $\Delta_{+} = \Delta_{-} = 0$. Finally, neglecting spontaneous emission and pumping, the total number of photons is conserved. With $\Delta_{\text{a}} = \omega - \omega_{\text{a}}$ we get,

$$\hat{H} = \omega\hat{a}_{+}^{\dagger}\hat{a}_{+} + \omega\hat{a}_{-}^{\dagger}\hat{a}_{-} + \omega_{0}(\hat{\sigma}^{+}\hat{\sigma} - \tfrac{1}{2}) + g\hat{a}_{+}^{\dagger}\hat{\sigma}^{-} + g\hat{a}_{-}^{\dagger}\hat{\sigma}^{-} + h.c. \ . \tag{45.54}$$

Expanding the operators $\hat{a}_{\pm} = \sum_{n_{\pm}} |n_{\pm} - 1\rangle\langle n_{\pm}|$ and $\hat{\sigma}^{-} = |1\rangle\langle 2|$ we can, expand the state of the system like,

$$|\psi(t)\rangle = \sum_{k=0}^{n} c_{j,n_{+},n_{-}}|j, n_{+}, n_{-}\rangle \ . \tag{45.55}$$

Alternatively, in analogy with Sec. 40.2.2, we may organize the Hilbert space in orthogonal subspaces, $\hat{H} = \bigoplus_{n}\hat{H}_{n}$, each one having $N \equiv j + n_{+} + n_{-}$ energy units distributed over the atomic excitation state $j = 0, 1$ and the numbers of photons $n_{\pm}$ in each mode. Hence, every subspace is of dimension $2N + 1$. In this dressed states picture, introducing the photon imbalance $D \equiv n_{+} - n_{-} = -N, ..., N$, we may expand the coupled state like,

$$\boxed{|\psi(t)\rangle = \sum_{N=0}^{\infty}\sum_{D=-N}^{N}\tilde{c}_{N,D}|N, D\rangle} \ . \tag{45.56}$$

Obviously, the set of three quantum numbers $\{j, n_{+}, n_{-}\}$ is equivalent to the set of two quantum numbers $\{N, D\}$ and can be recovered by,

$$j = 1 + (-1)^{N+D-1} \quad , \quad n_{\pm} = \tfrac{1}{2}(N \pm D - j) \ . \tag{45.57}$$

Hence, states with odd $N+D$ are excited atomic states, and states with even $N+D$ are ground states. We may now write down the Hamiltonian,

$$\hat{H}_N = (N-\tfrac{1}{2})\omega\mathbb{I}_{2N+1} + \tag{45.58}$$
$$+\frac{1}{2}\begin{pmatrix} \Delta & g_+\sqrt{N} & & & & & \\ g_+\sqrt{N} & -\Delta & g_-\sqrt{1} & & & & \\ & g_-\sqrt{1} & \Delta & g_+\sqrt{N-1} & & & \\ & & g_+\sqrt{N-1} & \ddots & g_-\sqrt{N-1} & & \\ & & & g_-\sqrt{N-1} & \Delta & g_+\sqrt{1} & \\ & & & & g_+\sqrt{1} & -\Delta & g_-\sqrt{N} \\ & & & & & g_-\sqrt{N} & \Delta \end{pmatrix} .$$

The subscripts of the coupling constants $g_+ = g_-$ are there only to clarify to which mode the photon belongs. Very far from resonance, where the interaction is dispersive, we may treat the light field perturbatively, as shown in (40.40),

$$\hat{H}_N = (N-\tfrac{1}{2})\omega\mathbb{I}_{2N+1} + \tag{45.59}$$
$$+\begin{pmatrix} \frac{\Delta}{2}+\frac{Ng_+^2+0g_-^2}{4\Delta} & & & & \\ & -\frac{\Delta}{2}-\frac{Ng_+^2+1g_-^2}{4\Delta} & & & \\ & & \frac{\Delta}{2}+\frac{(N-1)g_+^2+1g_-^2}{4\Delta} & & \\ & & & -\frac{\Delta}{2}-\frac{(N-1)g_+^2+2g_-^2}{4\Delta} & \\ & & & & \ddots \end{pmatrix} ,$$

or with $g_+ = g_-$,

$$(\hat{H}_N)_{DD'} = \left[\left(N+\frac{1}{2}\right)\omega - \frac{1}{2}\frac{g^2}{4\Delta} + (-1)^{N+D}\left(\frac{\Delta}{2}+\left(N+\frac{1}{2}\right)\frac{g^2}{4\Delta}\right)\right]\delta_{DD'} . \tag{45.60}$$

If only the upper level of the atom interacts with both light fields, all terms with negative light shift disappear,

$$(\hat{H}_N)_{DD'} = \left[\left(N+\frac{1}{2}\right)\omega + \frac{1}{2}\frac{Ng^2}{4\Delta} + (-1)^{N+D}\left(\frac{\Delta}{2}+\frac{N}{2}\frac{g^2}{4\Delta}\right)\right]\delta_{DD'} . \tag{45.61}$$

As shown in Sec. 40.2.2, we propagate the evolution of the coupled state via $|\psi(t)\rangle = e^{-\imath\hat{H}t}|\psi(0)\rangle$. As the initial condition we may choose the atom to be in its ground state and the two field modes in uncorrelated Glauber states,

$$c_{j,n_+,n_-} = \langle j,n_+,n_-|\psi\rangle = e^{-|\alpha_+|^2/2-|\alpha_-|^2/2}\frac{\alpha_+^{n_+}\alpha_-^{n_-}}{\sqrt{n_+!n_-!}}\delta_{j,0} \tag{45.62}$$
$$= \tilde{c}_{N,\delta} = e^{-|\alpha_+|^2/2-|\alpha_-|^2/2}\frac{\alpha_+^{(N+\delta-j)/2}\alpha_-^{(N-\delta-j)/2}}{\sqrt{(\frac{N+\delta-j}{2})!(\frac{N-\delta-j}{2})!}}\delta_{1+(-1)^{N+\delta-1},0} .$$

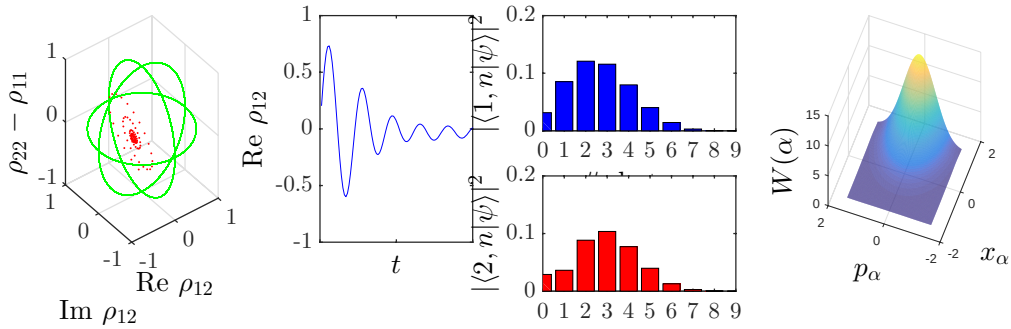

Figure 45.5: (code) Evolution of the coupled atom-ring cavity system. (a) Bloch vector, (b) photon distributions, and (c) Husimi function.

The observables of interest are the atomic Bloch vector (39.126), whose components are obtained from,

$$\rho_{ij} = \langle i|\mathrm{Tr}_{n_+,n_-}\hat{\rho}|j\rangle = \sum_{n_+,n_-} \langle i, n_+, n_-|\psi\rangle\langle\psi|j, n_+, n_-\rangle \tag{45.63}$$
$$= \sum_{n_+,n_-} c^*_{i,n_+,n_-} c_{j,n_+,n_-} = \sum_{n_+,n_-} \tilde{c}^*_{n_++n_-+i,n_+-n_-} \tilde{c}_{n_++n_-+j,n_+-n_-} \ ,$$

the photon statistics in each mode,

$$p_{n_+} = \langle n_+|\mathrm{Tr}_{i,n_-}\hat{\rho}|n_+\rangle = \sum_{j,n_-} \langle j, n_+, n_-|\psi\rangle\langle\psi|j, n_+, n_-\rangle \tag{45.64}$$
$$= \sum_{j,n_-} |c_{j,n_+,n_-}|^2 = \sum_{j,n_-} |\tilde{c}_{n_++n_-+j,n_+-n_-}|^2 \ ,$$

and analogously for p_{n_-}, and the field distribution functions, such as the Husimi function,

$$\pi Q_+(\alpha) \equiv \langle\alpha_+|\mathrm{Tr}_{\ i,n_-}\hat{\rho}|\alpha_+\rangle \tag{45.65}$$
$$= e^{-|\alpha_+|^2} \sum_{n_-} \left(\left| \sum_{n_+} c_{1,n_+,n_-} \frac{\alpha^n}{\sqrt{n!}} \right|^2 + \left| \sum_{n_+} c_{2,n_+,n_-} \frac{\alpha^n}{\sqrt{n!}} \right|^2 \right) \ ,$$

and analogously for $Q_-(\alpha)$, or the Wigner functions $W_\pm(\alpha)$ from the coefficients $\tilde{c}_{j,n_+,n_-}$, respectively, $\tilde{c}_{N,\delta}$, as shown in Secs. 37.3.2 and 40.2.3.

45.1.4 Normal-mode splitting in linear and ring cavities

The Jaynes-Cummings model introduced in Sec. 40.2 represents an idealized model of the interaction of a single cavity mode with a single atom. In this section we reconsider this model taking into account the facts that the coupling strength may vary in space (via the introduction of mode functions) and that the cavity may interact with a reservoir (via the introduction of couplings to pump fields and losses.

We will also study the phenomenon of *normal mode splitting*, which is one of the most direct witnesses of an ongoing atom-cavity interaction (see the vacuum Rabi splitting discussed in Exc. 40.2.5.4).

45.1.4.1 Linear cavities

The starting point is the full Jaynes-Cummings Hamiltonian within the RWA (45.52) for an atom interacting with one mode of a linear optical cavity,

$$\boxed{\hat{H}_{\rm JC} = -\Delta_{\rm a}\hat{\sigma}^+\hat{\sigma}^- - \Delta_{\rm c}\hat{a}^\dagger\hat{a} + g\sin kz(\hat{a}^\dagger\hat{\sigma}^- + \hat{a}\hat{\sigma}^+) - \imath\eta(\hat{a} - \hat{a}^\dagger)} \ . \tag{45.66}$$

For linear cavities normal mode splitting is derived in Exc. 45.1.11.5, where we compare the solution obtained by full numerical integration of the Jaynes-Cummings Hamiltonian (45.52) with an analytical approximation obtained in the weak excitation limit $g|\alpha|^2 \ll \Gamma, \Delta_{\rm a}$ [1],

$$\alpha \simeq \frac{\eta}{\kappa - \imath\Delta_{\rm c} + \frac{Ng^2}{\Gamma - \imath\Delta_{\rm a}}} = \frac{\eta}{\kappa + N\gamma_0 + \imath(NU_0 - \Delta_{\rm c})} \ . \tag{45.67}$$

The solution coincides with one obtained for a system, where the atomic degree of freedom is adiabatically eliminated atom (see Sec. 45.1.5).

45.1.4.2 Ring cavities

The starting point is the full Jaynes-Cummings Hamiltonian within the RWA (45.53) for an atom interacting with two modes of an optical cavity. For two counter-propagating modes of a ring cavity it reads,

$$\boxed{\hat{H}_{\rm JC} = -\Delta_{\rm a}\hat{\sigma}^+\hat{\sigma}^- - \sum_{\pm}\Delta_{\rm c}\hat{a}_\pm^\dagger\hat{a}_\pm + g(\hat{a}_\pm^\dagger\hat{\sigma}^- e^{\mp\imath kz} + \hat{a}_\pm\hat{\sigma}^+ e^{\pm\imath kz}) - \imath\eta_\pm(\hat{a}_\pm - \hat{a}_\pm^\dagger)} \ . \tag{45.68}$$

Note, that here, we do not treat the recoil $e^{\mp\imath kz}$ as a degree of freedom, but just as a parameter depending on the location of the atom. (We will come back to this in Chp. 48.) Decay processes can be considered in a master or in Heisenberg equations via jump operators $\hat{L}_k = \hat{\sigma}^-,\ \hat{\sigma}^+,\ \hat{a}_+, \hat{a}_-$ describing decay processes occurring, respectively, at rates $\gamma_k = 2\Gamma,\ 2R,\ 2\kappa,\ 2\kappa$.

45.1.4.3 (Anti-)Symmetric modes

Let us now introduce symmetric and anti-symmetric modes by,

$$\hat{b}_{\rm s} = \tfrac{1}{\sqrt{2}}(\hat{a}_+ e^{\imath kz} + \hat{a}_- e^{-\imath kz}) \qquad \text{and} \qquad \hat{b}_{\rm a} = \tfrac{1}{\sqrt{2}}(\hat{a}_+ e^{\imath kz} - \hat{a}_- e^{-\imath kz}) \ , \tag{45.69}$$

[1] Note that for N uncorrelated atoms, defining a bunching parameter via $b \equiv \frac{1}{N}\sum_j \sin kz_j$ and introducing the abbreviations $U_\gamma \equiv U_0 - \imath\gamma_0$ and $\Delta_\kappa \equiv \Delta_{\rm c} + \imath\kappa$, the result (45.67) can be generalized to,

$$\alpha \simeq \frac{-\imath\eta}{NbU_\gamma - \Delta_\kappa} \ .$$

that is,

$$\hat{a}_+ = \frac{\hat{b}_\mathrm{s} + \hat{b}_\mathrm{a}}{\sqrt{2}e^{\imath kz}} \qquad \text{and} \qquad \hat{a}_- = \frac{\hat{b}_\mathrm{s} - \hat{b}_\mathrm{a}}{\sqrt{2}e^{-\imath kz}} \ , \tag{45.70}$$

which satisfy the commutations rules $[\hat{b}_\mathrm{s}, \hat{b}_\mathrm{s}^\dagger] = 1 = [\hat{b}_\mathrm{a}, \hat{b}_\mathrm{a}^\dagger]$. We can then rewrite the Hamiltonian,

$$\begin{aligned}\hat{H}_\mathrm{JC} &= -\Delta_\mathrm{a}\hat{\sigma}^+\hat{\sigma}^- + \sqrt{2}g(\hat{b}_\mathrm{s}^\dagger\hat{\sigma}^- + \hat{b}_\mathrm{s}\hat{\sigma}^+) - \sum_\pm \Delta_\mathrm{c}\hat{a}_\pm^\dagger\hat{a}_\pm - \imath\eta_\pm(\hat{a}_\pm - \hat{a}_\pm^\dagger) \\ &= \hat{H}_\mathrm{atom} + \hat{H}_\mathrm{atom:cav} + \hat{H}_\mathrm{cav} + \hat{H}_\mathrm{laser:cav} \ .\end{aligned} \tag{45.71}$$

We see that only the symmetric mode couples to the atom. On the other hand, both modes contribute to the field energy,

$$\hat{H}_\mathrm{cav} = \Delta_\mathrm{c}(\hat{a}_+^\dagger\hat{a}_+ + \hat{a}_-^\dagger\hat{a}) = \Delta_\mathrm{c}(\hat{b}_\mathrm{s}^\dagger\hat{b}_\mathrm{s} + \hat{b}_\mathrm{a}^\dagger\hat{b}_\mathrm{a}) \ . \tag{45.72}$$

Now, let us check the pump terms,

$$\begin{aligned}\hat{H}_\mathrm{laser:cav} &= \imath\eta_+(\hat{a}_+ - \hat{a}_+^\dagger) + \imath\eta_-(\hat{a}_- - \hat{a}_-^\dagger) \\ &= \tfrac{\imath}{\sqrt{2}}\Big[(\eta_+e^{-\imath kz} + \eta_-e^{\imath kz})\hat{b}_\mathrm{s} - (\eta_+e^{\imath kz} + \eta_-e^{-\imath kz})\hat{b}_\mathrm{s}^\dagger \\ &\qquad +(\eta_+e^{-\imath kz} - \eta_-e^{\imath kz})\hat{b}_\mathrm{a} - (\eta_+e^{\imath kz} - \eta_-e^{-\imath kz})\hat{b}_\mathrm{a}^\dagger\Big] \ .\end{aligned} \tag{45.73}$$

For $\eta_+ = \eta_- = \eta$ we get,

$$\hat{H}_\mathrm{laser:cav} = \eta\sqrt{2}\left[\imath(\hat{b}_\mathrm{s} - \hat{b}_\mathrm{s}^\dagger)\cos kz + (\hat{b}_\mathrm{a} + \hat{b}_\mathrm{a}^\dagger)\sin kz\right] \ . \tag{45.74}$$

Hence, for $kz = 0$ only the symmetric mode is pumped (no central peak). On the other hand, for $kz = \frac{\pi}{2}$ only the anti-symmetric mode is pumped, so that no normal-mode splitting is expected.

For $\eta_- = 0$ we get,

$$\hat{H}_{laser:cav} = \tfrac{\imath\eta_+}{\sqrt{2}}\left[e^{-\imath kz}(\hat{b}_\mathrm{s} + \hat{b}_\mathrm{a}) - e^{\imath kz}(\hat{b}_\mathrm{s}^\dagger + \hat{b}_\mathrm{a}^\dagger)\right] \ . \tag{45.75}$$

Hence, both modes are pumped and we observe three peaks. The normal-mode splitting can be observed in transmission spectra, as we will demonstrate in the following.

45.1.4.4 Normal modes of a ring cavity

We start from the Hamiltonian (45.68) and derive the Heisenberg equations,

$$\begin{aligned}\dot{\hat{\sigma}}^- &= (\imath\Delta_\mathrm{a} - \tfrac{\Gamma}{2})\hat{\sigma}^- - \imath g(e^{\imath kz}\hat{a}_+ + e^{-\imath kz}\hat{a}_-)\hat{\sigma}^z \\ \dot{\hat{\sigma}}^z &= 2\imath g(e^{\imath kz}\hat{a}_+ + e^{-\imath kz}\hat{a}_-)\hat{\sigma}^+ - 2\imath g\hat{\sigma}^-(e^{-\imath kz}\hat{a}_+^\dagger + e^{\imath kz}\hat{a}_-^\dagger) - \Gamma(\mathbb{I}_2 + \hat{\sigma}^z) \\ \dot{\hat{a}}_\pm &= (\imath\Delta_\mathrm{c} - \kappa)\hat{a}_\pm - \imath g\hat{\sigma}^-e^{\mp\imath kz} + \eta_\pm \ .\end{aligned} \tag{45.76}$$

The stationary solution follows from the expectation values of these equations,

$$\begin{aligned}0 &= (\imath\Delta_\mathrm{a} - \tfrac{\Gamma}{2})\langle\hat{\sigma}^-\rangle + \imath g(e^{\imath kz}\langle\hat{a}_+\hat{\sigma}^z\rangle + e^{-\imath kz}\langle\hat{a}_-\hat{\sigma}^z\rangle) \\ 0 &= 2\imath g(e^{\imath kz}\langle\hat{a}_+\hat{\sigma}^+\rangle + e^{-\imath kz}\langle\hat{a}_-\hat{\sigma}^+\rangle) - 2\imath g(e^{-\imath kz}\langle\hat{a}_+^\dagger\hat{\sigma}^-\rangle + e^{\imath kz}\langle\hat{a}_-^\dagger\hat{\sigma}^-\rangle) - \Gamma(1 + \langle\hat{\sigma}^z\rangle) \\ 0 &= (\imath\Delta_\mathrm{c} - \kappa)\langle\hat{a}_\pm\rangle - \imath g\langle\hat{\sigma}^-\rangle e^{\mp\imath kz} + \eta_\pm \ .\end{aligned} \tag{45.77}$$

Neglecting all correlations, we derive from (45.77)(i),

$$\langle\hat{\sigma}^-\rangle = \frac{-\imath g}{\frac{\Gamma}{2}-\imath\Delta_{\rm a}}(e^{\imath kz}\alpha_+ + e^{-\imath kz}\alpha_-)\langle\hat{\sigma}^z\rangle \ . \tag{45.78}$$

Substituting $\langle\hat{\sigma}^\pm\rangle$ in (45.77)(ii),

$$\left(1+\frac{2g^2}{\frac{\Gamma^2}{4}+\Delta_{\rm a}^2}(|\alpha_+|^2+|\alpha_-|^2+e^{2\imath kz}\alpha_-^*\alpha_+ + e^{-2\imath kz}\alpha_+^*\alpha_-)\right)\langle\hat{\sigma}^z\rangle = -1 \ , \tag{45.79}$$

and in (45.77)(iii),

$$(\kappa-\imath\Delta_{\rm c})\alpha_\pm - \frac{g^2}{\frac{\Gamma}{2}-\imath\Delta_{\rm a}}(e^{\imath kz\mp\imath kz}\alpha_+ + e^{-\imath kz\mp\imath kz}\alpha_-)\langle\hat{\sigma}^z\rangle = \eta_\pm \ . \tag{45.80}$$

Substituting $\langle\hat{\sigma}^z\rangle$ from (45.77) in (45.77),

$$(\kappa-\imath\Delta_{\rm c})\alpha_\pm - \frac{g^2(\frac{\Gamma}{2}+\imath\Delta_{\rm a})(\alpha_\pm + e^{\mp 2\imath kz}\alpha_\mp)}{\frac{\Gamma^2}{4}+\Delta_{\rm a}^2+2g^2(|\alpha_+|^2+|\alpha_-|^2+e^{2\imath kz}\alpha_-^*\alpha_+ + e^{-2\imath kz}\alpha_+^*\alpha_-)} = \eta_\pm \ . \tag{45.81}$$

Assuming weak excitation, $g|\alpha_\pm|^2 \ll \Gamma, \Delta_{\rm a}$, this last expression simplifies to,

$$\left(\kappa-\imath\Delta_{\rm c}-\frac{g^2}{\frac{\Gamma}{2}-\imath\Delta_{\rm a}}\right)\alpha_\pm - \frac{g^2}{\frac{\Gamma}{2}-\imath\Delta_{\rm a}}e^{\mp 2\imath kz}\alpha_\mp \simeq \eta_\pm \ , \tag{45.82}$$

or, using the abbreviations,

$$U_\gamma \equiv U_0 - \imath\gamma_0 \equiv \frac{g^2}{\Delta_{\rm a}+\imath\Gamma} = \frac{g^2(\Delta_{\rm a}-\imath\frac{\Gamma}{2})}{\frac{\Gamma^2}{4}+\Delta_{\rm a}^2} \ , \tag{45.83}$$

we write,

$$[\kappa+\imath(U_\gamma-\Delta_{\rm c})]\alpha_\pm + \imath U_\gamma e^{\mp 2\imath kz}\alpha_\mp \simeq \eta_\pm \ . \tag{45.84}$$

Resolving for $\alpha_\pm$,

$$\boxed{\alpha_\pm \simeq \frac{\eta_\pm\,[\kappa+\gamma_0+\imath(U_0-\Delta_{\rm c})] - \eta_\mp(\gamma_0+\imath U_0)e^{\mp 2\imath kz}}{[\kappa+\gamma_0+\imath(U_0-\Delta_{\rm c})]^2-(\gamma_0+\imath U_0)^2}} \ , \tag{45.85}$$

from which we can determine the transmission,

$$T_\pm = \left|\frac{\kappa\alpha_\pm}{\eta_\pm}\right|^2 \ . \tag{45.86}$$

This is illustrated in Fig. 45.6.

Example 311 (*Generalization for many atoms*): For N uncorrelated atoms, defining a bunching parameter via $b \equiv \frac{1}{N}\sum_j e^{2\imath kz_j}$ and introducing the abbreviations $U_\gamma \equiv U_0 - \imath\gamma_0$ and $\Delta_\kappa \equiv \Delta_{\rm c} + \imath\kappa$, the result (45.67) can be generalized to,

$$\alpha_\pm \simeq -\imath\frac{\eta_\pm(NU_\gamma-\Delta_\kappa)-\eta_\mp NbU_\gamma}{(NU_\gamma-\Delta_\kappa)^2-(N|b|^2U_\gamma)^2} \ . \tag{45.87}$$

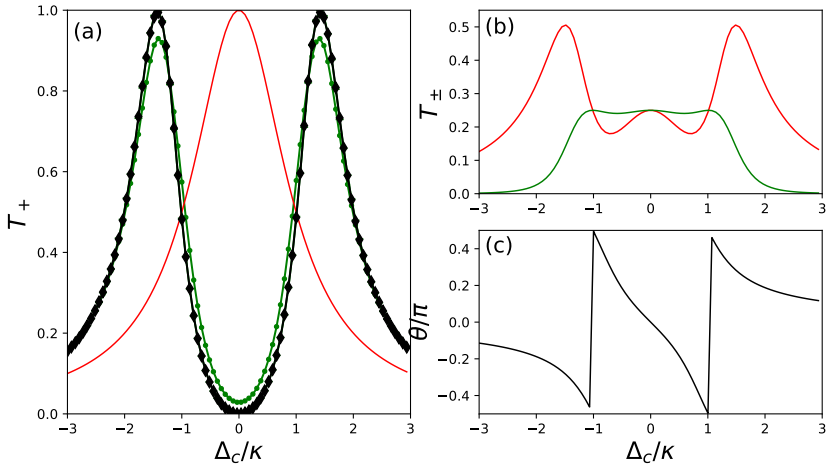

Figure 45.6: (code) Normal-mode splitting in a ring cavity observed in transmission spectra T_+ calculated from (45.86) with $g = \kappa$, $\eta_+ = 0.1\kappa$, and $\Gamma = R = 0$. (a) The blue curve is obtained for one-sided pumping ($\eta_- = 0$), the green curve for symmetric pumping ($\eta_- = \eta_+$ and $kz = 0$), and the red curve for anti-symmetric pumping ($\eta_- = \eta_+$ and $kz = \pi/2$). The green dots are obtained for symmetric pumping via numerical integration of the Hamiltonian (45.68). (b) Transmission spectra T_+ (green) and T_- (red) for one-sided pumping. (c) Phase of the standing wave formed by backscattering of probe light into the mode α_-.

Example 312 (*Level splitting for some limiting cases*): The first limiting case consists in setting $\eta_\pm = 0$ and assuming the light field to be classical. Then we obtain the Rabi Hamiltonian studied in previous sections,

$$\hat{H}_{\text{Rabi}} = -\Delta_{\text{a}}\hat{\sigma}^+\hat{\sigma}^- + \tfrac{1}{2}\Omega(\hat{\sigma}^+ + \hat{\sigma}^-) = \begin{pmatrix} 0 & \frac{1}{2}\Omega \\ \frac{1}{2}\Omega & -\Delta_{\text{a}} \end{pmatrix} .$$

Its eigenvalues: $E_{1,2} = -\frac{1}{2}\Delta_{\text{a}} \pm \sqrt{\Delta_{\text{a}}^2 + \Omega^2}$ exhibit the famous Autler-Townes splitting.
The second limiting case consists adiabatically eliminating the atomic states. This is valid if $|\Delta_{\text{a}}| \gg \Gamma$. Then we obtain the cavity Hamiltonian,

$$\hat{H}_{\text{cav}} = U_0(e^{-2\imath kz}\hat{a}_+^\dagger\hat{a}_- + e^{2\imath kz}\hat{a}_+\hat{a}_-^\dagger) + \sum_\pm (U_0 - \Delta_{\text{c}})\hat{a}_\pm^\dagger\hat{a}_\pm - \imath\eta_\pm(\hat{a}_\pm - \hat{a}_\pm^\dagger) ,$$

with $L_k = \hat{a}_+, \hat{a}_-$ and $\gamma_k = 2\kappa, 2\kappa$, again for the case $z = \eta_\pm = 0$. The spectrum is asymmetric because $\Delta_{\text{a}} \neq 0$ [2,3]

[2]We note that, setting $z = \eta_\pm = 0$, the cavity Hamiltonian $\hat{H}_{\text{cav}} = U_0(\hat{a}_+^\dagger\hat{a}_- + \hat{a}_+\hat{a}_-^\dagger) - (\Delta_{\text{c}} - U_0)\sum_\pm \hat{a}_\pm^\dagger\hat{a}_\pm$ has the same structure as the Rabi Hamiltonian, which we can write, introducing annihilation and creation operators $\hat{\psi}_{g,e}$ and $\hat{\psi}_{g,e}^\dagger$ for atoms in ground and excited states, $\hat{H}_{\text{Rabi}} = \frac{1}{2}\Omega(\hat{\psi}_e^\dagger\hat{\psi}_g + \hat{\psi}_g^\dagger\hat{\psi}_e) - \Delta_{\text{a}}\sum_{j=g,e}\hat{\psi}_j^\dagger\hat{\psi}_j$. This emphasizes the analogy between Autler-Townes and normal-mode splitting.

[3]As the atomic degrees of freedom have been eliminated, spontaneous emission must be reintroduced by hand when required.

45.1.5 Adiabatic elimination of internal states

The equations of motion (38.38) describe the evolution of the light fields in counter-propagating modes of a ring cavity. Without scatterer located in the mode volume, the modes evolve independently. In contrast, a scatterer (e.g. an atom or a beam splitter) may redistribute photons between the modes, whose dynamics thereby becomes coupled.

We will in the following assume the scatterer as immobile, except for Sec. 45.1.8, where we consider a vibrating scatterer. Immobile scatterers can, for example, be heavy masses, such as imperfections on the surfaces of the mirrors of the cavity (scratches, dust particles, etc.), which can scatter light both, out of the cavity and into the reverse cavity mode. In *laser gyroscopes* this backscattering may induce a locking of counterpropagating modes and hamper their proper operation.

45.1.5.1 Classical derivation of coupled atom-ring cavity equations

The equations of motion (38.38) describe the light fields classically. Hence, it is not surprising that they can be derived with entirely classical arguments. Here, we will show this for a ring cavity in the presence of an atom sitting at a fixed position z on the cavity's optical axis. We understand the atom as a beamsplitter located within the mode volume of the resonator and partially reflecting and transmitting incident light with reflection and transmission coefficients $(r_\beta, t_\beta) = (\imath\beta, 1 + \imath\beta)$ such that $r_\beta^2 + t_\beta^2 = 1$. Transmitted (forward scattered) photons may be phase-shifted, while reflected photons are backscattered into the counterpropagating mode of the resonator.

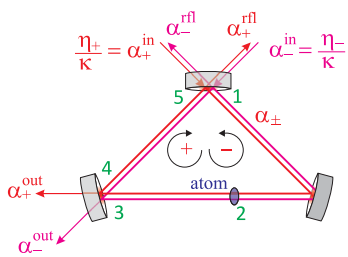

Figure 45.7: Scheme of a ring cavity containing an atom.

Similarly, we treat the incoupling mirror as a beam splitter with coefficients $(r_{\rm in}, t_{\rm in})$. The incident field $\alpha_{\rm in}$ produces, in the cavity, field amplitudes of $\alpha_\pm$ for the co- and counterpropagating waves. As in (38.34), we normalize the amplitudes by the numbers of photons $n_\pm \equiv |\alpha_\pm|^2$. After a round-trip time $\tau = \delta_{\rm fsr}^{-1}$ through the mode volume we have in the position of the incoupling mirror (marked as (1) in Fig. 45.7) the field,

$$\begin{aligned}\alpha_+(t+\tau) &= -r_{\rm in}(1+\imath\beta)e^{\imath kL}\alpha_+(t) + \imath\beta r_{\rm in}^2 e^{2\imath kL - 2\imath kz}\alpha_-(t) + t_{\rm in}\alpha_+^{in}(t) \\ \alpha_-(t+\tau) &= -r_{\rm in}(1+\imath\beta)e^{\imath kL}\alpha_-(t) + \imath\beta e^{2\imath kz}\alpha_+(t) + t_{\rm in}(1+\imath\beta)e^{\imath kL}\alpha_-^{in}(t)\ .\end{aligned} \tag{45.88}$$

L is the total length of the ring cavity. For the three mirror ring cavity depicted in

Fig. 45.7 we have after one round trip $\tau\dot{\alpha}_\pm = \alpha_\pm(t+\tau) + \alpha_\pm(t)$ [4]. Thus, we obtain,

$$\begin{aligned}\tau\dot{\alpha}_+ &= -\left[1 + r_{\rm in}(1+\imath\beta)e^{\imath kL}\right]\alpha_+ + \imath\beta r_{\rm in}^2 e^{2\imath kL - 2\imath kz}\alpha_- + t_{\rm in}\alpha_+^{in} \\ \tau\dot{\alpha}_- &= -\left[1 + r_{\rm in}(1+\imath\beta)e^{\imath kL}\right]\alpha_- + \imath\beta e^{2\imath kz}\alpha_+ + t_{\rm in}(1+\imath\beta)e^{2\imath kL}\alpha_-^{\rm in}\ .\end{aligned} \tag{45.89}$$

Obviously, we have $kL = \omega/\delta_{\rm fsr}$. In the vicinity of a resonance we have, $\Delta_{\rm c} \ll \delta_{\rm fsr}$, and the quantity $\omega/\delta_{\rm fsr}$ is almost integer, $\omega = 2\pi N\delta_{\rm fsr} - \Delta_{\rm c}$, such that we can expand the exponential, $e^{\imath kL} \simeq 1 - \imath\Delta_{\rm c}/\delta_{\rm fsr}$. Neglecting the exponential $e^{\imath kL}$ in all terms except the first ones of both equations and also using $\tau = \delta_{\rm fsr}^{-1}$, we get,

$$\begin{aligned}\dot{\alpha}_+ &= -\delta_{\rm fsr}\left[1 - r_{\rm in}(1+\imath\beta)\left(1 - \imath\Delta_{\rm c}/\delta_{\rm fsr}\right)\right]\alpha_+(t) + \delta_{\rm fsr}\imath\beta r_{\rm in}^2 e^{-2\imath kz}\alpha_-(t) + \delta_{\rm fsr}t_{\rm in}\alpha_+^{\rm in}(t) \\ \dot{\alpha}_- &= -\delta_{\rm fsr}\left[1 - r_{\rm in}(1+\imath\beta)\left(1 - \imath\Delta_{\rm c}/\delta_{\rm fsr}\right)\right]\alpha_-(t) + \delta_{\rm fsr}\imath\beta e^{2\imath kz}\alpha_+(t) + \delta_{\rm fsr}t_{\rm in}(1+\imath\beta)\alpha_-^{\rm in}(t)\ .\end{aligned} \tag{45.90}$$

We now connect the transmission of the coupling mirror $t_{\rm in}$ with the decay constant κ assuming that the light can only leave the cavity through this mirror. We identify,

$$\kappa_{\rm int} = \kappa = \frac{T_{\rm in}}{\tau} = \frac{t_{\rm in}^2}{\tau} \tag{45.91}$$

as the part of the light *intensity* lost during one round trip. Thus, $t_{\rm in} = \sqrt{\kappa/\delta_{\rm fsr}}$. Now, we simplify the prefactor of the first term in Eqs. (45.90) neglecting β and replacing $r_{\rm in} = \sqrt{1 - t_{\rm in}^2} \simeq 1 - \frac{t_{\rm in}^2}{2} = 1 - \frac{2\kappa\tau}{2}$,

$$\delta_{\rm fsr}\left[1 - r_{\rm in}(1+\imath\beta)\left(1 - \tfrac{\imath\Delta_{\rm c}}{\delta_{\rm fsr}}\right)\right] \simeq \delta_{\rm fsr}\left[1 - \left(1 - \tfrac{t_{\rm in}^2}{2}\right)\left(1 - \tfrac{\imath\Delta_{\rm c}}{\delta_{\rm fsr}}\right)\right] = \kappa + \imath\Delta_{\rm c}\ . \tag{45.92}$$

It gives the cavity losses for the two modes during one round trip. We assume here that losses can only occur via the coupling mirror. However, all losses can be included in a single appropriate κ. There are usually other losses due to scattering on the surface of the mirrors or absorption by the atoms. Finally, we obtain for weak atomic reflection and in resonance, that is, for $\beta \ll \kappa$ and $\Delta_{\rm c} = 0$ the system of equations,

$$\begin{aligned}\dot{\alpha}_+ &= -(\kappa + \imath\Delta_{\rm c})\alpha_+ + \imath\delta_{\rm fsr}\beta e^{-2\imath kz}\alpha_- + \sqrt{\kappa\delta_{\rm fsr}}\alpha_+^{\rm in} \\ \dot{\alpha}_- &= -(\kappa + \imath\Delta_{\rm c})\alpha_- + \imath\delta_{\rm fsr}\beta e^{2\imath kz}\alpha_+ + \sqrt{\kappa\delta_{\rm fsr}}\alpha_-^{\rm in}\end{aligned} \tag{45.93}$$

To calculate the value of β, we need the reflection coefficient of a single atom. It depends on the polarizability,

$$r_\beta = \frac{k}{\pi w^2}\frac{\alpha_{\rm pol}}{\varepsilon_0}\ \left(= \frac{\sigma_0}{\pi w^2}\frac{\Gamma}{2\Delta_{\rm a}}\right)\ . \tag{45.94}$$

The optical potential to which the atom is exposed is,

$$\phi = \frac{I}{2c}\frac{\alpha_{\rm pol}}{\varepsilon_0}\ , \tag{45.95}$$

[4] For a four mirror ring cavity we would have $\tau\dot{\alpha}_\pm(t+\tau) = \alpha_\pm(t+\tau) - \alpha_\pm(t)$, and the sign of the first term in (45.88) would have to be inverted, because any reflection of the intracavity field at a cavity mirror introduces a phase shift of π.

where we write the intensity of light as,

$$I = 2\varepsilon_0 c \mathcal{E}_1^2 |\alpha_+ e^{\imath kZ} + \alpha_- e^{-\imath kZ}| \ . \tag{45.96}$$

We normalize once more to the field generated by a single photon, $\mathcal{E}_1 = \sqrt{\hbar\omega/2\varepsilon_0 V_\mathrm{m}}$ with the mode volume, $V_\mathrm{m} = \frac{\pi}{2} L w^2$. On the other hand, the potential can be determined directly through the Rabi frequency,

$$\phi(\mathbf{r}) = \frac{\hbar\Omega(\mathbf{r})^2}{4\Delta_\mathrm{a}} \ , \tag{45.97}$$

The Rabi frequency $\Omega(\mathbf{r})^2 = 4g^2|\alpha_+ e^{\imath kZ} + \alpha_- e^{-\imath kZ}|^2$ is normalized to the frequency of Rabi generated by a photon g. Using the frequency shift (light-shift) by photon (45.37), $U_0 = \frac{g^2}{\Delta_\mathrm{a}}$, we can also write,

$$\phi(\mathbf{r}) = \hbar U_0 |\alpha_+ e^{\imath kZ} + \alpha_- e^{-\imath kZ}|^2 \ . \tag{45.98}$$

A comparison of the above equations gives,

$$r_\beta = \frac{\imath U_0}{\delta_\mathrm{fsr}} \ . \tag{45.99}$$

With an atom in the resonator, we have,

$$\beta = \frac{\imath U_0}{\delta_\mathrm{fsr}} \ . \tag{45.100}$$

We define for convenience, $\eta_\pm = \sqrt{\kappa\delta_\mathrm{fsr}}\alpha_\pm^{in}$ and we suppose, that $t_\mathrm{in} \ll 1$, $r_\beta \ll 1$ and $\beta \ll 1$. This ultimately leads to the result,

$$\dot{\alpha}_\pm = -\kappa\alpha_\pm - \imath U_0 e^{\mp 2\imath kz}\alpha_\mp + \eta_\pm \ . \tag{45.101}$$

Example 313 (*Classical CARL equations*): If we were to treat the atomic position z as a degree of freedom, we could calculate the classical potential of the stationary light wave, and therefore the dipole force,

$$F = -\nabla\phi = -\hbar U_0 \nabla_{Z=z} |\alpha_+ e^{\imath kZ} + \alpha_- e^{-\imath kZ}|^2 \ , \tag{45.102}$$

and, consequently, derive the dynamics of the scatterer via,

$$m\ddot{z} = -2\imath\hbar k U_0 (\alpha_+\alpha_-^* e^{2\imath kz} - \alpha_+^*\alpha_- e^{-2\imath kz}) \ . \tag{45.103}$$

This will be studied in Chp. 48. In the remaining sections of this chapter we will assume the atom to be located at a fixed position.

In the above derivation we assumed, for simplicity, the pump laser on resonance with the cavity, $\Delta_\mathrm{c} = 0$. Relaxing this condition, an analogous derivation yields [5],

$$\dot{\alpha}_\pm = (-\kappa + \imath\Delta_\mathrm{c} - \imath U_0)\alpha_\pm - \imath U_0 e^{\mp 2\imath kz}\alpha_\mp + \eta_\pm \ . \tag{45.104}$$

[5] Note, that we have not allowed for spontaneous emission by the atomic scatterer out of the cavity mode. This approximation is only good far from resonance, $\Delta_\mathrm{a} \gg \Gamma$. We will see in Sec. 48.1.3, how to generalize the equations of motion for near resonance cases.

45.1.5.2 Adiabatically simplified Hamiltonian

In a ring cavity, the simplified Hamiltonian,

$$\boxed{\hat{H} = (U_0 - \Delta_c)\sum_{\pm} \hat{a}_{\pm}^{\dagger}\hat{a}_{\pm} - \imath\eta_{\pm}(\hat{a}_{\pm} - \hat{a}_{\pm}^{\dagger}) + U_0(\hat{a}_{+}\hat{a}_{-}^{\dagger}e^{2\imath kz} + \hat{a}_{+}^{\dagger}\hat{a}_{-}e^{-2\imath kz})} \ , \tag{45.105}$$

which can be obtained from the full Hamiltonian via adiabatic elimination of the excited atomic state, already exhibits this phenomenon. With the above Hamiltonian we derive from the Heisenberg equation,

$$\dot{\hat{a}}_{\pm} = -\imath[\hat{a}_{\pm}, \hat{a}] - \kappa\hat{a}_{\pm} = (-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_{\pm} - \imath U_0 e^{\mp 2\imath kz}\hat{a}_{\mp} + \eta_{\pm} \ , \tag{45.106}$$

which, after taking the expectation values and disregarding correlations, reproduces the equations of motion (45.104). Of course, as we eliminated the internal atomic degree of freedom, spontaneous emission is not accounted for. We may, however, include it phenomenologically via the substitution $U_0 \to U_\gamma \equiv U_0 - \imath\gamma_0$. The stationary solution of Eq. (45.106) is *exactly the same* as the one derived for the full Jaynes-Cummings model (45.85) under the assumption of weak excitation, $g|\alpha_{\pm}| \ll \Gamma, \Delta_a$,

$$\boxed{\alpha_{\pm} = -\imath\frac{\eta_{\pm}(U_\gamma - \Delta_\kappa) - U_\gamma e^{\mp 2\imath kz}\eta_{\mp}}{(U_\gamma - \Delta_\kappa)^2 - U_\gamma^2}} \tag{45.107}$$

with the abbreviations,

$$U_\gamma \equiv U_0 - \imath\gamma_0 \quad , \quad \Delta_\kappa \equiv \Delta_c + \imath\kappa \ . \tag{45.108}$$

Solve the Exc. 45.1.11.6.

45.1.6 Normal mode splitting induced by beam splitting

The fact that (in the weak excitation limit) normal mode splitting is fully described by the classical field equations (45.104) shows that the phenomenon clearly is *not a quantum effect*: a classical beam splitter inserted into the cavity does the same job. We will now discuss the normal mode splitting in detail based on the adiabatically simplified equations (45.108).

The equation (45.104) can be written as follows,

$$\imath\dot{\vec{\alpha}} = W\vec{\alpha} + \imath\vec{\eta} \ , \tag{45.109}$$

where $\vec{\alpha}$ and $\vec{\eta}$ regroup the amplitudes $\alpha_{\pm}$ and $\eta_{\pm}$. This equation takes the form of a Schrödinger equation, where,

$$W \equiv \begin{pmatrix} U_0 - \Delta_c - \imath\kappa & U_0 e^{-2\imath kz} \\ U_0 e^{2\imath kz} & U_0 - \Delta_c - \imath\kappa \end{pmatrix} \tag{45.110}$$

would be the Hamiltonian describing the coupling between counterpropagating modes. The eigenvalues of this matrix are,

$$W^{(1,2)} = 2U_0 - \Delta_c - \imath\kappa \quad , \quad -\Delta_c - \imath\kappa \ . \tag{45.111}$$

This *normal mode splitting* [6] of the cavity results from the coupling of the two cavity modes $\hat{a}_+^\dagger \hat{a}_-$. Obviously, the energies and widths of the eigenvalues do not depend neither on the pump intensities $\eta_\pm$ nor the z-position of the atom. On the other hand, the spectral behavior of $\alpha_\pm$, and hence the observable quantities, such as the transmission

$$T_\pm \equiv \left|\frac{\kappa\alpha_\pm}{\eta_\pm}\right|^2 \tag{45.112}$$

depend on these parameters. In the following, we will study normal mode splitting in a ring cavity by a discussion of the expression (45.85) for the cases of (i) anti-symmetric pumping, (ii) symmetric pumping, and (iii) uni-directional pumping.

(i) Assuming $\gamma_0 = 0$ and anti-symmetric pumping, $\eta_- = \eta_+$ and $kz = \pi/2$, the expression (45.85) becomes,

$$\begin{aligned} \alpha_+ &= \eta_+ \frac{\kappa - \imath(\Delta_\mathrm{c} - 2U_0)}{[\kappa - \imath(\Delta_\mathrm{c} - U_0)]^2 + U_0^2} \\ \Rightarrow \quad \left|\frac{\alpha_+}{\eta_+}\right|^2 &= \frac{1}{\kappa^2 + \Delta_\mathrm{c}^2} \ . \end{aligned} \tag{45.113}$$

That is, the transmission profile is a Lorentzian.

(ii) For symmetric pumping, $\eta_- = \eta_+$ and $kz = 0$,

$$\begin{aligned} \alpha_+ &= \eta_+ \frac{\kappa - \imath\Delta_\mathrm{c}}{[\kappa - \imath(\Delta_\mathrm{c} - U_0)]^2 + U_0^2} \\ \Rightarrow \quad \left|\frac{\alpha_+}{\eta_+}\right|^2 &= \frac{1}{\kappa^2 + (\Delta_\mathrm{c} - 2U_0)^2} \ . \end{aligned} \tag{45.114}$$

Setting $\Delta_\mathrm{c} = \Delta_\mathrm{a}$ we find from $0 \equiv \frac{d}{d\Delta_\mathrm{c}} \left|\frac{\alpha_+}{\eta_+}\right|^2$ a minimum at $\Delta_\mathrm{c} = 0$ and two maxima at $\Delta_\mathrm{c} = 2U_0 = \sqrt{2}g$. This is the usual normal mode splitting for a ring cavity.

(iii) For uni-directional pumping, $\eta_- = 0$,

$$\begin{aligned} \alpha_+ &= \eta_+ \frac{\kappa - \imath(\Delta_\mathrm{c} - U_0)}{[\kappa - \imath(\Delta_\mathrm{c} - U_0)]^2 + U_0^2} \\ \Rightarrow \quad \left|\frac{\alpha_+}{\eta_+}\right|^2 &= \frac{\kappa^2 + (\Delta_\mathrm{c} - U_0)^2}{[\kappa^2 - \Delta_\mathrm{c}(\Delta_\mathrm{c} - 2U_0)]^2 + 4\kappa^2(\Delta_\mathrm{c} - U_0)^2} \ . \end{aligned} \tag{45.115}$$

That is, the transmission profile is a more complicated and may exhibit up to three peaks.

45.1.6.1 Unidirectional pumping

For unilateral pumping, $\eta_- = 0$, and approximating $\gamma_0 = 0$, the solution (45.85) simplifies to,

$$\alpha_+(\infty) = \eta_+ \frac{\chi}{\chi^2 + U_0^2} \qquad \text{and} \qquad \alpha_-(\infty) = \eta_+ \frac{\imath U_0 e^{2\imath kz}}{\chi^2 + U_0^2} \ . \tag{45.116}$$

[6] The splitting is not exactly the *vacuum Rabi splitting*, which occurs when the excitation can not be eliminated adiabatically. The vacuum Rabi splitting results from the Jaynes-Cummings [912, 210] and is caused by the coupling of internal and external states $\hat{a}^\dagger\hat{\sigma}$.

These formulas show that, for weak coupling, $U_0 \ll \kappa$, the counterpropagating mode receives little light. On the other side, for strong coupling (or very high finesse) and $\Delta_c = 0$, the intensity is equally distributed, $|\alpha_+|^2 = |\alpha_-|^2 = \frac{\eta_+}{2\kappa}$ [7]. We calculate the splitting of normal modes in Exc. 45.1.11.7.

The counterpropagating modes form, by interference, a standing light wave giving rise to a dipole potential in the form of a one-dimensional optical lattice. Defining the phase $\theta = \theta_1 - \theta_2$ through,

$$\alpha_+ \equiv |\alpha_+| e^{-\imath\theta_1} \qquad \text{and} \qquad \alpha_- \equiv |\alpha_-| e^{-\imath\theta_2} \ , \tag{45.117}$$

we verify by the equation (38.34),

$$\mathcal{E}^+(\zeta, t) = \mathcal{E}_1 |\alpha_+(t)| e^{\imath k\zeta} + \mathcal{E}_1 |\alpha_-(t)| e^{-\imath\theta(t)} e^{-\imath k\zeta} \ , \tag{45.118}$$

and,

$$\begin{aligned} \tfrac{1}{2\varepsilon_0 c \mathcal{E}_1^2} I(\zeta, t) &= \tfrac{1}{\mathcal{E}_1^2} \mathcal{E}^+(\zeta, t) \mathcal{E}^-(\zeta, t) \\ &= |\alpha_+(t)|^2 + |\alpha_-(t)|^2 + 2|\alpha_+(t)||\alpha_-(t)| \cos(2k\zeta + \theta) \ . \end{aligned} \tag{45.119}$$

That is, the phase indicates the positions of the potential maxima. Inserting the stationary solution for unilateral pumping (45.116), we derive the expression,

$$\tan\theta = \frac{\mathfrak{Im}\, \alpha_+(\infty)\alpha_-^*(\infty)}{\mathfrak{Re}\, \alpha_+(\infty)\alpha_-^*(\infty)} = \frac{\mathfrak{Im}\, \chi \imath e^{-2\imath kz}}{\mathfrak{Re}\, \chi \imath e^{-2\imath kz}} = \frac{\kappa \cos 2kz + (U_0 - \Delta_c) \sin 2kz}{\kappa \sin 2kz - (U_0 - \Delta_c) \cos 2kz} \ . \tag{45.120}$$

Or in other words, the phase of light determines the equilibrium position of the atom (or vice versa). Two cases are interesting: (i) For $\Delta_c = 0$ and $U_0 \gg \kappa$ the condition (45.124) turns into $\tan\theta = -\tan 2kz$. In this case, the phase of the backscattered field adjusts in such a way, that the atom stays at the valleys of the anti-nodes. (ii) For $\Delta_c = U_0$ (or alternatively, when $\kappa \gg U_0, \Delta_c$) the condition (45.124) turns into $\tan\theta = -\tan(2kx + \frac{\pi}{2})$, such that the atom is at half height of the potential slope, exactly at the position, where it is able to backscatter the maximum of photons from the pumped mode α_+ to the mode α_-.

45.1.6.2 (Anti-)Symmetric pumping

Let us assume equal intensities for the pumps, but variable phases, $\eta_\pm = \eta e^{\pm\imath\phi}$, such that $\xi = e^{-2\imath kz - \imath\phi}$. Then, equation (45.85) simplifies to,

$$\alpha_\pm(\infty) = \eta_\pm \frac{\chi - \imath U_\gamma \xi^\pm}{\chi^2 + U_\gamma^2} = \eta \frac{\chi - \imath U_\gamma e^{\mp 2\imath kz \mp \imath\phi}}{\chi^2 + U_\gamma^2} \ . \tag{45.121}$$

The potential is calculated in the same way as in (45.119). The coherences are,

$$\begin{aligned} \alpha_\pm(\infty)\alpha_\pm^*(\infty) &= \eta^2 \tfrac{(\kappa - \imath\Delta_c \mp 2U_0 e^{\mp\imath kz} \sin kz)(\kappa + \imath\Delta_c \mp 2U_0 e^{\pm\imath kz} \sin kz)}{(\kappa^2 + 2U_0\Delta_c - \Delta_c^2)^2 + 4\kappa^2 (U_0 - \Delta_c)^2} \\ \alpha_\pm(\infty)\alpha_\mp^*(\infty) &= \eta^2 \tfrac{\kappa^2 + (\Delta_c \mp 2\imath U_0 e^{\mp\imath kz} \sin kz)^2}{(\kappa^2 + 2U_0\Delta_c - \Delta_c^2)^2 + 4\kappa^2 (U_0 - \Delta_c)^2} \\ e^{\pm 2\imath kz} &= \tfrac{\alpha_\mp \alpha_\pm^*}{|\alpha_- \alpha_+^*|} \end{aligned} \ , \tag{45.122}$$

[7] This observation explains why perturbing effects such as backscattering from mirrors imperfections are dramatically magnified when the finesse is high.

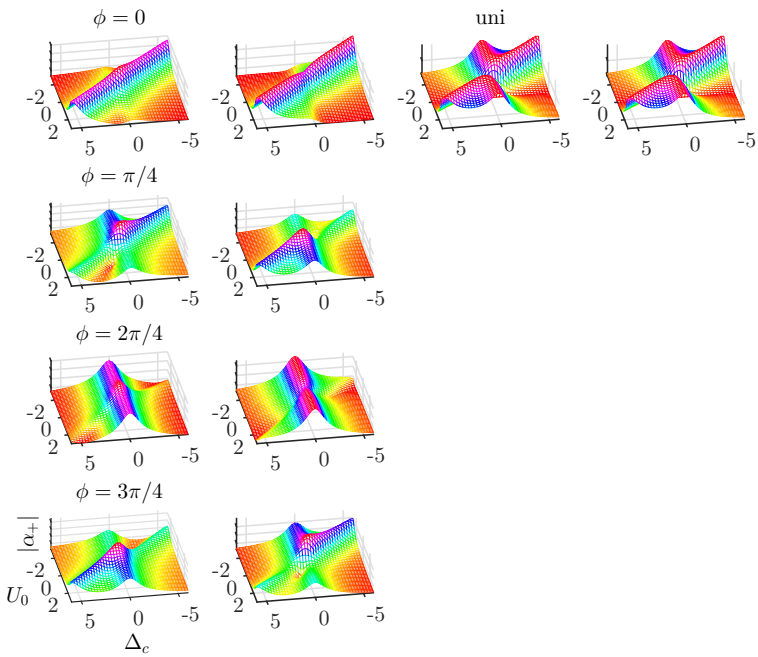

Figure 45.8: (code) (columns 1 and 2) Steady state field values according to (45.109) for bidirectional pumping with a single scatterer located at ϕ. (columns 3 and 4) Same for unidirectional pumping. Here the location of the scatterer does not matter.

such that the relative phase of the counter-propagating waves adjusts itself to,

$$\tan\theta = \frac{\mathfrak{Im}\,\alpha_+(\infty)\alpha_-^*(\infty)}{\mathfrak{Re}\,\alpha_+(\infty)\alpha_-^*(\infty)} = \frac{\kappa^2\sin 2\phi + 4U_0^2\sin^2(kz+\phi)\sin 2kz}{\kappa^2\cos 2\phi - 4U_0^2\sin^2(kz+\phi)\cos 2kz}\ . \tag{45.123}$$

The quantity η^2/κ^2 denotes the number of intracavity photons. According to the formula (45.123), for a weak atom-field coupling, $U_0 \ll \kappa$, the phase adjusts itself to the external pumps, $\theta \to 2\phi$, while for strong coupling, it adjusts to the position of the atom, $\theta \to 2kz$.

Example 314 (*'Pulling' of the optical mode by the atom*): We study the case $U_0 \simeq \kappa$ considering $\gamma_0 = 0 = \Delta_c$ and a particular external phase [337], $\phi = \pi/2$,

$$\alpha_\pm(\infty) = \pm\imath\eta\frac{\kappa + \imath U_0 \pm U_0 e^{\mp 2\imath kz}}{\kappa^2 + 2\imath\kappa U_0} \tag{45.124}$$

$$\theta(\infty) = \arctan\frac{-4U_0^2\cos^2 kz\sin 2kz}{\kappa^2 + 4U_0^2\cos^2 kz\cos 2kz} \simeq \arctan\frac{-8U_0^2}{\kappa^2+4U_0^2}kz\ ,$$

expanding the last formula around $kz = 0$. Fig. 45.9 shows how, with the increase in the coupling force between the field and the atoms, U_0, the phase tends to lock to the atomic position. However, the phase imposed by the external pump competes for this privilege. Curiously, this is independent of laser power, but depends only on the ratio between U_0 and κ.

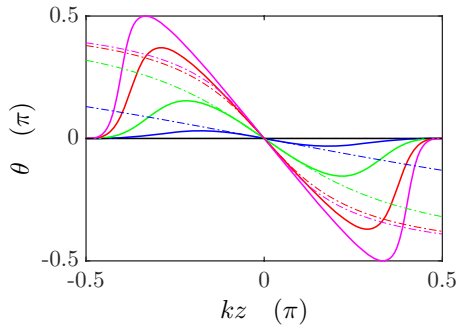

Figure 45.9: (code) 'Pulling' of the phase by the atoms for $U_0/\kappa = 0$, 0.2, 0.5, 1 and $\sqrt{2}$. The solid curves show the exact phase, the 'dash-dotted' curves the linear approximation (45.128).

Example 315 (*Resonant case*): Assuming that the cavity is in resonance, $\Delta_c = 0$, and pumped in a single direction, $\eta_- = 0$, neglecting spontaneous emission, $\gamma_0 = 0$, and assuming low backscattering rates, $U_s \ll \kappa$,

$$\alpha_+(\infty) \simeq \frac{\eta_+}{\kappa} \qquad \text{and} \qquad |\alpha_-(\infty)| = \frac{U_s}{\kappa}|\alpha_+(\infty)| \ .$$

Looking at short times, we find that the dynamics of the unpumped mode is delayed, since,

$$\dot{\alpha}_+(0) \simeq \eta_+ \qquad \text{and} \qquad \dot{\alpha}_-(0) \simeq -\imath U_s \alpha_+ e^{-2\imath k r_s} \ ,$$

giving,

$$\alpha_+(0) \simeq \eta_+ t \qquad \text{and} \qquad \alpha_-(0) \simeq -\imath U_s \eta_+ \frac{t^2}{2} e^{-2\imath k r_s} \ .$$

The complete solution of the equations (45.112) with unidirectional pumping, $\eta_- = 0$, will be derived in Exc. 45.1.11.8.

45.1.7 Time-dependent solutions

45.1.7.1 Time-dependent solution without pump

To calculate the homogeneous time-dependent solution of the equation of motion of the ring cavity with $\eta_\pm = 0$, we solve the Schrödinger equation (45.109) the way we learned in quantum mechanics. We start by diagonalizing the matrix (45.110),

$$\begin{aligned} W &= \begin{pmatrix} U_0 - \imath\kappa & U_0 e^{-2\imath k z} \\ U_0 e^{2\imath k z} & U_0 - \imath\kappa \end{pmatrix} \\ &= \begin{pmatrix} e^{-2\imath k z} & -e^{-2\imath k z} \\ 1 & 1 \end{pmatrix} \begin{pmatrix} 2U_0 - \imath\kappa & 0 \\ 0 & -\imath\kappa \end{pmatrix} \begin{pmatrix} e^{-2\imath k z} & -e^{-2\imath k z} \\ 1 & 1 \end{pmatrix}^{-1} = U E_W U^{-1} \ , \end{aligned} \tag{45.125}$$

where E_W is the matrix of eigenvalues and U a unitary transformation. So,

$$\begin{aligned} \vec{\alpha} &= e^{-\imath W t}\vec{\alpha}_0 = U e^{-i E_W t} U^{-1}\vec{\alpha}_0 \\ &= e^{-\kappa t - \imath U_0 t} \begin{pmatrix} \cos U_0 t & -\imath e^{-2\imath k z}\sin U_0 t \\ -\imath e^{2\imath k z}\sin U_0 t & \cos U_0 t \end{pmatrix} \vec{\alpha}_0 \ . \end{aligned} \tag{45.126}$$

In Exc. 45.1.11.6 we study the equation of motion numerically. We'll see an alternative calculation in Exc. 45.1.11.10. We calculate the coherence by,

$$\begin{aligned}\alpha_+(t)\alpha_-^*(t) &= e^{-2\kappa t}\left[\alpha_{0+}\alpha_{0-}(\cos^2 U_0 t + e^{-4\imath kz}\sin^2 U_0 t) + \tfrac{1}{2}(\alpha_{0+}^2 - \alpha_{0-}^2)\imath e^{-2\imath kz}\sin 2U_0 t\right] \\ &\xrightarrow{z\to 0} e^{-2\kappa t}\left[\alpha_{0+}\alpha_{0-} + \tfrac{1}{2}(\alpha_{0+}^2 - \alpha_{0-}^2)\imath \sin 2U_0 t\right] \ , \end{aligned} \tag{45.127}$$

making the transition to the Lamb-Dicke regime by $z \to 0$. The phase of the standing wave is,

$$\tan\theta = \frac{\mathfrak{Im}\,\alpha_+(t)\alpha_-^*(t)}{\mathfrak{Re}\,\alpha_+(t)\alpha_-^*(t)} \xrightarrow{z\to 0} \frac{\alpha_{0+}^2 - \alpha_{0-}^2}{2\alpha_{0+}\alpha_{0-}}\sin 2U_0 t \ . \tag{45.128}$$

We see that, in resonance and without pumping, the field adjusts its phase to the atom and also decays with the rate κ, while the atom redistributes the photons between modes with the (Rabi-)frequency $2U_0$. The formula (45.128) does not show any damping of the phase dynamics in the Lamb-Dicke regime. Thus, in the absence of pumping, the cavity dissipation reduces only the field amplitudes, but does not damp the adjustment of the phase to the atomic position.

45.1.7.2 Time-dependent solution with fixed pump

To find the complete solution of the inhomogeneous Schrödinger equation (45.109), we first calculate the stationary solution,

$$\vec{\alpha}(\infty) = -\imath W^{-1}\vec{\eta} \ . \tag{45.129}$$

This particular solution of the inhomogeneous equation, added to the general solution of the homogeneous equation, gives the general solution of the inhomogeneous Schrödinger equation,

$$\vec{\alpha}(t) = e^{-\imath W t}\vec{\alpha}(0) + (1 - e^{-\imath W t})\vec{\alpha}(\infty) \ . \tag{45.130}$$

We derive and analyze this solution in the Exc. 45.1.11.11.

Analytical solutions only exist in particular cases. However, they allow a better understanding of the dynamics. So let's consider some limiting cases. In Exc. 45.1.11.12 we determine the steady state of an atom interacting with the modes of a unidirectionally pumped annular cavity and calculate the stationary position of the atom in a unidirectionally pumped ring cavity. In Exc. 45.1.11.13 we derive motion equations for the 'intensities' $\alpha_\pm\alpha_\pm^*$ and 'coherences' $\alpha_\pm\alpha_\mp^*$.

45.1.8 Forced atomic vibration in a ring cavity

We now assume, that the atom is forced to vibrate by an external force. The vibration is described by,

$$kz = kz_0 \sin\omega t \ . \tag{45.131}$$

We consider small modulation excursions, $1 \gtrsim kz_0 = \frac{kv}{\omega} = \frac{2\omega_{\rm rec}}{\omega}$, which is equivalent to saying that the oscillation frequency should exceed to recoil shift. In this (Lamb-Dicke) regime the Bessel-expansion yields,

$$e^{\pm 2\imath kz_0 \sin\omega t} = \sum_n J_n(\pm 2kz_0)e^{\imath n\omega t} \simeq J_0(2kz_0) \pm 2\imath J_1(2kz_0)\sin\omega t \simeq 1 \pm 2\imath kz_0 \sin\omega t \ . \tag{45.132}$$

The differential equations for the two counterpropagating ring cavity-field (45.104) can then be written:

$$\boxed{\dot{\alpha}_\pm = (\mathbf{L} - 2\imath\mathbf{X}\sin\omega t)\alpha_\pm + \eta_\pm}\ , \tag{45.133}$$

where,

$$\mathbf{L} = \begin{pmatrix} -\kappa - \imath U_0 & -\imath U_0 J_0 \\ -\imath U_0 J_0 & -\kappa - \imath U_0 \end{pmatrix} \quad \text{and} \quad \mathbf{X} = \begin{pmatrix} 0 & -\imath U_0 J_1 \\ \imath U_0 J_1 & 0 \end{pmatrix}\ . \tag{45.134}$$

We insert the ansatz $\alpha_\pm = \sum_n \alpha_\pm^{(n)} e^{\imath n\omega t}$, where $\dot{\alpha}_\pm^{(n)} = 0$, into the equations and project onto the basis $e^{\imath n\omega t}$:

$$\begin{aligned} \imath n\omega_x \sum_n \alpha_\pm^{(n)} e^{\imath n\omega t} &= \big(\mathbf{L} - \mathbf{X}(e^{\imath\omega t} - e^{-\imath\omega t})\big) \sum_n \alpha_\pm^{(n)} e^{\imath n\omega t} + \eta_\pm \\ \Longrightarrow (\mathbf{L} - \imath n\omega)\alpha_\pm^{(n)} &+ \mathbf{X}(\alpha_\pm^{(n+1)} - \alpha_\pm^{(n-1)}) = -\eta_\pm \delta_{n0}\ . \end{aligned} \tag{45.135}$$

We define operators $\mathbf{S}_n^{\uparrow\downarrow}$ by $\alpha_\pm^{(n+1)} = \mathbf{S}_n^\uparrow \alpha_\pm^{(n)}$ for $n \geq 0$ and $\alpha_\pm^{(n-1)} = \mathbf{S}_n^\downarrow \alpha_\pm^{(n)}$ for $n \leq 0$ and obtain,

$$\left[\mathbf{L} - \imath n\omega + \mathbf{X}(\mathbf{S}_n^\uparrow - \mathbf{S}_n^\downarrow)\right] \alpha_\pm^{(n)} = -\eta_\pm \delta_{n0}\ . \tag{45.136}$$

For $n = 0$, we get,

$$\alpha_\pm(\infty) = \alpha_\pm^{(0)} = -\left[\mathbf{L} + \mathbf{X}(\mathbf{S}_0^\uparrow - \mathbf{S}_0^\downarrow)\right]^{-1} \eta_\pm\ . \tag{45.137}$$

If we substitute in equation (45.135) $\alpha_\pm^{(n)} = \mathbf{S}_{n-1}^\uparrow \alpha_\pm^{(n-1)} = \mathbf{S}_{n+1}^\downarrow \alpha_\pm^{(n+1)}$, we get for $n \gtrless 0$,

$$\mathbf{S}_{n-1}^\uparrow = \left[\mathbf{L} - \imath n\omega + \mathbf{X}\mathbf{S}_n^\uparrow\right]^{-1} \mathbf{X} \quad \text{and} \quad \mathbf{S}_{n+1}^\downarrow = \left[\mathbf{L} - \imath n\omega - \mathbf{X}\mathbf{S}_n^\downarrow\right]^{-1} \mathbf{X}\ . \tag{45.138}$$

By recursive substitution of the lower into the upper equation, the stationary solution can now be written by means of continued fractions,

$$\mathbf{S}_0^{\uparrow\downarrow} \equiv \frac{1}{\mathbf{L} - \imath\omega \pm \mathbf{X}\frac{1}{\mathbf{L} - 2\imath\omega \pm \mathbf{X}\frac{1}{\cdots}}\mathbf{X}}\mathbf{X}\ . \tag{45.139}$$

$\alpha_\pm(\infty)$ in Eq. (45.137) gives us the stationary solution of the differential equation, time-averaged over an oscillation period.

If we are deep in the Lamb-Dicke regime, we need only consider the first order of the continued fractions. We set $\mathbf{S}_1^{\uparrow\downarrow} = \mathbf{1}$ and obtain the simplified equations,

$$\begin{aligned} \mathbf{S}_0^\uparrow &= [\mathbf{L} - \imath\omega + \mathbf{X}]^{-1}\mathbf{X} \quad \text{and} \quad \mathbf{S}_0^\downarrow = [\mathbf{L} - \imath\omega - \mathbf{X}]^{-1}\mathbf{X} \\ \alpha_\pm^{(0)} &= -\left[\mathbf{L} + \mathbf{X}\left(\mathbf{S}_0^\uparrow - \mathbf{S}_0^\downarrow\right)\right]^{-1} \eta_\pm \\ \alpha_\pm^{(1)} &= \mathbf{S}_0^\uparrow \alpha_\pm^{(0)} \quad \text{and} \quad \alpha_\pm^{(-1)} = \mathbf{S}_0^\downarrow \alpha_\pm^{(0)}\ . \end{aligned} \tag{45.140}$$

Explicitly,

$$\begin{aligned}
\mathbf{S}_0^{\uparrow\downarrow} &= \frac{U_0 k z_0}{(\kappa + \imath U_0 + \imath\omega)^2 + U_0^2(1-k^2x_0^2)} \begin{pmatrix} -U_0(1 \pm k z_0) & \imath(\kappa + \imath U_0 + \imath\omega) \\ -\imath(\kappa + \imath U_0 + \imath\omega) & -U_0(-1 \pm k z_0) \end{pmatrix} \\
\mathbf{S}_0^{\uparrow} - \mathbf{S}_0^{\downarrow} &= \frac{-2U_0^2 k^2 x_0^2}{(\kappa + \imath U_0 + \imath\omega)^2 + U_0^2(1-k^2x_0^2)} \mathbb{I}_2 \\
\alpha_\pm &= \alpha_\pm^{(0)} + \alpha_\pm^{(1)} e^{\imath\omega t} + \alpha_\pm^{(-1)} e^{-\imath\omega t} \ . \qquad (45.141)
\end{aligned}$$

Finally,

$$\boxed{\alpha_\pm = -[1 + \mathbf{S}_0^{\uparrow} e^{\imath\omega t} + \mathbf{S}_0^{\downarrow} e^{-\imath\omega t}][\mathbf{L} + \mathbf{X}(\mathbf{S}_0^{\uparrow} - \mathbf{S}_0^{\downarrow})]^{-1}\eta_\pm} \ . \qquad (45.142)$$

The Fig. 45.10 shows how the phase of the ring cavity behaves in time for various atom-field coupling constants.

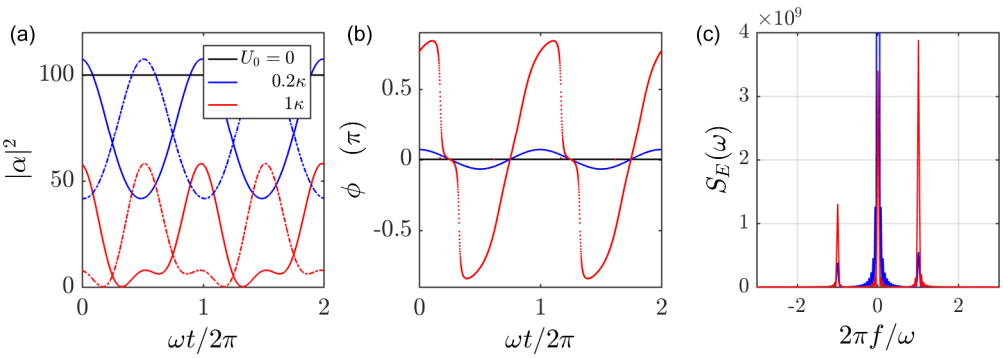

Figure 45.10: (code) (a) Photon number and (b) phase shift of the cavity in response to a modulated atomic position. The parameters are $kz_0 = 1$, $\kappa = (2\pi)\ 20\,\mathrm{kHz}$, $\omega = 2.5\kappa$, and $\eta_\pm = 10\kappa$. (c) Spectrum recorded behind a cavity mirror with the transmittivity t_{hr}. The spectrum is obtained as the Fourier transform of the $g^{(1)}(\tau)$ correlation function of the transmitted field $\mathcal{E}_{\mathrm{out}} = t_{\mathrm{hr}} e^{\imath k a} \mathcal{E}_{\mathrm{cav}}$, where $e^{\imath k a}$ is a fixed phase factor depending on the mirror position a (see Sec. 40.3.2).

It is interesting to study the oscillatory response of the cavity-field to a forced atomic vibration, because it yields information about the cavity backaction. In fact, as shown above, the vibrating atom imprints sidebands to the intracavity refractive index [810, 7]. The sidebands appear in the cavity transmission spectrum. A more sophisticated method to detect the backaction could be to watch the response in the beat signal to a periodic modulation of the incoupled fields with a vibrating atom,

$$\dot{\alpha}_\pm = (-\kappa - \imath U_0)\alpha_\pm - \imath U_0 e^{\mp 2\imath k z_0 \sin\omega t}\alpha_\mp + \eta e^{\pm\imath\phi_0 \sin\omega_\phi t} \ . \qquad (45.143)$$

We would expect a clear signature for resonance, $\omega_\phi = \omega$. The sidebands of the modulated pump would be coupled in, if they coincide. Instead of monitoring the cavity field, we could search the signature of the backaction in the atomic response. We will come back to this, when we discuss collective effects and the frequency shift of the center-of-mass motion. Do the Exc. 45.1.11.14.

45.1.9 Input-output theory for a single-ended linear cavity

Until now, we treated the in- and output fields of a cavity as classical variables (see Secs. 38.2.1), which is not helpful if we wish to detect quantum correlations outside the cavity. On the other hand, we treated the coupling of a cavity to free space as beam splitters in steady-state in Sec. 37.5.1. A generalization to time-dependent systems is provided by the so-called *input-output theory* [190, 340, 442, 552].

We consider a Hamiltonian containing the cavity and the input field as independent variables subject to noise,

$$\begin{aligned}\hat{H} &= \hat{H}_{\rm atm} + \hat{H}_{\rm cav} + \hat{H}_{\rm int} \\ &= \hat{H}_{\rm atm} - \hbar\Delta_{\rm c}\hat{a}^\dagger\hat{a} + \hbar g(\hat{a}\hat{S}_+ + \hat{S}_-\hat{a}^\dagger) - \hbar\imath\sqrt{\kappa\delta_{\rm fsr}}(\hat{a}\hat{a}_{\rm in}^\dagger - \hat{a}^\dagger\hat{a}_{\rm in})\end{aligned} \tag{45.144}$$

with

$$\hat{\mathbf{S}} = \sum_{j=1}^{N}\hat{\mathbf{s}}_j \qquad \text{and} \qquad \eta \to \sqrt{\kappa\delta_{\rm fsr}}\hat{a}_{\rm in}^\dagger\ . \tag{45.145}$$

With this Hamiltonian the Heisenberg equations of motion can be derived for every dynamic variable $\hat{a}$, $\hat{S}_+$, $\hat{S}_z$, and $\hat{a}_{\rm in}$.

45.1.10 Emission spectra of cavities interacting with atoms

The spectral features of light emitted from cavities reveal important information on the physical processes underlying the atom-cavity interaction. For example, when atoms interacting with a 'bad cavity' are incoherently pumped rather than the cavity mode itself, in certain parameter regimes the emission spectra reveals extremely narrow bandwidths [632, 149] known as superradiant lasing. When in contrast the cavity is pumped, at sufficiently high collective cooperativity we expect normal-mode splitting of the emission spectrum.

Below saturation, the atomic states can be adiabatically eliminated, i.e. we end up with equations of motion only depending on $\hat{a}$ and $\hat{a}^\dagger$. An interesting question is whether this may facilitate the calculations of $\langle\hat{a}^\dagger(t+\tau)\hat{a}(t)\rangle \longrightarrow \langle\alpha^*(t+\tau)\alpha(t)\rangle$. It is not obvious and certainly wrong for the saturated regime. In Exc. 45.1.11.15 we study the spectrum of resonance fluorescence emitted by a ring cavity incorporating a beam splitter.

Numerically, the spectra can easily be calculated using the 'QuantumOptics.jl' or the 'QuantumCumulants.jl' frameworks for the Julia programming language [149, 741]. Fig. ?? shows an example calculated for a single atom and a cavity mode expanded into a Fock basis assuming various photon cut-off numbers.

The spectra exhibited in Fig. 45.11 are understood within the Jaynes-Cummings model as transitions between the lowest-lying levels, whose energies E_n in the resonant case $\Delta_{\rm c} = 0 = \Delta_{\rm a}$ are given by $E_0 = 0$, $E_1 = \omega \pm g$, $E_1 = 2\omega, 2\omega \pm g\sqrt{2}$ and $E_2 = 3\omega \pm (\sqrt{3}-\sqrt{2}), 3\omega \pm g(\sqrt{3}+\sqrt{2})$.

The approach used in Fig. 45.11 is limited to modest cut-off photon numbers and thus relatively low saturation parameters, $ns_1 \approx 11.7\eta_+^2/\kappa^2$. An alternative approach is the cumulant expansion method [741]. In Exc. 45.1.11.16 we study the spectrum of resonance fluorescence emitted by a linear cavity interacting with a single atom.

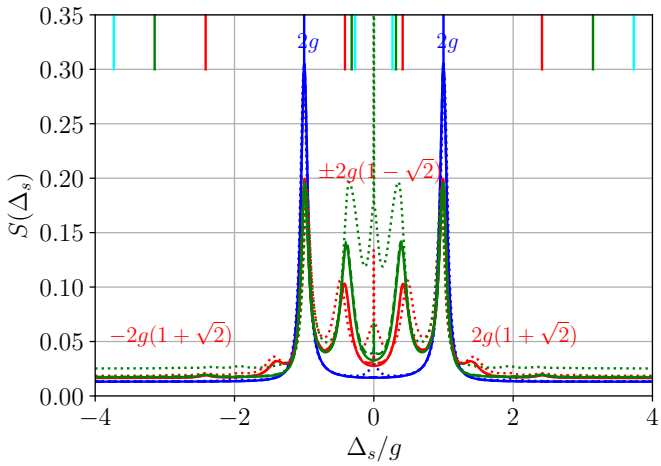

Figure 45.11: (code) Emission spectra of a linear cavity interacting with $N = 1$ atom and $\Gamma = 0.0022\kappa$, $g = 6\kappa$, and $\eta_- = 0$. The lines colors denote pump rates of (blue) $\eta_+ = 0.1$, (red) $\eta_+ = 0.5\kappa$, and (green) $\eta_+ = 1\kappa$. The line styles denote photon cut-off numbers of (solid) $n_{\text{cutoff}} = 1$, (dashed) $n_{\text{cutoff}} = 2$, and $n_{\text{cutoff}} = 5$.

45.1.11 Exercises

45.1.11.1 Ex: Cooperative Lamb shift in a cavity

Calculate the cooperative Lamb shift in a cavity from the second formula (45.12) and plot the result as a function of the cavity detuning.

45.1.11.2 Ex: Cooperative amplification for a rubidium gas in a cavity

Consider an non-degenerate cavity characterized by $\delta_{\text{fsr}} = 2\,\text{GHz}$, $F = 80$, and $w_0 = 6\,\mu\text{m}$. In order to benefit from the cooperativity of the cavity, the atoms must be within a volume axially delimited by the Rayleigh length and radially by the diameter of the mode near its waist.
a. Calculate the Rayleigh length for a wavelength of 780 nm and the mode volume.
b. For a given partial pressure of rubidium at room temperature of $p \approx 10^{-5}\,\text{Pa}$, calculate the average number of atoms within the mode volume.
c. Of these atoms only those with an axial Doppler shift below $kv_z < \kappa$ emit resonantly into the cavity. Calculate the number of these atoms from the Maxwell-Boltzmann distribution.
d. Calculate the cooperative amplification of the emission rate into the cavity.

45.1.11.3 Ex: Characteristic parameters for various atom-cavity systems

Complete the following table calculating κ, $V_{\rm m}$, ω_r, g_1, Υ, s, and r,

	rubidium	strontium
Γ	6 MHz	6.8 kHz
$\mathcal{F}$	250000	250000
L	100 µm	3 cm
w_0	20 µm	70 µm

45.1.11.4 Ex: Number of photons in a cavity

a. How many photons are in the mode of a cavity with finesse $F = 80000$ (i) in resonance and (ii) out of resonance resonantly pumped with a laser power of $P_{\rm in} = 100\,\mu$W?
b. What power must be injected to produce 1 photon inside the cavity?
c. Resonant backscattering by the cavity mirrors can scatter photons into the reverse mode. Typically, $P_-/P_+ \simeq 0.005$. Hence, $n^{on}_{-,cav} = 1.5\times10^7$ and $n^{off}_{-,cav} = 0.01$. Using advanced techniques it is possible to reduce the number of backscattered photons by factor of > 20. Assuming that the losses due to backscattering are $S = 1$ ppm. Can the resonant backscattering by the mirrors destroy a BEC?
d. What is the amplitude of the output signal in terms of photons?

45.1.11.5 Ex: Saturation-induced bistability in a linear cavity

a. Derive the equations of motion for N immobile atoms located at positions z_j along the optical axis of and interacting with a linear cavity.
b. Assuming steady-state and doing the mean-field approximation isolate an equation for the cavity field $\alpha \equiv \langle \hat{a} \rangle$.
c. Simplify the equation for α for the case of perfect bunching $z_j = z$ and solve it analytically. Identify the instability.
d. Discuss the weak excitation limit.
e. Derive the transmission spectrum in the weak excitation limit.
f. Write down the equation for $n = |\alpha|^2$ for the resonant case, $\Delta_{\rm c} = 0 = \Delta_{\rm a}$, in terms of the single-atom cooperativity parameter $\Upsilon \equiv 4g^2/\gamma\Gamma$ and the single-photon saturation parameter $s_1 \equiv 8g^2/\Gamma^2$.

45.1.11.6 Ex: PDH-probing atoms in a ring cavity

Calculate the steady-state reflection of a phase-modulated laser beam from a ring cavity neglecting backscattering from the atoms. Demodulate the reflection signal with the modulation frequency.

45.1.11.7 Ex: Normal mode splitting of a ring cavity

Consider the stationary fields (45.87) developing in a ring cavity containing a homogeneous cloud of atoms and pumped in one direction, $\eta_- = 0$. For this system.
a. Calculate the transmission of the cavity in the direction of mode α_+ as a function of the detunings $\Delta_{\rm a}$ and $\Delta_{\rm c}$ and the number of atoms.

Transmission spectra can be recorded under various boundary conditions. Calculate the transmission
b. keeping the laser at a fixed frequency ω and varying the cavity length ω_c;
c. tuning a cavity resonance to the atomic transition, $\omega_c = \omega_a$, and varying the laser frequency ω;
d. same as (d), but now calculate the detunings Δ_{ch} where the transmission drops to 1/2;
e. keeping the cavity constant at an *arbitrary* frequency ω_c and varying the laser frequency ω;
f. keeping the laser locked to the cavity, $\omega = \omega_c + NU_0$, and now ramping the cavity across the atomic resonance.

45.1.11.8 Ex: Time-dependent solution for a ring cavity pumped from one side below saturation

Derive the complete solution of the adiabatic field equations (45.104).

45.1.11.9 Ex: Filling and drainage of a ring cavity with one fixed atom

Calculate by simulation of the classical cavity equations, how a laser-pumped ring cavity fills and looses photons in the presence of a single immobile atom.

45.1.11.10 Ex: Position of the phase without pumping of the cavity

Solve the Schrödinger equation (45.110) by inserting ansatz,

$$\vec{\alpha} = \vec{\alpha}_1 e^{-\lambda_1 t} + \vec{\alpha}_2 e^{-\lambda_2 t} \ ,$$

where $\lambda_1 = \kappa + 2\imath U_0$ and $-\lambda_2 = \kappa$ are the eigenvalues of the matrix (45.110).

45.1.11.11 Ex: Dynamics of a standing wave in a symmetrically pumped ring cavity

Solve and discuss the equation (45.130).

45.1.11.12 Ex: Stationary position of the atom in a unidirectionally pumped ring cavity

What is the steady state position of an atom interacting with the modes of a unidirectionally pumped ring cavity?

45.1.11.13 Ex: Equations of motion for intensities and coherences in a ring cavity

Derive from the equations (45.104) the equations of motion for intermodal coherences $\alpha_+\alpha_+^*$, $\alpha_-\alpha_-^*$, $\alpha_+\alpha_-^*$, and $\alpha_-\alpha_+^*$.

45.1.11.14 Ex: Backaction of atomic vibration on the modes of a symmetrically pumped ring cavity

a. Calculate the Lamb-Dicke parameter for gravitation-induced Bloch oscillations in a strontium gravimeter, as well as the modulation index. Is the continued fractions method applicable?
b. Study the dynamics of the counterpropagating light modes of a ring cavity in the presence of an atom whose position is periodically modulated with a given frequency by numerical integration of the equations of motion (45.104). Compare with the results obtained by the method of continued fractions proposed in Sec. 45.1.8.

45.1.11.15 Ex: Fluorescent emission of a ring cavity for one-sided pumping in the adiabatic approximation

Based on the solution of the adiabatic field equations derived in Exc. 45.1.11.8 calculate the emission spectrum of the ring cavity driven below saturation (where the adiabatic approximation is good) from one side ($\eta_- = 0$) for both counter-propagating directions ($\alpha_\pm$). Compare with numerical solutions.

45.1.11.16 Ex: Emission spectrum of atoms in a linear cavity below saturation

a. Derive the mean-field evolution equation for the intracavity field $\alpha(t) = \langle \hat{a}(t) \rangle$ for a linear cavity driven below saturation.
b. Is it possible to calculate the autocorrelation spectrum and the emission spectrum of the cavity from $\langle \alpha^*(t+\tau)\alpha(t) \rangle$ [149, 741]?
c. Calculate numerically the emission spectrum of a linear cavity interacting with many atoms using for the cavity mode a Fock state expansion up to a cut-off photon number of $n_{\text{cutoff}} = 10$. Assume $(\eta, \Gamma, N, g_1, \Delta) = (0.1\kappa, 0.002\kappa, 100000, 0.002\kappa, 0)$. Interpret the result [689, 345].

45.2 Interaction of atoms with surfaces

45.2.1 Local density of states for atoms near surfaces

In the following sections we consider two-level atoms interacting with meta-materials. An atom consists of a discrete set of levels between which electric or magnetic transitions characterized by dipole moments $\mathbf{d}$ can be excited via vectorial laser light. The meta-material medium is defined by its spatially and frequency dependent relative permittivity, $\varepsilon(\mathbf{r};\omega)$ and relative permeability, $\mu(\mathbf{r};\omega)$ [8].

The way how the atom and the medium interact can be understood introducing the notion of the photonic local density of states (LDOS). The medium shapes, via ε and μ, the LDOS for any radiation field the medium can sustain, assuming that the atom itself does not modify the LDOS. To calculate the density of states one must solve Maxwell equations and obtain the Green function $\mathcal{G}(\mathbf{r}, \mathbf{r}'; \omega)$, which completely describes the material. The density of states is proportional to the imaginary part

[8] Note that the assumption of Drude type function is often a good one.

of Green function. Furthermore, the Green function permits to calculate easily the propagation of an incident light field through the medium [9], and hence the local radiation intensity $\vec{\mathcal{E}}(\mathbf{r};\omega)$.

After this, one has to set up the Hamiltonian for the atom located at position $\mathbf{r}_a$ near the dielectric and solve, with a suitable ansatz, the Schrödinger equation. This yields the time evolution of the atomic state excitation probabilities [490, **?**].

45.2.1.1 Density of states from Maxwell's equations

The density of states (DOS), the group velocity, and the distribution function are necessary for calculating various macroscopic quantities like specific heat, thermal conductivity, energy density, and radiation intensity. The local density of states (LDOS) is a generalization of the DOS and, unlike the DOS, a position dependent quantity. Like the DOS, the LDOS depends on the type of carrier - electron, phonon, or photon. It is generally related to the Green's function of the appropriate governing equation (Schrödinger equation for electrons, wave equation for long wavelength phonons, and Maxwell's equation for photons) and boundary conditions. Here, we are concerned with the photonic or electromagnetic LDOS [686].

The electromagnetic LDOS is related to the dyadic Green's function (DGF) of the vector Helmholtz equation. In free space the electric field and the magnetic field contributions are equal in the absence of scatterers. In other circumstances, however, there is a contribution to the LDOS from the magnetic field energy, and it is related to the magnetic DGF. Since the pioneering work of *Purcell* it is well known that the spontaneous emission rate of molecules is strongly affected by their vicinity to macroscopic objects. The LDOS (both electric and magnetic) also plays an important role in *Casimir* forces between objects. The Maxwell stress tensor in vacuum at thermal equilibrium can be expressed compactly in terms of the electric and magnetic DGF.

The spectral electric and magnetic fields are governed by the macroscopic Maxwell's equations (15.182). These equations can be converted to the vector Helmholtz equation for electric and magnetic fields (15.183). To invert these equations and express the electric and magnetic fields as integrals over the source regions, we make use of the dyadic Green's function (DGF) which also obeys the dyadic version of the vector Helmholtz equation (15.185). The electric field is obtained as a convolution integral (15.184).

45.2.1.2 Local density of states (LDOS) and the decay rate

The concepts of density of states (DOS) and local density of states (LDOS) can be introduced starting from the situation of a non-absorbing and non-dispersive medium, $\varepsilon(\mathbf{r};\omega) = \varepsilon(\mathbf{r}) \in R^{>0}$, embedded in a closed cavity with volume $V = L^3$ assuming that $L \ll \lambda$, λ being the wavelength in vacuum). Then, a discrete set of eigenmodes of the vector Helmholtz equation can be obtained solving the eigenvalue equation [157],

$$\nabla \times \nabla \times \mathbf{e}_n(\mathbf{r}) = \varepsilon(\mathbf{r})\frac{\omega_n^2}{c^2}\mathbf{e}_n(\mathbf{r}) \ , \tag{45.146}$$

[9] Note that even without incident radiation the medium influences the atomic dynamics via the LDOS.

yielding the eigenvalues ω_n/c as well as the eigenfunctions $\mathbf{e}_n(\mathbf{r})$. Since the differential operator is Hermitian, the eigenfunctions are orthogonal,

$$\int \varepsilon(\mathbf{r})\mathbf{e}_m^*(\mathbf{r})\cdot\mathbf{e}_n(\mathbf{r})d^3r = \delta_{mn} \ . \tag{45.147}$$

The DOS $\rho(\omega)$ at a frequency ω counts the number of eigenmodes in an infinitely small frequency range and is defined as,

$$\rho(\omega) = \tfrac{1}{V}\sum_n \delta(\omega-\omega_n) \ . \tag{45.148}$$

This DOS is a global quantity that characterizes the spectral density of eigenmodes of the medium as a whole. A local quantity $\rho(\mathbf{r},\omega)$ (LDOS) can be introduced through a summation weighted by the amplitude of the eigenmodes at point $\mathbf{r}$,

$$\boxed{\rho(\mathbf{r},\omega) = \sum_n |\hat{\mathbf{e}}_n(\mathbf{r})|^2\delta(\omega-\omega_n)} \ . \tag{45.149}$$

This relation defines the LDOS in the particular case of a medium for which a discrete set of eigenmodes can be introduced.

The (electric) LDOS (45.149) can be reformulated in terms of the electric Green function $\mathcal{G}(\mathbf{r},\mathbf{r}',\omega)$ being the solution of the vector Helmholtz equation (15.185) setting $\mu_r(\mathbf{r},\omega)=1$. The solution can be cast into the shape,

$$\boxed{\mathcal{G}(\mathbf{r},\mathbf{r}',\omega) = c^2\sum_n \hat{\mathbf{e}}_n^*(\mathbf{r}')\otimes\hat{\mathbf{e}}_n(\mathbf{r})\left[\mathcal{PV}\left(\frac{1}{\omega_n^2-\omega^2}\right)+\frac{\imath\pi}{2\omega_n}\delta(\omega-\omega_n)\right]} \ . \tag{45.150}$$

With this result, the LDOS can be written,

$$\begin{aligned}\rho(\mathbf{r},\omega) &= \frac{2\omega}{\pi c^2}\mathfrak{Im}\,\mathrm{Tr}\ \mathcal{G}(\mathbf{r},\mathbf{r},\omega) \qquad (45.151)\\ &= \frac{2\omega}{\pi c^2}\mathrm{Tr}\ c^2\sum_n \mathbf{e}_n^*(\mathbf{r})\otimes\mathbf{e}_n(\mathbf{r})\frac{\pi}{2\omega_n}\delta(\omega-\omega_n) = \sum_n \mathbf{e}_n^*(\mathbf{r})\cdot\mathbf{e}_n(\mathbf{r})\delta(\omega-\omega_n) \ .\end{aligned}$$

This result shows that shows that the correct counting of eigenmodes is implicit in the Green function, although the latter can be computed by solving the Helmholtz equation without referring to any set of eigenmodes. In particular, the expression (45.151) even holds for lossy media, when a basis of eigenmodes cannot be defined [157].

45.2.1.3 Power radiated by a classical dipole

The Green tensor defined by (15.187) permits the calculation of the electric field generated by a current density according to (15.184).

For a classical point-dipole the solution can be given explicitly (see example 119). The radiated power is simply,

$$P = -\tfrac{1}{2}\mathfrak{Re}\int \mathbf{j}^*(\mathbf{r})\cdot\vec{\mathcal{E}}(\mathbf{r})d^3r \ . \tag{45.152}$$

With the current density parametrized as $\mathbf{j}(\mathbf{r}) = \dot{\mathbf{d}}_{eg}\delta(\mathbf{r}-\mathbf{r}_s) = -\imath\omega\mathbf{d}_{eg}\delta(\mathbf{r}-\mathbf{r}_s)$ we get,

$$P = \frac{\omega}{2}\mathfrak{Im}\left[\mathbf{d}_{eg}^* \cdot \vec{\mathcal{E}}(\mathbf{r}_s)\right] . \tag{45.153}$$

From (45.152) we obtain,

$$P = \frac{\mu_0\omega^3}{2}|\mathbf{d}_{eg}|^2\mathfrak{Im}\left[\hat{\mathbf{e}}_d\ \mathcal{G}(\mathbf{r},\mathbf{r}',\omega)\ \hat{\mathbf{e}}_d\right] , \tag{45.154}$$

where $\hat{\mathbf{e}}_d$ is the unit vector along the dipole. In this expression we assume that the source point $\mathbf{r}_s$ is located in vacuum, but the Green function $\mathcal{G}(\mathbf{r},\mathbf{r}_s,\omega)$ can describe an arbitrary environment surrounding the emitter. In particular, the emitted power calculated in this way accounts both for far-field radiation and absorption in the environment.

In the case of a dipole with a fixed orientation $\hat{\mathbf{e}}_d$, we can define a projected LDOS (sometimes called partial LDOS),

$$\rho_{\mathbf{d}}(\mathbf{r}_s,\omega) = \frac{2\omega}{\pi c^2}\mathfrak{Im}\left[\hat{\mathbf{e}}_d\ \mathcal{G}(\mathbf{r}_s,\mathbf{r}_s,\omega)\ \hat{\mathbf{e}}_d\right] \tag{45.155}$$

so that the full LDOS is,

$$\rho(\mathbf{r}_s,\omega) = \sum_{\hat{\mathbf{e}}_{dx},\hat{\mathbf{e}}_{dy},\hat{\mathbf{e}}_{dz}} \rho_{\mathbf{d}}(\mathbf{r}_s,\omega) = \frac{2\omega}{\pi c^2}\mathfrak{Im}\,\mathrm{Tr}\ \mathcal{G}(\mathbf{r}_s,\mathbf{r}_s,\omega) . \tag{45.156}$$

The projected LDOS accounts for radiation by an electric dipole with a given orientation,

$$\boxed{P = \frac{\pi\omega^2}{4\varepsilon_0}|\mathbf{d}_{eg}|^2\rho_{\mathbf{d}}(\mathbf{r}_s,\omega)} . \tag{45.157}$$

Example 316 (*LDOS in free space*): In the particular case of a dipole placed in 3D free space, the power transferred to the environment equals the power radiated to far-field radiation. It can be obtained from the free-space dyadic Green function $\mathcal{G}_0(\mathbf{r},\mathbf{r}_s,\omega)$, whose imaginary part at $\mathbf{r}=\mathbf{r}_s$ is obtained from the Green tensor (15.195)calculated for a bulk medium by setting $\mathbf{r}=\mathbf{r}'=\mathbf{r}_s$,

$$\mathfrak{Im}\,\mathcal{G}^{(0)}(\mathbf{r}_s,\mathbf{r}_s,\omega) = \frac{k_0}{6\pi}\mathbb{I} . \tag{45.158}$$

With this, the projected LDOS (45.155) along $\hat{\mathbf{e}}_d$ becomes,

$$\rho_{\mathbf{d}}^{(0)}(\mathbf{r}_s,\omega) = \frac{\omega^2}{3\pi^2c^3} , \tag{45.159}$$

and the full LDOS (45.156),

$$\rho^{(0)}(\mathbf{r}_s,\omega) = \frac{\omega^2}{\pi^2c^3} . \tag{45.160}$$

The emitted power becomes,

$$P^{(0)} = \frac{\omega^4}{12\pi\varepsilon_0c^3}|\mathbf{d}_{eg}|^2 . \tag{45.161}$$

45.2.1.4 Spontaneous emission by a quantum emitter in the weak coupling regime

In (15.127) we established a relationship between the power emitted by a classical radiator and a spontaneous emission by a quantized two-level system. The spontaneous emission rate can be evaluated in perturbation theory from Fermi's golden rule,

$$\frac{P}{\hbar\omega} \longrightarrow \frac{\pi\omega^2}{4\varepsilon_0}|\mathbf{d}|^2\rho_{\mathbf{d}}(\mathbf{r}_s,\omega) = \frac{\pi\omega_{eg}}{\hbar\varepsilon_0}|\hat{\mathbf{d}}_{eg}|^2\rho_{\mathbf{d}}(\mathbf{r}_s,\omega_{eg}) = \Gamma \ . \tag{45.162}$$

The correction factor comes from the fact that in quantum mechanics, unlike in in classical mechanics, positive and negative frequency components are treated separately as absorption resp. stimulated emission.

In free space, with the formula (45.159) we calculate for the relationship between spontaneous emission rate and the induced dipole moment,

$$\boxed{\Gamma^{(0)} = \frac{\omega_{eg}^3}{3\pi\hbar\varepsilon_0 c^3}|\mathbf{d}_{eg}|^2} \ , \tag{45.163}$$

which coincides with the expression (39.41).

45.2.1.5 Purcell factor and Lamb shift

The Purcell factor is defined as the ratio between the decay rates in the presence and in the absence of boundary conditions. It can this be evaluated from the expression (45.162) as,

$$\frac{\Gamma}{\Gamma^{(0)}} = \frac{\rho_{\mathbf{d}}(\mathbf{r}_s,\omega)}{\rho_{\mathbf{d}}^{(0)}(\mathbf{r}_s,\omega)} = \frac{6\pi c}{\omega_{eg}}\mathfrak{Im}\,\hat{\mathbf{e}}_d\ \mathcal{G}(\mathbf{r}_s,\mathbf{r}_s,\omega)\ \hat{\mathbf{e}}_d \ . \tag{45.164}$$

45.2.2 Interaction between atomic dipoles

Until now we concentrated on simple dipole in the environment of dielectric boundaries. We will now extend the formalism to interacting dipoles located at positions $\mathbf{r}_i$ and $\mathbf{r}_j$ continuing the discussion of Sec. 15.3.1.

Intermolecular energy transfer can occur through two mechanisms, namely, radiationless short-range transfer, also called *Förster transfer*, and radiative long-range transfer [281, 817]. In the former the distance R between donor and acceptor is small compared with the electronic-energy-transfer wavelength $R \ll \lambda_A$. The free-space transfer rate behaves as R^{-6}, which can be explained by the instantaneous (longitudinal) Coulomb interaction between the two molecules. In the latter the intermolecular distance substantially exceeds the transition wavelength, $R \gg \lambda_A$. The observed R^{-2} dependence of the transfer rate can be regarded as being the result of emission and reabsorption of real (transverse) photons, see Sec. 45.1.1.

The Purcell factor (45.164) allows us to calculate the modification of the decay rate in the presence of a Green tensor. In the absence of boundaries we use the bulk

medium Green tensor (15.207),

$$\begin{aligned}\Gamma^{(b)} &= 3\lambda\Gamma^{(0)}\hat{\mathbf{e}}_d^*\ \mathfrak{Im}\,\mathcal{G}_b(\mathbf{r},\mathbf{r}',\omega)\ \hat{\mathbf{e}}_d \\ &= \tfrac{3}{2}\Gamma^{(0)}\left[\left(j_0(kR)-\frac{j_1(kR)}{kR}\right)\mathbb{I}+j_2(kR)(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2\right] \\ &= \tfrac{3}{2}\Gamma^{(0)}\left[(1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\frac{\sin kR}{kR}+(1-3(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\left(\frac{\cos kR}{k^2R^2}-\frac{\sin kR}{k^3R^3}\right)\right]\ ,\end{aligned} \tag{45.165}$$

where $k^2=(\omega/c)^2\varepsilon\mu$ and $\mathbf{R}\equiv\mathbf{r}-\mathbf{r}'$ and j_n are the spherical Bessel functions of the first kind.

Similarly, the Lamb shift can be calculated,

$$\begin{aligned}\Delta^{(b)} &= -\tfrac{3}{2}\lambda\Gamma^{(0)}\hat{\mathbf{e}}_d^*\ \mathfrak{Re}\,\mathcal{G}_b(\mathbf{r},\mathbf{r}',\omega)\ \hat{\mathbf{e}}_d \\ &= \tfrac{3}{4}\Gamma^{(0)}\left[\left(y_0(kR)-\frac{y_1(kR)}{kR}\right)\mathbb{I}+y_2(kR)(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2\right] \\ &= \tfrac{3}{4}\Gamma^{(0)}\left[(1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\frac{\cos kR}{kR}-(1-3(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2)\left(\frac{\sin kR}{k^2R^2}+\frac{\cos kR}{k^3R^3}\right)\right]\ ,\end{aligned} \tag{45.166}$$

where y_n are the spherical Bessel functions of the second kind. Again, the second line is obtained for free space using (15.207).

At long distances, $kR>1$, the results (45.165) and (45.166) simplify to,

$$\boxed{\begin{aligned}\Delta^{(b)} &\simeq \tfrac{3}{4}\Gamma^{(0)}[1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2]\tfrac{\cos kR}{kR} \\ \Gamma^{(b)} &\simeq \tfrac{3}{2}\Gamma^{(0)}[1-(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R)^2]\tfrac{\sin kR}{kR}\end{aligned}}\ , \tag{45.167}$$

and at very long distances, $kR\gg 1$, $\Delta^{(b)}\to 0\leftarrow\Gamma^{(b)}$. This atomic dipole-dipole interaction will play a role in the generation of interatomic correlations studied in Sec. 46.3.2. Do the Exc. 45.2.3.1.

At short distances, $kR\ll 1$, and assuming, $\hat{\mathbf{e}}_d=\hat{\mathbf{e}}_R$, the same formula becomes,

$$\boxed{\begin{aligned}\Delta^{(b)} &\simeq -\tfrac{3}{2}\lambda\Gamma^{(0)}\hat{\mathbf{e}}_d^*\mathfrak{Re}\,\mathcal{G}_b(\mathbf{r},\mathbf{r}',\omega)\hat{\mathbf{e}}_d\to-\tfrac{C_3}{R^3} \\ \Gamma^{(b)} &\simeq 3\lambda\Gamma^{(0)}\hat{\mathbf{e}}_d^*\mathfrak{Im}\,\mathcal{G}_b(\mathbf{r},\mathbf{r}',\omega)\hat{\mathbf{e}}_d\to 0\end{aligned}} \tag{45.168}$$

with $C_3=\frac{3\Gamma^{(0)}}{2k^3}$. See also Secs. 15.3.1 and 46.3.3.

45.2.2.1 Derivation of the Hamiltonian

First for one atom interacting with a dielectric then for two atoms,

$$\hat{H}=\int d^3r\int_0^\infty d\omega\hbar\omega\hat{\mathbf{f}}^\dagger(\mathbf{r},\omega)\hat{\mathbf{f}}(\mathbf{r},\omega)+\sum_{i=0}^N\hbar\omega_i\hat{\sigma}_i^+\hat{\sigma}_i-\sum_{i=0}^N\int_0^\infty d\omega\left[\hat{\mathbf{d}}_i\cdot\vec{\mathcal{E}}(\mathbf{r}_i,\omega)+H.c.\right]\ . \tag{45.169}$$

Here, $\hat{\mathbf{f}}(\mathbf{r},\omega)$ are polaritonic bosonic operators associated with the annihilation of the corresponding matter-light elementary excitations. The field operator is [332, 853],

$$\vec{\mathcal{E}}(\mathbf{r},\omega)=\imath\vec{\epsilon}\sqrt{\frac{\hbar}{\pi\varepsilon_0}}\frac{\omega^2}{c^2}\int\sqrt{\mathfrak{Im}\,\varepsilon_r(\mathbf{r}',\omega)}\mathcal{G}(\mathbf{r},\mathbf{r}',\omega)\hat{\mathbf{f}}(\mathbf{r}',\omega)d^3r'\ . \tag{45.170}$$

45.2.3 Exercises

45.2.3.1 Ex: Coupled dipoles model near dielectrics

Develop the vectorial coupled dipoles model in the vicinity of a dielectric using the Green tensor formalism.

45.2.3.2 Ex: Scattering Green tensor above a dielectric surface

In this exercise we calculate the Green tensor for two atomic dipoles above a homogeneous dielectric filling the $z < 0$ half space.
a. Formulate the problem.
b. Simplify the scattering Green tensor obtained by [490] for that situation.
c. Simplify the Green tensor by assuming all atoms aligned along the y-axis at equal height from the dielectric.
d. Assume the atomic dipole moment to be aligned along the z-axis.
e. Derive the Green tensor for a single atom above the dielectric.

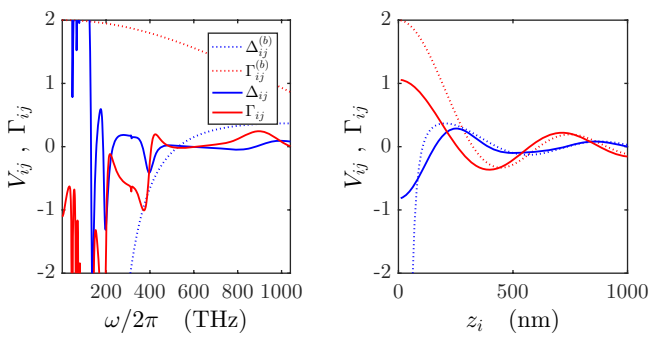

Figure 45.12: Scattering Green tensor for region-wise homogeneous dielectrics.

Chapter 46

Dicke model and spin squeezing

In Chps. 39 to 43 we concentrated on understanding the interaction of *single* atoms with light fields. In particular, we introduced the Rabi and the Jaynes-Cummings model. In Chp. 44 we introduced the coupled dipoles model for the interaction of many atoms with a single photon. In the following chapters, we will extend these models to several and many atoms and many photons.

It does not come as a surprise that totally new phenomena arise from the collective interaction of several atoms with a single light mode. For instance, the atomic cloud can evolve toward a spin-squeezed or an entangled state, or it can emit light in a super- and subradiant way. The interplay between collective processes and processes favoring an individualization of the atom-light interaction is subtle, and the different models used to understand the processes only grasp partial aspects. The difficulty arises from the complexity of the task of describing the dynamics of N evolving in a Hilbert space of dimension 2^N. Approximations used to reduce the complexity of the Hilbert space come at the price of eventually loosing some interesting features. On the other hand, they may also help to crystallize fundamental symmetries, which allow us to deepen our intuition on the collective behavior of the many-body system.

Famous models used in the description of collective scattering are (among others) the Dicke model and the Tavis-Cummings model (see table above). The Dicke model (presented in Sec. 46.1) assumes a total indistinguishability of the atoms, the Tavis-Cummings (discussed in Sec. 46.2 and used for the purpose of quantum computation) makes use of the rotating-wave approximation. Both models are based on the assumption of non-interacting atoms, neither by ground state collisions nor via radiation exchange, which certainly is a good assumption in the case of dilute atomic samples. On the other hand, we saw in the discussion of the coupled dipoles model in Chp. 44 that already the presence of a single photon in an atomic cloud leads noticeable interatomic interaction effects. In Sec. 46.3 we will extend the Dicke model to interacting atoms.

Finally, new phenomena arise from the presence of optical cavities shaping the spatial and spectral distribution of electromagnetic vacuum modes (see Chp. 45) and from the consideration of photonic recoil (see Chp. 48).

46.1 The Dicke model in the mean-field approximation

As we have seen in Sec. 23.5.8, the Hilbert space increases exponentially with the numbers of particles considered, the dimension of the Hilbert space of N particles being 2^N. This obviously presents a problem for numerical simulations, and simplifying models are needed. One of them is the *Dicke model*, where the N atoms are described as spin-$\frac{1}{2}$ particles and their collective interaction with a *single mode* light field via a single collective spin $\mathbf{S}$ with $S = N/2$. In this model, the dimension of the Hilbert space only scales polynomially as $2S + 1$.

In the next sections, we will introduce this model detailing its advantages and limitations and emphasizing its relations to super- and subradiance, spin squeezing and entanglement. In particular we will show that, when the coupling between the light and matter crosses a critical value, the Dicke model shows a mean-field phase transition to a superradiant phase.

46.1.1 Dicke states

The Hilbert space of the Dicke model [256, 433] is given by (the tensor product of) the states of the cavity and of the two-level atoms [1]. The Hilbert space of the cavity can be spanned by Fock states $|n\rangle$. Choosing the basis $|+\rangle \equiv \binom{0}{1}$ and $|-\rangle \equiv \binom{1}{0}$, the states of each two-level atom $j = 1, 2, .., N$ are defined through the spin operators $\hat{\mathbf{s}}_j = (\hat{s}_j^x, \hat{s}_j^y, \hat{s}_j^z)$ acting only an individual atom [2],

$$\begin{aligned} \hat{s}_j^x|... \pm ...\rangle &= \tfrac{1}{2}|... \mp ...\rangle \\ \hat{s}_j^y|... \pm ...\rangle &= \pm\imath\tfrac{1}{2}|... \mp ...\rangle \\ \hat{s}_j^z|... \pm ...\rangle &= \pm\tfrac{1}{2}|... \pm ...\rangle \ , \end{aligned} \tag{46.1}$$

and satisfying the spin algebra,

$$[\hat{s}_j^x, \hat{s}_k^y] = \imath\hat{s}_j^z\delta_{j,k} \ , \tag{46.2}$$

and related to the *Pauli spin matrices* (23.154) via,

$$\hat{\mathbf{s}} = \tfrac{1}{2}\vec{\hat{\sigma}} \quad , \quad \hat{s}^{\pm} = \hat{s}^x \pm \imath\hat{s}^y = \tfrac{1}{2}(\hat{\sigma}_x \pm \imath\hat{\sigma}_y) = \hat{\sigma}^{\pm} \ . \tag{46.3}$$

The Hamiltonian of the Dicke model is,

$$\hat{H} = -\Delta_{\mathrm{c}}\hat{a}^\dagger\hat{a} + \sum_{j=1}^{N}\left(-\Delta_{\mathrm{a}}\hat{s}_j^z + 2g(\hat{a} + \hat{a}^\dagger)\hat{s}_j^x + 2\imath g(\hat{a} - \hat{a}^\dagger)\hat{s}_j^y\right) \ . \tag{46.4}$$

Sometimes in literature the single-atom coupling strength (or half the single-atom single-photon Rabi frequency) is normalized to the atom number, $g \equiv \lambda/\sqrt{N}$. The coupling can be written as the sum of two terms: a co-rotating term that conserves

[1] Dicke states can also be introduced in the context of the Jaynes-Cummings model (see Sec. 46.1.1).

[2] Note, that here and in the following we set $\hbar \equiv 0$ for simplicity.

the number of excitations and is proportional to $\hat{a}\hat{\sigma}^+ + \hat{a}^\dagger\hat{\sigma}^-$ and a counter-rotating term proportional to $\hat{a}\hat{\sigma}^- + \hat{a}^\dagger\hat{\sigma}^+$.

The above Hamiltonian assumes that all the spins are identical, i.e. they have the same transition frequency, they do not interact with each other, and they equally couple to the radiation field (e.g. a cavity mode). For the simple system of only two not mutually interacting spins, $\mathbf{s}_1$ and $\mathbf{s}_2$, simultaneously coupling to the same radiation field, the Dicke model has been introduced in Sec. 25.4.2. There, we have shown that the spin operators can be added, $\hat{\mathbf{S}} = \hat{\mathbf{s}}_1 + \hat{\mathbf{s}}_2$, and the total system be represented in a coupled basis, where $[\hat{s}_1 \cdot \hat{s}_2, \hat{\mathbf{S}}^2] = 0 = [\hat{s}_1 \cdot \hat{s}_2, \hat{S}_z^2]$. This concept can be generalized to an arbitrary number of spins, that is, under the above assumption, one can define macroscopic collective spin operators,

$$\hat{S}_\alpha \equiv \sum_{j=1}^{N} \hat{s}_j^\alpha \qquad \text{with} \qquad [\hat{S}_x, \hat{S}_y] = \imath \hat{S}_z \ , \tag{46.5}$$

and $\alpha = x, y, z$. Using these operators, one can rewrite the above Hamiltonian as

$$\boxed{\hat{H} = -\Delta_\mathrm{c}\hat{a}^\dagger\hat{a} - \Delta_\mathrm{a}\hat{S}_z + 2g\hat{a}_\mathrm{r}\hat{S}_x - 2g\hat{a}_\mathrm{i}\hat{S}_y} \tag{46.6}$$

with $\hat{a} = \hat{a}_\mathrm{r} + \imath\hat{a}_\mathrm{i}$, and it is easy to see that,

$$[\hat{H}, \hat{\mathbf{S}}^2] = 0 \neq [\hat{H}, \hat{S}_z] \ . \tag{46.7}$$

That is, the Dicke Hamiltonian preserves the spin $\langle\hat{\mathbf{S}}^2\rangle$, but interaction with a light field can change the projection $\langle\hat{S}_z\rangle$. We will see in the following that this fact as important consequences for interaction dynamics of atomic ensembles coupled to a single light mode.

Example 317 (*Conservation of total spin under coherent interaction*): More generally, a coherent interaction described by a Hamiltonian that only depends on collective spin components, $H = H(\hat{S}_x, \hat{S}_y, \hat{S}_z)$, cannot change the total spin $|\mathbf{S}|$. This is easy to see by doing a Taylor expansion of the Hamiltonian in the spin components and using $[\hat{\mathbf{S}}, \hat{\mathbf{S}}^2] = 0$. As a consequence a coherent (superradiant) spin state will stay coherent forever, unless individual atom-light interactions or decay processes occur.

46.1.1.1 Degeneracies of Dicke states

Let us now look at states having the same number N of energy packets counting free photons n and atomic excitations $N-n$. For example with $N = 2$, the following states are possible. The normalization factors are simply the Clebsch-Gordan coefficients. See Exc. 46.1.8.1.

$\lvert S, M\rangle$ $\lvert n\rangle$	$\lvert\frac{N}{2}, M\rangle$ $\# = 1$	$\lvert\frac{N}{2} - 1, M\rangle$ $\# = 1$
0	$\lvert 1, 1\rangle = \lvert + +\rangle$	
1	$\lvert 1, 0\rangle = \frac{1}{\sqrt{2}}(\lvert + -\rangle + \lvert - +\rangle)$	$\lvert 0, 0\rangle = \frac{1}{\sqrt{2}}(\lvert + -\rangle - \lvert - +\rangle)$
2	$\lvert 1, -1\rangle = \lvert - -\rangle$	

The right column of the above table contains a singlet state, which decouples from the triplet states (center column). The fact that it decouples from the deexcited triplet state makes the singlet state stable or *subradiant* [3]. See also Fig. 46.9.

For example with $N = 3$ (see also Exc. 25.4.5.14),

$\|S, M\rangle$	$\|\frac{N}{2}, M\rangle$	$\|\frac{N}{2} - 1, M\rangle$
n	$\# = 1$	$\# = 2$
0	$\|\frac{3}{2}, \frac{3}{2}\rangle = \|+++\rangle$	
1	$\|\frac{3}{2}, \frac{1}{2}\rangle \sim \|++-\rangle + \|+-+\rangle + \|-++\rangle$	$\|\frac{1}{2}, \frac{1}{2}\rangle$
2	$\|\frac{3}{2}, -\frac{1}{2}\rangle \sim \|+--\rangle + \|-+-\rangle + \|--+\rangle$	$\|\frac{1}{2}, -\frac{1}{2}\rangle$
3	$\|\frac{3}{2}, -\frac{3}{2}\rangle = \|---\rangle$	

Example with N arbitrary,

$\|S, M\rangle$	$\|\frac{N}{2}, M\rangle$	$\|\frac{N}{2} - 1, M\rangle$	$\|\frac{N}{2} - 2, M\rangle$
$\|n\rangle$	$\# = 1$	$\# = N - 1$	$\# = \frac{N(N-3)}{2}$
0	$\|\frac{N}{2}, \frac{N}{2}\rangle = \|++++...\rangle$		
1	$\|\frac{N}{2}, \frac{N}{2} - 1\rangle \sim \sum_{\text{perm.}} \|-+++...\rangle$	$\|\frac{N}{2} - 1, \frac{N}{2} - 1\rangle$	
2	$\|\frac{N}{2}, \frac{N}{2} - 2\rangle \sim \sum_{\text{perm.}} \|--++...\rangle$	$\|\frac{N}{2} - 1, \frac{N}{2} - 2\rangle$	$\|\frac{N}{2} - 2, \frac{N}{2} - 1\rangle$
$\vdots$	$\vdots$	$\vdots$	
N	$\|\frac{N}{2}, -\frac{N}{2}\rangle = \|----..\rangle$		

We see that the Dicke states are not made to unambiguously label degenerate states. States $|S, M\rangle$ with $S < |M|$ are largely degenerate. The degeneracy of a Dicke state with $S \leq \frac{N}{2}$, that is, the number of states $|+\rangle^{N_+}|-\rangle^{N_-}$ composing a single Dicke state labeled by $|S, M\rangle$ is [342],

$$\# = \frac{(2S+1)N!}{(\frac{N}{2} + S + 1)!(\frac{N}{2} - S)!} \ . \tag{46.8}$$

Transitions between energetically degenerate states $|S, M\rangle$ and $|S, M'\rangle$ with $M = M'$ but $S \neq S'$ are prohibited.

46.1.1.2 Mean-field approximation and light field elimination

The *mean-field approximation* consists in replacing the photonic operators by their expectation values, i.e. assuming classical light. This allows us to remove the light energy term from the Hamiltonian and replace the coupling strength by the n-photon Rabi frequency, $\Omega = 2g\sqrt{n}$. The Hamiltonian then becomes just a generalization of the semiclassical one-atom Hamiltonian (39.129) to large spins,

$$\boxed{\hat{H} = \hat{\mathbf{S}} \cdot \mathbf{G} = -\Delta_{\text{a}} \ \hat{S}_z + \mathfrak{Re}\,\Omega \ \hat{S}_x + \mathfrak{Im}\,\Omega \ \hat{S}_y \ ,} \tag{46.9}$$

allowing for complex Rabi frequencies. We will see in Sec. 46.4.1 how this simplified Hamiltonian can be derived from (46.6) for the case that the light field is a single mode in a 'bad cavity'.

[3] Note that, while superradiance as well as subradiance can be explained by classical radiator models, such as the coupled dipoles model.

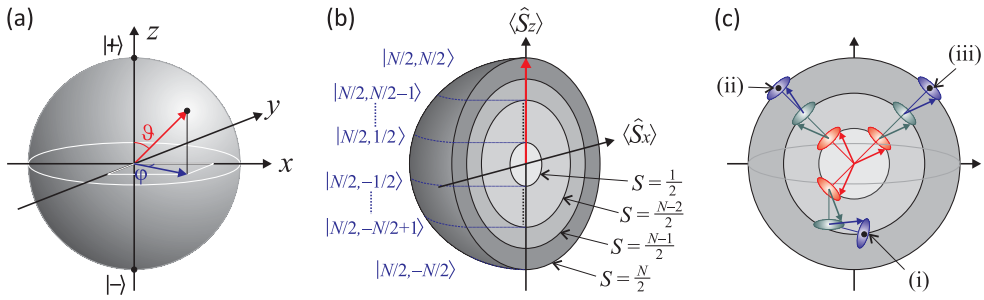

Figure 46.1: (a) Illustration of the Bloch sphere. (b) Bloch spheres of the various super/-subradiant states with $N = 5$ atoms. (c) Illustration of (i) a subradiant state, (ii) a fully stretched coherent spin state, and (iii) a spin-correlated state for $N = 3$ atoms.

In the absence of spontaneous emission, any pure *single-atom* state is given by,

$$|\psi\rangle = |\vartheta, \varphi\rangle = \cos\tfrac{\vartheta}{2}|+\rangle + e^{\imath\varphi}\sin\tfrac{\vartheta}{2}|-\rangle \ , \tag{46.10}$$

where the angles ϑ and φ point to a location on the Bloch sphere characterizing the state of the atom. For example, a single initially deexcited atom having been subject to a $\frac{\pi}{2}$-pulse ends up in the state $|\frac{\pi}{2}, 0\rangle$. The expectation value of the spin operator in this state is simply obtained from,

$$\begin{aligned}\langle\vartheta,\varphi|\hat{S}_z|\vartheta,\varphi\rangle &= \cos^2\tfrac{\vartheta}{2}\langle+|\hat{S}_z|+\rangle + \sin^2\tfrac{\vartheta}{2}\langle-|\hat{S}_z|-\rangle = \tfrac{1}{2}\cos\vartheta \\ \langle\vartheta,\varphi|\hat{S}_+|\vartheta,\varphi\rangle &= e^{\imath\varphi}\sin\tfrac{\vartheta}{2}\cos\tfrac{\vartheta}{2}\langle+|\hat{S}_+|-\rangle = \tfrac{1}{2}e^{\imath\varphi}\sin\vartheta \ ,\end{aligned} \tag{46.11}$$

yielding,

$$\langle\vartheta,\varphi|\hat{\mathbf{S}}|\vartheta,\varphi\rangle = \tfrac{1}{2}\begin{pmatrix}\cos\varphi\sin\vartheta \\ \sin\varphi\sin\vartheta \\ \cos\vartheta\end{pmatrix} \ . \tag{46.12}$$

We will also denote the probability of finding the system in state $|\pm\rangle$ by,

$$p_+ = \langle\hat{P}_\pm\rangle = |\langle+|\psi\rangle|^2 = \cos^2\tfrac{\vartheta}{2} = 1 - p_- \ . \tag{46.13}$$

46.1.1.3 Collective spin states

Let us now study the system obeying the Hamiltonian (46.9) in detail. The spin operators $\hat{\mathbf{S}}$ satisfy a SU(2) algebra explained in Sec. 25.3.2, i.e. $\hat{\mathbf{S}} \times \hat{\mathbf{S}} = \imath\hat{\mathbf{S}}$. The common eigenstates of $\hat{\mathbf{S}}^2$ and $\hat{S}_z$ are denoted by $|S, M\rangle$,

$$\begin{aligned}\hat{S}_z = \hat{S}_+\hat{S}_- - \hat{S}_-\hat{S}_+ \qquad &\text{with} \qquad \hat{S}_z|S,M\rangle = M|S,M\rangle \\ \hat{N}_\pm \equiv \tfrac{1}{2}(N\mathbb{I} \pm \hat{S}_z) \qquad &\text{with} \qquad \hat{N}_\pm|S,M\rangle = \tfrac{1}{2}(N \pm M)|S,M\rangle \ .\end{aligned} \tag{46.14}$$

From this we conclude that $S = N/2$ is half the number of atoms and M the inversion.

We consider an ensemble of $N = N_+ + N_-$ two-level atoms excited by a definite number of M photons, such that,

$$N = N_+ + N_- \qquad \text{and} \qquad 2M = N_+ - N_- \ . \tag{46.15}$$

Hence, $N_\pm = \frac{N}{2} \pm M$ is the number of atoms in each of the two states. The N atoms can occupy 2^N different collective states. However, when the atoms are identical and couple uniformly to the same light mode, all states where the same number of atoms is excited are energetically degenerate, and the total energy available to the system is,

$$E = M\omega_{\rm c} \ . \tag{46.16}$$

The degeneracy of each many-body state with a given inversion M is given by the binomial coefficient,

$$\# = \binom{N}{\frac{N}{2}+M} = \binom{N}{N_+} = \binom{N}{N_-} \qquad \text{such that} \qquad \sum_{N_+=0}^{N} \binom{N}{N_+} = 2^N \ . \tag{46.17}$$

Therefore, we may set,

$$\boxed{|S,M\rangle \equiv |+\rangle^{N_+}|-\rangle^{N_-}} \ . \tag{46.18}$$

These states are called *Dicke states* [4].

For the special case $N=2$ the transformation from the basis $|+\rangle^{N_+}|-\rangle^{N_-}$, used in the *Tavis-Cummings model*, to the basis $|S,M\rangle$, used in the Dicke model, is a unitary transformation. It has been extensively discussed in Sec. 25.4 at the example of two spins, whose complete Hilbert space can be expanded in the uncoupled or in the coupled basis. For $N>2$ the situation is more complicated, since the degeneracies of both models are different. It is important to be aware that S is not simply half the atom number, but runs over $S = \frac{N}{2}, \frac{N}{2}-1, ...$, depending on how the individual spins couple together. The degeneracy of an angular momentum state $|S,M\rangle$ with a specific inversion M but undefined orbital momentum S is determined by the condition $0 \le S \le M$, and given by,

$$\# = \tfrac{N}{2} - |M| + 1 \ . \tag{46.19}$$

For example, for $N=2$ the possible spin states are given by $|s_1 - s_2| \le S \le s_1 + s_2$, that is, $S = 0, 1$. And for $N=5$, $M = \frac{3}{2}$ is supported by $S = \frac{3}{2}$ and $\frac{5}{2}$. Obviously, the degeneracy (46.19) is lower than (46.17) except for $N=2$. Dicke states may be represented as vectors pointing to the surface of a so-called Bloch sphere of radius,

$$\|\langle N,S,M|\hat{\mathbf{S}}^2|N,S,M\rangle\| = S(S+1) \ , \tag{46.20}$$

as illustrated in Fig. 46.1(b).

Example 318 (*Schwinger bosonization*): The two levels $|+\rangle$ and $|-\rangle$ may be interpreted as bosonic modes $\hat{a}$ and $\hat{b}$ populated with $S+M$ respectively $S-M$ atoms,

$$\hat{S}_+ = \hat{a}^\dagger \hat{b} \quad , \quad \hat{S}_- = \hat{a}\hat{b}^\dagger \quad , \quad \hat{N} = \hat{a}^\dagger\hat{a} + \hat{b}^\dagger\hat{b} \ . \tag{46.21}$$

[4] In Sec. 25.4.3 we used for the coupling of two spins the notation $|(s_1,s_2)s,m\rangle$. For coupling N spins, we should write in analogy,

$$|(\overbrace{\tfrac{1}{2},..,\tfrac{1}{2}}^{N}),S,M\rangle \equiv |N,S,M\rangle \ .$$

Mostly, we will however drop the (constant) number N.

Consequently,

$$\hat{S}_x = \tfrac{1}{2}(\hat{a}^\dagger\hat{b} + \hat{b}^\dagger\hat{a}) \quad , \quad \hat{S}_y = \tfrac{1}{2\imath}(\hat{a}^\dagger\hat{b} - \hat{b}^\dagger\hat{a}) \quad , \quad \hat{S}_z = \tfrac{1}{2}(\hat{a}^\dagger\hat{a} - \hat{b}^\dagger\hat{b}) \ . \tag{46.22}$$

This is the so-called *Schwinger bosonization*.

46.1.1.4 Dicke Hamiltonian for 2 atoms from the Tavis-Cummings model

We start from the collective Dicke Hamiltonian (46.4) for two atoms assuming $\omega_{\mathrm{a}1} = \omega_{\mathrm{a}2}$ and $g_1 = g_2$, that is, both atoms are identical and inside the mode volume of the field to which they couple with equal strength, and apply the rotating wave approximation. The Hamiltonian then factorizes into a diagonal matrix of 4 by 4 blocks characterized by a given number of total excitations,

$$\hat{H}_n = \begin{pmatrix} (n+1)\omega_{\mathrm{c}} - \omega_{\mathrm{a}} & g\sqrt{n} & g\sqrt{n} & 0 \\ g\sqrt{n} & n\omega_{\mathrm{c}} & 0 & g\sqrt{n} \\ g\sqrt{n} & 0 & n\omega_{\mathrm{c}} & g\sqrt{n} \\ 0 & g\sqrt{n} & g\sqrt{n} & (n-1)\omega_{\mathrm{c}} + \omega_{\mathrm{a}} \end{pmatrix} \ . \tag{46.23}$$

Each block has two degenerate non-shifted eigenvalues and two non-degenerate shifted eigenvalues,

$$E = n\omega_{\mathrm{c}} \quad \text{and} \quad E = n\omega_{\mathrm{c}} \pm \varpi_n \quad \text{with} \quad \varpi_n \equiv \sqrt{(\omega_{\mathrm{c}} + \omega_{\mathrm{a}})^2 - 4g^2 n} \ . \tag{46.24}$$

The description of the dynamics can be simplified by reducing the order of the matrix by calculating the average of the lines 2 and 3,

$$\hat{H}_{\mathrm{D}} = \begin{pmatrix} (n+1)\omega_{\mathrm{c}} - \omega_{\mathrm{a}} & g\sqrt{2n} & 0 \\ g\sqrt{2n} & n\omega_{\mathrm{c}} & g\sqrt{2n} \\ 0 & g\sqrt{2n} & (n-1)\omega_{\mathrm{c}} + \omega_{\mathrm{a}} \end{pmatrix} \ , \tag{46.25}$$

and opting for a new base defined by,

$$|\psi\rangle = \sum_n \begin{pmatrix} c_{22\ n-1} \\ c_{12\ n} \\ c_{11\ n+1} \end{pmatrix} |n\rangle \ , \tag{46.26}$$

with $c_{12\ n} = c_{21\ n}$. The new Hamiltonian (46.25) has exactly the same eigenvalues as the complete one (46.25), $\lambda = n\omega_{\mathrm{c}}, n\omega_{\mathrm{c}} \pm \varpi_n$, but without degeneracies. If we assume furthermore that the excitation is resonant, $\omega_{\mathrm{c}} = \omega_{\mathrm{a}}$, with high intensity, $n = |\alpha|^2$ for all n, defining the Rabi frequency $\Omega \equiv 2g\sqrt{n}$ our matrix becomes,

$$\hat{H}_{\mathrm{D}} \simeq \begin{pmatrix} |\alpha|\omega & \frac{\Omega}{\sqrt{2}} & 0 \\ \frac{\Omega}{\sqrt{2}} & |\alpha|\omega & \frac{\Omega}{\sqrt{2}} \\ 0 & \frac{\Omega}{\sqrt{2}} & |\alpha|\omega \end{pmatrix} \ , \tag{46.27}$$

with the eigenvalue matrix,

$$E_n = \mathcal{U}_n^\dagger \hat{H}_{\mathrm{D}} \mathcal{U}_n \simeq \begin{pmatrix} |\alpha|\omega - \Omega & & \\ & |\alpha|\omega & \\ & & |\alpha|\omega + \Omega \end{pmatrix} \ , \tag{46.28}$$

and the eigenvector matrix,

$$\mathcal{U}_n \simeq \tfrac{1}{2}\begin{pmatrix} -1 & \sqrt{2} & 1 \\ \sqrt{2} & 0 & -\sqrt{2} \\ 1 & -\sqrt{2} & -1 \end{pmatrix} . \tag{46.29}$$

With this we can derive the propagator,

$$\begin{aligned} e^{-\imath \hat{H}_n t} &= \tfrac{1}{2} e^{-\imath \alpha^2 \omega \mathbf{t}} \begin{pmatrix} 1+\cos\alpha\Omega t & -\sqrt{2}\imath\sin\alpha\Omega t & -1+\cos\alpha\Omega t \\ -\sqrt{2}\imath\sin\alpha\Omega t & 2\cos\alpha\Omega t & -\sqrt{2}\imath\sin\alpha\Omega t \\ -1+\cos\alpha\Omega t & -\sqrt{2}\imath\sin\alpha\Omega t & 1+\cos\alpha\Omega t \end{pmatrix} \\ &\xrightarrow{\alpha\Omega t=\pi/2} \tfrac{1}{2} e^{-\imath\pi/2\cdot\alpha\omega/\Omega} \begin{pmatrix} 1 & -\sqrt{2}\imath & -1 \\ -\sqrt{2}\imath & 0 & -\sqrt{2}\imath \\ -1 & -\sqrt{2}\imath & 1 \end{pmatrix} . \end{aligned}$$

The generalization to three atoms or N atoms is straightforward and will be left to Exc. 46.1.8.2.

46.1.2 Coherent spin states

By the fact that the individual spins are additive and the Hamiltonian linear in the spin operators, $\hat{H} \propto \hat{S}_z$, we know that the Schrödinger equation will be satisfied by *product states*,

$$|\Psi_N\rangle = \prod_{k=1}^{N} |\vartheta_k, \varphi_k\rangle_k \ , \tag{46.30}$$

where $|\vartheta_k, \varphi_k\rangle_k$ is the state of the k-the atom given by (46.10).

Coherent spin states now consist of N atoms, all being in the same state. In Exc. 46.1.8.3 we present another equivalent definition. Since the atoms are indistinguishable by the radiation field, we may as well drop the labeling index k,

$$\begin{aligned} |\Psi_N\rangle = |S,\vartheta,\varphi\rangle = |\vartheta,\varphi\rangle^N &= \left(\cos\tfrac{\vartheta}{2}|+\rangle + e^{\imath\varphi}\sin\tfrac{\vartheta}{2}|-\rangle\right)^N \\ &= \sum_{k=0}^{N} \sqrt{\binom{N}{k}} \cos^{N-k}\tfrac{\vartheta}{2}|+\rangle^{N-k}\ e^{\imath k\varphi}\sin^k\tfrac{\vartheta}{2}|-\rangle^k \ , \end{aligned} \tag{46.31}$$

in agreement with (41.30), or equivalently, using the Dicke state notation (46.18),

$$\boxed{|\vartheta,\varphi\rangle^N = \sum_{k=0}^{2S} \sqrt{\binom{2S}{k}} \cos^{2S-k}\tfrac{\vartheta}{2}\ e^{\imath k\varphi}\sin^k\tfrac{\vartheta}{2}|S,S-k\rangle} \ . \tag{46.32}$$

Hence, similarly to the coherent state of a harmonic oscillator, which consists of a Poissonian distribution of number states, the coherent spin state consists of a binomial distribution of N_+ atoms in one state and $N - N_+$ in the other. Note also, that by construction, the coherent spin states are **stretched**, $S = N/2$. That is, they can be represented by a vector of length N equal to the radius of the (generalized)

Bloch sphere [5]. In other words, S is a conserved quantum number as already shown in (46.7), and this feature does not change under the influence of the Hamiltonian (46.9). These states are called superradiant. Nevertheless, other states $|S, M\rangle$ are possible with $S \leq \frac{N}{2}$. These are squeezed, subradiant, or entangled states.

In the following we will study some of the properties of the coherent spin states. For instance, in Exc. 46.1.8.5(a) we calculate the expectation values of coherent spin states,

$$\langle\vartheta,\varphi|^N \hat{\mathbf{S}} |\vartheta,\varphi\rangle^N = S \begin{pmatrix} \cos\varphi\sin\vartheta \\ \sin\varphi\sin\vartheta \\ \cos\vartheta \end{pmatrix} . \tag{46.33}$$

Hence, the spin evolves on the surface of a Bloch sphere with radius,

$$\|\langle\vartheta,\varphi|^N \hat{\mathbf{S}} |\vartheta,\varphi\rangle^N\| = S \qquad \text{while still} \qquad \|\langle\vartheta,\varphi|^N \hat{\mathbf{S}}^2 |\vartheta,\varphi\rangle^N\| = S(S+1) . \tag{46.34}$$

For the number of atoms in each state we expect,

$$\langle\hat{N}_+\rangle = \tfrac{N}{2} + \tfrac{1}{2}\langle\hat{S}_z\rangle = N\cos^2\tfrac{\vartheta}{2} = Np_+ = N(1-p_-) = N - \langle N_-\rangle . \tag{46.35}$$

46.1.3 Rotations, spin excitation and precession

We learn in quantum mechanics how to use Pauli matrices to describe rotations in the Bloch vector space (see Exc. 23.5.9.5). We will now extend this formalism to our collective spin space. A useful rule for the subsequent calculations, proved in Exc. 46.1.8.6, is the following,

$$e^{\imath F(\hat{S}_z)} \hat{S}_+ e^{-\imath F(\hat{S}_z)} = \hat{S}_+ e^{\imath[F(\hat{S}_z+\mathbb{I})-F(\hat{S}_z)]} , \tag{46.36}$$

where F is an arbitrary function. For $F(\hat{S}_z) \equiv \phi\hat{S}_z$ the unitary transform $e^{\imath F(\hat{S}_z)}$ denotes a rotation about the z-axis, which we will study in the example below. For $F(\hat{S}_z) \equiv \zeta\hat{S}_z^2$ it generates squeezing along the z-axis, which we will study in the next section. Furthermore, we define the rotation matrices about the Cartesian axis (for clockwise rotation about the respective axis),

$$R_x(\gamma) \equiv \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\gamma & -\sin\gamma \\ 0 & \sin\gamma & \cos\gamma \end{pmatrix} , \qquad R_y(\gamma) \equiv \begin{pmatrix} \cos\gamma & 0 & \sin\gamma \\ 0 & 1 & 0 \\ -\sin\gamma & 0 & \cos\gamma \end{pmatrix} ,$$
$$R_z(\gamma) \equiv \begin{pmatrix} \cos\gamma & -\sin\gamma & 0 \\ \sin\gamma & \cos\gamma & 0 \\ 0 & 0 & 1 \end{pmatrix} , \tag{46.37}$$

for which it is possible to show (with $\alpha = x, y, z$),

$$\boxed{R_\alpha(\gamma)\hat{\mathbf{S}} = e^{\imath\gamma\hat{S}_\alpha}\hat{\mathbf{S}}e^{-\imath\gamma\hat{S}_\alpha}} . \tag{46.38}$$

[5] An illustration of the generalized Bloch sphere is attempted in Fig. 47.10.

Example 319 (*Rotation about* $\hat{S}_z$): Defining $F(\hat{S}_z) \equiv \phi \hat{S}_z$ the relationship (46.36) tells us,

$$e^{\imath\phi\hat{S}_z}\hat{S}_+ e^{-\imath\phi\hat{S}_z} = \hat{S}_+ e^{\imath\phi} ,$$

and consequently,

$$e^{\imath\phi\hat{S}_z}\hat{\mathbf{S}}e^{-\imath\phi\hat{S}_z} = \begin{pmatrix} \frac{1}{2}(e^{\imath\phi}\hat{S}_+ + e^{-\imath\phi}\hat{S}_-) \\ \frac{1}{2\imath}(e^{\imath\phi}\hat{S}_+ - e^{-\imath\phi}\hat{S}_-) \\ \hat{S}_z \end{pmatrix} = \begin{pmatrix} \cos\phi & -\sin\phi & 0 \\ \sin\phi & \cos\phi & 0 \\ 0 & 0 & 1 \end{pmatrix} \hat{\mathbf{S}} \equiv R_z(\phi)\hat{\mathbf{S}} .$$

Furthermore,

$$\begin{aligned} e^{-\imath\phi\hat{S}_z}|\vartheta,\varphi\rangle^N &= \sum_{k=0}^{2S}\sqrt{\binom{2S}{k}}\cos^{N-k}\tfrac{\vartheta}{2}e^{\imath k\varphi}\sin^k\tfrac{\vartheta}{2}e^{-\imath\phi(S-k)}|S,S-k\rangle \\ &= e^{-\imath\phi S}\left(e^{-\imath\phi}\cos\tfrac{\vartheta}{2}|+\rangle + e^{\imath(\varphi+\phi)}\sin\tfrac{\vartheta}{2}|-\rangle\right)^N = e^{-\imath\phi S}|\vartheta,\varphi+\phi\rangle^N . \end{aligned}$$

We also find,

$$\langle\vartheta,\varphi|^N R_z(\phi)\hat{\mathbf{S}}|\vartheta,\varphi\rangle^N = \tfrac{N}{2}\begin{pmatrix} \cos(\varphi+\phi)\sin\vartheta \\ \sin(\varphi+\phi)\sin\vartheta \\ \cos\vartheta \end{pmatrix} = \langle\vartheta,\varphi+\phi|^N\hat{\mathbf{S}}|\vartheta,\varphi+\phi\rangle^N .$$

To vary the polar angle ϑ of a coherent spin state $|\vartheta,\varphi\rangle$, we first rotate the coordinate system about the z-axis until $\varphi = 0$, then rotate about the y-axis by the desired angle θ, and finally rotate back about the z-axis to reach the initial azimuth φ,

$$\langle\vartheta,\varphi|^N R_z(\varphi)R_y^{-1}(\theta)R_z^{-1}(\varphi)\hat{\mathbf{S}}|\vartheta,\varphi\rangle^N = \tfrac{N}{2}\begin{pmatrix} \cos\varphi\sin(\theta+\vartheta) \\ \sin\varphi\sin(\theta+\vartheta) \\ \cos(\theta+\vartheta) \end{pmatrix} = \langle\vartheta{+}\theta,\varphi|^N\hat{\mathbf{S}}|\vartheta{+}\theta,\varphi\rangle^N .$$

The rotation about the x-axis is derived in Exc. 46.1.8.7, and in Exc. 46.1.8.8 we write down the explicit rotation matrix for two atoms.

Rotations such as the ones described by $R_\alpha(\gamma)$ are generated by the Dicke Hamiltonian (46.9), since the solution of the Schrödinger equation is,

$$\boxed{|\Psi(t)\rangle = e^{-\imath\hat{H}t}|\Psi(0)\rangle = e^{-\imath t\hat{S}_x\mathfrak{Re}\,\Omega_x - \imath t\hat{S}_y\mathfrak{Im}\,\Omega_y - \imath t\hat{S}_z\Delta}|\Psi(0)\rangle} . \tag{46.39}$$

That is, the Dicke Hamiltonian generates rotations $R_x(\mathfrak{Re}\,\Omega_x t)$, $R_y(\mathfrak{Im}\,\Omega_y t)$, and $R_z(\Delta t)$. This confirms that rotations do only transform coherent states into each other. Nevertheless, there are other unitary operations that transform coherent states into states that cannot be represented by coherent states. One example for this is squeezing.

46.1.3.1 Rotation algebra

The example 319 shows that rotations from an initial towards an arbitrary coherent spin states can be parametrized by a pair of Euler angles. Using (23.302) [224],

$$\begin{aligned} &\mathcal{U}_{\rm rt}(\vartheta,\varphi) = e^{\imath\varphi\hat{S}_z}e^{\imath\vartheta\hat{S}_y} = e^{-\imath\vartheta\hat{\mathbf{e}}_\varphi\cdot\hat{\mathbf{S}}} = e^{-\imath\vartheta(-\hat{S}_x\sin\varphi+\hat{S}_y\cos\varphi)} = e^{-\frac{\vartheta}{2}(\hat{S}_+e^{-\imath\varphi}-\hat{S}_-e^{\imath\varphi})} = e^{-\imath\vartheta\hat{S}_\varphi} \\ &R(\vartheta,\varphi)\hat{\mathbf{S}} \equiv \mathcal{U}_{\rm rt}^\dagger(\vartheta,\varphi)\hat{\mathbf{S}}\mathcal{U}_{\rm rt}(\vartheta,\varphi) \end{aligned} \tag{46.40}$$

with $\hat{\mathbf{e}}_\varphi = -\hat{\mathbf{e}}_x \sin\varphi + \hat{\mathbf{e}}_y \cos\varphi$. With this we find,

$$|\vartheta,\varphi\rangle^N = \mathcal{U}_{\rm rt}(\vartheta,\varphi)|S,S\rangle \ . \tag{46.41}$$

46.1.4 Uncertainties, quantum projection noise and spin squeezing

Measuring the population of a coherently excited two-level system by projecting it onto an energy eigenstate introduces *quantum projection noise*. Although this inherent noise spoils the determination of the resonance frequency, it can to some extent be surpassed by *spin squeezing* [974]. The projection noise limit has been observed with ions [467, 459] and with atomic clouds [811]. The reduction of the noise by spin squeezing has been observed with ions [800], micromasers [766], and atomic clouds [406, 548]. Also, a weakly entangled state of two modes was observed for continuous spin variables [494]. Very strong squeezing spin can be obtained in a *Mott insulator* state, as demonstrated by [379].

First, we want to show that the Heisenberg uncertainty of a coherent spin state is nothing else than the quantum projection noise studied in Sec. 41.2.2. On one hand, we have,

$$\begin{aligned}\langle\vartheta,\varphi|^N(\Delta\hat{S}_z)^2|\vartheta,\varphi\rangle^N &= \langle\vartheta,\varphi|^N\hat{S}_z^2|\vartheta,\varphi\rangle^N - (\langle\vartheta,\varphi|^N\hat{S}_z|\vartheta,\varphi\rangle^N)^2 \\ &= \sum_{k=0}^N \binom{N}{k}(\tfrac{N}{2}-k)^2 p_+^{N-k}p_-^k - \left(\sum_{k=0}^N\binom{N}{k}(\tfrac{N}{2}-k)p_+^{N-k}p_-^k\right)^2 \\ &= \left(\tfrac{N^2}{4} - N^2p_+p_- + Np_+p_-\right) - \left(\tfrac{N}{2}(p_+-p_-)\right)^2 = Np_+p_- \ .\end{aligned} \tag{46.42}$$

On the other hand, we have seen in (41.29) that this results corresponds to the variance of quantum projection noise,

$$\begin{aligned}(\Delta r)^2 &= \sum_{r=0}^N (r-Np_\pm)^2 P_{N,r,\pm} \\ &= \sum_{k=0}^N (\tfrac{N}{2}-k+\tfrac{N}{2}(p_+-p_-))^2\binom{N}{k}p_+^{N-k}p_-^k = Np_+p_- \ .\end{aligned} \tag{46.43}$$

The Heisenberg uncertainty relation (23.201) applied to angular momentum operator satisfying $[\hat{S}_x,\hat{S}_y] = \imath\hat{S}_z$ states,

$$\langle\Delta\hat{S}_x\rangle\langle\Delta\hat{S}_y\rangle \geq \tfrac{1}{2}|\langle\hat{S}_z\rangle| \ . \tag{46.44}$$

Since there are no quantum correlations between the particles, the uncertainty of coherent spin states is additive (see Exc. 25.3.4.5),

$$(\Delta\hat{S}_\alpha)^2 = \sum_{k=0}^N(\Delta\hat{s}_k^\alpha)^2 \ . \tag{46.45}$$

For a coherent spin state we can calculate explicitly [see Exc. 46.1.8.5(b)],

$$\langle\vartheta,\varphi|^N \begin{pmatrix} \Delta\hat{S}_x^2 \\ \Delta\hat{S}_y^2 \\ \Delta\hat{S}_z^2 \end{pmatrix} |\vartheta,\varphi\rangle^N = \tfrac{N}{4} \begin{pmatrix} 1-\sin^2\vartheta\cos^2\varphi \\ 1-\sin^2\vartheta\sin^2\varphi \\ \sin^2\vartheta \end{pmatrix} . \tag{46.46}$$

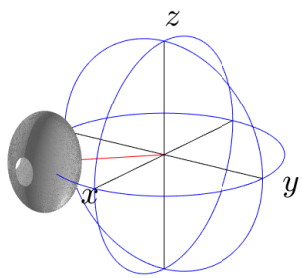

Figure 46.2: Illustration of the uncertainty of the spin components of a coherent spin state.

Example 320 (*Uncertainty of a coherent spin state after a $\frac{\pi}{2}$-pulse*): A $\frac{\pi}{2}$-pulse applied to a cloud in the collective ground state generates the state $|\vartheta,\varphi\rangle = |\frac{\pi}{2},0\rangle$. This is somewhat analogous to the beam splitting of a photonic Fock state discussed in Sec. 37.5. Interestingly, a Fock state seems more natural for an atomic cloud, while the Glauber state is more natural for a photonic mode. For example, for the particular state $|\frac{\pi}{2},0\rangle$ we find from (46.46),

$$(\Delta\hat{S}_x)^2 = 0 \qquad \text{and} \qquad (\Delta\hat{S}_y)^2 = (\Delta\hat{S}_z)^2 = \tfrac{S}{2} .$$

Note, that spin squeezing along the z-axis could be obtained by quantum non-demolition measurement of the inversion, that is, by measuring $\hat{S}_z$ without influencing the populations of the ground and excited state.

46.1.4.1 Spin squeezing by one-axis twisting

We have seen in the last section, that rotations influence the distribution of the uncertainty among the Cartesian coordinates in a specific way. It is, however, possible to manipulate the uncertainty distribution without rotating the collective spin state. An example with great practical importance is the concept of spin squeezing. It consists in establishing appropriate quantum correlations are between the individual spins, such as to partly cancel out fluctuations in one direction augmenting them in the other direction.

Squeezing of spin is not as straightforward as squeezing of bosons, since the uncertainty relations are essentially different [519]. To study spin-squeezing along the z-axis let as analyze the unitary transformation,

$$\boxed{\mathcal{Q}_z(\zeta)\hat{\mathbf{S}} \equiv e^{\imath\zeta\hat{S}_z^2}\hat{\mathbf{S}}e^{-\imath\zeta\hat{S}_z^2}} . \tag{46.47}$$

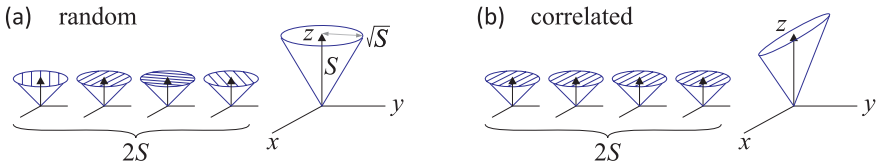

Figure 46.3: Illustration of the uncertainty in (a) a coherent state and (b) a spin-squeezed state.

Specifying the rule (46.36) for the particular case $F(\hat{S}_z) \equiv \zeta \hat{S}_z^2$, we get,

$$e^{\imath\zeta\hat{S}_z^2}\hat{S}_+ e^{-\imath\zeta\hat{S}_z^2} = \hat{S}_+ e^{2\imath\zeta(\hat{S}_z+1/2)} \ , \tag{46.48}$$

and hence,

$$\mathcal{Q}_z(\zeta)\hat{\mathbf{S}} = e^{\imath\zeta\hat{S}_z^2}\hat{\mathbf{S}}e^{-\imath\zeta\hat{S}_z^2} = \begin{pmatrix} \frac{1}{2}(\hat{S}_+ e^{2\imath\zeta(\hat{S}_z+1/2)} + e^{-2\imath\zeta(\hat{S}_z+1/2)}\hat{S}_-) \\ \frac{1}{2\imath}(\hat{S}_+ e^{2\imath\zeta(\hat{S}_z+1/2)} - e^{-2\imath\zeta(\hat{S}_z+1/2)}\hat{S}_-) \\ \hat{S}_z \end{pmatrix} \ . \tag{46.49}$$

Let us now apply the *squeezing operator* to the state $|\frac{\pi}{2},0\rangle$. In Exc. 46.1.8.9 we show that,

$$\langle\tfrac{\pi}{2},0|^N e^{\imath\zeta\hat{S}_z^2}\hat{\mathbf{S}}e^{-\imath\zeta\hat{S}_z^2}|\tfrac{\pi}{2},0\rangle^N = \begin{pmatrix}1\\0\\0\end{pmatrix}\tfrac{N}{2}\cos^{N-1}\zeta \tag{46.50}$$

$$\langle\tfrac{\pi}{2},0|^N e^{\imath\zeta\hat{S}_z^2}\begin{pmatrix}\hat{S}_x^2\\ \hat{S}_y^2\\ \hat{S}_z^2\end{pmatrix}e^{-\imath\zeta\hat{S}_z^2}|\tfrac{\pi}{2},0\rangle^N = \begin{pmatrix}N+1\\N+1\\2\end{pmatrix}\tfrac{N}{8} + \begin{pmatrix}1\\-1\\0\end{pmatrix}\tfrac{N(N-1)}{8}\cos^{N-2}2\zeta \ .$$

The dependencies of the uncertainties as a function of the squeezing parameter are plotted in Fig. 46.4. We see that the uncertainties never get smaller than the unsqueezed value. The reason is that, since the unitary transform $e^{\imath\zeta\hat{S}_z^2}$ commutes with $\hat{S}_z$, the prescription (46.47) does not immediately lead to squeezing along the z-axis.

Nevertheless, the prescription does generate quantum correlations in $\hat{S}_x$ and $\hat{S}_y$, which can be transformed to squeezing by subsequently rotating the collective spin about the x-axis [519]. As shown in Exc. 46.1.8.10, a rotation by an angle ν does not modify the x-component,

$$\begin{aligned}\langle\tfrac{\pi}{2},0|^N e^{\imath\nu\hat{S}_x}e^{\imath\zeta\hat{S}_z^2}\Delta\hat{S}_x^2 e^{-\imath\zeta\hat{S}_z^2}e^{-\imath\nu\hat{S}_x}|\tfrac{\pi}{2},0\rangle^N \\ = \tfrac{N(N+1)}{8} + \tfrac{N(N-1)}{8}\cos^{N-2}2\zeta - \tfrac{N^2}{4}\cos^{2N-2}\zeta \ ,\end{aligned} \tag{46.51}$$

but it modifies the other ones,

$$\begin{aligned}\langle\tfrac{\pi}{2},0|^N e^{\imath\nu\hat{S}_x}e^{\imath\zeta\hat{S}_z^2}\Delta\hat{S}_{y,z}^2 e^{-\imath\zeta\hat{S}_z^2}e^{-\imath\nu\hat{S}_x}|\tfrac{\pi}{2},0\rangle^N \\ = \tfrac{N}{4}\{1 + \tfrac{N-1}{4}[A \pm \sqrt{A^2+B^2}\cos(2\nu + \arctan\tfrac{B}{A})]\} \ ,\end{aligned} \tag{46.52}$$

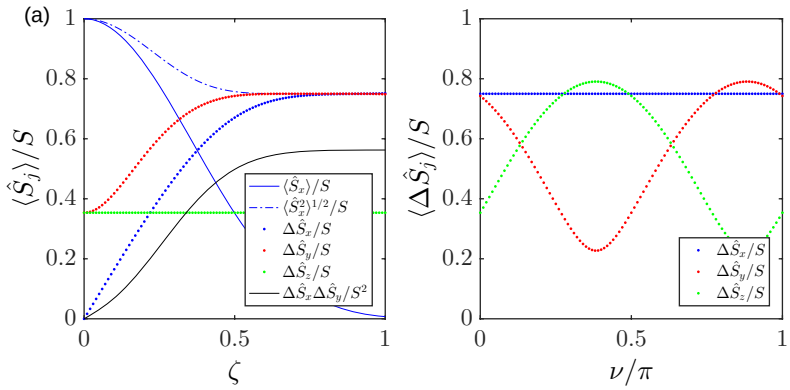

Figure 46.4: (code) (a) Uncertainties calculated in (46.50) as a function of the squeezing parameter. (b) Uncertainties after application of squeezing operator as a function of the rotation angle ν about the x-axis.

with $A \equiv 1 - \cos^{N-2} 2\zeta$ and $B \equiv 4 \sin\zeta \cos^{N-2}\zeta$. We study spin squeezing in Exc. 46.1.8.11 to 46.1.8.14. In Exc. 46.1.8.15 we investigate, whether double Fock states can lead to Heisenberg-limited interferometry, and in Exc. 46.1.8.16 we study entanglement witnesses with coherent spin states.

Obviously, since squeezed states are obtained from coherent states by unitary transform, they are still normalized,

$$\langle \vartheta, \varphi |^N e^{-\imath\zeta \hat{S}_z^2} e^{\imath\zeta \hat{S}_z^2} | \vartheta, \varphi \rangle^N = 1 \ . \tag{46.53}$$

Example 321 (*Conditional spin-squeezing by non-demolition measurement*): Technically, spin-squeezed states can be generated in experiments by quantum non-demolition measurements [105, 207, 804]. Another idea would be to arrange for totally uniform spin-spin coupling, since this generates terms like,

$$\hat{H}_{\rm ss} = \sum_{i,j\neq i}^{N} \kappa_{ij} \hat{s}_i^z \hat{s}_j^z \simeq \kappa \sum_{i,j\neq i}^{N} \hat{s}_i^z \hat{s}_j^z = \kappa \hat{S}_z^2 \ . \tag{46.54}$$

In a cloud this latter idea is not realizable, because the interatomic coupling strength depends on the distance between the atoms, but if the atoms are coupled via their interaction with a common mode of an optical cavity it should be feasible.

46.1.4.2 Construction of coherent states spin

The goal of this example is to demonstrate, in analogy to the construction of optical coherent states from vacuum using photon creation operators, that the coherent spin states can be constructed from the ground/inverted state using rising/lowering operators.

First we calculate the impact of the rising/lowering operator on the ground/in-

verted state,

$$\hat{S}_{\pm}^{k}|S,\mp S\rangle = \prod_{m=0}^{k-1}\sqrt{S(S+1)-(\mp S\pm m)(\mp S+1\pm m)}|S,\mp S\pm k\rangle \tag{46.55}$$
$$= k!\sqrt{\binom{N}{k}}|S,\mp S\pm k\rangle \ ,$$

where we made use of the formulas $k! = \Gamma(k+1)$ and $(-1)^k\Gamma(k-N)\Gamma(N-k+1) = \Gamma(-N)\Gamma(1+N)$. Let us now study the impact of the rotation operator $e^{\mu\hat{S}_{\pm}}$,

$$e^{\mu\hat{S}_{\pm}}|S,\mp S\rangle = \sum_{k=0}^{n}\frac{\mu^k}{k!}\hat{S}_{\pm}^{k}|S,\mp S\rangle = \sum_{k=0}^{n}\sqrt{\binom{N}{k}}\mu^k|S,\mp S\pm k\rangle \ . \tag{46.56}$$

Setting $\mu \equiv e^{\imath\varphi}\tan\frac{\vartheta}{2}$ we find [758],

$$\frac{1}{(1+|\mu|^2)^S}e^{\mu\hat{S}_-}|S,S\rangle = \cos^{2S}\tfrac{\vartheta}{2}\sum_{k=0}^{n}\sqrt{\binom{N}{k}}e^{\imath k\varphi}\tan^k\tfrac{\vartheta}{2}|S,S-k\rangle \tag{46.57}$$
$$= \sum_{k=0}^{n}\sqrt{\binom{N}{k}}\cos^{N-k}\tfrac{\vartheta}{2}e^{\imath k\varphi}\sin^k\tfrac{\vartheta}{2}|S,S-k\rangle \ ,$$

and analogically for $\hat{S}_+$. The result is identical to the definition of a coherent spin state (46.32). Thus, coherent spin states can be constructed from the ground/inverted state using rising/lowering operator,

$$|\mu\rangle \equiv |\vartheta,\varphi\rangle^n = \frac{1}{(1+|\mu^{\mp 1}|^2)^S}e^{\mu^{\mp 1}\hat{S}_{\pm}}|S,\mp S\rangle \ . \tag{46.58}$$

They are not orthogonal, since $\langle\mu|\mu\rangle = \langle\vartheta,\varphi|^n\vartheta,\varphi\rangle^n = 1$, but

$$\langle\lambda|\mu\rangle = \left(\frac{(1+\lambda^*\mu)^2}{(1+|\lambda|^2)(1+|\mu|^2)}\right)^S \tag{46.59}$$
$$= \left(\cos\tfrac{\theta}{2}\cos\tfrac{\vartheta}{2} + e^{\imath(\varphi-\phi)}\sin\tfrac{\theta}{2}\sin\tfrac{\vartheta}{2}\right)^{2S} = \langle\theta,\phi|^n\vartheta,\varphi\rangle^n \ .$$

However, they are complete in the sense,

$$\frac{2S+1}{\pi}\int\frac{|\mu\rangle\langle\mu|}{(1+|\mu|^2)^2}d^2\mu = \frac{2S+1}{\pi}\int\cos^4\tfrac{\vartheta}{2}|\mu\rangle\langle\mu|d^2\mu = \mathbb{I} \ . \tag{46.60}$$

Also,

$$\langle\lambda|\hat{S}_+|\mu\rangle = \langle\theta,\phi|^n Se^{\imath\varphi}\sin\vartheta|\vartheta,\varphi\rangle^n = \frac{2S}{e^{-\imath\varphi}\cot\frac{\vartheta}{2} + e^{-\imath\phi}\tan\frac{\theta}{2}}\langle\lambda|\mu\rangle$$
$$= \frac{2Se^{\imath\varphi}\tan\frac{\vartheta}{2}}{1+e^{-\imath\phi}\tan\frac{\theta}{2}e^{\imath\varphi}\tan\frac{\vartheta}{2}}\langle\lambda|\mu\rangle = \frac{2S\mu}{1+\lambda^*\mu}\langle\lambda|\mu\rangle$$

and analogously,

$$\langle\lambda|\hat{S}_-|\mu\rangle = ... = \frac{2S\lambda^*}{1+\lambda^*\mu}\langle\lambda|\mu\rangle \ . \tag{46.61}$$

In particular

$$\langle\mu|\hat{S}_+|\mu\rangle = \langle\mu|\hat{S}_-|\mu\rangle^* = \frac{2S\mu}{1+|\mu|^2} = Se^{\imath\varphi}\sin\vartheta = \langle\vartheta,\varphi|^n\hat{S}_+|\vartheta,\varphi\rangle^n \ . \tag{46.62}$$

46.1.5 Bosonic modes: Harmonic oscillators and collective spin states

Owing to the equidistant spectrum of their excitation levels, harmonic oscillator modes and collective spin states share many particularities, which will allow us to transfer various notions from the well-known harmonic oscillator studied in Sec. 24.6 to the spin ensembles. Respectively expanded on Fock states and Dicke states, the oscillator operators and the spin operators are approximately linked by the Holstein-Primakoff prescription, which will be worked out below. Also, we appreciated in Sec. 37.3 the utility of quasi-probability distributions for the estimation of quantum correlations in light modes, which we will apply to spin systems below. Light fields and spin systems are examples of what is called a *bosonic mode*.

46.1.5.1 Mapping Fock and Dicke states

The operators $\hat{a},\hat{a}^\dagger$ contain all information on a light mode. Similarly, $\hat{S}_+,\hat{S}_-,\hat{S}_z$ contain all information on a collective spin state. In the Heisenberg picture their unitary evolution under some operation (displacement, rotation, squeezing, etc.) is obtained from,

$$\hat{a}^\pm(t) = \mathcal{U}(t)\hat{a}^\pm(0)\mathcal{U}^\dagger(t) \qquad \text{versus} \qquad \hat{\mathbf{S}}(t) = \mathcal{U}(t)\hat{\mathbf{S}}(0)\mathcal{U}^\dagger(t) \ . \tag{46.63}$$

While the state of a light mode is given by an expectation value corresponding to a point in an infinite two-dimensional quadrature phase space, the state of a spin ensemble is represented as a vector in a generalized Bloch sphere,

$$\alpha(t) = \langle\psi(0)|\hat{a}^\pm(t)|\psi(0)\rangle \qquad \text{versus} \qquad \mathbf{S}(t) = \langle\Psi_N(0)|\hat{\mathbf{S}}(t)|\Psi_N(0)\rangle \ . \tag{46.64}$$

By the fact that the light mode is represented by a 2D complex plane, the commutation rule involves two field operators, while for the Bloch sphere, which is embedded in 3D space, with respect to a fixed coordinate system the commutation rule involves three field operators,

$$[\hat{a},\hat{a}^\dagger] = 1 \qquad \text{versus} \qquad [\hat{S}_+,\hat{S}_-] = 2\hat{S}_z \ . \tag{46.65}$$

This has consequences for the uncertainty relations,

$$[\hat{x},\hat{p}^\dagger] \geq \tfrac{1}{2} \qquad \text{versus} \qquad [\hat{S}_x,\hat{S}_y] \geq \tfrac{1}{2}|\langle S_z\rangle| \ . \tag{46.66}$$

On the other hand, as long as we are only interested in coherent evolutions, as shown in the example 317, the total angular momentum is a constant of motion. This means that an initially fully stretched collective spin state is restricted to evolve on the

outer (superradiant) shell of the generalized Bloch sphere, which is a two-dimensional surface,

$$|\alpha\rangle = |\mathfrak{Re}\,\alpha, \mathfrak{Im}\,\alpha\rangle \qquad \text{versus} \qquad |\Psi_N\rangle = |\vartheta, \varphi\rangle^N \ . \tag{46.67}$$

As shown in Sec. 46.1.3, rotations do not influence any spin correlations. Therefore, we may as well introduce a local Cartesian coordinate system, rotated such that $\hat{S}_z$ is diagonal on this basis, and calculate its expectation value $\langle S_z\rangle = M$. We immediately see that the commutation rules (46.65) then become equivalent,

$$[\hat{a}, \hat{a}^\dagger] = 1 \qquad \text{versus} \qquad [\hat{S}_+, \hat{S}_-] = 2M \ , \tag{46.68}$$

as well as the corresponding uncertainty relations. In this basis the correlations can be expanded on a 2D phase space parametrized by the angles ϑ and φ.

46.1.6 The Holstein-Primakoff prescription

In the limit of large atom numbers the Dicke Hamiltonian can be approximated by a system of two coupled quantum oscillators. The mapping is done via the so-called *Holstein-Primakoff transformation*. The transformation is a mapping of the spin operators to boson creation and annihilation operators, effectively truncating their infinite-dimensional Fock space to finite-dimensional subspaces. Let us consider a spin operator $\hat{\mathbf{S}}$ defined by its commutation behavior $[\hat{S}_x, \hat{S}_y] = \imath \hat{S}_z$ and characterized by its eigenvectors $|S, M\rangle$,

$$\hat{\mathbf{S}}^2|S, M\rangle = S(S+1)|S, M\rangle \qquad , \qquad \hat{S}_z|S, M\rangle = M|S, M\rangle \ , \tag{46.69}$$

with the projection quantum number $M = -S, -S+1, \ldots, S-1, S$. We consider a single particle of spin S and take the state $|S, M = +S\rangle$ as a vacuum for a set of boson operators, and each subsequent state with lower projection quantum number as a boson excitation of the previous one,

$$|S, S-n\rangle \mapsto \frac{1}{\sqrt{n!}}(\hat{b}^\dagger)^n|0\rangle \ . \tag{46.70}$$

Each additional boson then corresponds to a decrease of M in the spin projection. Thus, the spin raising and lowering operators $\hat{S}_\pm = \hat{S}_x \pm \imath \hat{S}_y$ satisfying so that $[\hat{S}_+, \hat{S}_-] = 2\hat{S}_z$ correspond to bosonic annihilation and creation operators, respectively. The precise relations between the operators must be chosen to ensure the correct commutation relations for the spin operators. The resulting Holstein-Primakoff transformation can be written as,

$$\boxed{\hat{S}_+ = \sqrt{2S}\sqrt{1 - \tfrac{\hat{b}^\dagger \hat{b}}{2S}}\ \hat{b} \quad , \quad \hat{S}_- = \sqrt{2S}\ \hat{b}^\dagger \sqrt{1 - \tfrac{\hat{b}^\dagger \hat{b}}{2S}} \quad , \quad \hat{S}_z = S - \hat{b}^\dagger \hat{b}} \ . \tag{46.71}$$

The transformation is particularly useful in the case where S is large, when the square roots can be expanded as Taylor series, to give an expansion in decreasing powers of S [897, 91]. We will verify the commutation relations in Exc. 46.1.8.17.

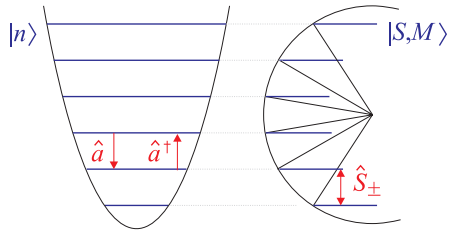

Figure 46.5: Illustration of the Holstein-Primakoff transformation.

The Holstein-Primakoff approximation allows us to rewrite the Hamiltonian (46.6) as,

$$\begin{aligned}\hat{H}_{\text{HoPr}} &= -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \Delta_{\text{a}}\hat{S}_z + 2g(\hat{a}+\hat{a}^\dagger)\hat{S}_x \qquad (46.72)\\ &= -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \Delta_{\text{a}}(S-\hat{b}^\dagger\hat{b}) + 2g(\hat{a}+\hat{a}^\dagger)\sqrt{2S}\left(\sqrt{1-\tfrac{\hat{b}^\dagger\hat{b}}{2S}}\;\hat{b} + \hat{b}^\dagger\sqrt{1-\tfrac{\hat{b}^\dagger\hat{b}}{2S}}\right)\\ &\simeq -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \tfrac{1}{2}\Delta_{\text{a}}\hat{b}^\dagger\hat{b} + 2g_N(\hat{a}+\hat{a}^\dagger)(\hat{b}+\hat{b}^\dagger)\ ,\end{aligned}$$

with the collective coupling strength $g_N \equiv g\sqrt{N}$. The Hamiltonian (46.72) describes two coupled quantum oscillators without rotating-wave approximation [303] [6], a system which has already been discussed in Sec. 37.5.5 in the context of beam splitters.

Example 322 (*Eigenvalue spectrum in the Holstein-Primakoff approximation*): We can rewrite the Dicke Hamiltonian (Eq. (11) in [779]), simplifying for a linear cavity, neglecting the pumping term, and assuming perfect bunching as,

$$\hat{H} = -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \Delta_{\text{a}}\hat{S}_+\hat{S}_- + g(\hat{a}\hat{S}_+ + \hat{a}^\dagger\hat{S}_-)\ . \qquad (46.73)$$

For large atom numbers we apply the Holstein-Primakoff prescription (46.71) [1, 342], yielding,

$$\hat{H} = -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \Delta_{\text{a}}\hat{b}^\dagger\hat{b} + g\sqrt{N}(\hat{a}\hat{b}^\dagger + \hat{a}^\dagger\hat{b})\ . \qquad (46.74)$$

For $\Delta_{\text{c}} = \Delta_{\text{a}} \equiv \Delta$ the Hamiltonian (46.74) describes two resonant coupled harmonic oscillators. It can easily be transformed into a normal-mode basis via,

$$\begin{pmatrix}\hat{A}\\ \hat{A}^\dagger\\ \hat{B}\\ \hat{B}^\dagger\end{pmatrix} = \tfrac{1}{\sqrt{2}}\begin{pmatrix}1&0&1&0\\0&1&0&1\\1&0&-1&0\\0&1&0&-1\end{pmatrix}\begin{pmatrix}\hat{a}\\ \hat{a}^\dagger\\ \hat{b}\\ \hat{b}^\dagger\end{pmatrix}\ , \qquad (46.75)$$

yielding,

$$\hat{H} = -(\Delta - g\sqrt{N})\hat{A}^\dagger\hat{A} - (\Delta + g\sqrt{N})\hat{B}^\dagger\hat{B}\ . \qquad (46.76)$$

With the Holstein-Primakoff bosons satisfying $[\hat{b},\hat{b}^\dagger] = 1$, the quadratures defined as

$$\hat{x} \equiv \tfrac{1}{\sqrt{2}}(\hat{b}+\hat{b}^\dagger) \qquad \text{and} \qquad \hat{p} \equiv \tfrac{1}{\imath\sqrt{2}}(\hat{b}-\hat{b}^\dagger) \qquad (46.77)$$

[6] The Jaynes-Cummings model describes coupling of an atom to a harmonic oscillator mode [303]. In contrast (see 4.4).

obviously satisfy $[\hat{x},\hat{p}]=\imath$. This allows us to extend the Holstein-Primakoff prescription to Cartesian coordinates. Using the expansion,

$$\sqrt{1-\tfrac{\hat{b}^\dagger\hat{b}}{2S}}\simeq 1-\tfrac{\hat{b}^\dagger\hat{b}}{4S}\ , \tag{46.78}$$

which holds for large atom numbers, we find the length of the collective spin,

$$\boxed{\begin{array}{llll}\hat{S}_x & =\frac{1}{2}(\hat{S}_-+\hat{S}_+) & \simeq \hat{x}\sqrt{S}-\frac{\hat{b}^\dagger\hat{x}\hat{b}}{4\sqrt{S}} & =\hat{x}\sqrt{S}-O(S^{-1/2})\\ \hat{S}_y & =\frac{1}{2\imath}(\hat{S}_--\hat{S}_+) & \simeq -\hat{p}\sqrt{S}+\frac{\hat{b}^\dagger\hat{p}\hat{b}}{4\sqrt{S}} & =-\hat{p}\sqrt{S}+O(S^{-1/2})\\ \hat{S}_z & =\frac{1}{2}[\hat{S}_+,\hat{S}_-] & \simeq S-\frac{3}{4}\hat{b}^\dagger\hat{b}+\frac{4}{S}\hat{b}^\dagger\hat{b}^\dagger\hat{b}\hat{b} & =S+O(S^0)\end{array}}\ . \tag{46.79}$$

46.1.6.1 The Holstein-Primakoff prescription on a local coordinate system

In the limit of large particle numbers, we may regard the outer shell of the generalized Bloch as being locally flat. This allows us to map the harmonic oscillator formalism on a tangent plane touching the Bloch sphere at point $\hat{\mathbf{S}}$. Concentrating on the meridian $\varphi=0$ and defining a local coordinate system, as illustrated in Fig. 46.6,

$$\begin{pmatrix}\hat{S}_\vartheta\\ \hat{S}_y\\ \hat{S}_\rho\end{pmatrix}=\begin{pmatrix}\cos\vartheta & 0 & -\sin\vartheta\\ 0 & 1 & 0\\ \sin\vartheta & 0 & \cos\vartheta\end{pmatrix}\begin{pmatrix}\hat{S}_x\\ \hat{S}_y\\ \hat{S}_z\end{pmatrix}\simeq\begin{pmatrix}\hat{x}\sqrt{S}\\ -\hat{p}\sqrt{S}\\ S\end{pmatrix}\ , \tag{46.80}$$

or resolving by the Cartesian spin,

$$\begin{pmatrix}\hat{S}_x\\ \hat{S}_y\\ \hat{S}_z\end{pmatrix}=\begin{pmatrix}\cos\vartheta & 0 & \sin\vartheta\\ 0 & 1 & 0\\ -\sin\vartheta & 0 & \cos\vartheta\end{pmatrix}\begin{pmatrix}\hat{S}_\vartheta\\ \hat{S}_y\\ \hat{S}_\rho\end{pmatrix}\ . \tag{46.81}$$

We verify easily,

$$[\hat{S}_\vartheta,\hat{S}_y]=\imath\hat{S}_\rho\simeq\imath S=[\hat{x}\sqrt{S},\hat{p}\sqrt{S}]\ . \tag{46.82}$$

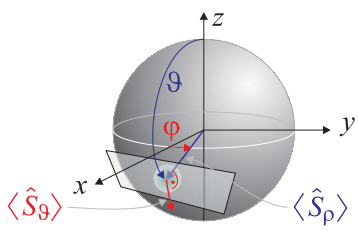

Figure 46.6: Scheme of a local coordinate system.

Solve Excs. 46.1.8.18 and 46.1.8.19. We will use this description in Sec. 46.5.2.

46.1.7 Quasi-probability distributions on the Bloch sphere

The operators contain all information on possible quantum correlations, and it is now interesting to quantify and illustrate the formation of such correlations under some manipulation. This is the purpose of the quasi-probability distributions.

The evolution of collective states and operators of a harmonic oscillator (resp. spin system) under the influence of a Hamiltonian is conveniently calculated by expanding them on a Fock (resp. Dicke) basis and evaluating propagators via unitary transformations, as in Eq. (46.63). On the other hand, quantum correlations become more visible on a Glauber (resp. coherent spin state) basis.

Now, the close analogy between harmonic oscillators and spin systems allows us to apply concepts elaborated for the harmonic oscillator to collective spin states. One example is the notion of quasi-probability distributions introduced in Sec. 37.3 for Glauber states, which we will apply to collective spin states below. In quantum optics a frequently used distribution function is the Wigner function $W_\rho(\alpha,\alpha^*)$ characterizing a light mode via an expansion into a coherent states basis $|\alpha\rangle$ spanning the complex quadrature plane. The purpose of this section is to derive an analogous function for collective spin states $W_\rho(\vartheta,\varphi)$.

We proceed by expanding an arbitrary state of a light mode on the Fock basis (24.93), which is similar to expanding coherent spin states on the Dicke basis (46.32),

$$|\psi\rangle = \sum_{n=0}^{\infty} c_n |n\rangle \qquad \text{versus} \qquad |\Psi_N\rangle = \sum_{M=+S,..,-S} c_{S,M}|S,M\rangle \tag{46.83}$$

with

$$c_n(t) = \langle n|e^{-\imath\hat{H}t}\psi(0)\rangle \qquad \text{versus} \qquad c_{S,M}(t) = \langle n|e^{-\imath\hat{H}t}\Psi_N(0)\rangle \ . \tag{46.84}$$

In particular for coherent states (resp. spin states),

$$|\alpha\rangle = \sum_{n=0}^{\infty} \frac{e^{-|\alpha|^2/2}\alpha^n}{\sqrt{n!}}|n\rangle \tag{46.85}$$

$$\text{versus} \qquad |\vartheta,\varphi\rangle^N = \sum_{M=+S,..,-S} \sqrt{\binom{N}{S+M}} \cos^{S-M}\tfrac{\vartheta}{2} e^{\imath(S+M)\varphi} \sin^{S+M}\tfrac{\vartheta}{2}|S,M\rangle \ .$$

We note that both Fock and Dicke states have no phase in phase space. Phases are generated by summing Fock (resp. Dicke) states with different dynamical phase factors corresponding to their energies.

For numerical simulations we also expand operators on the Fock (resp. Dicke) basis,

$$\hat{a} = \sum_{n,n'=0}^{\infty} \delta_{n',n-1}\sqrt{n}|n'\rangle\langle n| \quad , \quad \hat{a}^\dagger = \sum_{n,n'=0}^{\infty} \delta_{n',n+1}\sqrt{n+1}|n'\rangle\langle n|$$

$$\text{versus} \qquad \hat{S}_\pm = \sum_{M,M'=+S,..,-S} \delta_{M',M\pm1}\sqrt{S(S+1)-M(M\pm1)}|S,M'\rangle\langle S,M|$$

$$\hat{S}_z = \sum_{M,M'=+S,..,-S} \delta_{M',M} M|S,M'\rangle\langle S,M| \ . \tag{46.86}$$

In the case of light modes, any point in phase space is reached via a displacement operator (see Eq. (24.130)). Similarly, any point on the Bloch sphere is reached via rotations about two axes [524, 224] (see Eq. (46.40)),

$$\begin{aligned} |\alpha\rangle &= D(\alpha)|0\rangle \qquad \text{versus} \qquad |\vartheta,\varphi\rangle^N = U_{\rm rt}(\vartheta,\varphi)|S,-S\rangle \\ &= e^{\alpha\hat{a}^\dagger-\alpha^*\hat{a}}|0\rangle \qquad\qquad\qquad\qquad = e^{-(\vartheta/2)e^{-\imath\varphi}\hat{S}_+ + (\vartheta/2)e^{\imath\varphi}\hat{S}_-}|S,-S\rangle \ . \end{aligned} \tag{46.87}$$

The Fock (resp. Dicke) basis may not the best one to reveal the existence of quantum correlations. The purpose of quasi-probability distributions defined on a basis of Glauber (resp. coherent spin) states is to provide a better characterization, in particular, on non-Gaussian collective states.

46.1.7.1 Distributions for Gaussian spin states (coherent and squeezed)

Let us now define proper quasi-probability distributions in analogy to those introduced for Glauber space in Sec. 37.3 [7]. In analogy to the example 263 we may, based on the rotation operator $R(\vartheta,\varphi)|S,S\rangle = e^{\imath\vartheta(\hat{S}_x\sin\varphi-\hat{S}_y\cos\varphi)}|S,S\rangle|\vartheta,\varphi\rangle^N$ introduced in (46.40) and the parity operator for rotations given by [731, 524],

$$M_s = \frac{1}{R}\sum_{\ell=0}^{2S}\sqrt{\frac{2\ell+1}{4\pi}}(\gamma_\ell)^{-s}\mathbf{T}_{\ell 0} \qquad \text{with} \qquad \gamma_\ell = \frac{R\sqrt{4\pi}(2S)!}{\sqrt{(2S+\ell+1)!}\sqrt{(2S-\ell)!}} \tag{46.88}$$

$$\text{and} \qquad \mathbf{T}_{\ell m} = \sqrt{\frac{2\ell+1}{2S+1}}\sum_{M,M'=-S}^{S}\left(\begin{array}{cc|c} S & \ell & S \\ M' & m & M \end{array}\right)|S,M'\rangle\langle S,M|$$

with $R=\sqrt{S/2\pi}$ define a generalized probability distribution,

$$X_\rho(\vartheta,\varphi,s) = \text{Tr}\ \hat{\rho}\mathcal{U}_{\rm rt}(\vartheta,\varphi)M_s\mathcal{U}_{\rm rt}^\dagger(\vartheta,\varphi) \longrightarrow \langle\Psi_N|\mathcal{U}_{\rm rt}(\vartheta,\varphi)M_s\mathcal{U}_{\rm rt}^\dagger(\vartheta,\varphi)|\Psi_N\rangle \ , \tag{46.89}$$

where the second expression holds for pure states. The displacement operator from (37.70) is here replaced by a rotation parametrized by two Euler angles. From (46.89) the usual probability distributions follow as,

$$Q_\rho(\vartheta,\varphi) \equiv X_\rho(\vartheta,\varphi,-1) \quad , \quad W_\rho(\vartheta,\varphi) \equiv X_\rho(\vartheta,\varphi,0) \quad , \quad P_\rho(\vartheta,\varphi) \equiv X_\rho(\vartheta,\varphi,1) \tag{46.90}$$

The parity operator is expanded on the Dicke basis according to the recipe (46.88). To visualize a distribution function, we evaluate (46.89) for every point (ϑ,φ) of the Bloch sphere.

With increasing spin number S, the parity operators M_s converge to the infinite-dimensional operators Π_s of (37.71), while rotations transform into translations along the tangent of a sphere. For pure states the Wigner function is thus given by a rotation of the parity operator.

46.1.7.2 Expansion of non-Gaussian spin states

As long as a collective spin state can be expanded on a collective Dicke basis of superradiant states or reached by coherent evolution from such a state, it remains

[7] Compare (37.79) to (24.158).

pure and can be represented by a probability distribution using the procedure outlined in (46.90). But non-Gaussian spin states can be represented as well. The Dicke state $|S,0\rangle$, the cat state $|\text{cat}\rangle$, the coherent state $|\vartheta,\varphi\rangle^N$, and a squeezed state are illustrated in Fig. 46.7,

$$\begin{aligned}
|\text{W}\rangle &= |S,S-1\rangle \\
|\text{GHZ}\rangle &= \tfrac{1}{\sqrt{2}}(|\uparrow\rangle^{2S}|\downarrow\rangle^0 + |\uparrow\rangle^0|\downarrow\rangle^{2S}) = \tfrac{1}{\sqrt{2}}(|S,S\rangle + |S,-S\rangle) \\
|\text{N00N}\rangle &= \tfrac{1}{\sqrt{2}}(|\uparrow\rangle^{2S}|\downarrow\rangle^0 + e^{\imath N\vartheta}|\uparrow\rangle^0|\downarrow\rangle^{2S}) = \tfrac{1}{\sqrt{2}}(|S,S\rangle + e^{\imath 2S\vartheta}|S,-S\rangle) \\
|\text{cat}\rangle &= \cos\tfrac{\vartheta}{2}|S,S\rangle + e^{\imath\varphi}\sin\tfrac{\vartheta}{2}|S,-S\rangle \\
|\text{squeezed}\rangle &= e^{\imath\zeta\hat{S}_y^2/2}|\pi/2,\pi/2\rangle^N \ .
\end{aligned} \tag{46.91}$$

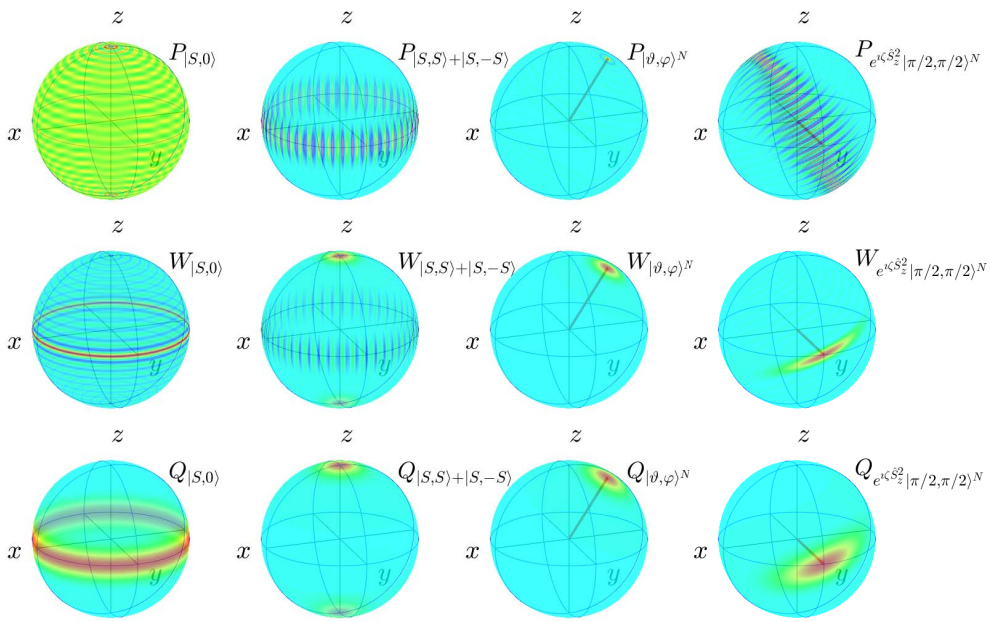

Figure 46.7: (code) P, W, and Q-distributions on the Bloch sphere for various states with $N = 50$.

Note that the Dicke state labeled as $|S,0\rangle$ in Fig. 46.7 corresponds to a twin Fock state [731], as it corresponds to exactly half the atoms in the lower and in the upper state. Rotating this state about the x or the y-axis, we obtain a state with a perfectly defined phase but completely undefined population.

For pure states the density matrix is readily obtained in the Dicke basis via,

$$\hat{\rho}_{|\psi\rangle} = |\psi\rangle\langle\psi| \ . \tag{46.92}$$

For some states it is illustrated in Fig. 46.8

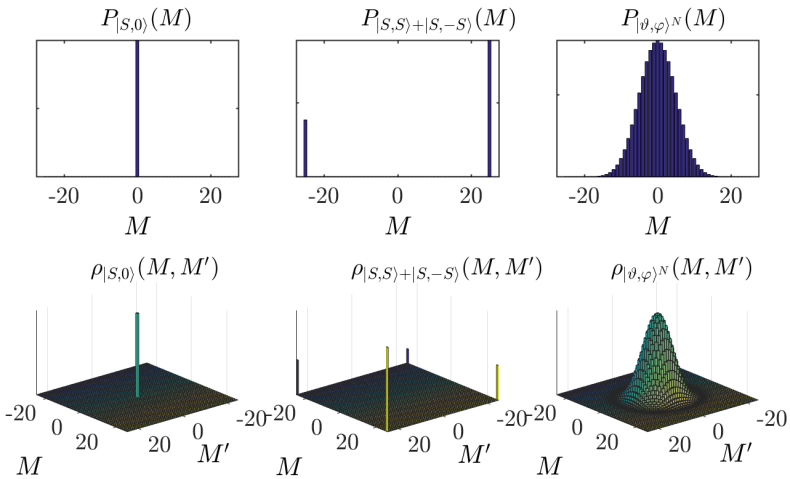

Figure 46.8: (code) Density matrix of several states in the Dicke basis.

46.1.8 Exercises

46.1.8.1 Ex: Dicke states and Clebsch-Gordan coefficients

Discuss the relationship between coherent Dicke states and Clebsch-Gordan coefficients at the example of two coupled spins.

46.1.8.2 Ex: Dicke Hamiltonian for 3 atoms

Generalize the Dicke Hamiltonian (46.25) to 3 atoms.

46.1.8.3 Ex: Coherent spin states

Show that the coherent spin state is an eigenstate of the operator $\hat{S}_{\vartheta,\varphi} \equiv \hat{S}_x \sin\vartheta\cos\varphi + \hat{S}_y \sin\vartheta\sin\varphi + \hat{S}_z\cos\vartheta$.

46.1.8.4 Ex: Orthogonality and completeness of CSS

Check the orthogonality and completeness of CSS in analogy the Glauber states studied in Excs. 24.6.6.3 and 24.6.6.5.

46.1.8.5 Ex: Collective spin of a coherent spin state

a. Calculate the expectation values for all spin components of the collective spin $\hat{\mathbf{S}}$ in a coherent spin state see also Exc. 25.3.4.8.
b. Calculate the uncertainties for all spin components of the collective spin $\hat{\mathbf{S}}$ in a coherent spin state and check the uncertainty relation.

46.1.8.6 Ex: Unitary spin transformations

Prove the relationship $e^{\imath F(\hat{S}_z)}\hat{S}_+ e^{-\imath F(\hat{S}_z)} = \hat{S}_+ e^{\imath[F(\hat{S}_z+\mathbb{I})-F(\hat{S}_z)]}$.

46.1.8.7 Ex: Rotation about the x-axis

How does the collective spin transform under rotation about the x-axis?

46.1.8.8 Ex: Spin operators for two atoms

Calculate explicitly for the case of two atoms the rotation matrices $e^{\imath\gamma\hat{S}_\alpha}$ for $\alpha = x, y, z$. Check the relationship $e^{\imath\gamma\hat{S}_\alpha}\hat{\mathbf{S}}e^{-\imath\gamma\hat{S}_\alpha} = R_\alpha(\gamma)\hat{\mathbf{S}}$ by explicit calculation.

46.1.8.9 Ex: Spin squeezing

a. Calculate $\langle\frac{\pi}{2}, 0|^N e^{\imath\zeta\hat{S}_z^2}\hat{\mathbf{S}}e^{-\imath\zeta\hat{S}_z^2}|\frac{\pi}{2}, 0\rangle^N$.
b. Calculate $\langle\frac{\pi}{2}, 0|^N e^{\imath\zeta\hat{S}_z^2}\Delta\hat{S}^2_{x,y,z}e^{-\imath\zeta\hat{S}_z^2}|\frac{\pi}{2}, 0\rangle^N$.

46.1.8.10 Ex: Rotation of spin squeezed states

Calculate $\langle\frac{\pi}{2}, 0|^N e^{\imath\nu\hat{S}_x}e^{\imath\zeta\hat{S}_z^2}\Delta\hat{S}^2_{x,y,z}e^{-\imath\zeta\hat{S}_z^2}e^{-\imath\nu\hat{S}_x}|\frac{\pi}{2}, 0\rangle^N$.

46.1.8.11 Ex: Spin squeezing with two atoms

a. For a system of two atoms, write down the coherent state $|\vartheta, \varphi\rangle^2 = |\frac{\pi}{2}, 0\rangle^2$ in the Tavis-Cummings basis and in the Dicke state basis.
b. Derive the matrix representation for the squeezing operator along the z-axis and apply this operator to the above coherent spin state.
c. Compare spin squeezing with entanglement.

46.1.8.12 Ex: Mølmer-Sørensen gate

Derive the matrix representation for the two-qubit Mølmer-Sørensen gate $e^{\imath\zeta\hat{S}_x^2}$.

46.1.8.13 Ex: Spin-squeezing via one-axis twisting

For a Dicke state with $N = 8$ atoms, program the matrix representations of the operators $\hat{S}_\pm$, $\hat{\mathbf{S}}$, $R_\alpha(\theta)$, and $\mathcal{Q}_\alpha(\zeta)$ for $\alpha = x, y, z$ defined in the script, as well as the vector representation of the state $|\vartheta, \varphi\rangle$.
a. Starting from the ground state $|\vartheta, \varphi\rangle = |0, 0\rangle$, simulate the following time evolution: (i) $\frac{\pi}{2}$-pulse with the Hamiltonian $\hat{H} = \Omega\hat{S}_x$, where Ω is the Rabi frequency, (ii) interaction-free precession with the Hamiltonian $\hat{H} = \Delta\hat{S}_z$ where Δ is the detuning during a time T, (iii) $\frac{\pi}{2}$-pulse with the Hamiltonian $\hat{H} = \Omega\hat{S}_x$, (iv) projection of the energy axis. Plot the time evolution of the expectation values $\langle\hat{S}_\alpha\rangle$ and $\Delta\hat{S}_\alpha$.
b. Starting from the ground state $|\vartheta, \varphi\rangle = |0, 0\rangle$, simulate the following time evolution: (i) $\frac{\pi}{2}$-pulse with the Hamiltonian $\hat{H} = \Omega\hat{S}_y$, where Ω is the Rabi frequency, (ii) squeezing pulse along the z-axis with the squeezing parameter $\zeta = 0.6$, (iii) $\frac{\pi}{2}$-pulse with the Hamiltonian $\hat{H} = \Omega\hat{S}_x$. Plot the time evolution of the expectation values $\langle\hat{S}_\alpha\rangle$ and $\Delta\hat{S}_\alpha$. Movies can be seen at (watch movie).

46.1.8.14 Ex: Two-axis countertwisting

Study the Hamiltonian,

$$\hat{H} = \zeta(\hat{S}^2_{\pi/2,\pi/4} - \hat{S}^2_{\pi/2,-\pi/4}) = \tfrac{\zeta}{2\imath}(\hat{S}^2_+ - \hat{S}^2_-)$$

with $\hat{S}_{\vartheta,\varphi}$ defined in Exc. 46.1.8.3 in view of its squeezing features of an initial coherent spin state $|0,\varphi\rangle$ [519].

46.1.8.15 Ex: Interferometry with double Fock states

Discuss numerically whether, assuming as the initial state a double spin Fock state of the form $|+\rangle^{N_1}|-\rangle^{N_2}$, Heisenberg limited interferometry can be done within the Dicke model [120, 573].

46.1.8.16 Ex: Entanglement criteria

A sufficient entanglement criterion for an N-qubit state is, that it violates one of the following inequalities [924, 925],

$$\begin{aligned}
\frac{\langle\Delta\hat{S}^2_z\rangle}{\langle\hat{S}_x\rangle^2 + \langle\hat{S}_y\rangle^2} &\geq \frac{1}{N} \\
\langle\hat{S}^2_x\rangle + \langle\hat{S}^2_y\rangle + \langle\hat{S}^2_z\rangle &\leq \tfrac{N(N+2)}{4} \\
\langle\Delta\hat{S}^2_x\rangle + \langle\Delta\hat{S}^2_y\rangle + \langle\Delta\hat{S}^2_z\rangle &\geq \tfrac{N}{2} \\
\langle\hat{S}^2_k\rangle + \langle\hat{S}^2_m\rangle - \tfrac{N}{2} &\leq (N-1)\langle\Delta\hat{S}^2_n\rangle \\
(N-1)[\langle\Delta\hat{S}^2_k\rangle + \langle\Delta\hat{S}^2_m\rangle] &\geq \langle\hat{S}^2_k\rangle + \tfrac{N(N-2)}{4} \ ,
\end{aligned}$$

for $(kmn) = (123)$. Verify that, according to these criteria, coherent Dicke states are not entangled.

46.1.8.17 Ex: Consistency of the Holstein-Primakoff transform

Verify that the relations (46.71) satisfy $[\hat{S}_+, \hat{S}_-] \simeq 2\hat{S}_z$ and $[\hat{S}_x, \hat{S}_y] \simeq \frac{\imath}{2}\hat{S}_z$.

46.1.8.18 Ex: Holstein-Primakoff expansion on the Bloch sphere for coherent spin states

Calculate the uncertainties for coherent spin states $|\vartheta_N\rangle \equiv |\vartheta, 0\rangle^{\otimes N}$ in the local basis.

46.1.8.19 Ex: Uncertainty relation in different bases

In Exc. 46.1.8.5 the principal axes of the uncertainty ellipsoid of a coherent spin state have been derived for a fixed Cartesian coordinate system. Now, express the uncertainty ellipsoid in a local Cartesian basis anchored to spherical coordinates by $\hat{\mathbf{e}}'_x = \hat{\mathbf{e}}_r$, $\hat{\mathbf{e}}'_y = \hat{\mathbf{e}}_\theta$, and $\hat{\mathbf{e}}'_z = \hat{\mathbf{e}}_\phi$. Why is the radial projection onto the surface of the generalized Bloch sphere invariant upon rotation? Interpret the projection of the uncertainty ellipsoid onto the radial axis and its dependency on rotation.

46.1.8.20 Ex: Dicke model of Bloch oscillations in the two-mode approximation

In the limit where Bloch oscillations can be modeled by a two-level system [808] we may try a representation within the Dicke model and illustrate the dynamics on a Bloch sphere [804]. The gravitational acceleration corresponds to a modification of kinetic energy without modification of the momentum state populations and without excitation of quantum coherences between them. That is, at any time the system remains in an eigenstate of the momentum operator. Since the kinetic energy is represented by the vertical axis of the Bloch sphere, we may visualize acceleration via a rotation of the Bloch sphere, e.g. about the y-axis. The interpretation of the rotated Bloch sphere remains the same: the xy-plane shows the coherences and the z-axis the populations. Once this works, we can treat the thermal atomic cloud as a coherent spin state, e.g. squeeze it [519] or simulate trajectory of individual atoms inhomogeneously [238] [8,9]. A movie can be seen at (watch movie).

46.1.8.21 Ex: Error estimation in Rabi and Ramsey experiments

The precision of the estimation of a parameter ϑ from a measurement of an observable $\hat{A}$ which depends on that parameter is obtained from error propagation (see Secs. 47.4.3) [923],

$$(\Delta\vartheta)^2 = \frac{\langle\Delta\hat{A}\rangle^2}{|\partial_\vartheta\langle\hat{A}\rangle|^2} = \frac{\langle\hat{A}^2\rangle - \langle\hat{A}\rangle^2}{|\partial_\vartheta\langle\hat{A}\rangle|^2} \ .$$

a. Estimate for a coherent collective spin state the uncertainty in determining the angle ϑ from a measurements of one of the spin components, that is, $\hat{A} \equiv \hat{S}_{x,y,z}$.
b. Consider a Ramsey experiment where the collective spin state has been rotated into the equatorial plane by a first $\pi/2$ nutation pulse, such that the state becomes an eigenstate of $\hat{S}_x$. Now, the spin starts precessing about the z-axis according to $\mathcal{U} = e^{\imath\hat{H}t}$ due to an interaction $\hat{H} = \varphi\hat{S}_z$. Estimate for a coherent collective spin state the uncertainty in determining the angle φ from a measurement of $\hat{S}_y$.

46.2 Super- and subradiance in open systems

The abstract spin formalism developed in the last sections revealed propagators allowing us to rotate and squeeze coherent spin states, but it did not tell us how to implement them physically. For this, we need to solve equations of motion derived from Hamiltonians realizable in the laboratory. In the following sections, we will set up the fundamental equations of motion (master or Heisenberg-Liouville) for open systems of N atoms subject to spontaneous emission collectively interacting with a single light mode subject to cavity decay and pumped by an external source.

We will discuss constants of motion of the Dicke and of the Tavis-Cummings model and phase transitions to superradiant states in the mean-field and in the Holstein-Primakoff approximation. Finally, we will present recent experimental realizations of Dicke phase transitions, namely superradiant self-ordering and superradiant lasing.

[8] Note that, in order to simulate a series of Bloch oscillations, we must change the basis by hand after each Bragg reflection.

[9] An interesting question is, whether the Dicke picture can be extended to CARL (see Sec. 48.3.4).

46.2.1 Models for open systems and phase transitions

We have already seen, that the spin quantum number S is preserved under the effect of the Dicke Hamiltonian (46.6). The spherical harmonics $|S, M\rangle$ are orthonormal and the spin operators $\hat{S}_\pm$ and $\hat{S}_{x,y,z}$ or their combinations do not allow for transitions between states with different S,

$$\begin{aligned} &[\hat{H}, \hat{\mathbf{S}}^2] = 0 \qquad \text{with} \qquad \hat{\mathbf{S}}^2 = \tfrac{1}{2}(\hat{S}_+\hat{S}_- + \hat{S}_-\hat{S}_+) + \hat{S}_z^2 \\ \text{but} \qquad &[\hat{H}, \hat{S}_z] = \imath(\mathfrak{Im}\,\Omega\ \hat{S}_x - \mathfrak{Re}\,\Omega\ \hat{S}_y) \neq 0\ . \end{aligned} \tag{46.93}$$

Hence, under the effect of the Dicke Hamiltonian an initial state $|N, S, M\rangle$ can only change its magnetic quantum number $|N, S, M\rangle \longrightarrow |N, S, M'\rangle$, and the manifolds with a given S form closed sub-spaces (see Exc. 46.2.4.2). In other words, once we start in a superradiant state $|N, S, M\rangle = |N, \frac{N}{2}, +\frac{N}{2}\rangle$, spin conservation excludes subradiant states, which allowed us to restrict to the superradiant Dicke subspace. Transitions between Dicke subspaces are only possible via physical processes that act on individual atoms, e.g. decay or phase fluctuation processes, as we will see later [346, 1011].

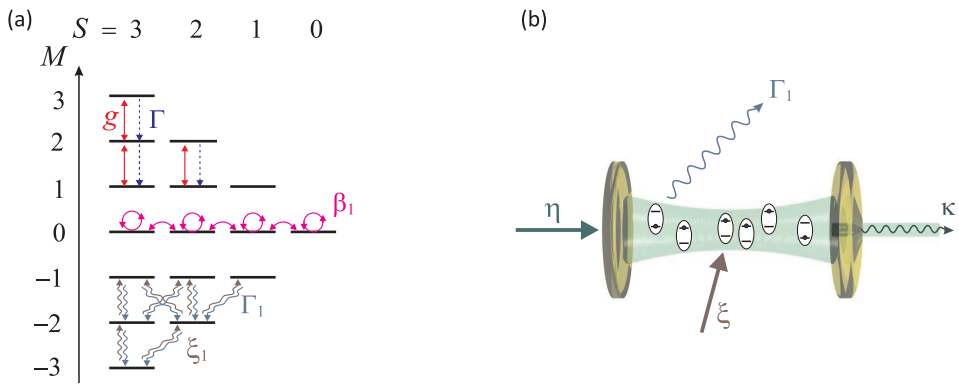

Figure 46.9: (a) Illustration of the Dicke states for $N = 6$. Hamiltonian interactions are in depicted in red. Superradiant decay occurs through a cascade from state $M = S$ to state $M = -S$. Spontaneous emission and phase noise leads to transitions along the blue arrows. The lowest states in each S subspace are dark and can only decay through a (subradiant) dark states cascade. (b) Scheme of the Dicke model.

46.2.1.1 The generalized open Dicke model

In the presence of spontaneous decay or dephasing, superradiant spin conservation is no longer guaranteed. Let us have a look at the master equation for a set of N atoms coupled with the strength g to the mode of a cavity and additionally pumped by a classical laser field η [88, 517] (see (38.27)). After transformation into the rotating frame we have,

$$\dot{\hat{\rho}} = \imath[\hat{\rho}, \hat{H}_{gD}] + \sum_\gamma \mathfrak{L}_{\gamma,\hat{L}}\hat{\rho} \qquad \text{or} \qquad \dot{\hat{A}} = -\imath[\hat{A}, \hat{H}_{gD}] + \sum_\gamma \mathfrak{L}^\dagger_{\gamma,\hat{L}}\hat{A}$$

$$\hat{H}_{gD} = -\Delta_\mathrm{c}\hat{a}^\dagger\hat{a} - \Delta_\mathrm{a}\hat{S}_z + g(\hat{a}\hat{S}_+ + \hat{S}_-\hat{a}^\dagger) + g'(\hat{a}\hat{S}_- + \hat{S}_+\hat{a}^\dagger) - \imath\eta(\hat{a} - \hat{a}^\dagger)$$

$$\text{and} \quad \mathfrak{L}_{\gamma,\hat{L}}\hat{\rho} \equiv \gamma(2\hat{L}\hat{\rho}\hat{L}^\dagger - \hat{L}^\dagger\hat{L}\hat{\rho} - \hat{\rho}\hat{L}^\dagger\hat{L})$$

$$\text{and} \quad \mathfrak{L}^\dagger_{\gamma,\hat{L}}\hat{A} \equiv \gamma(2\hat{L}^\dagger\hat{A}\hat{L} - \hat{L}^\dagger\hat{L}\hat{A} - \hat{A}\hat{L}^\dagger\hat{L}) \tag{46.94}$$

The different coupling strengths g and g' allow us to isolate the counter-rotating terms, in order to discuss their relevance. The usual *open Dicke model* is obtained from the generalized Dicke Hamiltonian $\hat{H}_{gD}$ by setting $g' \equiv g$, while the rotating wave approximation is done by setting $g' \equiv 0$. The rates γ describe possible decay processes to which the degrees of freedom $\hat{L}$ are subject. The most relevant decay processes are listed in the following table:

decay rate γ	dissipative operator $\hat{L}$	physical process
κ	$\hat{a}$	cavity decay
ϕ	$\hat{a}^\dagger\hat{a}$	cavity phase jitter
$\gamma = \Gamma/2$	$\hat{S}_- = \sum_j \hat{s}_j^-$	collective (superradiant) atomic decay
$\gamma_1 = \Gamma_1/2$	$\hat{s}_j^-$	(transverse) single-atom decay
ξ_1	$\hat{s}_j^+$	single-atom optical pumping
β_1	$\hat{s}_j^z$	single-atom dephasing

$\Gamma = 2\gamma$ is the collective longitudinal atomic decay, κ and ϕ describe collective decay respectively collective phase noise of the cavity, while $\Gamma_1 = 2\gamma_1$, ξ_1, and β_1 stand for spontaneous emission, optical pumping via higher-lying levels, and phase fluctuation of individual atoms. The latter decay processes are described by sums of Lindbladians over all atoms. In Exc. 46.2.4.4 we derive the Heisenberg equations for the relevant degrees of freedom,

$$\begin{aligned}
\dot{\hat{a}} &= (\imath\Delta_\mathrm{c} - \kappa - \phi)\hat{a} - \imath(g\hat{S}_- + g'\hat{S}_+) + \eta \\
\dot{\hat{S}}_- &= (\imath\Delta_\mathrm{a} - \gamma_1 - \xi_1 - \beta_1 + \Gamma\hat{S}_z)\hat{S}_- + 2\imath\hat{S}_z(g\hat{a} + g'\hat{a}^\dagger) \\
\dot{\hat{S}}_z &= -\imath\hat{S}_+(g\hat{a} + g'\hat{a}^\dagger) + \imath(g\hat{a}^\dagger + g'\hat{a})\hat{S}_- - \Gamma\hat{S}_+\hat{S}_- - N(\gamma_1 - \xi_1)\mathbb{I} - 2(\gamma_1 + \xi_1)\hat{S}_z \\
\dot{\hat{s}}_j^- &= (\imath\Delta_\mathrm{a} - \gamma_1 - \xi_1 - \beta_1)\hat{s}_j^- + 2\imath(g\hat{a} + g'\hat{a}^\dagger)\hat{s}_j^z \\
\dot{\hat{s}}_j^z &= -\imath(g\hat{a} + g'\hat{a}^\dagger)\hat{s}_j^+ + \imath(g\hat{a}^\dagger + g'\hat{a})\hat{s}_j^- - \gamma_1(\mathbb{I} - 2\hat{s}_j^z) + \xi_1(\mathbb{I} + 2\hat{s}_j^z)\ .
\end{aligned} \tag{46.95}$$

In Exc. 46.2.4.5 we verify that these equations of motion do not change the spin $\hat{\mathbf{S}}$. Neglecting all dissipation processes but Γ, the Eqs. (46.95) can be rewritten in terms of observables as,

$$\dot{\hat{\mathbf{S}}} = \begin{pmatrix} (g+g')(\hat{a}+\hat{a}^\dagger) \\ \imath(g-g')(\hat{a}-\hat{a}^\dagger) \\ -\Delta_\mathrm{a} \end{pmatrix} \times \hat{\mathbf{S}} + \tfrac{\Gamma}{2}\begin{pmatrix} -\hat{S}_x + \{\hat{S}_x, \hat{S}_z\} \\ -\hat{S}_y + \{\hat{S}_y, \hat{S}_z\} \\ -2\hat{S}_z - 2\hat{S}_x^2 - 2\hat{S}_y^2 \end{pmatrix}\ . \tag{46.96}$$

Only the terms $\mathfrak{L}_{\gamma_1}$, $\mathfrak{L}_{\xi_1}$, and $\mathfrak{L}_{\beta_1}$ can change $\hat{\mathbf{S}}^2$. The $\hat{\mathbf{S}}^2$ and $\hat{S}_z$ eigenvalues determine the coupling strength of the many-atom (Dicke) state to the cavity mode and the coherent, external drive. This coupling determines the rate of cavity photon generation as well as the pumping strength. The magnitude of the coupling strength distinguishes between superradiance and subradiance. For superradiant states the coupling strength scales superlinear in N, while for subradiant states the scaling is sublinear in N, and some subradiant states are dark. Dark means that the collective coupling to the cavity and the coherent, external drive of these states vanishes, meaning these states cannot decay via collective interactions e.g. by creating a cavity photon. However these states still decay into other states via the decay and dephasing processes $\mathfrak{L}_{\gamma_1}$ and $\mathfrak{L}_{\beta_1}$ acting individually on the emitters, see Fig. 46.9. Hence, spontaneous decay is an individualization process [346]. Generally, the spin preserving contributions in the master equation (46.98) generate quantum correlations leading to collective behavior (both super- and subradiance are collective effects) and the non-preserving terms destroy correlations leading to individualization (all properties scale exactly linear in N). However only the spin non-preserving contributions introduce coupling between superradiant and subradiant states, thus in order to prepare subradiant states an interplay of collectivity and individualization is necessary. Based on these considerations, we may distinguish between collective versus individual behavior and superradiant versus subradiant behavior. The latter are special cases of collective behavior. This twofold distinction seems crucial when investigating super- and subradiance in the presence of dephasing and individual decay. In Exc. 46.2.4.6 we study superradiant decay.

46.2.1.2 Symmetries of the Dicke model with/out rotating wave approximation

The total number of excitations,

$$\hat{N}_{\text{ex}} \equiv \hat{a}^\dagger \hat{a} + \hat{S}_z \tag{46.97}$$

is a constant of motion only for the Tavis-Cummings Hamiltonian, i.e. the Dicke Hamiltonian with RWA, $g' = 0$, and in the absence of pumping, $\eta = 0$, commutes with the excitation number,

$$[\hat{H}_{\text{gD}}, \hat{N}_{\text{ex}}] = \eta(\hat{a} - \hat{a}^\dagger) + 2g'(\hat{S}_- \hat{a} - \hat{S}_+ \hat{a}^\dagger) \xrightarrow{\eta=0} 0 \ . \tag{46.98}$$

That is, the Dicke Hamiltonian preserves the excitation number, except for the counter-rotating terms, which can only change the excitation number by ± 2.

The Dicke model without RWA, $g' = g$, has one global symmetry [10],

$$(\hat{a}, \hat{\sigma}^\pm) \xrightarrow{\mathcal{P}} (-\hat{a}, -\hat{\sigma}^\pm) \ , \tag{46.99}$$

where the parity operator is,

$$\mathcal{P} = e^{\imath\pi\hat{N}} \quad , \quad [\hat{H}_{\text{gD}}, \mathcal{P}] = 0 \ , \tag{46.100}$$

[10] For a Dicke picture of CARL see Exc. 48.5.7.1.

as shown in Exc. 46.2.4.1. Because $\mathcal{P}$ squares to unity, it has two eigenvalues, 1 and -1. This symmetry is associated with a conserved quantity: the parity of the total number of excitations, $\mathcal{P} = (-1)^{N_{\rm ex}}$. This parity conservation is a consequence of the preserved excitation number. A state of the Dicke model is said to be normal when this symmetry is preserved, and superradiant when this symmetry is spontaneously broken.

Note that, at low coupling strength the two subspaces belonging to different parities are degenerate, but in the thermodynamic limit $N \to \infty$ at high enough coupling strength they may split upon a Dicke quantum phase transition [11].

model	RWA	symmetry	atom #	photon #	section
Rabi	no	$\mathcal{P}$	1	n	39.3
Jaynes-Cummings	yes	$U(1)$	1	n	40.2
Dicke	no	$\mathcal{P}$	> 1	n	46.1
Tavis-Cummings	yes	$U(1)$	> 1	n	46.2.2, 46.4

46.2.2 Superradiant Dicke phase transition

The interesting feature of the set of equations (46.95) is, that the degrees of freedom are macroscopically populated, yet, they follow the rules of quantum mechanics. For instance, we may expect them to behave as order parameters for macroscopic phase transitions. We will study one such example in the following.

46.2.2.1 Equilibrium Dicke phase transition

The Dicke model predicts a phase transition to a superradiant state, when the coupling strength g exceeds a certain critical value. To see this we simplify the Hamiltonian (46.6) by the mean-field approximation,

$$\Delta_{\rm c}\hat{a}^\dagger\hat{a} = \Delta_{\rm c}\alpha^2 \ , \tag{46.101}$$

where the field amplitude α is a real number, and calculate the free energy as a function of α,

$$\begin{aligned} F(\alpha) \equiv -\tfrac{1}{\beta}\ln\Xi(\alpha) \qquad \text{with} \qquad & \Xi(\alpha) = \mathrm{Tr}\, e^{-\beta\hat{H}} \\ \text{and} \qquad & \hat{H} = -\Delta_{\rm c}\alpha^2 + \sum\nolimits_j \hat{h}_j \\ \text{and} \qquad & \hat{h}_j = -\Delta_{\rm a}\hat{s}_j^z + 4g\alpha\hat{s}_j^x \ . \end{aligned} \tag{46.102}$$

$\Xi(\alpha)$ is the partition function, $\hat{h}_j$ the single-atom Hamiltonian, and $\beta \equiv 1/k_{\rm B}T$. Carried out in Exc. 46.2.4.7, the calculation results in,

$$\begin{aligned} F(\alpha) &= \Delta_{\rm c}\alpha^2 - \tfrac{N}{\beta}\ln(2\cosh\beta E) \\ \text{where} \qquad \pm E &\equiv \langle\hat{h}_j\rangle = \pm\sqrt{\left(\tfrac{\Delta_{\rm a}}{2}\right)^2 + (g\alpha)^2} \end{aligned} \tag{46.103}$$

[11] Other models, such as the Ising model, the Heisenberg model, or the Bose-Hubbard model are not treated here.
$\mathcal{P}$ is the parity operator defined in Eq. (46.99). The unitary group $U(1)$ corresponds to the circle group consisting of all complex numbers with absolute value 1 under multiplication.

are the single-atom energy eigenvalues. The minimum of the free energy as a function of the field amplitude, $F'(\alpha) = 0$, yields a critical coupling strength g_c,

$$g_c\sqrt{N} = \frac{1}{2}\sqrt{\Delta_c\Delta_a \coth\frac{\beta\Delta_a}{2}}\ , \tag{46.104}$$

Below g_c the free energy minimizes for $\alpha = 0$, and beyond g_c it minimizes for $\alpha > 0$, as seen in Fig. 46.10.

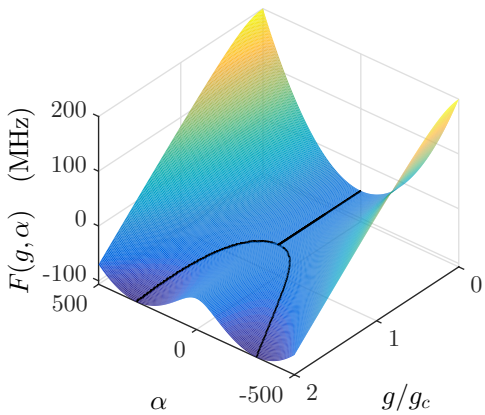

Figure 46.10: (code) Free energy as a function of coupling strength and photon number. Beyond the critical coupling strength g_c the minimum of the free energy splits opening the way for two possible equilibrium states of the mean-field phase.

Note that the critical coupling smoothly evolves down to zero temperature ($\beta \to 0$), where one obtains $g_c = \sqrt{\Delta_c\Delta_a/2N}$ [12].

46.2.3 Beyond mean-field

We already applied the mean-field approximation in the derivation of the semiclassical Dicke Hamiltonian (46.9) and the Dicke phase transition (46.101). Some effects, however, are intrinsically to the existence of interatomic correlations, as for example, superradiant lasing [13]

46.2.3.1 Cumulant expansion

Often we are interested in quantum correlations rather than in the mean-field behavior of an operator. The *cumulant expansion* allows to study higher-order correlations

[12] Note, that in the thermodynamic limit, $N \to \infty$, the operators can be replaced by [517]:

$$\hat{S}_x \overset{N\to\infty}{\longrightarrow} \frac{1}{2}\hat{N}\cos\hat{\varphi} \qquad \text{and} \qquad \hat{S}_y \overset{N\to\infty}{\longrightarrow} \frac{1}{2}\hat{N}\sin\hat{\varphi}\ .$$

In this case, the operators commute $[\hat{S}_x, \hat{S}_y] \to 0$.

[13] Interestingly, spin-squeezing, which is also based on interatomic correlations, can be described within the mean-field approximation.

by gradually removing lower-order ones. We introduce the correlation or cumulant expectation value between operators $\hat{A}$ and $\hat{B}$ [543, 809],

$$\begin{aligned}\langle\hat{A}\rangle &\equiv \langle\hat{A}\rangle_{\rm c} \\ \langle\hat{A}\hat{B}\rangle &\equiv \langle\hat{A}\rangle\langle\hat{B}\rangle + \langle\hat{A}\hat{B}\rangle_{\rm c} \\ \langle\hat{A}\hat{B}\hat{C}\rangle &\equiv \langle\hat{A}\rangle\langle\hat{B}\rangle\langle\hat{C}\rangle + \langle\hat{A}\rangle\langle\hat{B}\hat{C}\rangle_{\rm c} + \langle\hat{B}\rangle\langle\hat{A}\hat{C}\rangle_{\rm c} + \langle\hat{C}\rangle\langle\hat{A}\hat{B}\rangle_{\rm c} + \langle\hat{A}\hat{B}\hat{C}\rangle_{\rm c}\ .\end{aligned} \tag{46.105}$$

The lowest order mean-field approximation consists in neglecting $\langle\hat{A}\hat{B}\rangle_{\rm c} \simeq 0$.

Example 323 (*Superradiant lasing*): In a conventional laser amplification and optical phase coherence are established by stimulated photon emission from a population-inverted medium. This results in the Schawlow-Townes spectral linewidth, proportional to the square of the cavity decay width and inversely proportional to the photon number in the cavity. As Dicke showed, the coherence can also be stored in the emitters that constitute the gain medium provided they interact collectively with common radiation field modes [234]. If the spontaneous decay rate is much smaller than the cavity decay rate very narrow emission bandwidths far below the cavity decay width can be achieved. In Exc. 46.2.4.8 we study *superradiant lasing* in the Dicke model [632]. Cavity-mediated superradiance can also be described within the *Tavis-Cummings model* [149]. It represents an extension of the Jaynes-Cummings model for several atoms. We will discuss such systems in Sec. 47.2.

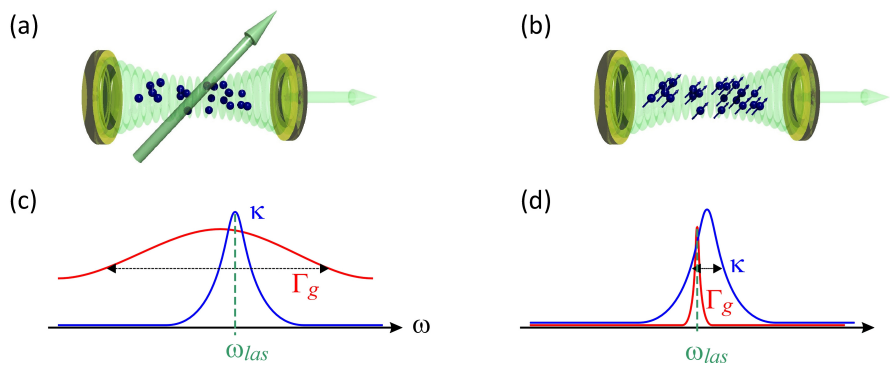

Figure 46.11: (a) Principle scheme of standard lasing. Here, the coherence is stored in the cavity field. The gain profile is much larger than the cavity width (good-cavity limit, $\kappa \ll \frac{1}{2}\Gamma_{\rm g}$), as shown in (c). The laser frequency follows any (technical) cavity fluctuation: $\omega_{\rm las} = \omega_{\rm cav} + \omega_{\rm g}\frac{2\kappa}{\Gamma_{\rm g}}$. (b) *Superradiant lasing*. Here, the coherence is stored in the gain. We are in the bad-cavity limit, $\kappa \gg \Gamma_{\rm g}$, as shown in (d). The laser frequency is robust to cavity fluctuations: $\omega_{\rm las} = \omega_{\rm g} + \omega_{\rm cav}\frac{\Gamma_{\rm g}}{2\kappa}$.

46.2.3.2 Superradiant lasing in the Holstein-Primakoff approximation

The superradiant phase transition was originally predicted by the Dicke model [256, 433]. It occurs when the strength of the interaction between the atoms and the field

is greater than the energy of the non-interacting part of the system [14]. The collective Lamb shift, relating to the system of atoms interacting with the vacuum fluctuations, becomes comparable to the energies of atoms alone, and the vacuum fluctuations cause the spontaneous self-excitation of matter.

The transition can be readily understood by the use of the Holstein-Primakoff transformation applied to an ensemble of two-level atoms, as shown in Sec. 46.1.5, as a result of which the atoms become harmonic oscillators with frequencies equal to the difference between the energy levels. If the interaction between the atomic and the field oscillator is so strong that the system collapses in a ferroelectric-like phase transition. In Exc. 46.2.4.10 we will derive the Heisenberg equations for the open Dicke model in the Holstein-Primakoff approximation.

Example 324 (*Finding instabilities via retarded Green's functions*): Let us consider a set of linear Heisenberg equations,

$$\dot{v}_i(t) = M_{ij} v_j(t) \qquad \text{and} \qquad \dot{v}_i^\dagger(t) = M_{ij}^\dagger v_j^\dagger(t) \ .$$

The retarded *Green's function* is defined by,

$$G_{ij}(t) \equiv -\imath \langle [v_i(t), v_j^\dagger(0)] \rangle \theta(t) \ .$$

Its time derivative is,

$$\dot{G}_{ij}(t) \equiv -\imath \langle [v_i(t), v_j^\dagger(0)] \rangle \delta(t) - \imath \langle \dot{v}_i(t) v_j^\dagger(t) \rangle \theta(t) + \imath \langle v_j^\dagger(t) \dot{v}_i(t) \rangle \theta(t) \ .$$

Defining the equal-time correlation function by,

$$S_{ij} \equiv \langle [v_i(0), v_j^\dagger(0)] \rangle \ ,$$

we get,

$$\begin{aligned} \dot{G}_{ij}(t) &= -\imath S_{ij} \delta(t) - \imath M_{ik} \langle v_k(t) v_j^\dagger(t) \rangle \theta(t) + \imath M_{ik} \langle v_j^\dagger(t) v_k(t) \rangle \theta(t) \\ &= -\imath S_{ij} \delta(t) - \imath M_{ik} \langle [v_k(t), v_j^\dagger(t)] \rangle \theta(t) = -\imath S_{ij} \delta(t) + M_{ik} G_{kj}(t) \ . \end{aligned}$$

With the Fourier transform $f(\omega) = \int_{-\infty}^{\infty} dt e^{\imath \omega t} f(t)$ we finally get,

$$G(\omega) = (M + \imath \omega \mathbb{I})^{-1} \imath S \ .$$

For example, we may consider the system of two coupled oscillators studied in Sec. 37.5.5. In this case,

$$\mathbf{v} \equiv \begin{pmatrix} \hat{a} \\ \hat{a}^\dagger \\ \hat{b} \\ \hat{b}^\dagger \end{pmatrix} \qquad \text{such that} \qquad S = \text{diag}\ (1, -1, 1, -1) \ .$$

In Exc. 37.5.8.8 we have shown that (setting $\Omega' \equiv \Omega$),

$$M = \begin{pmatrix} -\imath\omega - \kappa_{\rm a} & 0 & -\frac{\imath\Omega}{2} & -\frac{\imath\Omega}{2} \\ 0 & \imath\omega - \kappa_{\rm a} & \frac{\imath\Omega}{2} & \frac{\imath\Omega}{2} \\ -\frac{\imath\Omega}{2} & -\frac{\imath\Omega}{2} & -\imath\omega - \kappa_{\rm b} & 0 \\ \frac{\imath\Omega}{2} & \frac{\imath\Omega}{2} & 0 & \imath\omega - \kappa_{\rm b} \end{pmatrix} \ .$$

[14] This is similar to the case of superconductivity in ferromagnetism, which leads to the dynamic interaction between ferromagnetic atoms and the spontaneous ordering of excitations below the critical temperature.

Thus,

$$G^{\mathrm{R}}(\omega)^{-1} = S^{-1}(\omega\mathbb{I}-\imath M) = \begin{pmatrix} \omega-\omega_{\mathrm{a}}+\imath\kappa_{\mathrm{a}} & 0 & -\frac{\Omega}{2} & -\frac{\Omega}{2} \\ 0 & -\omega-\omega_{\mathrm{a}}-\imath\kappa_{\mathrm{a}} & -\frac{\Omega}{2} & -\frac{\Omega}{2} \\ -\frac{\Omega}{2} & -\frac{\Omega}{2} & \omega-\omega_{\mathrm{b}}+\imath\kappa_{\mathrm{b}} & 0 \\ -\frac{\Omega}{2} & -\frac{\Omega}{2} & 0 & -\omega-\omega_{\mathrm{b}}-\imath\kappa_{\mathrm{b}} \end{pmatrix} .$$

The superradiant transition corresponds to the requirement that one of the eigenvalues of M goes to zero [234, 517], or equivalently,

$$0 = \det G^{\mathrm{R}}(\omega)^{-1} = \omega_{\mathrm{a}}^2\omega_{\mathrm{b}}^2 + \omega_{\mathrm{a}}^2\kappa_{\mathrm{b}}^2 - \omega_{\mathrm{a}}\Omega^2\omega_{\mathrm{b}} + \kappa_{\mathrm{a}}^2\omega_{\mathrm{b}}^2 + \kappa_{\mathrm{a}}^2\kappa_{\mathrm{b}}^2 ,$$

yielding,

$$\Omega = \sqrt{\frac{(\omega_{\mathrm{a}}^2+\kappa_{\mathrm{a}}^2)(\omega_{\mathrm{b}}^2+\kappa_{\mathrm{b}}^2)}{\omega_{\mathrm{a}}\omega_{\mathrm{b}}}} .$$

Example 325 (*Dicke phase transition with a superfluid gas in an optical cavity*): [68].

46.2.3.3 Zeeman splitting in the Holstein-Primakoff approximation

The Dicke Hamiltonian in the Holstein-Primakoff approximation has been derived in Eq. (46.72). We now generalize it for the presence of three collective atomic modes $\hat{b}_{0\pm}$ accounting for Zeeman splitting [973],

$$\begin{aligned} \hat{H} \simeq & -\Delta_{\mathrm{c}}\hat{a}^\dagger\hat{a} \\ & -\tfrac{1}{2}(\Delta_{\mathrm{a}}+\Delta_{\mathrm{zeem}})\hat{b}_-^\dagger\hat{b}_- - \tfrac{1}{2}\Delta_{\mathrm{a}}\hat{b}_0^\dagger\hat{b}_0 - \tfrac{1}{2}(\Delta_{\mathrm{a}}-\Delta_{\mathrm{zeem}})\hat{b}_+^\dagger\hat{b}_+ \\ & + 2g_N(\hat{b}_-^\dagger\hat{a}+\hat{a}^\dagger\hat{b}_-) + 2g_N(\hat{b}_0^\dagger\hat{a}+\hat{a}^\dagger\hat{b}_0) + 2g_N(\hat{b}_+^\dagger\hat{a}+\hat{a}^\dagger\hat{b}_+) + \eta(\hat{a}-\hat{a}^\dagger) . \end{aligned} \tag{46.106}$$

From this we derive the equations of motion,

$$\begin{aligned} \dot{\hat{a}} &= (\imath\Delta_{\mathrm{c}}-\kappa)\hat{a} - 2\imath g_N\hat{b}_- - 2\imath g_N\hat{b}_0 - 2\imath g_N\hat{b}_+ + \imath\eta \\ \dot{\hat{b}}_\mu &= \tfrac{1}{2}(\imath\Delta_{\mathrm{a}} - \mu\imath\Delta_{\mathrm{zeem}} - \Gamma)\hat{b}_\mu - 2\imath g_N\hat{a} , \end{aligned} \tag{46.107}$$

with $\mu = 0, \pm 1$. Their solution is shown in Fig. 46.12.

46.2.4 Exercises

46.2.4.1 Ex: Parity considerations

a. Show that the excitation number $\hat{N} = \hat{a}^\dagger\hat{a} + \hat{S}_z + S$ is conserved by the Hamiltonian within rotating wave approximation,

$$\hat{H}_{\mathrm{rw}} = -\Delta_{\mathrm{a}}\hat{S}_z - \Delta_{\mathrm{c}}\hat{a}^\dagger\hat{a} + g(\hat{a}^\dagger\hat{S}_- + \hat{a}\hat{S}_+) .$$

b. Show that the parity operator defined by $\mathcal{P} = e^{\imath\pi\hat{N}}$ is conserved by the Hamiltonian without rotating wave approximation [295],

$$\hat{H} = -\Delta_{\mathrm{a}}\hat{S}_z - \Delta_{\mathrm{c}}\hat{a}^\dagger\hat{a} + g(\hat{a}^\dagger + \hat{a})(\hat{S}_+ + \hat{S}_-) .$$

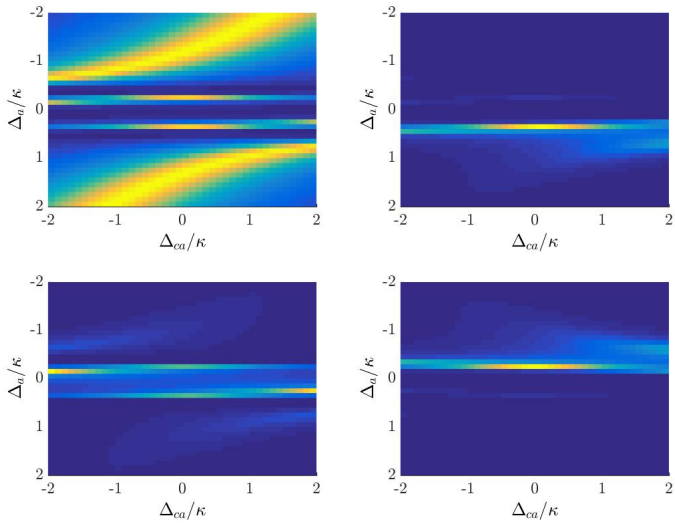

Figure 46.12: (left) inversion $(\hat{\sigma}^z + 1)/2$, (right) light transmission $\kappa^2|\alpha|^2/\eta^2$ through the cavity.

46.2.4.2 Ex: Coupling super- and subradiant modes

a. Discuss whether super- and subradiant states can be transformed into each other via unitary transformations.

46.2.4.3 Ex: Relationship between super- and subradiance and cooperativity

Seek an interpretation of super- and subradiance as a modification of the structure factor by cooperativity.

46.2.4.4 Ex: Heisenberg equation for the open Dicke model

Derive the Heisenberg equation for the open Dicke model.

46.2.4.5 Ex: Spin conservation in the open Dicke model

a. Show that the Dicke Hamiltonian (46.94) with $g' = g$ preserves the spin $\hat{\mathbf{S}}^2$.
b. Show that the Dicke Hamiltonian (46.94) with $g' = 0$ preserves the spin $\hat{\mathbf{S}}^2$.
c. Verify whether the dissipative terms of the open Dicke model preserve the spin $\hat{\mathbf{S}}^2$.

46.2.4.6 Ex: Superradiant enhancement

For the open Dicke model consider the Heisenberg equations (46.95) without coherent mean-field, $\hat{a} = 0$, and disregarding single-atom decoherence, $\gamma_1 = \xi_1 = \beta_1 = 0$. Solve the equation of motion for the collective spin projection $\hat{S}_z$ for an arbitrary coherent

spin state $|S, M\rangle$ and discuss the collective decay rate as a function of the collective inversion $\langle \hat{S}_z \rangle$.

46.2.4.7 Ex: Equilibrium phase transition

a. Calculate the free energy of the Hamiltonian (46.6) in the mean-field approximation.
b. Minimize the free energy as a function of the field amplitude α for various coupling strengths g. **Help:** Expand the expression for $F'(\alpha)$ for small values of α. Derive the expression for the critical coupling strength.

46.2.4.8 Ex: Superradiant lasing

a. Consider the generalized open Dicke model Hamiltonian (46.94) neglecting counter-rotating terms, $g' \equiv 0$, as well as pumping and phase fluctuations of the cavity modes, $\eta = \phi \equiv 0$. Derive the Heisenberg equations for the operators $\hat{a}$, $\hat{s}_j^-$, $\hat{s}_j^z$, $\hat{a}^\dagger \hat{s}_j^-$, $\hat{s}_i^+ \hat{s}_j^-$, and $\hat{a}^\dagger \hat{a}$.
b. Calculate the expectation values of the equations of motion for all degrees of freedom and for the products specified in (a) assuming that all atoms are equal. Now, assume that the phase-invariance is not broken, $\langle \hat{a} \rangle = \langle \hat{a}^\dagger \rangle = \langle \hat{s}_1^\pm \rangle = 0$, and apply a cumulant expansion up to second order.
c. Assuming the system to be in steady state solve the system of equations for the operators and products specified in (a) analytically. Assume $\gamma_1 \ll g \ll \kappa$ and plot $\hat{a}^\dagger \hat{a}$ as a function of the atom number N and the optical pumping rate ξ_1.
d. In which parameter regimes do you observe superradiant lasing?
e. Express $\langle \hat{\mathbf{S}}^2 \rangle$ and $\langle S_z \rangle$ in terms of single particle spin operators.
f. Evaluating $\langle \mathbf{S}^2 \rangle$ and $\langle S_z \rangle$ via the solution of the equations of motion, we find the steady-state quantum numbers always around $M \simeq \pm S$ [234]. Explain how this fact can induce squeezing, once $\langle S_z \rangle > 0$.

46.2.4.9 Ex: Superradiant lasing and the Schawlow-Townes limit

Discuss whether superradiant lasing beats the Schawlow-Townes limit.

46.2.4.10 Ex: Heisenberg equation for the open Dicke model in the Holstein-Primakoff approximation

Derive the Heisenberg equations for the open Dicke model in the Holstein-Primakoff approximation.

46.2.4.11 Ex: Critical exponent of the phase transitions

Calculate the critial exponent of the superradiant phase transition.

46.2.4.12 Ex: Schrieffer-Wolff transform of the Dicke Hamiltonian

a. Calculate the operator $\hat{H}_{\rm SW} = \mathcal{U} \hat{H} \mathcal{U}^\dagger$, where $\mathcal{U} \equiv e^{\imath\eta(\hat{a}^\dagger + \hat{a})\hat{S}_y}$ is the called the *Schrieffer-Wolff transform* [355].
b. Show that the states,

$$\mathcal{S}(\xi)\rangle |n\rangle \otimes |S, -S\rangle \quad \text{with} \quad \mathcal{S}(\xi) \equiv e^{(\xi/2)\hat{a}^{\dagger 2} - (\xi^*/2)\hat{a}^2} \quad \text{and} \quad \xi = -\tfrac{1}{4} \ln[1 - (g/g_{\rm c})^2]$$

where $g_c \equiv \sqrt{\Delta_c \Delta_a}$ are eigenstates of the Dicke-Schrieffer-Wolff Hamiltonian provided $g < g_c$.

46.3 Atoms interacting in free space

When two atoms excited to an internal level of energy hc/λ are so close together that the range of their dipole moments overlap without forming a molecular bonding, $a_B \ll R \ll \lambda$, they may exhibit cooperative relaxation. The atoms are coupled via the radiation that they are susceptible to emit into the same continuum. The coupled atomic dipoles oscillate and decay in phase. The decays is accelerated one leads to an intense burst of coherent and spatially directional radiation. This phenomenon is termed *superradiance* [256, 768]. We may view superradiance as destructive interference of the dipolar radiation patterns of all atoms in all but one direction of space triggered by the first spontaneous decay. The superradiant enhancement is largest when half of the atoms are deexcited. The correlated atoms can be in a Dicke state (then the total dipole moment is always zero) or in a product state (then the net dipole moment is non-zero at half-deexcitation). In the second case, we also talk about *superfluorescence*. In this case, an excited initially incoherent sample develops correlations due to the emission process. One can also imagine the case that the emission patterns pairwise cancel, and the decay is thus inhibited. This is called *subradiance*. Superradiance has been used in the microwave domain as a spectroscopic method in the observation of photon echoes.

Correlated quantum jumps are, in a sense, the few-atoms precursors of superradiance. Accelerated spontaneous decay has been predicted for atoms whose distance is shorter than the wavelength of the decaying transition [829, 572]. Super- and subradiance has been observed in a system of two ion trapped in a Paul trap [254].

46.3.1 Rydberg blockade

Rydberg atoms (i.e. atoms in excited Rydberg states) exhibit huge polarizabilities inducing large interaction energies even at relatively modest densities. These can be so strong, that the presence of a single Rydberg-excited atom can drive out of resonance the frequencies of transitions connected to the Rydberg state for several neighboring atoms once the exciting laser is sufficiently narrow-band. This effect called *Rydberg blockade* can be described by the following interaction Hamiltonian [787, 877],

$$\hat{H}_{\text{Rydberg}} = \sum_{i>j} \kappa_{ij} \tfrac{1}{2}(\hat{\sigma}_i^z - 1)\tfrac{1}{2}(\hat{\sigma}_j^z - 1) \qquad \text{with} \qquad \kappa_{ij}/2\pi = \frac{C_6}{r_{ij}^6} \ , \tag{46.108}$$

where $\frac{1}{2}(\hat{\sigma}_i^z - 1) = |e\rangle_i\langle e|$ is the probability of finding the i-th atom in an excited state and C_6 interatomic van der Waals interaction coefficient of the transition.

Example 326 (*Two interacting Rydberg atoms*): In this example we study Rydberg blockade for two interacting Rydberg atoms. In this case, the Hamil-

tonian can be cast into the matrix form,

$$\hat{H} = -\Delta_{\rm a}\hat{S}_z + \Omega\hat{S}_+ + \Omega^*\hat{S}_- + \hat{H}_{\rm Rydberg} = \begin{pmatrix} \Delta_{\rm a} & \frac{1}{2}\Omega & \frac{1}{2}\Omega^* & 0 \\ \frac{1}{2}\Omega^* & 0 & 0 & \frac{1}{2}\Omega^* \\ \frac{1}{2}\Omega & 0 & 0 & \frac{1}{2}\Omega \\ 0 & \frac{1}{2}\Omega & \frac{1}{2}\Omega^* & -\Delta_{\rm a} + \kappa_{12} \end{pmatrix} .$$

The master equation can be numerically solved using the procedure outlined in example 326. The result of such a simulation is shown in Fig. 46.13. Comparing

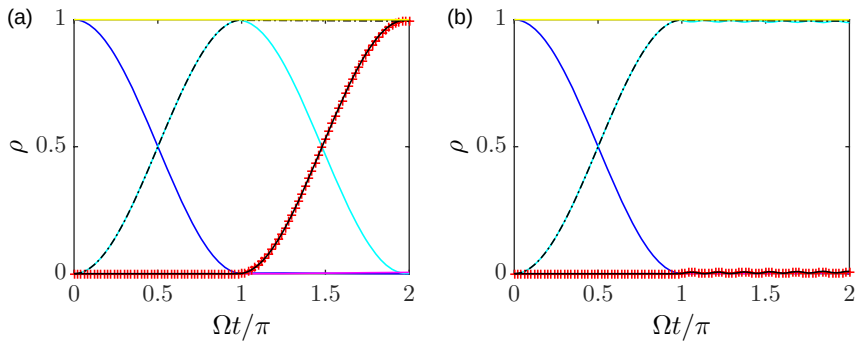

Figure 46.13: (code) Populations in a system of two two-level atoms interaction via van der Waals forces. Initially ($\Omega t < \pi$) only one atom is driven, after that only the other. We assume $\Omega \gg \Gamma$ and $C_6 = 4 \cdot 10^7$. The interatomic distance is (a) $kr_{12} = 0.5$, respectively, (a) $kr_{12} = 5$. (blue) $\rho_{11,11}$, (cyan) $\rho_{12,12}$, (magenta) $\rho_{21,21}$, (red) $\rho_{22,22}$, (black dotted) $\rho_{22}^{(1)}$, and (black) $\rho_{22}^{(2)}$.

the evolutions calculated in Fig. 46.13 for large and small interatomic distances, we see that the excitation of the first atom impedes the excitation of the second one when the interaction is strong.

Note, that an interesting situation occurs when the coupling is completely uniform (e.g. mediated by a cavity), $\kappa_{ij} \simeq \kappa$,

$$\hat{H}_{\rm Rydberg} \simeq \tfrac{1}{8}\kappa(\hat{S}_z^2 - 2\hat{S}_z + 1) \ , \tag{46.109}$$

as pointed out in Eq. (46.54). Such Hamiltonians may be interesting for the generation of spin-squeezing.

46.3.2 Dipole-dipole interactions in the non-linear optics regime

The mean-field Dicke model totally neglects interactions between the atoms due to the exchange of real or virtual photons, i.e. neither resonant dipole-dipole interactions nor van der Waals interactions are considered [32, 88, 271, 295, 778, 787, 842]. That is, interaction terms such as,

$$\hat{H}_{\rm Ising} = -\sum_{i,j\neq i}^{N} \Delta_{ij}\hat{\sigma}_j^+\hat{\sigma}_i^- \tag{46.110}$$

are absent from the Hamiltonian. Spin-spin interactions are studied in the so-called *Ising model*, which is interesting in the context of (anti-)*ferromagnetism* [334, 335, 347, 517, 1013]. The negligence of interaction was, of course, the reason for the simplicity of the Dicke model and its manageability for large atom numbers. On the other hand, in Sec. 44.1.2 we have studied dipole-dipole interactions in the linear optics regime allowing for at most a single photon to interact with the cloud.

In this section, we will consider dipole-dipole interactions in very small dilute clouds interacting with an arbitrary number of photons. The possibility for the cloud of storing as many photons as there are atoms is common to the Dicke model. Here, we will call it the *non-linear optics* regime, as several photons may team up to excite higher Dicke excitations states. In particular, we will study two interacting atoms as done by the milestone experiment of DeVoe and Brewer [254]. Do the Exc. 46.3.4.1.

The starting point is the collective many-atoms Hamiltonian (44.9) of the scalar coupled dipoles model. After tracing over the vacuum modes, one obtains the master equation [15] [774],

$$\begin{aligned}
\hat{H} &= \tfrac{1}{2}\sum_j \left[\Omega(\mathbf{r}_j)\hat{\sigma}_j^+ + h.c.\right] - \sum_{i,j}\Delta_{ji}\hat{\sigma}_j^+\hat{\sigma}_i^- \\
\mathfrak{L}[\hat{\rho}] &= \tfrac{1}{2}\textstyle\sum_{i,j}\Gamma_{ij}\left(2\hat{\sigma}_j^-\hat{\rho}\hat{\sigma}_i^+ - \hat{\sigma}_i^+\hat{\sigma}_j^-\hat{\rho} - \hat{\rho}\hat{\sigma}_i^+\hat{\sigma}_j^-\right) \\
\mathfrak{L}^\dagger[\hat{A}] &= \tfrac{1}{2}\textstyle\sum_{i,j}\Gamma_{ij}\left(2\hat{\sigma}_i^+\hat{A}\hat{\sigma}_j^- - \hat{\sigma}_i^+\hat{\sigma}_j^-\hat{A} - \hat{A}\hat{\sigma}_i^+\hat{\sigma}_j^-\right) \\
\Delta_{i\neq j} &\equiv -\tfrac{3\lambda\Gamma}{2}\,\hat{\mathbf{e}}_d^*\,\mathfrak{Re}\,\mathcal{G}(\mathbf{r}_i,\mathbf{r}_j,\omega_0)\,\hat{\mathbf{e}}_d \quad \text{and} \quad \Delta_{jj}\equiv\Delta_{\mathrm{a}} \\
\Gamma_{i\neq j} &\equiv 3\lambda\Gamma\,\hat{\mathbf{e}}_d^*\,\mathfrak{Im}\,\mathcal{G}(\mathbf{r}_i,\mathbf{r}_j,\omega_0)\,\hat{\mathbf{e}}_d \quad \text{and} \quad \Gamma_{jj}\equiv\Gamma
\end{aligned} \tag{46.111}$$

The expression for the line shifts Δ_{ij} and the decay rates Γ_{ij} have been derived in Sec. 45.2.1 from the bulk Green's tensor in free space. Assuming $\Delta_{ji} = 0 = \Gamma_{ji}$ and $\Omega(\mathbf{r}_j) = \Omega$ we recover the mean-field Dicke model, where interaction terms are completely neglected,

$$\hat{H} = \tfrac{1}{2}\Omega\sum_j(\hat{\sigma}_j^+ + h.c.) - \Delta_{\mathrm{a}}\sum_j\hat{\sigma}_j^+\hat{\sigma}_j^- \ . \tag{46.112}$$

With (46.108) we set up either the master or the Heisenberg-Liouville equations,

$$\begin{aligned}
\dot{\hat{\rho}} &= -\imath[\hat{H},\hat{\rho}] + \mathfrak{L}[\hat{\rho}] \\
\dot{\hat{A}} &= -\imath[\hat{A},\hat{H}] + \mathfrak{L}^\dagger[\hat{A}] \ .
\end{aligned} \tag{46.113}$$

Note that in principle, the collective many-atom system (46.108) can be mapped to a single-atom multilevel system,

$$\frac{d}{dt}\hat{\vec{\varrho}} = \mathcal{M}\vec{\varrho}\ , \tag{46.114}$$

which is more amenable to numeric simulation using the methods presented in Sec. 39.6. However, analytically this is only simple to do in the case of two atoms, which can be mapped to a four-level system. This will be shown in Exc. 46.3.4.2.

[15] In return, the equations of motion (44.26) for the excitation amplitude should follow as the Heisenberg equation with the above Hamiltonian.

Example 327 (*Diagonalizing collective decay*): The Lindbladian describing collective decay in (46.111) can be recast into a standard form by diagonalizing the real matrix $\mathbf{\Gamma} \equiv (\Gamma_{ij})$ [774], that is, we define a unitary transformation $\mathcal{T} = (\mathcal{T}^\intercal)^{-1} \equiv (T_{jk})$,

$$D = \mathcal{T}^\intercal \mathbf{\Gamma} \mathcal{T} \Longrightarrow \tilde{\Gamma}_k \delta_{kj} = \sum_j T^\intercal_{ik} \Gamma_{ij} T_{jk}$$

$$\text{or} \qquad \mathbf{\Gamma} = \mathcal{T} D \mathcal{T}^\intercal \Longrightarrow \Gamma_{ij} = \sum_k T_{jk} \tilde{\Gamma}_k \delta_{kj} T^\intercal_{jk} \ .$$

Note that all coefficients not ornamented by a 'hat' can be moved around freely. Now, substituting the Γ_{ij},

$$\mathfrak{L}[\hat{\rho}] = \tfrac{1}{2} \sum_{k,i,j} \left[2\hat{\sigma}_i^- T_{ik} \tilde{\Gamma}_k \delta_{ki} T^\intercal_{jk} \hat{\rho} \hat{\sigma}_j^+ - \hat{\sigma}_i^+ T_{ik} \tilde{\Gamma}_k \delta_{ki} T^\intercal_{jk} \hat{\sigma}_j^- \hat{\rho} - \hat{\rho} \hat{\sigma}_i^+ T_{ik} \tilde{\Gamma}_k \delta_{ki} T^\intercal_{jk} \hat{\sigma}_j^- \right] \ .$$

Now, defining new composite decay channels,

$$\hat{\Pi}_k^- = \sum_j T_{kj} \hat{\sigma}_j^- \qquad , \qquad \hat{\Pi}_k^+ = \sum_j \hat{\sigma}_j^+ T^\intercal_{kj} \ ,$$

we find,

$$\mathfrak{L}[\hat{\rho}] = \tfrac{1}{2} \sum_k \tilde{\Gamma}_k [2\hat{\Pi}_k^+ \hat{\rho} \hat{\Pi}_k^- - \hat{\Pi}_k^+ \hat{\Pi}_k^- \hat{\rho} - \hat{\rho} \hat{\Pi}_k^+ \hat{\Pi}_k^-] \ .$$

Single-atom spontaneous emission simply follows from the assumption that $\Gamma_{ij} = \Gamma_1 \delta_{ij}$,

$$\mathfrak{L}[\rho] = \tfrac{1}{2} \sum_j \Gamma [2\hat{\sigma}_j^- \hat{\rho} \hat{\sigma}_j^+ - \hat{\sigma}_j^+ \hat{\sigma}_j^- \hat{\rho} - \hat{\rho} \hat{\sigma}_j^+ \hat{\sigma}_j^-] \ .$$

On the other hand, Dicke superradiance follows from the assumption that $\Gamma_{ij} = \Gamma$. Introducing the collective spin operator, $\hat{S}^\pm \equiv \sum_j \hat{\sigma}_j^\pm$,

$$\begin{aligned} \mathfrak{L}[\rho] &= \tfrac{1}{2} \sum_{i,j} \Gamma [2\hat{\sigma}_i^- \hat{\rho} \hat{\sigma}_j^+ - \hat{\sigma}_i^+ \hat{\sigma}_j^- \hat{\rho} - \hat{\rho} \hat{\sigma}_i^+ \hat{\sigma}_j^-] \\ &= \tfrac{1}{2} \Gamma [2\hat{S}^- \hat{\rho} \hat{S}^+ - \hat{S}^+ \hat{S}^- \hat{\rho} - \hat{\rho} \hat{S}^+ \hat{S}^-] \ . \end{aligned}$$

The uniform all-to-all coupling required for Dicke superradiance can be realized, when the atoms are localized in an area of space smaller than λ^3 or in a cavity.

46.3.2.1 Equations of motion in the presence of dipole-dipole coupling

We start from the Hamiltonian and jump operators (46.108) and derive the Heisenberg-Liouville equation (46.113),

$$\begin{aligned} \dot{\hat{\sigma}}_k^- &= -\imath [\hat{\sigma}_k^-, \hat{H}] + \mathfrak{L}^\dagger [\hat{\sigma}_k^-] \qquad (46.115) \\ &= \tfrac{\imath}{2} \Omega(\mathbf{r}_k) \hat{\sigma}_k^z - \imath \Delta_\mathrm{a} \hat{\sigma}_k^z \hat{\sigma}_k^- - \imath \sum_{j \neq k}^N \Delta_{kj} \hat{\sigma}_k^z \hat{\sigma}_j^- + \tfrac{\Gamma}{2} \hat{\sigma}_k^z \hat{\sigma}_k^- + \sum_{j \neq k}^N \tfrac{\Gamma_{kj}}{2} \hat{\sigma}_k^z \hat{\sigma}_j^- \ . \end{aligned}$$

Now, we assume low atomic excitation, $\langle\hat{\sigma}_k^z\rangle \simeq -1$, that is, most atoms are in the ground state. Then we may neglect correlations and find [16],

$$\dot{\hat{\sigma}}_k^- \simeq \left(\imath\Delta_{\rm a} - \tfrac{\Gamma}{2}\right)\hat{\sigma}_k^- - \tfrac{\imath}{2}\Omega(\mathbf{r}_k) + \sum_{j\neq k}^{N}\left(\imath\Delta_{kj} - \tfrac{\Gamma_{kj}}{2}\right)\hat{\sigma}_j^- \tag{46.116}$$

or taking the expectation values,

$$\dot{\beta}_k \simeq \left(\imath\Delta_{\rm a} - \tfrac{\Gamma}{2}\right)\beta_k - \tfrac{\imath}{2}\Omega(\mathbf{r}_k) + \sum_{j\neq k}^{N}\left(\imath\Delta_{kj} - \tfrac{\Gamma_{kj}}{2}\right)\beta_j \ . \tag{46.117}$$

These are just the equations of motion of the coupled dipoles model derived in Sec. 44.1.2. Evaluation of the coeffficients (46.108)(iv-v) yields the exponential kernel postulated in (44.29).

In Exc. 46.3.4.3 we derive them from the linear optics scalar coupled dipoles model,

$$\Delta_{j\neq i} \equiv -\frac{\Gamma\cos kr_{ji}}{kr_{ji}} \qquad \text{and} \qquad \Gamma_{j\neq i} \equiv \frac{\Gamma\sin kr_{ji}}{kr_{ji}} \tag{46.118}$$

with $r_{ji} = |\mathbf{r}_j - \mathbf{r}_i|$. These terms arise from the so-called scalar approximation of (45.167), where we neglect $1/R^2$ and $1/R^3$ terms and set $(\hat{\mathbf{e}}_d\cdot\hat{\mathbf{e}}_R) = 0$.

Example 328 (*Two atoms with dipole-dipole interactions*): For the case of only two atoms located at $\mathbf{r}_j$, using the basis defined in (25.75), we find the Hamiltonian [175],

$$\hat{H} = \begin{pmatrix} 0 & \frac{1}{2}\Omega^*(\mathbf{r}_2) & \frac{1}{2}\Omega^*(\mathbf{r}_1) & 0 \\ \frac{1}{2}\Omega(\mathbf{r}_2) & -\Delta_{\rm a} & \frac{1}{2}\Delta_{21} & \frac{1}{2}\Omega^*(\mathbf{r}_1) \\ \frac{1}{2}\Omega(\mathbf{r}_1) & \frac{1}{2}\Delta_{12} & -\Delta_{\rm a} & \frac{1}{2}\Omega^*(\mathbf{r}_2) \\ 0 & \frac{1}{2}\Omega(\mathbf{r}_1) & \frac{1}{2}\Omega(\mathbf{r}_2) & -2\Delta_{\rm a} \end{pmatrix} , \tag{46.119}$$

with $\Omega(\mathbf{r}) = \Omega_0 e^{\imath\mathbf{k}\cdot\mathbf{r}_j}$. For two atoms the master equations (46.108) can easily be solved numerically by setting [17],

$$\hat{\sigma}_1^\pm = \hat{\sigma}^\pm\otimes\mathbb{I} \qquad \text{and} \qquad \hat{\sigma}_2^\pm = \mathbb{I}\otimes\hat{\sigma}^\pm \ , \tag{46.120}$$

as usual and,

$$\langle i,j|\hat{\rho}|m,n\rangle = \rho_{ij,mn} \ , \tag{46.121}$$

where the indices $i,m = 1,2$ refer to the first atom and the indices $j,n = 1,2$ to the second. The populations of the Dicke states $|11\rangle$, $|12\rangle$, $|21\rangle$, and $|22\rangle$

[16] Note that the same result is obtained from $\dot{\hat{\sigma}}_k^- = -\imath[\hat{\sigma}_k^-, \hat{H}_{eff}]$ using the effective Hamiltonian $\hat{H}_{eff} \equiv \hat{H}_{\rm coh} - \imath\hat{H}_{diss}$ with,

$$\hat{H}_{\rm coh} = -\Delta_{\rm a}\sum_j \hat{\sigma}_j^+\hat{\sigma}_j^- + \tfrac{\Omega_0}{2}\sum_j(\hat{\sigma}_j^- e^{-\imath\mathbf{k}_0\cdot\mathbf{r}} + \hat{\sigma}_j^+ e^{\imath\mathbf{k}_0\cdot\mathbf{r}})$$

$$\hat{H}_{diss} = \tfrac{\Gamma}{2}\sum_j \hat{\sigma}_j^+\hat{\sigma}_j^- + \tfrac{1}{2}\sum_{j\neq i}(\Gamma_{ji} + \imath\Delta_{ji})\hat{\sigma}_j^+\hat{\sigma}_i^-$$

[17] Remember, that the formal solution of coherent part of the master equation can be written as $\hat{\rho}(t) = \mathfrak{L}(t)\hat{\rho}(0) = e^{-\imath\hat{H}t}\hat{\rho}(0)e^{\imath\hat{H}t}$.

are then given by $\rho_{ij,ij}$, and the populations of the (anti-)symmetric states $|\psi\rangle^{(s,a)} = \frac{1}{\sqrt{2}}(|1,2\rangle \pm |2,1\rangle)$ are calculated via,

$$\langle\psi|^{(s,a)}\hat{\rho}|\psi\rangle^{(s,a)} = \tfrac{1}{2}(\rho_{12,12} \pm \rho_{12,21} \pm \rho_{21,12} + \rho_{21,21}) \ . \tag{46.122}$$

The temporal evolution of the populations in one and two atom systems, initially driven by a laser field which is then suddenly switched off, is shown in Fig. 46.14. Note that super and subradiance do occur for $\Delta_{12} = 0 = \Delta_{\rm a}$ but necessitate $\Gamma_{ij} \neq 0$.

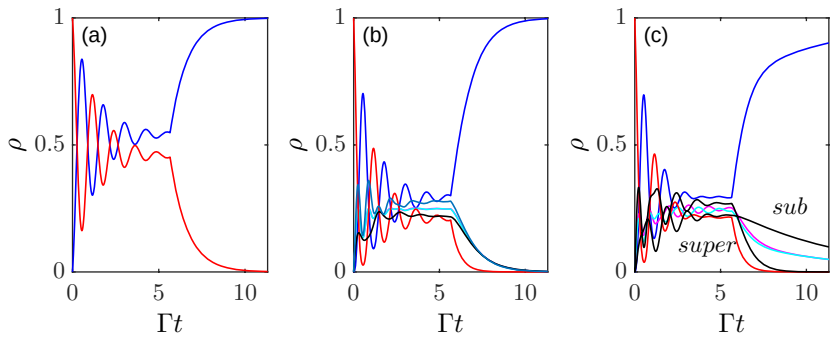

Figure 46.14: (code) (a) Response of a single two-level atom driven by a laser light with $\Omega = 5\Gamma$, $\Delta = -\Gamma$. The curves show (blue) the ground state and (red) the excited state populations. The light is switched off at $\Gamma t = 0.5$. (b) Response of two atoms $j = 1, 2$ located at $kz_j = \pm 5$ driven by the same laser light as in (a). (cyan and magenta) populations of the states $|eg\rangle$ and $|ge\rangle$. The two black lines show the populations of the (anti-)symmetric states $\frac{1}{\sqrt{2}}(|eg\rangle \pm |ge\rangle)$. (c) Same as (b) but with $kz_j = \pm 0.5$.

In Excs. 46.3.4.4 to 46.3.4.6 we study the impact of dipole-dipole interactions on super- and subradiance. In Exc. 46.3.4.7 we study three interacting two-level atoms. In Exc. 46.3.4.8 we compare Rydberg blockade and dipole-dipole interaction.

Example 329 (*Blackbody radiation-induced superradiance*): In Exc. 39.5.6.9 we studied blackbody radiation-induced transitions in a single atom. The procedure can be generalized to several atoms [958]. For two atoms the Liouvillean reads,

$$\begin{aligned}\dot{\hat{\rho}} &= \mathfrak{L}_{bb}\hat{\rho} \\ &= -\tfrac{1}{2}\sum_{i,j=1,2}\Gamma_{ij}\left([\hat{\rho}\hat{\sigma}_i, \hat{\sigma}_j^\dagger] + [\hat{\sigma}_i, \hat{\sigma}_j^\dagger\hat{\rho}]\right) - \tfrac{1}{2}\sum_{i,j=1,2}(\Gamma_{ij} + \gamma\delta_{ij})\left([\hat{\rho}\hat{\sigma}_j^\dagger, \hat{\sigma}_i] + [\hat{\sigma}_j^\dagger, \hat{\sigma}_i\hat{\rho}]\right) \ ,\end{aligned}$$

with $\Gamma_{ij}\delta(t-t') \propto \langle\hat{E}_i(t)\hat{E}_j(t')\rangle$ containing both the real and the virtual photon exchange.

46.3.2.2 Van der Waals interactions

The scalar kernel (46.118) for dipole-dipole interactions represents a good approximation at low densities. At higher density the vectorial kernel must be used. However, then other interatomic forces come into play, in particular van der Waals interactions.

46.3.3 Interacting atoms in a cooperative environment

The interactions studied so far in this section were described by Hamiltonians only containing direct interaction terms [see Eqs. (46.119) and (46.119)]. Doing so we conceal the fact that these interactions are necessarily mediated by electromagnetic forces. That is, the full Hamiltonian contains terms such as,

$$\hat{a}_{\mathbf{k}\lambda}\hat{\sigma}_j^+ + \hat{\sigma}_j^-\hat{a}_{\mathbf{k}\lambda}^\dagger \ , \tag{46.123}$$

which describe the exchange of photons through a local common field mode ($\mathbf{k}\lambda$). As these modes rapidly decay, they may be *adiabatically eliminated*, leaving behind terms like $\hat{\sigma}_j^+\hat{\sigma}_i^-$ [18].

Let us now consider several excited atoms labeled by j, located at $\mathbf{r}_j$, and described by two of their eigenstates, $\{|g_j\rangle, |e_j\rangle\}$. As usual, $|g_j\rangle$ is the eigenstate with lowest energy ($E_{g_j} = -\frac{1}{2}\hbar\omega_j$) and longer lifetime, i.e. the ground state, whereas $|e_j\rangle$ is the eigenstate with highest energy ($E_{e_j} = +\frac{1}{2}\hbar\omega_j$). In presence of an external electromagnetic field, the Hamiltonian of the two atom-field system in the electric dipolar approximation is,

$$\begin{aligned} \hat{H} &= \sum_{j=1,2}[\hat{H}_{\text{atom}}^{(j)} + \hat{H}_{\text{atom:field}}^{(j)}] + \hat{H}_{\text{field}} \\ \text{where} \quad \hat{H}_{\text{atom}}^{(j)} &\equiv \tfrac{1}{2}\omega_j\hat{\sigma}_j^z \quad , \quad \hat{H}_{\text{atom:field}}^{(j)} \equiv -\hat{\mathbf{d}}_j\cdot\hat{\vec{\mathcal{E}}}(\mathbf{r}_j) \ . \end{aligned} \tag{46.124}$$

The electric dipole moment operator satisfies $\langle e_j|\hat{\mathbf{d}}_j|e_j\rangle = \mathbf{0} = \langle g_j|\hat{\mathbf{d}}_j|g_j\rangle$ and has non-vanishing off-diagonal elements, i.e. the eigenstates have no permanent dipole moment. We define the dipole-moment matrix element as $\mathbf{d}_j \equiv \langle e_j|\hat{\mathbf{d}}_j|g_j\rangle$. The description of the field is identical to the case of one atom (45.3).

For weak-coupling between the atoms and the field, the interaction Hamiltonian becomes [865, 569],

$$\hat{H}_{\text{atom:field}} = -\imath\sum_{\mathbf{k},\lambda}\sum_j(\hat{\sigma}_j^+ + \hat{\sigma}_j^-)[g_{\mathbf{k}\lambda}(\mathbf{r}_j)\hat{a}_{\mathbf{k}\lambda} - g_{\mathbf{k}\lambda}^*(\mathbf{r}_j)\hat{a}_{\mathbf{k}\lambda}^\dagger] \ . \tag{46.125}$$

By solving the Heisenberg equations of motion for the atomic and field operators within the Born and Markov approximations, one obtains the spontaneous emission rate on a transition $|e_j\rangle \to |g_j\rangle$ of frequency ω_j, as done in Sec. 45.1.1,

$$\Gamma_j = 2\pi\sum_{\mathbf{k},\lambda}|g_{\mathbf{k}\lambda}(\mathbf{r}_j)|^2\delta(\omega_{\mathbf{k}} - \omega_j) = \frac{\pi\omega_j}{\varepsilon_0\hbar}\sum_{\mathbf{k},\lambda}|\mathbf{d}_j\cdot\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r}_j)|^2\delta(\omega_{\mathbf{k}} - \omega_j) \ , \tag{46.126}$$

which is the same result obtained by the Weisskopf-Wigner theory [650]. In addition, due to the coupling between the atoms through the vacuum field, one also has the cross-damping spontaneous emission rate:

$$\Gamma_q(\mathbf{r}_i,\mathbf{r}_j) = \Gamma_q(\mathbf{r}_j,\mathbf{r}_i) = \frac{\pi\omega_0}{\varepsilon_0\hbar}\sum_{\mathbf{k},\lambda}\mathfrak{Re}\left[\mathbf{d}_i\cdot\mathbf{u}_{\mathbf{k}\lambda}(\mathbf{r}_i)\mathbf{u}_{\mathbf{k}\lambda}^*(\mathbf{r}_j)\cdot\mathbf{d}_j^*\right]\delta(\omega_{\mathbf{k}} - \omega_j) \ , \tag{46.127}$$

[18] The adiabatic elimination procedure for the case of cavity modes will be studied in Sec. 46.4.1

which shows explicitly the cooperative effect of the dipole-dipole interaction in the spontaneous emission rate. See also Secs. 15.3.1 and 45.2.1 and Excs. 45.2.3.1 and 45.2.3.2.

46.3.4 Exercises

46.3.4.1 Ex: Calculating with collective operators

The collective spin operators for an ensemble of J atoms with M internal levels are defined as,

$$\hat{S} = \sum_{j=1}^{J} \hat{\sigma}_j = \hat{\sigma} \otimes \mathbb{I}_M \otimes \mathbb{I}_M \otimes ... + \mathbb{I}_M \otimes \hat{\sigma} \otimes \mathbb{I}_M \otimes + ... \ ,$$

or more explicitly,

$$\hat{S}_{kl} = \sum_{j=1}^{J} \hat{\sigma}_j^{kl} = |k\rangle\langle l| \otimes \mathbb{I}_M \otimes \mathbb{I}_M \otimes ... + \mathbb{I}_M \otimes |k\rangle\langle l| \otimes \mathbb{I}_M \otimes + ... \ ,$$

with the spin matrices satisfying,

$$\begin{aligned} \hat{\sigma}_j^{kl}\hat{\sigma}_j^{mn} &= \delta_{lm}\hat{\sigma}_j^{kn} \qquad \text{and} \qquad [\hat{\sigma}_i^{kl}, \hat{\sigma}_j^{mn}] = \delta_{ij}(\delta_{lm}\hat{\sigma}_j^{kn} - \delta_{kn}\hat{\sigma}_j^{ml}) \\ \textstyle\sum_{m=1}^{M} \hat{\sigma}_j^{mm} &= \mathbb{I}_M \qquad \text{and} \qquad \textstyle\sum_{j=1}^{J}\sum_{m=1}^{M} \hat{\sigma}_j^{mm} = N\mathbb{I}_M \ . \end{aligned}$$

Verify that for the case of atoms subject to spin-spin interaction,

$$\hat{H} \neq \sum_{j,m} \hat{\sigma}_j^{mm} \hat{H} \hat{\sigma}_j^{mm} \ .$$

46.3.4.2 Ex: Liouvillean for two dipole-coupled atoms

a. From the master equation (46.108) set up the Liouvillean $\mathcal{M}$ for a system of two atoms coupled via dipolar radiation allowing to write the master equation as $\dot{\vec{\varrho}} = \mathcal{M}\vec{\varrho}$.
b. Discuss the Lindblad term in the limit, $kr_{12} \to 0$.
c. We have seen in Exc. 39.5.6.9, how to write down the master equation for a two-level atom whose levels are coupled by blackbody radiation. Extend the procedure to two dipole-coupled two-level atoms whose levels are only coupled by blackbody radiation.

46.3.4.3 Ex: Super- and subradiant linewidth and decay rates from the coupled dipoles model

Calculate super- and subradiance linewidth and lineshifts for two atoms interacting via dipole-dipole interaction using the linear optics scalar coupled dipoles model culminating in Eq. (44.26) using the exponential kernel (44.29).

46.3.4.4 Ex: Super- and subradiance in a two atom system

Calculate the temporal behavior of the (anti-)symmetric states $\rho_{S,A} = \frac{1}{2}(\rho_{12,12} + \rho_{21,21} \pm \rho_{12,21} \pm \rho_{21,12})$ from the master equation (46.113)(i) or the Liouville equation (46.113)(ii). Consider in particular the case of absent driving, $\Omega = 0$.

46.3.4.5 Ex: Two-atom toy model for super- and subradiance

Calculate the eigenvalues and eigenvectors of the Hamiltonian (46.119) for two two-level atoms located at $\mathbf{r}_j = \pm\frac{r_{12}}{2}\hat{\mathbf{e}}_z$ with $r_{ji} = |\mathbf{r}_j - \mathbf{r}_i| \ll \lambda$ [254]. Consider the limits (a) absent coupling, $\Delta_{12} = 0$, (b) resonant driving, $\Delta_{\mathrm{a}} = 0$, and (c) absent driving, $\Omega = 0$. (d) Analyze the full Hamiltonian.

46.3.4.6 Ex: Impact of dipole-dipole interactions on super- and subradiance

Here, we use the two-atom toy model studied in Fig. 46.14 to demonstrate the emergence of subradiant modes as a consequence of dipole-dipole interaction [254, 175]. Calculate numerically the anti-symmetric state population $\hat{\rho}_{\mathrm{a}}$ given in Eq. (46.122) at very long times as a function of the saturation parameter s and the interatomic distance kr_{ij}. Interpret the results. Note that subradiant modes may saturate at lower intensities than single atoms.

46.3.4.7 Ex: Three interacting atoms

Numerically integrate the master equation (46.108) for three atoms.

46.3.4.8 Ex: Rydberg blockade versus spin-spin interaction

a. Direct interactions (e.g. dipole-dipole coupling or van der Waals interaction) generate collective energy shifts Δ_{ij} and collective decay Γ_{ij} (see Sec. 46.3.2 or examples 326 and 327). Discuss why these terms are not observed in Hamiltonians describing Rydberg blockade.
b. Verify whether the operators $\hat{S}_z\hat{S}_z$ or $\hat{S}_+\hat{S}_-$ generate anti-diagonal terms in the Hamiltonian [693].

46.4 Cavity-mediated spin-exchange interactions

In the preceding sections we got to know two fundamentally different types of interatomic interactions, that is, Rydberg and dipole-dipole type interactions. Both are generally nearest neighbor interactions and thus inhomogeneous. Let us nevertheless make the assumption of uniform coupling to simplify the discussion. Then the Rydberg blockade term (46.119) reads,

$$\hat{H} = \frac{1}{2}\sum_{i\neq j}\kappa_{ij}\hat{\sigma}_j^z\hat{\sigma}_i^z \simeq \kappa\hat{S}_z^2 \ , \tag{46.128}$$

and the Ising interaction term (46.110) becomes,

$$\hat{H}_{\text{Ising}} = -\sum_{i\neq j} \Delta_{ij}\hat{\sigma}_j^+\hat{\sigma}_i^- \simeq -\Delta_{\text{Ising}}\hat{S}_+\hat{S}_- \ . \tag{46.129}$$

A way of achieving uniform coupling consists in coupling all atoms with the same strength to the same cavity mode. This is what we will discuss in the next subsection.

In the full open system Dicke model κ and, Γ_1 describe physical processes, namely cavity decay and atomic spontaneous emission, while Γ is introduced as a mere collective decay rate, not rooted in a physical process. In reality, collective decay processes may be caused by interatomic contact interactions, but as we will see in the following, they can also be induced by coupling of the atoms to a common light mode.

Indeed, in the bad cavity limit, upon adiabatic elimination of the light mode, the cavity parameters Δ_{c} and κ are replaced by U_{c} and κ_{c}, which take over the role of a collective shift and decay process. This is seen in the Hamiltonian and the Lindbladian, after adiabatic elimination of the light mode, by the fact that the terms depending on κ_{c} have exactly the same structure as those for which collective decay at a rate Γ had been postulated in the full open Dicke model.

The systems do not differ in concept, but only in details: uniform coupling versus nearest neighbors, inhomogeneities of the light field versus disordered clouds, etc..

46.4.1 Adiabatic elimination of the modes of a bad high-finesse cavity

The collective Jaynes-Cummings Hamiltonian (46.94) for a linear cavity (see Exc. 45.1.11.5),

$$\hat{H}_{\text{JC}} = -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \imath\eta(\hat{a}-\hat{a}^\dagger) + \sum_{i=1}^{N}\left[-\tfrac{\Delta_{\text{a}}}{2}(\mathbb{I}_2+\hat{\sigma}_i^z) + g\sin kz_i(\hat{\sigma}_i^+\hat{a}+\hat{a}^\dagger\hat{\sigma}_i^-)\right] \ , \tag{46.130}$$

becomes in the case of perfect bunching, $z_i = z$, using the abbreviation $g \longrightarrow g\sin kz$,

$$\boxed{\hat{H}_{\text{JC}} = -\Delta_{\text{c}}\hat{a}^\dagger\hat{a} - \imath\eta(\hat{a}-\hat{a}^\dagger) - \Delta_{\text{a}}(\tfrac{N}{2}\mathbb{I}+\hat{S}_z) + g(\hat{S}_+\hat{a}+\hat{a}^\dagger\hat{S}_-) \ ,} \tag{46.131}$$

where we introduced collective operators, $\hat{S}_\alpha \equiv \frac{1}{2}\sum_{i=1}^N \hat{\sigma}_i^\alpha$ for $\alpha = x, y, z$. The Heisenberg equations are those derived in (46.95), but now we consider the rotating wave approximation, $g' = 0$, and disregard optical pumping, $\xi_1 = 0$, and phase fluctuations, $\beta_1 = 0$,

$$\boxed{\begin{aligned} \dot{\hat{a}} &= (\imath\Delta_{\text{c}} - \kappa)\hat{a} - \imath g\hat{S}_- + \eta \\ \dot{\hat{S}}_- &= (\imath\Delta_{\text{a}} - \tfrac{\Gamma_1}{2} + \Gamma\hat{S}_z)\hat{S}_- + 2\imath g\hat{S}_z\hat{a} \\ \dot{\hat{S}}_z &= -(\Gamma_1\tfrac{N}{2}\mathbb{I} + \Gamma_1\hat{S}_z + \Gamma\hat{S}_+\hat{S}_-) - \imath g(\hat{S}_+\hat{a} - \hat{a}^\dagger\hat{S}_-) \end{aligned}} \ . \tag{46.132}$$

Γ stands for collective decay and Γ_1 for single-atom decay. Using $\eta \equiv \eta_{\text{r}} + \imath\eta_{\text{i}}$ we can

reshape (46.132) in a real notation,

$$
\begin{aligned}
\dot{\hat{a}}_{\mathrm{r}} &= \tfrac{1}{2}(\dot{\hat{a}}+\dot{\hat{a}}^{\dagger}) &&= -\kappa\hat{a}_{\mathrm{r}} - \Delta_{\mathrm{c}}\hat{a}_{\mathrm{i}} - g\hat{S}_y + \eta_{\mathrm{r}} \\
\dot{\hat{a}}_{\mathrm{i}} &= \tfrac{1}{2\imath}(\dot{\hat{a}}-\dot{\hat{a}}^{\dagger}) &&= -\kappa\hat{a}_{\mathrm{i}} + \Delta_{\mathrm{c}}\hat{a}_{\mathrm{r}} - g\hat{S}_x + \eta_{\mathrm{i}} \\
\dot{\hat{S}}_x &= \tfrac{1}{2}(\dot{\hat{S}}_- + \dot{\hat{S}}_+) &&= -(\tfrac{\Gamma_1}{2}+\tfrac{\Gamma}{2})\hat{S}_x + \Delta_{\mathrm{a}}\hat{S}_y - g\{\hat{a}_{\mathrm{i}},\hat{S}_z\} - \imath g[\hat{a}_{\mathrm{r}},\hat{S}_z] + \tfrac{\Gamma}{2}\{\hat{S}_x,\hat{S}_z\} \\
\dot{\hat{S}}_y &= \tfrac{\imath}{2}(\dot{\hat{S}}_- - \dot{\hat{S}}_+) &&= -(\tfrac{\Gamma_1}{2}+\tfrac{\Gamma}{2})\hat{S}_y - \Delta_{\mathrm{a}}\hat{S}_x - g\{\hat{a}_{\mathrm{r}},\hat{S}_z\} + \imath g[\hat{a}_{\mathrm{i}},\hat{S}_z] + \tfrac{\Gamma}{2}\{\hat{S}_y,\hat{S}_z\} \\
\dot{\hat{S}}_z &= \partial_t\tfrac{1}{2}[\hat{S}_+,\hat{S}_-] &&= -(\Gamma_1+\Gamma)\hat{S}_z + g(\{\hat{a}_{\mathrm{i}},\hat{S}_x\} + \{\hat{a}_{\mathrm{r}},\hat{S}_y\} + \imath[\hat{a}_{\mathrm{r}},\hat{S}_x] - \imath[\hat{a}_{\mathrm{i}},\hat{S}_y]) \\
&&& \quad -\tfrac{N}{2}\Gamma_1\mathbb{I} - \Gamma(\hat{S}_x^2+\hat{S}_y^2)
\end{aligned}
\tag{46.133}
$$

The equations are equivalent to those derived by [582].

Example 330 (*Simplification for uncorrelated $\hat{a}$ and $\hat{\mathbf{S}}$*): As long as $\hat{a}$ and $\hat{\mathbf{S}}$ are uncorrelated, we may simply set $\{\hat{a},\hat{\mathbf{S}}\} = 2\hat{a}\hat{\mathbf{S}}$ and $[\hat{a},\hat{\mathbf{S}}] = 0$. Assuming furthermore that $[\hat{S}_k,\hat{S}_l] \simeq 0$ the equations (46.133) can then be written in compact matrix notation,

$$
\begin{aligned}
\dot{\hat{\mathbf{S}}} &= -\imath[\hat{\mathbf{S}},\hat{H}] + \mathfrak{L}_{\Gamma_1/2}\hat{\mathbf{S}} \qquad (46.134)\\
&= \begin{pmatrix} -\frac{1}{2}(\Gamma_1+\Gamma) & \Delta_{\mathrm{a}} & -2g\hat{a}_{\mathrm{i}} \\ -\Delta_{\mathrm{a}} & -\frac{1}{2}(\Gamma_1+\Gamma) & -2g\hat{a}_{\mathrm{r}} \\ 2g\hat{a}_{\mathrm{i}} & 2g\hat{a}_{\mathrm{r}} & -(\Gamma_1+\Gamma) \end{pmatrix}\begin{pmatrix}\hat{S}_x\\ \hat{S}_y\\ \hat{S}_z\end{pmatrix} - \Gamma_1\begin{pmatrix}0\\0\\ \frac{N}{2}\mathbb{I}\end{pmatrix} - \Gamma\begin{pmatrix}-\hat{S}_x\hat{S}_z\\ -\hat{S}_y\hat{S}_z\\ \hat{S}_x^2+\hat{S}_y^2\end{pmatrix} \\
&= \begin{pmatrix}2g\hat{a}_{\mathrm{r}}\\ -2g\hat{a}_{\mathrm{i}}\\ -\Delta_{\mathrm{a}}\end{pmatrix} \times \begin{pmatrix}\hat{S}_x\\ \hat{S}_y\\ \hat{S}_z\end{pmatrix} - \Gamma_1\begin{pmatrix}\frac{1}{2}\hat{S}_x\\ \frac{1}{2}\hat{S}_y\\ \frac{N}{2}\mathbb{I}+\hat{S}_z\end{pmatrix} .
\end{aligned}
$$

The equations (46.133) are just the Heisenberg-Liouville equations (46.96) derived from the open Dicke model and the open Tavis-Cummings model Hamiltonian, restricting to many immobile atoms and a single cavity mode. In the bad cavity limit, $\kappa \gg g$, the cavity field is effectively slaved to the internal atomic dynamics. Hence, we may assume $\dot{\hat{a}} \equiv 0$ and adiabatically eliminate the field. Setting $\dot{\hat{a}}_{\mathrm{r}} = 0 = \dot{\hat{a}}_{\mathrm{i}}$ in Eq. (46.133)(i-ii) we calculate,

$$
\begin{aligned}
\hat{\Omega}_{\mathrm{r}} &\equiv 2g\hat{a}_{\mathrm{r}} = 2U_{\mathrm{c}}(\hat{S}_x - \eta_{\mathrm{i}}/g) - 2\kappa_{\mathrm{c}}(\hat{S}_y - \eta_{\mathrm{r}}/g) \qquad (46.135)\\
\hat{\Omega}_{\mathrm{i}} &\equiv 2g\hat{a}_{\mathrm{i}} = -2\kappa_{\mathrm{c}}(\hat{S}_x - \eta_{\mathrm{i}}/g) - 2U_{\mathrm{c}}(\hat{S}_y - \eta_{\mathrm{r}}/g) ,
\end{aligned}
$$

where we introduced the abbreviations,

$$
U_\kappa \equiv U_{\mathrm{c}} - \imath\kappa_{\mathrm{c}} \qquad \text{with} \qquad U_{\mathrm{c}} \equiv \frac{g^2\Delta_{\mathrm{c}}}{\Delta_{\mathrm{c}}^2+\kappa^2} \qquad \text{and} \qquad \kappa_{\mathrm{c}} \equiv \frac{g^2\kappa}{\Delta_{\mathrm{c}}^2+\kappa^2} . \tag{46.136}
$$

U_{c} is the cooperative cavity Lamb-shift and κ_{c} is the Purcell-enhanced cavity decay

rate. Substituting (46.135) in the Eqs. (46.133)(iii-v) leads to [19,20],

$$\boxed{\begin{aligned}
\dot{\hat{S}}_x &= -(\tfrac{\Gamma_1}{2}+\tfrac{\Gamma_c}{2})\hat{S}_x + (\Delta_a - U_c)\hat{S}_y - 2(U_c\bar{\eta}_r + \kappa_c\bar{\eta}_i)\hat{S}_z + U_c\{\hat{S}_y,\hat{S}_z\} + \tfrac{\Gamma_c}{2}\{\hat{S}_x,\hat{S}_z\} \\
\dot{\hat{S}}_y &= -(\tfrac{\Gamma_1}{2}+\tfrac{\Gamma_c}{2})\hat{S}_y - (\Delta_a - U_c)\hat{S}_x + 2(U_c\bar{\eta}_i - \kappa_c\bar{\eta}_r)\hat{S}_z - U_c\{\hat{S}_x,\hat{S}_z\} + \tfrac{\Gamma_c}{2}\{\hat{S}_y,\hat{S}_z\} \\
\dot{\hat{S}}_z &= -(\Gamma_1+\Gamma_c)\hat{S}_z - \tfrac{N}{2}\Gamma_1\mathbb{I} + 2(U_c\bar{\eta}_r + \kappa_c\bar{\eta}_i)\hat{S}_x - 2(U_c\bar{\eta}_i - \kappa_c\bar{\eta}_r)\hat{S}_y - \Gamma_c(\hat{S}_x^2 + \hat{S}_y^2)
\end{aligned}} \; , \tag{46.137}$$

with the definitions,

$$\bar{\eta} \equiv \eta/g \qquad \text{and} \qquad \Gamma_c \equiv \Gamma + 2\kappa_c \qquad \text{and} \qquad \Gamma_{tot} \equiv \Gamma_1 + \Gamma_c \; . \tag{46.138}$$

The colored terms correspond to those in Eqs. (46.133). It is interesting to note that, after adiabatic elimination of the cavity, the cavity decay rate κ_c appears in the equations of motion at the same locations as the collective decay rate Γ introduced *ad hoc* in the open Dicke model (46.94) via a Liouvillean $\mathfrak{L}^\dagger_{\Gamma_c/2,\hat{S}_-}$.

The number of intracavity photons is found via,

$$\hat{n} = \tfrac{1}{2g}(\hat{\Omega}_r^2 + \hat{\Omega}_i^2) = 2|U_\kappa/g|^2[(g\hat{S}_x - \eta_i)^2 + (g\hat{S}_y - \eta_r)^2] \; . \tag{46.139}$$

It is always interesting to consider special cases. In Exc. 46.4.4.1 we show that in for strong driving the cavity feedback disappears such that we recover the linear collective Dicke model. And in Exc. 46.4.4.2 we show that for weak driving the detuning-dependence of $\langle\hat{n}\rangle$ exhibits standard normal mode splitting.

46.4.1.1 Constants of motion

Let us now address the question, under which conditions the equations of motions (46.137) preserve the total spin. We find readily,

$$\begin{aligned}
\frac{d}{dt}\hat{\mathbf{S}}^2 &= \hat{S}_x\dot{\hat{S}}_x + \dot{\hat{S}}_x\hat{S}_x + \hat{S}_y\dot{\hat{S}}_y + \dot{\hat{S}}_y\hat{S}_y + \hat{S}_z\dot{\hat{S}}_z + \dot{\hat{S}}_z\hat{S}_z \\
&= -(\Gamma_1 + \Gamma_c)(\hat{S}_x^2 + \hat{S}_y^2 + 2\hat{S}_z^2) - N\Gamma_c\hat{S}_z - \Gamma_c\hat{S}_z \; ,
\end{aligned} \tag{46.140}$$

where the term $-\Gamma_c\hat{S}_z = \imath\Gamma_c[\hat{S}_x,\hat{S}_y]$ describes longitudinal decay. Thus all terms in (46.137) depending on Γ_1 or Γ_c induce decay of the total spin (see Exc. 46.4.4.3).

In the mean field approximation, we neglect quantum correlations, which implies that the anticommutators in (46.137) can be replaced by simple products, which in turn means that the longitudinal decay term $-\Gamma_c\hat{S}_z$ disappears.

[19] Equivalently, in complex notation,

$$\begin{aligned}
\Delta_\kappa\hat{a} &= g\hat{S}_- + \imath\eta \\
(\partial_t + \tfrac{\Gamma_1}{2})\hat{S}_- &= \imath\Delta_a\hat{S}_- + 2U_\kappa(\imath\hat{S}_- - \tfrac{1}{g}\eta)\hat{S}_z \\
(\partial_t + \Gamma_1)\hat{S}_z &= -\Gamma_1\tfrac{N}{2}\mathbb{I} - \kappa_c\{\hat{S}_+,\hat{S}_-\} + \tfrac{1}{g}\eta U_\kappa\hat{S}_+ + \tfrac{1}{g}\eta^* U_\kappa^*\hat{S}_- \; .
\end{aligned}$$

[20] According to [866] the adiabatic elimination does only hold for $g\sqrt{N} \ll \kappa$. The question is then, why do our bistability curves agree so well?

46.4.1.2 Hamiltonian for the Tavis-Cummings model after adiabatic elimination of the modes

Alternatively, we can try to derive a simplified Hamiltonian from which the Heisenberg-Liouville equations under adiabatic elimination of the cavity mode can be derived directly.

We have seen in Sec. 39.4.3, using the effective Hamiltonian approach, that the Heisenberg equation decomposes in a commutator and an anti-commutator. The complete Heisenberg-Liouville equation reads,

$$\begin{aligned} \dot{\hat{\mathbf{S}}} &= -\imath[\hat{\mathbf{S}}, \hat{H}] + \mathfrak{L}^\dagger_{\kappa_\mathrm{c},\hat{S}_-}\hat{\mathbf{S}} + \mathfrak{L}^\dagger_{\Gamma/2,\hat{S}_-}\hat{\mathbf{S}} + \sum_j \mathfrak{L}^\dagger_{\Gamma_1/2,\hat{s}_j^-}\hat{\mathbf{S}} \\ \hat{H}_\mathrm{ad} &= -2\mathfrak{Im}\left(\bar{\eta}U_\kappa\right)\hat{S}_x - 2\mathfrak{Re}\left(\bar{\eta}U_\kappa\right)\hat{S}_y - \Delta_\mathrm{a}\hat{S}_z + U_\mathrm{c}\hat{S}_+\hat{S}_- \end{aligned} \quad . \tag{46.141}$$

As shown in Exc. 46.4.4.4, we recover exactly the equations of motion (46.137). The complete absence of the field from the equations of motion shows that, in the bad cavity limit, any coherence of the coupled atom-cavity system is entirely contained in the atomic cloud.

Comparing this model to the one of the open system Dicke model (46.94), we notice that the cavity decay plays an important role not only in collective decay, but also in the coherent evolution of the system. We can calculate the intracavity field from (46.135),

$$\hat{a} = \hat{a}_\mathrm{r} + \imath\hat{a}_\mathrm{i} = \tfrac{U_\kappa}{g}\left(\hat{S}_x - \imath\hat{S}_y + \tfrac{\imath\eta}{g}\right) = \tfrac{U_\kappa}{g}\left(\hat{S}_- + \imath\tfrac{\eta}{g}\right) \quad . \tag{46.142}$$

Example 331 (*Alternative notations*): The Hamiltonian (46.141) can also be expressed in complex notation [569],

$$\hat{H} = \tfrac{\Omega}{2}\hat{S}_+ + \tfrac{\Omega^*}{2}\hat{S}_- - \Delta_\mathrm{a}\hat{S}_z + U_\mathrm{c}\hat{S}_+\hat{S}_- \ ,$$

with the abbreviation $\Omega \equiv 2\imath\bar{\eta}U_\kappa$. Particularly interesting is the non-linear term, which contributes to the equations of motion as,

$$\begin{aligned} \hat{H} = U_\mathrm{c}\hat{S}_+\hat{S}_- \quad \Longrightarrow \quad & -\imath[\hat{\mathbf{S}}, \hat{H}] = -\imath U_\mathrm{c}[\hat{\mathbf{S}}, \hat{S}_+\hat{S}_-] \\ & \mathfrak{L}_{\kappa_\mathrm{c},\hat{S}_-}\hat{\mathbf{S}} = \kappa_\mathrm{c}(2\hat{S}_+\hat{\mathbf{S}}\hat{S}_- - \hat{\mathbf{S}}\hat{S}_+\hat{S}_- - \hat{S}_+\hat{S}_-\hat{\mathbf{S}}) \end{aligned}$$

or using an effective Hamiltonian with $U_\kappa = U_\mathrm{c} - \imath\kappa_\mathrm{c}$,

$$\begin{aligned} \hat{H}_\mathrm{eff} = U_\kappa\hat{S}_+\hat{S}_- \quad \Longrightarrow \quad & -\imath[\hat{\mathbf{S}}\hat{H}_\mathrm{eff} - \hat{H}^\dagger_\mathrm{eff}\hat{\mathbf{S}}] = -\imath U_\mathrm{c}[\hat{\mathbf{S}}, \hat{S}_+\hat{S}_-] - \kappa_\mathrm{c}(\hat{\mathbf{S}}\hat{S}_+\hat{S}_- + \hat{S}_+\hat{S}_-\hat{\mathbf{S}}) \\ & \mathfrak{L}^\mathrm{eff}_{\kappa_\mathrm{c},\hat{S}_-}\hat{\mathbf{S}} = 2\kappa_\mathrm{c}\hat{S}_+\hat{\mathbf{S}}\hat{S}_- \ . \end{aligned}$$

That is, two terms of the Liouvillean can be attributed to an effective Hamiltonian.

46.4.1.3 Stationary mean field equations and saturation-induced non-linearity

It is interesting to study the stationary behavior of Eqs. (46.132) and (46.137) by setting $\dot{\hat{a}} = 0 = \hat{\mathbf{S}}$. We must, however, be aware that by this assumption we *miss some important physics*, as discussed in Sec. 46.5.

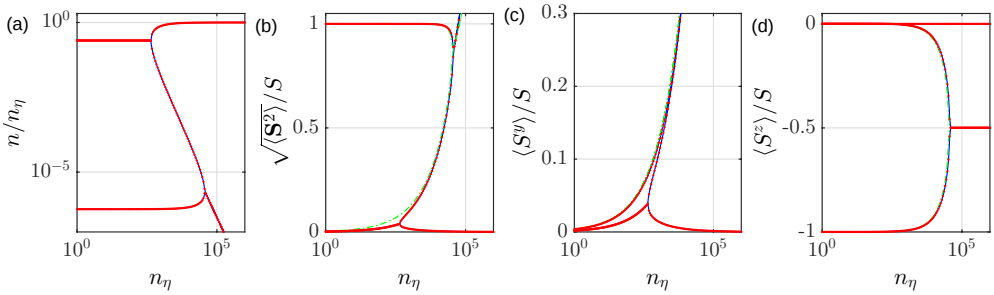

Figure 46.15: (code) Pump power dependence of (a) the intracavity photon number, (b) the stationary value of the mean field total atomic spin, and (c,d) its projection onto the y- and z-axis. The red dotted lines are numerical solutions of the full equations Eqs. (46.133), the blue solid lines are analytical solutions of the adiabatically simplified Eqs. (46.137) under the assumption of resonance, $\Delta_\mathrm{c} = \Delta_\mathrm{a} = \bar{\eta}_\mathrm{i} = 0$, and the green dash-dotted lines are analytical approximations (see Exc. 46.4.4.3 and Ref. [569]). The other parameters are taken from [779].

46.4.2 Spin squeezing in the XX-Heisenberg model

Without pumping and neglecting spontaneous emission, $\eta = \Gamma_1 = 0$, we obtain the simplified Hamiltonian of the Tavis-Cummings model (46.96) with RWA, $g' = 0$,

$$\hat{H}_\mathrm{XX} = -\Delta_\mathrm{a}\hat{S}_z + U_\mathrm{c}\hat{S}_+\hat{S}_- \ , \tag{46.143}$$

also known as the effective Hamiltonian of the *XX-Heisenberg model*. For large $N \gg 1$ the second term can safely be approximated by $\frac{1}{2}U_\mathrm{c}\{\hat{S}_+, \hat{S}_-\}$ [693], because $[\hat{S}_+, \hat{S}_-] = 2\hat{S}_z$ is small compared to terms scaling with $\hat{S}_z^2$. The Heisenberg-Liouville equations can then be written,

$$\dot{\hat{\mathbf{S}}} = \begin{pmatrix} 2U_\mathrm{c}\hat{S}_x - 2\kappa_\mathrm{c}\hat{S}_y \\ 2U_\mathrm{c}\hat{S}_y + 2\kappa_\mathrm{c}\hat{S}_x \\ -\Delta_\mathrm{a} \end{pmatrix} \times \hat{\mathbf{S}} = \begin{pmatrix} \hat{\Omega}_\mathrm{r} \\ -\hat{\Omega}_\mathrm{i} \\ -\Delta_\mathrm{a} \end{pmatrix} \times \hat{\mathbf{S}} \ . \tag{46.144}$$

Analogously, for the Dicke model (46.96) without RWA, $g' = g$, we obtain,

$$\dot{\hat{\mathbf{S}}} = \begin{pmatrix} 4U_\mathrm{c}\hat{S}_x - 4\kappa_\mathrm{c}\hat{S}_y \\ 0 \\ -\Delta_\mathrm{a} \end{pmatrix} \times \hat{\mathbf{S}} \ . \tag{46.145}$$

The intracavity field (46.135) takes for $\eta = 0$ a particularly simple form,

$$\hat{a} = \tfrac{U_\mathrm{c}}{g}\hat{S}_- \ . \tag{46.146}$$

Example 332 (*One-axis twisting in the XX-Heisenberg model*): The coupling strength $\sqrt{N_+N_-} \leq \frac{N}{2}$ between the cavity mode and the atoms depends on the inversion. Hence, this leads to an inversion-dependent frequency shift known as *one-axis twisting* [21]. In the mean field treatment we simply replace

[21] This is somewhat analogous to the photon number-dependent phase shift observed in dispersive interaction in the Jaynes-Cummings model.

the operators by their expectation values. Setting $\Delta_{\rm a} = 0$ in the Heisenberg-Liouville equations (46.144) and neglecting terms $\dot{\hat{S}}_z \propto \hat{S}_z$, we get,

$$\dot{\hat{\mathbf{S}}} \simeq \begin{pmatrix} 2(\kappa_{\rm c}\hat{S}_x + U_{\rm c}\hat{S}_y)\hat{S}_z \\ 2(\kappa_{\rm c}\hat{S}_y - U_{\rm c}\hat{S}_x)\hat{S}_z \\ -2\kappa_{\rm c}(\hat{S}_x^2 + \hat{S}_y^2) \end{pmatrix} .$$

Starting from the initial condition, $\langle\hat{\mathbf{S}}\rangle = (0, 0, N/2)$, we see that the instantaneous collective dipole moment $\hat{S}_x^2 + \hat{S}_y^2$ determines the decay of the inversion, while the inversion $\hat{S}_z$ twists the dipole moment [632, 609, 695, 694, 693]. Collective decay occurs at a rate $\hat{S}_-\sqrt{\kappa_{\rm c}/2}$. It is easy to see that $\partial_t\hat{\mathbf{S}}^2 = \hat{\mathbf{S}}\cdot\dot{\hat{\mathbf{S}}} + \dot{\hat{\mathbf{S}}}\cdot\hat{\mathbf{S}} = 0$. In the equator plane, where $\langle\hat{S}_z\rangle \simeq 0$, the equations of motion simplify to,

$$\dot{\hat{\mathbf{S}}} \simeq \begin{pmatrix} 0 \\ 0 \\ -2\kappa_{\rm c}S^2 \end{pmatrix} .$$

Near the poles, where $\langle\hat{S}_z\rangle \simeq \pm\frac{N}{2}$,

$$\dot{\hat{\mathbf{S}}} \simeq \pm N \begin{pmatrix} \kappa_{\rm c}\hat{S}_x + U_{\rm c}\hat{S}_y \\ \kappa_{\rm c}\hat{S}_y - U_{\rm c}\hat{S}_x \\ 0 \end{pmatrix} \quad \Longrightarrow \quad \dot{\hat{S}}_\pm \simeq \pm N(\kappa_{\rm c} \pm \imath U_{\rm c})\hat{S}_\pm .$$

Hence, near the poles the cavity field will oscillate at a frequency of about $\pm\imath 2NU_{\rm c}$ and decay at a rate $\kappa_{\rm c}$.

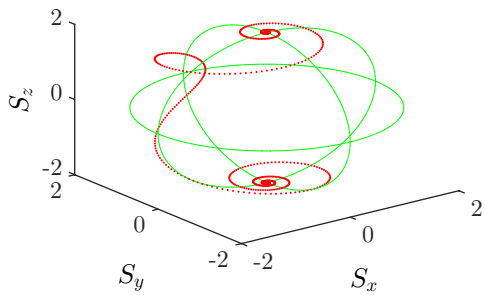

Figure 46.16: (code) One-axis twisting.

Example 333 (*Experimental observation of one-axis twisting*): In the experiment [693] the main inhomogeneity arises because they trap the atoms in a standing wave at 813 nm which is incommensurate with 698 nm (where of course they cannot trap). They first drive the transition by pumping the cavity, then switch off the cavity and measure the field subsequently emitted from the cavity by heterodyne beating. In this way they extract the frequency shift and superradiant decay rate of the cavity,

$$S(\omega) = \mathcal{F}\langle\hat{a}^\dagger(t+\tau)\hat{a}(t)\rangle$$
$$\text{with} \quad \langle\hat{a}^\dagger(t+\tau)\hat{a}(t)\rangle = \langle\hat{S}_+(t+\tau)\hat{S}_-(t)\rangle \simeq \langle\hat{S}_+(t+\tau)\rangle\langle\hat{S}_-(t)\rangle ,$$

in the mean-field approximation.

46.4.2.1 Repumping on a narrow transition

Saturation-induced bistability has been observed in the bad cavity limit [779]. Here, we want to analyze, how incoherent optical pumping at a rate R will affect the normal mode spectra. The ultimate goal is to prepare studies of superradiant lasing [694, 582].

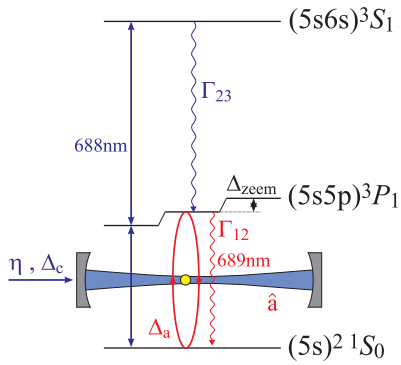

Figure 46.17: (code) Scheme for optical pumping of a metastable excited state, here for the case of atomic strontium [779], in order to generate inversion. The cavity drives the narrow transition.

We consider the situation sketched in Fig. 46.17 and start from the Hamiltonian (11) of [779] for the interaction between strontium atoms and the modes of a ring cavity. We simply add a jump operator for incoherent transfer from the ground to the excited state. With the definition of $\hat{\mathcal{L}}^\dagger_{\gamma,\hat{L}}\hat{A}$ given in (46.94) the relevant jump operators are,

$$\begin{aligned}
\hat{\mathcal{L}}^\dagger_{\kappa,\hat{a}}\hat{a} &= -\kappa\hat{a} \\
\hat{\mathcal{L}}^\dagger_{\Gamma/2,\hat{\sigma}_i^-}\hat{\sigma}_j^- &= -\delta_{ij}\tfrac{\Gamma}{2}\hat{\sigma}_i^- \quad , \quad \hat{\mathcal{L}}^\dagger_{R/2,\hat{\sigma}_i^+}\hat{\sigma}_j^- = -\delta_{ij}\tfrac{R}{2}\hat{\sigma}_i^- \quad . \\
\hat{\mathcal{L}}^\dagger_{\Gamma/2,\hat{\sigma}_i^-}\hat{\sigma}_j^z &= -\delta_{ij}\Gamma(\mathbb{I}+\hat{\sigma}_i^z) \quad , \quad \hat{\mathcal{L}}^\dagger_{R/2,\hat{\sigma}_i^+}\hat{\sigma}_j^z = \delta_{ij}R(\mathbb{I}-\hat{\sigma}_i^z)
\end{aligned} \tag{46.147}$$

Therefore, the generalized Heisenberg-Liouville equations read,

$$\begin{aligned}
\dot{\hat{\sigma}}_i^- &= (\imath\Delta_\mathrm{a} - \tfrac{\Gamma}{2} - \tfrac{R}{2})\hat{\sigma}_i^- + \imath g(e^{\imath kz_i}\hat{a}_+ + e^{-\imath kz_i}\hat{a}_-)\hat{\sigma}_i^z \\
\dot{\hat{\sigma}}_i^z &= -2\imath g(e^{\imath kz_i}\hat{a}_+ + e^{-\imath kz_i}\hat{a}_-)\hat{\sigma}_i^+ + 2\imath g(e^{-\imath kz_i}\hat{a}_+^\dagger + e^{\imath kz_i}\hat{a}_-^\dagger)\hat{\sigma}_i^- - (\Gamma - R)\mathbb{I} - (\Gamma + R)\hat{\sigma}_i^z \\
\dot{\hat{a}}_\pm &= (\imath\Delta_\mathrm{c} - \kappa)\hat{a}_\pm - \imath g\sum_j \hat{\sigma}_j^- e^{\mp\imath kz_j} + \eta_\pm \ .
\end{aligned} \tag{46.148}$$

With this and the abbreviations,

$$\Gamma_\pm \equiv \Gamma \pm R \qquad \text{and} \qquad \tilde{U}_\gamma \equiv \frac{g^2(\Delta_\mathrm{a} - \imath\frac{\Gamma_+}{2})}{\Delta_\mathrm{a}^2 + \frac{\Gamma_+^2}{4}} \ , \tag{46.149}$$

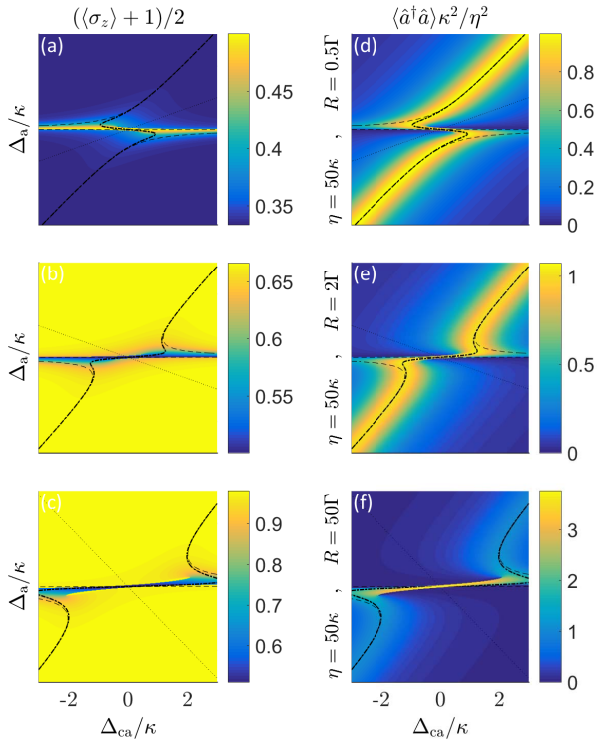

Figure 46.18: (left) inversion $(\hat{\sigma}^z+1)/2$, (right) light transmission $\kappa^2|\alpha|^2/\eta^2$ through the cavity. The repumping rate is set to $R=0.5\Gamma$ (upper row), $R=2\Gamma$ (center row), and $R=50\Gamma$ (lower row). The other parameters are taken from [779].

the calculation of [779] is straightforward to generalize, yielding,

$$\sum_j \frac{-\frac{\Gamma_-}{\Gamma_+}\tilde{U}_\gamma(\alpha_+ + e^{\mp 2\imath k z_j}\alpha_-)}{1+2|\tilde{U}_\gamma/g|^2|e^{\imath k z_j}\alpha_+ + e^{-\imath k z_j}\alpha_-|^2} = \imath\eta_\pm - \Delta_\kappa\alpha_\pm \ . \tag{46.150}$$

That is, all results obtained for $R=0$ remain valid, one just has to redefine $\tilde{U}_\gamma$ and rescale η and Δ_κ. For one-sided probing and a homogeneous cloud and with this and the abbreviations $\bar{\eta}_\pm \equiv \frac{\Gamma_+}{\Gamma_-}\eta_\pm$ and $\tilde{\Delta}_\kappa \equiv \frac{\Gamma_+}{\Gamma_-}\Delta_\kappa$ we recover the same Eq. (3) of [779],

$$\boxed{\alpha_+ = \frac{\imath\bar{\eta}_\pm}{\tilde{\Delta}_\kappa - \frac{N\tilde{U}_\gamma}{1+2|\tilde{U}_\gamma/g|^2|\alpha_+|^2}}} \tag{46.151}$$

and

$$\boxed{\langle\hat{\sigma}_i^z\rangle = \frac{-\Gamma_-/\Gamma_+}{1+2|\tilde{U}_\gamma/g|^2|\alpha_+|^2}} \ . \tag{46.152}$$

The graphs in Fig. 46.18 were obtained for the experimental parameters of [779] and additional repumping. We find inversion once $R>\Gamma$. Close to resonance $\Delta_a=0$

but $\Delta_{\rm ca} \simeq \kappa$ the transmission becomes slightly > 1. The ridges are obtained in the same way as in [779] by setting $\mathfrak{Im}\,\alpha_+ \equiv 0$, yielding,

$$\Delta_{\rm ca} = \Delta_{\rm a} - \frac{\Gamma_-}{\Gamma_+} \frac{N g^2 \Delta_{\rm a}}{\Delta_{\rm a}^2 + \frac{\Gamma_+^2}{4} + 2g^2 n} \ . \tag{46.153}$$

46.4.3 Cumulant expansion of the open Dicke model

In the Heisenberg-Liouville equations applied to the Dicke Hamiltonian for a laser-pumped linear cavity are,

$$\begin{aligned}
[\partial_t - \imath\Delta_{\rm c} + \kappa]\hat{a} &= -\imath g \textstyle\sum_j \hat{\sigma}_j^- \sin kz_j + \eta \\
[\partial_t - \imath\Delta_{\rm a} + \tfrac{\Gamma}{2}]\hat{\sigma}_i^- &= -\imath g \hat{a}\hat{\sigma}_i^z \sin kz_i \\
[\partial_t - \Gamma]\hat{\sigma}_i^z &= 2\imath g \sin kz_i (\hat{a}\hat{\sigma}_i^+ - \hat{a}^\dagger \hat{\sigma}_i^-) - \Gamma \hat{\sigma}_i^z \ .
\end{aligned} \tag{46.154}$$

Note that the presence of pumping represents a serious complication with respect to superradiant lasing models [632, 149, 741], since phase-dependent terms such as $\langle \hat{a} \rangle$ and $\langle \hat{\sigma}^- \rangle$ only vanish if $\eta \neq 0$. Products of operators are differentiated like,

$$\frac{d}{dt}(\hat{A}\hat{B}) = \hat{A}\frac{d\hat{B}}{dt} + \frac{d\hat{A}}{dt}\hat{B} \ . \tag{46.155}$$

Hence,

$$\begin{aligned}
[\partial_t + 2\kappa]\hat{a}^\dagger \hat{a} &= \imath g \textstyle\sum_j \left(\hat{a}\hat{\sigma}_j^+ - \hat{a}^\dagger \hat{\sigma}_j^-\right) \sin kz_j + \eta(\hat{a}^\dagger + \hat{a}) \\
[\partial_t - \imath\Delta_{\rm a} + \imath\Delta_{\rm c} + \tfrac{\Gamma}{2} + \kappa]\hat{a}^\dagger \hat{\sigma}_i^- &= -\imath g \hat{a}^\dagger \hat{a}\hat{\sigma}_i^z \sin kz_i + \imath g \textstyle\sum_j \hat{\sigma}_j^+ \hat{\sigma}_i^- \sin kz_j + \eta \hat{\sigma}_i^- \\
[\partial_t + \imath\Delta_{\rm c} + \kappa - \Gamma]\hat{a}^\dagger \hat{\sigma}_i^z &= 2\imath g \sin kz_i (\hat{a}^\dagger \hat{a}\hat{\sigma}_i^+ - \hat{a}^\dagger \hat{a}^\dagger \hat{\sigma}_i^-) + \Gamma \hat{a}^\dagger + \imath g \textstyle\sum_j \hat{\sigma}_j^+ \hat{\sigma}_i^z \sin kz_j + \eta \hat{\sigma}_i^z \\
[\partial_t + \Gamma]\hat{\sigma}_i^+ \hat{\sigma}_j^- &= \imath g (\hat{a}^\dagger \hat{\sigma}_i^z \hat{\sigma}_j^- \sin kz_i - \hat{a}\hat{\sigma}_i^+ \hat{\sigma}_j^z \sin kz_j) \ .
\end{aligned} \tag{46.156}$$

For perfect bunching, $\sum_j g \sin kz \longrightarrow Ng$, and using $\hat{\sigma}^\pm \hat{\sigma}^z = \pm\hat{\sigma}^\pm$ and $\hat{\sigma}^z \hat{\sigma}^\pm = \mp\hat{\sigma}^\pm$,

$$\begin{aligned}
[\partial_t - \imath\Delta_{\rm c} + \kappa]\hat{a} &= -\imath N g \hat{\sigma}_j^- + \eta \\
[\partial_t - \imath\Delta_{\rm a} + \tfrac{\Gamma}{2})]\hat{\sigma}_i^- &= -\imath g \hat{a}\hat{\sigma}_i^z \\
[\partial_t - \Gamma]\hat{\sigma}_i^z &= 2\imath g (\hat{a}\hat{\sigma}_i^+ - \hat{a}^\dagger \hat{\sigma}_i^-) - \Gamma \hat{\sigma}_i^z \\
[\partial_t + 2\kappa]\hat{a}^\dagger \hat{a} &= \imath N g (\hat{a}\hat{\sigma}_j^+ - \hat{a}^\dagger \hat{\sigma}_j^-) + \eta(\hat{a}^\dagger + \hat{a}) \\
[\partial_t - \imath\Delta_{\rm a} + \imath\Delta_{\rm c} + \tfrac{\Gamma}{2} + \kappa]\hat{a}^\dagger \hat{\sigma}_i^- &= -\imath g \hat{a}^\dagger \hat{a}\hat{\sigma}_i^z + \imath g [\hat{\sigma}_i^+ \hat{\sigma}_i^- + (N-1)\hat{\sigma}_{j\neq i}^+ \hat{\sigma}_i^-] + \eta \hat{\sigma}_i^- \\
[\partial_t + \imath\Delta_{\rm c} + \kappa - \Gamma]\hat{a}^\dagger \hat{\sigma}_i^z &= 2\imath g (\hat{a}^\dagger \hat{a}\hat{\sigma}_i^+ - \hat{a}^\dagger \hat{a}^\dagger \hat{\sigma}_i^-) + \Gamma \hat{a}^\dagger + \imath g [\hat{\sigma}_i^+ + (N-1)\hat{\sigma}_{j\neq}^+ \hat{\sigma}_i^z] + \eta \hat{\sigma}_i^z \\
[\partial_t + \Gamma]\hat{\sigma}_i^+ \hat{\sigma}_j^- &= \imath g (\hat{a}^\dagger \hat{\sigma}_i^z \hat{\sigma}_j^- - \hat{a}\hat{\sigma}_i^+ \hat{\sigma}_j^z) \ .
\end{aligned} \tag{46.157}$$

For a single atom,

$$
\begin{aligned}
[\partial_t - \imath\Delta_{\rm c} + \kappa]\hat{a} &= -\imath N g\hat{\sigma}^- + \eta \\
[\partial_t - \imath\Delta_{\rm a} + \tfrac{\Gamma}{2})]\hat{\sigma}^- &= -\imath g\hat{a}\hat{\sigma}^z \\
[\partial_t - \Gamma]\hat{\sigma}^z &= 2\imath g(\hat{a}\hat{\sigma}^+ - \hat{a}^\dagger\hat{\sigma}^-) - \Gamma\hat{\sigma}^z \\
[\partial_t + 2\kappa]\hat{a}^\dagger\hat{a} &= \imath N g(\hat{a}\hat{\sigma}^+ - \hat{a}^\dagger\hat{\sigma}^-) + \eta(\hat{a}^\dagger + \hat{a}) \\
[\partial_t - \imath\Delta_{\rm a} + \imath\Delta_{\rm c} + \tfrac{\Gamma}{2} + \kappa]\hat{a}^\dagger\hat{\sigma}_i^- &= -\imath g\hat{a}^\dagger\hat{a}\hat{\sigma}_i^z + \imath g\hat{\sigma}_j^+\hat{\sigma}_i^- + \eta\hat{\sigma}_i^- \\
[\partial_t\hat{a}^\dagger\hat{\sigma}_i^z) &= 2\imath g(\hat{a}^\dagger\hat{a}\hat{\sigma}^+ - \hat{a}^\dagger\hat{a}^\dagger\hat{\sigma}^-) + \Gamma\hat{a}^\dagger + \imath N g\hat{\sigma}^+ + \eta\hat{\sigma}^z \\
[\partial_t\hat{\sigma}_i^+\hat{\sigma}_j^-) &= \imath g(\hat{a}^\dagger\hat{\sigma}^- - \hat{a}\hat{\sigma}^+) \ .
\end{aligned}
\tag{46.158}
$$

We now take the expectation values of these equations performing the cumulant expansion,

$$
\langle\hat{A}\hat{B}\hat{C}\rangle = \langle\hat{A}\hat{B}\rangle\langle\hat{C}\rangle + \langle\hat{A}\hat{C}\rangle\langle\hat{B}\rangle + \langle\hat{B}\hat{C}\rangle\langle\hat{A}\rangle - 2\langle\hat{A}\rangle\langle\hat{B}\rangle\langle\hat{C}\rangle \ . \tag{46.159}
$$

Assuming steady-state for $\langle\hat{a}\rangle$ and $\langle\hat{\sigma}^-\rangle$, $\langle\hat{\sigma}^z\rangle$, we obtain a linear set of differential equations,

$$
\frac{d}{dt}\begin{pmatrix}
\langle\hat{a}\rangle \\ \langle\hat{a}^\dagger\rangle \\ \langle\hat{\sigma}_i^-\rangle \\ \langle\hat{\sigma}_i^+\rangle\langle\hat{\sigma}_i^z\rangle \\ \langle\hat{a}^\dagger\hat{a}\rangle \\ \langle\hat{a}\hat{\sigma}_i^+\rangle \\ \langle\hat{a}^\dagger\hat{\sigma}_i^-\rangle \\ \langle\hat{a}\hat{\sigma}_i^z\rangle \\ \langle\hat{a}^\dagger\hat{\sigma}_i^z\rangle \\ \langle\hat{\sigma}_i^+\hat{\sigma}_i^-\rangle
\end{pmatrix}
= \mathcal{M}\begin{pmatrix}
\langle\hat{a}\rangle \\ \langle\hat{a}^\dagger\rangle \\ \langle\hat{\sigma}_i^-\rangle \\ \langle\hat{\sigma}_i^+\rangle \\ \langle\hat{\sigma}_i^z\rangle \\ \langle\hat{a}^\dagger\hat{a}\rangle \\ \langle\hat{a}\hat{\sigma}_i^+\rangle \\ \langle\hat{a}^\dagger\hat{\sigma}_i^-\rangle \\ \langle\hat{a}\hat{\sigma}_i^z\rangle \\ \langle\hat{a}^\dagger\hat{\sigma}_i^z\rangle \\ \langle\hat{\sigma}_i^+\hat{\sigma}_i^-\rangle
\end{pmatrix}
+ \begin{pmatrix}
\eta \\ \eta \\ 0 \\ 0 \\ \Gamma \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ \langle\hat{a}_\infty^\dagger\rangle\langle\hat{a}_\infty\rangle\langle\hat{\sigma}_\infty^z\rangle
\end{pmatrix} \ . \tag{46.160}
$$

with

$$
\mathcal{M} = \tag{46.161}
$$

$$
\begin{pmatrix}
\imath\Delta_{\rm c} - \kappa & 0 & -\imath N g & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & -\imath\Delta_{\rm c} - \kappa & 0 & \imath N g & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & \imath\Delta_{\rm a} - \frac{\Gamma}{2} & 0 & 0 & 0 & 0 & 0 & -\imath g & 0 & 0 \\
0 & 0 & 0 & -\imath\Delta_{\rm a} - \frac{\Gamma}{2} & 0 & 0 & 0 & 0 & 0 & \imath g & 0 \\
0 & 0 & 0 & 0 & \Gamma & 0 & 2\imath g & -2\imath g & 0 & 0 & 0 \\
\eta & \eta & 0 & 0 & 0 & -2\kappa & \imath N g & -\imath N g & 0 & 0 & 0 \\
0 & 0 & 0 & \eta & 0 & \imath N g\langle\hat{\sigma}_\infty^z\rangle & 0 & 0 & 0 & 0 & \imath N g \\
0 & 0 & \eta & 0 & 0 & -\imath N g\langle\hat{\sigma}_\infty^z\rangle & 0 & 0 & 0 & 0 & \imath N g \\
\Gamma & 0 & -\imath N g & \eta & \langle\hat{\sigma}^-\rangle & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & \Gamma & 0 & \imath N g & \eta & \langle\hat{\sigma}^+\rangle & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & -\imath g & \imath g & 0 & 0 & 0
\end{pmatrix}
$$

46.4.3.1 Correlation functions

Often it is interesting to analyze two-times *correlation functions* of the types $g^{(1)}(\tau) = \langle\hat{A}^\dagger(t+\tau)\hat{A}(t)\rangle$ or $g^{(2)}(\tau) = \langle\hat{A}^\dagger(t)\hat{A}^\dagger(t+\tau)\hat{A}(t+\tau)\hat{A}(t)\rangle$. As long as we are able to solve the Heisenberg-Liouville equation for the whole operator,

$$
\frac{d}{dt}\hat{A} = \mathfrak{L}[\hat{A},\hat{B},\hat{C}] \quad\Longrightarrow\quad \hat{A}(t+\tau) = \hat{A}(t) + \tau\ \mathfrak{L}[\hat{A},\hat{B},\hat{C}] \tag{46.162}
$$

this task is easy. In particular, for the case of unitary evolutions,

$$\hat{A}(t+\tau) = e^{-\imath\hat{H}\tau}\hat{A}(t)e^{\imath\hat{H}\tau} \quad \Longrightarrow \quad \langle\hat{A}^\dagger(t+\tau)\hat{A}(t)\rangle = \langle e^{-\imath\hat{H}\tau}\hat{A}(t)e^{\imath\hat{H}\tau}\hat{A}(t)\rangle \ . \tag{46.163}$$

Often, however, we just know the expectation values of equal time correlations, because they follow from a cumulant expansion of the Heisenberg-Liouville equations for all possible combinations, e.g. $\langle\hat{A}(t)\hat{B}(t)\rangle$. This is when we can use the *quantum regression theorem*,

$$\begin{aligned} &\langle\hat{A}(t+\tau)\rangle = \alpha(\tau)\langle\hat{A}(t)\rangle + \beta(\tau)\langle\hat{B}(t)\rangle \\ &\Longrightarrow \quad \langle\hat{A}(t+\tau)\hat{X}(t)\rangle = \alpha(\tau)\langle\hat{A}(t)\hat{X}(t)\rangle + \beta(\tau)\langle B(t)\hat{X}(t)\rangle \ . \end{aligned} \tag{46.164}$$

Applied to the Heisenberg-Liouville equations,

$$\begin{aligned} &\hat{A}(t+\tau) = \hat{A}(t) + \tau\ \mathfrak{L}[\hat{A},\hat{B},\hat{C}] \\ &\Longrightarrow \quad \langle\hat{A}^\dagger(t+\tau)\hat{A}(t)\rangle = \langle\hat{A}(t)^\dagger\hat{A}(t)\rangle + \tau\ \langle\mathfrak{L}[\hat{A},\hat{B},\hat{C}]^\dagger\hat{A}(t)\rangle \ , \end{aligned} \tag{46.165}$$

which only holds for very short times τ.

46.4.4 Exercises

46.4.4.1 Ex: No feedback in the strong driving limit

For strong driving, $\hat{S}_{x,y} \ll \eta$, the evolution of coupled atom-cavity system is externally controlled by the pump, which impedes a self-determined dynamics, i.e. a dynamics ruled by cavity feedback. Show that in this limit, which is obtained from (46.134) via decorrelation of the atomic spins, we recover the linear collective Dicke model.

46.4.4.2 Ex: Linearization for weak driving

For weak driving we may assume $\hat{S}_z \simeq -\frac{N}{2}\mathbb{I}$. This approximation underlies the *coupled dipoles model* and leads to a linearization of the equations of motion also known as *linear optics regime*.
a. Derive the stationary solution.
b. Setting $\Delta_\mathrm{a} = \Delta_\mathrm{c}$, show that $\langle\hat{n}\rangle$ exhibits the standard normal mode spectrum.

46.4.4.3 Ex: Solution of the mean field equations after adiabatic elimination of the cavity

a. Do the mean field approximation of the adiabatically simplified Eqs. (46.137) and assume $\Delta_\mathrm{c} = \Delta_\mathrm{a} = \bar{\eta}_\mathrm{r} = 0$.
b. Show that the total spin $\mathbf{S}^2$ is NOT a constant of motion, unless $\Gamma_1 = 0 = \Gamma_\mathrm{tot}$ with $\Gamma_\mathrm{tot} = \Gamma_1 + 2\kappa_\mathrm{c}$ even though $\kappa_\mathrm{c} \neq 0$ [569]. Interpret the result.
c. Derive the steady state solution of the equations obtained in (a).
d. Approximate the cubic equation by a quadratic one assuming $2\kappa_\mathrm{c} \ll \Gamma_1 \ll 2\kappa_\mathrm{c}S_z$.
e. Compare with the stationary solution of (46.132) assuming $\Delta_\mathrm{a} = \Delta_\mathrm{c} = \Gamma = 0$.
f. Perform a stability analysis of the equations derived under (a).

46.4.4.4 Ex: Adiabatic elimination of the cavity mode, general case

Derive the equations of motion (46.137) for a system consisting of many atoms interacting with a single cavity mode after adiabatic elimination of the cavity mode.

46.4.4.5 Ex: Comparison of collective Hamiltonians

Compile a list of all collective Hamiltonians studied so far, compare and discuss them.

46.5 Driven-dissipative Dicke model

Until now we mostly considered stationary or coherently evolving systems. We will now study driven-dissipative atom-cavity systems that may or may not reach equilibrium and exhibit phenomena such as *cooperative resonance fluorescence* (CRF) [277, 156]. The bistable behavior of the atom-cavity system in Sec. 46.4.1 and Exc. 46.4.4.3 was calculated in the mean field approximation and assuming complete stationarity, $\dot{\hat{a}} = 0 = \hat{\mathbf{S}}$. The bistability curves of Fig. 46.15 then represent the full mathematically exact solution. We show them again in Fig. 46.19 with a different scaling. Panel (b) emphasizes the eminent role played by the collective cooperativity in the bistability,

$$\Upsilon_N = \frac{4Ng^2}{\Gamma_1 \kappa} = \frac{4N\kappa_c}{\Gamma_1} \ . \tag{46.166}$$

Apparently, it rules the relation between collective and individual decay processes.

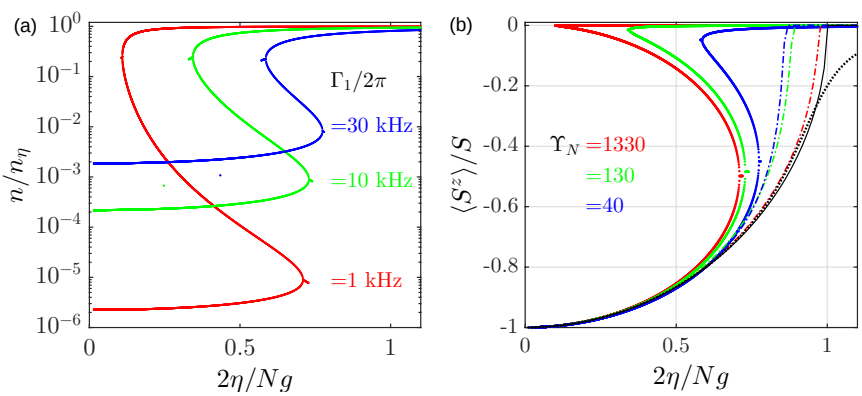

Figure 46.19: (code) The solid lines indicate bistability curves calculated under steady state conditions for various collective cooperativities using full or adiabatically simplified Heisenberg equations. (a) Intracavity photon number. (b) Collective atomic inversion. The dash-dotted lines indicate mean field values of the collective atomic inversion evaluated after long evolution times without steady state assumption. The black dotted line is an analytical solution [Eq. (46.206)] without mean field approximation but also without spontaneous emission for 30 atoms.

The stationarity assumption is, however, not always realistic. Let us think, for example, of the case of a single driven two-level atom whose dynamics is described by Bloch equations (see Sec. 39.4.1). Subject to strong driving the atom will undergo Rabi oscillations, and reach a steady state only after the oscillations are damped out due to spontaneous emission. If we want to observe such behavior in the collective Dicke model, we need to give up the stationarity condition [779].

Indeed, the equations of motion can have other solutions, which may not necessarily be stationary. In the following, we will study how the interplay between driving force (at a rate η), collective decay (at a rate $\kappa_{\rm c}$), and individual decay (at a rate Γ_1) rules the collective dynamics in the bistable region [569, 866].

46.5.1 Cooperative resonance fluorescence in mean field approximation

The major problem is however that, near phase transitions *quantum fluctuations may overwhelm decay terms*. In that case, we do not expect the mean field approximation to be good. In order to still get meaningful approximate results, and we shall rather neglect decay term at the profit of correlation terms.

46.5.1.1 Critical Rabi frequency

For the following we use the definition of the Rabi frequency proposed in Eqs. (46.135),

$$\hat{\Omega} = \hat{\Omega}_{\rm r} + \imath\hat{\Omega}_{\rm i} = 2U_{\rm c}(\hat{S}_x - \tfrac{\eta_{\rm i}}{g}) - 2\kappa_{\rm c}(\hat{S}_y - \tfrac{\eta_{\rm r}}{g}) = U_\kappa^*(\hat{S}_- + \imath\tfrac{\eta}{g}) + U_\kappa(\hat{S}_+ - \imath\tfrac{\eta^*}{g}) \ . \quad (46.167)$$

We evaluate this definition on resonance,

$$\hat{\Omega} \stackrel{\Delta_{\rm c}=0}{\longrightarrow} 2\kappa_{\rm c}(\hat{S}_y + \tfrac{\eta_{\rm r}}{g}) = \imath\kappa_{\rm c}\hat{S}_- - \imath\kappa_{\rm c}\hat{S}_+ + 2\kappa_{\rm c}\tfrac{\eta_{\rm r}}{g} \equiv \tfrac{1}{2}(\hat{\Omega}_- + \hat{\Omega}_+) + \Omega_\eta \ . \quad (46.168)$$

In the last expression we defined superradiant Rabi frequency operators

$$\hat{\Omega}_\mp \equiv \pm 2\imath\kappa_{\rm c}\hat{S}_\mp \quad (46.169)$$

and a pump Rabi frequency [that is, the maximum Rabi frequency in a resonant empty cavity,

$$\Omega_\eta \equiv 2\imath\tfrac{\eta}{g}U_\kappa = 2g\frac{\eta}{\kappa} = 2\kappa_{\rm c}\frac{\eta}{g} \ . \quad (46.170)$$

Now, the superradiant Rabi frequency is maximum at the equator, since

$$\langle\hat{S}_-\rangle \simeq \sqrt{S(S+1) - M(M\pm 1)} \lesssim \tfrac{N}{2} \ . \quad (46.171)$$

We call the upper limit the *critical Rabi frequency*,

$$\Omega_{\rm c} \equiv N\kappa_{\rm c} \geq 2\kappa_{\rm c}\langle\hat{S}_-\rangle = -\imath\langle\hat{\Omega}_-\rangle \ . \quad (46.172)$$

It can be used to normalize the pump Rabi frequency,

$$\tilde{\Omega}_\eta \equiv \frac{\Omega_\eta}{\Omega_{\rm c}} = \frac{2\eta}{Ng} \ . \quad (46.173)$$

We will see in the following, that for $\Omega_\eta < \Omega_{\rm c}$, drive and dissipative superradiance counter-balance until the system reaches a steady-state. For $\Omega_\eta > \Omega_{\rm c}$, the drive enforces Rabi flopping and no steady-state is reached (see Fig. 46.20).

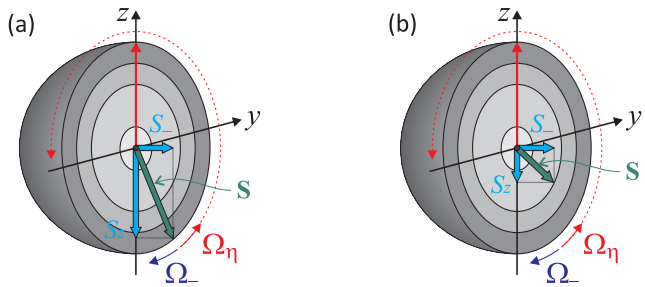

Figure 46.20: Illustration of the equilibrium between drive and superradiance. (a) In the absence of spontaneous emission the collective spin vector (green arrow) remains on the outer shell with its position determined by an equilibrium between superradiant decay Ω_- and the drive assumed to be weak, $\Omega_\eta < \Omega_c$ (blue and red solid arrows). If $\Omega_\eta > \Omega_c$, the overwhelming drive induced Rabi oscillations (dotted arrow). (b) In the presence of spontaneous emission the collective spin vector evolves into inner shells.

46.5.1.2 Mean field solution of the Heisenberg equations without adiabatic elimination

We start from the full equations (46.132) evaluated on resonance and neglecting collective decay Γ (other than the one induced by the cavity),

$$\begin{aligned}\dot{\hat{a}} &= -\kappa\hat{a} - \imath g\hat{S}_- + \eta \\ \dot{\hat{S}}_- &= -\tfrac{\Gamma_1}{2}\hat{S}_- + 2\imath g\hat{S}_z\hat{a} \\ \dot{\hat{S}}_z &= -\Gamma_1(\tfrac{N}{2} + \hat{S}_z) - \imath g(\hat{S}_+\hat{a} - \hat{a}^\dagger\hat{S}_-)\ .\end{aligned} \tag{46.174}$$

Disregarding for a while spontaneous decay Γ_1 and exploiting the above definitions,

$$\begin{aligned}\dot{\hat{a}} &= -\kappa\hat{a} + \tfrac{\kappa}{2g}(\Omega_\eta - \hat{\Omega}_-) \\ \dot{\hat{S}}_- &= 2\imath g\hat{S}_z\hat{a} \\ \dot{\hat{S}}_z &= -\imath g(\hat{S}_+\hat{a} - \hat{a}^\dagger\hat{S}_-)\ .\end{aligned} \tag{46.175}$$

From the second equation we see that steady-state requires $\hat{a} = 0$. Hence,

$$\imath\hat{S}_- = \tfrac{\eta}{g} \qquad \text{i.e.} \qquad \hat{\Omega}_- = \Omega_\eta\ . \tag{46.176}$$

That is, the superradiant Rabi frequency self-adjusts until it compensates the pump field. This, however, is only possible until the superradiant Rabi frequency reaches its maximum allowed value, that we will call the critical Rabi frequency [866].

Figs. 46.21 show the mean field behavior of the cavity field and the collective spin simulated from Eqs. (46.175). We see that, below the critical pumping strength $\Omega_\eta < \Omega_c$ (red curves), the cavity field quickly vanishes and the collective spin tends toward a stationary value. Above the critical pumping strength $\Omega_\eta > \Omega_c$ (blue curves) the cavity field and the collective spin both start to oscillate, such that no steady state is reached, unless we allow for single atom spontaneous decay. Then, a mean field

simulation of Eqs. (46.175) (dashed curves) shows relaxation toward finite stationary values for the cavity field the collective spin.

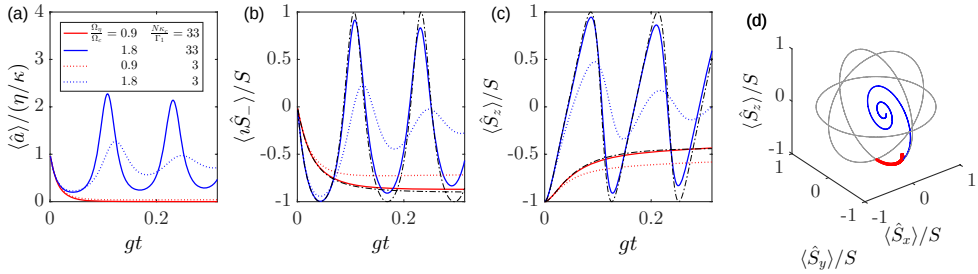

Figure 46.21: (code) Mean field values of cavity field and collective spin calculated from Eqs. (46.174) for various strength η of the drive and two different values of $\Gamma_1 = (2\pi)\,10\,\text{kHz}$ (solid lines) and $100\,\text{kHz}$ (dashed lines). The other parameters are $\kappa = (2\pi)\,3\,\text{MHz}$, $g = (2\pi)\,10\,\text{kHz}$, and $N = 10000$. Note that simulations of the adiabatically simplified Eqs.(46.185) yield exactly the same curves. The dash-dotted black lines are obtained from an analytical solution derived in example 334.

Example 334 (*Continuous superradiant transition*): In the mean field approximation,

$$\begin{aligned}\dot{\alpha} &= -\kappa\alpha - \imath g\langle\hat{S}_-\rangle + \eta \\ \langle\dot{S}_-\rangle &= -\tfrac{\Gamma_1}{2}\langle\hat{S}_-\rangle + 2\imath g\alpha\langle\hat{S}_z\rangle \\ \langle\dot{S}_z\rangle &= -\Gamma_1(\tfrac{N}{2} + \langle\hat{S}_z\rangle) - \imath g(\langle\hat{S}_+\rangle\alpha - \alpha^*\langle\hat{S}_-\rangle)\ .\end{aligned} \tag{46.177}$$

For $\Gamma_1 = 0$ assuming $\varphi = 0$, we expect,

$$\langle\hat{S}_-\rangle = \tfrac{N}{2}\sin\vartheta \qquad \text{and} \qquad \langle\hat{S}_z\rangle = \tfrac{N}{2}\cos\vartheta\ , \tag{46.178}$$

so that,

$$\begin{aligned}\dot{\alpha} &= -\kappa\alpha - \imath g\tfrac{N}{2}\sin\vartheta + \eta \\ \dot{\vartheta} &= 2\imath g\alpha = \imath g(\alpha - \alpha^*)\ .\end{aligned} \tag{46.179}$$

For steady state $\dot{\alpha} = 0 = \dot{\vartheta}$ we get,

$$\sin\vartheta = -\frac{2\imath\eta}{Ng}\ , \tag{46.180}$$

and consequently,

$$\langle\hat{S}_z\rangle = \frac{N}{2}\cos\vartheta = \frac{N}{2}\sqrt{1 - \left(\frac{2\imath\eta}{Ng}\right)^2}\ . \tag{46.181}$$

The solution is shown as black solid line in Fig. 46.19. It describes a continuous second-order phase transition, in contrast to the colored solid lines in this figure, which describe an abrupt first-order phase transition. Analytical solutions for this phase transition were derived in Exc. 46.4.4.3.

46.5.1.3 Mean field solution of the Heisenberg equations after adiabatic elimination of the cavity field

Let us now repeat the calculation using the adiabatically simplified Heisenberg-Liouville equations (46.137) for the resonant case, $\Delta_{\rm a} = 0 = \Delta_{\rm c}$, imaginary pump corresponding to a rotation about the y-axis, $\bar{\eta}_{\rm r} = 0$, and no collective decay apart from the cavity, $\Gamma = 0$,

$$\dot{\hat{\mathbf{S}}} = -\imath[\hat{\mathbf{S}}, \hat{H}] + \mathfrak{L}^{\dagger}_{\kappa_{\rm c},\hat{S}_-}\hat{\mathbf{S}} + \sum_j \mathfrak{L}^{\dagger}_{\Gamma_1/2,\hat{s}_j^-}\hat{\mathbf{S}} \qquad \text{with} \qquad \hat{H} = 2\bar{\eta}_{\rm i}\kappa_{\rm c}\hat{S}_y \ , \tag{46.182}$$

or in the effective Hamiltonian notation,

$$\boxed{\begin{aligned} \dot{\mathbf{S}} &= -\imath[\hat{\mathbf{S}}, \hat{H}_{\rm eff}] + 2\kappa_{\rm c}\hat{S}_+\hat{\mathbf{S}}\hat{S}_- + \Gamma_1\sum_j(2\hat{s}_j^+\hat{\mathbf{S}}\hat{s}_j^- - \hat{s}_j^+\hat{s}_j^-\hat{\mathbf{S}} - \hat{\mathbf{S}}\hat{s}_j^+\hat{s}_j^-) \\ \hat{H}_{\rm eff} &= 2\bar{\eta}_{\rm i}\kappa_{\rm c}\hat{S}_y - \imath\kappa_{\rm c}\hat{S}_+\hat{S}_- \end{aligned} \tag{46.183}}$$

We see that after adiabatic elimination of a bad cavity, one part of the cavity decay $\kappa_{\rm c}$ enters the Hamiltonian, another the Lindbladian. The corresponding equations of motion are,

$$\boxed{\begin{aligned} \dot{\hat{S}}_x &= -\kappa_{\rm c}(\hat{S}_x - \{\hat{S}_x, \hat{S}_z\}) - 2\bar{\eta}_{\rm i}\kappa_{\rm c}\hat{S}_z - \tfrac{\Gamma_1}{2}\textstyle\sum_j(\hat{s}_j^x - \{\hat{s}_j^x, \hat{s}_j^z\}) \\ \dot{\hat{S}}_y &= -\kappa_{\rm c}(\hat{S}_y - \{\hat{S}_y, \hat{S}_z\}) - \tfrac{\Gamma_1}{2}\textstyle\sum_j(\hat{s}_j^y - \{\hat{s}_j^y, \hat{s}_j^z\}) \\ \dot{\hat{S}}_z &= -2\kappa_{\rm c}(\hat{S}_z + \hat{S}_x^2 + \hat{S}_y^2) + 2\bar{\eta}_{\rm i}\kappa_{\rm c}\hat{S}_x - \Gamma_1\textstyle\sum_j(\hat{s}_j^z + \hat{s}_j^{x2} + \hat{s}_j^{y2}) \end{aligned}} \ . \tag{46.184}$$

Example 335 (*Evaluation of individual spins*): For the products of individual and collective spins we find [156],

$$\sum_j \hat{s}_j^\alpha\hat{s}_j^\beta = \hat{S}_\alpha\hat{S}_\beta - \sum_j \hat{s}_j^\alpha\sum_{i\neq j}\hat{s}_i^\beta = \hat{S}_\alpha\hat{S}_\beta - N(N-1)\hat{s}_1^\alpha\hat{s}_1^\beta \ . \tag{46.185}$$

With this the Eqs. (46.184) can be rewritten as [569],

$$\begin{aligned} \dot{\hat{S}}_x &= -(\kappa_{\rm c} + \tfrac{\Gamma_1}{2})(\hat{S}_x - \{\hat{S}_x, \hat{S}_z\}) - 2\bar{\eta}_{\rm i}\kappa_{\rm c}\hat{S}_z + \tfrac{\Gamma_1}{2}N(N-1)\{\hat{s}_1^x, \hat{s}_1^z\} \\ \dot{\hat{S}}_y &= -(\kappa_{\rm c} + \tfrac{\Gamma_1}{2})(\hat{S}_y - \{\hat{S}_y, \hat{S}_z\}) + \tfrac{\Gamma_1}{2}N(N-1)\{\hat{s}_1^y, \hat{s}_1^z\} \\ \dot{\hat{S}}_z &= -(2\kappa_{\rm c} + \Gamma_1)(\hat{S}_z + \hat{S}_x^2 + \hat{S}_y^2) + 2\bar{\eta}_{\rm i}\kappa_{\rm c}\hat{S}_x - \Gamma_1 N(N-1)(\hat{s}_1^{x2} + \hat{s}_1^{y2}) \ . \end{aligned} \tag{46.186}$$

Neglecting the quadratic terms of individual spins,

$$\begin{aligned} \dot{\hat{S}}_x &= -\kappa_{\rm c}(\hat{S}_x - 2\hat{S}_x\hat{S}_z + 2\bar{\eta}_{\rm i}\hat{S}_z) - \tfrac{\Gamma_1}{2}\hat{S}_x \\ \dot{\hat{S}}_y &= -\kappa_{\rm c}(\hat{S}_y - 2\hat{S}_y\hat{S}_z) - \tfrac{\Gamma_1}{2}\hat{S}_y \\ \dot{\hat{S}}_z &= -2\kappa_{\rm c}(\hat{S}_z + \hat{S}_x^2 + \hat{S}_y^2 - \bar{\eta}_{\rm i}\hat{S}_x) - \Gamma_1(\tfrac{N}{2} + \hat{S}_z) \ . \end{aligned} \tag{46.187}$$

The mean field solution of these equations yield exactly the same curves as shown in Fig. 46.21.

Example 336 (*Continuous superradiant transition*): We start from (46.187) doing the mean field approximation, $S_\alpha = \langle \hat{S}_\alpha \rangle$, and setting $\Gamma_1 = 0$ and $\kappa_c = 0$ *only in linear terms*,

$$\begin{aligned} \dot{S}_x &= 2\kappa_c S_x S_z - 2\kappa_c \bar{\eta}_i \hat{S}_z \\ \dot{S}_y &= 2\kappa_c S_y S_z \\ \dot{S}_z &= -2\kappa_c (S_x^2 + S_y^2) + 2\kappa_c \bar{\eta}_i \hat{S}_x \ . \end{aligned} \tag{46.188}$$

Under such circumstances and doing the mean field approximation, as shown in Exc. 46.4.4.3, the total spin $\mathbf{S}^2 = \frac{N^2}{4}$ is conserved. Hence, we may set,

$$S_x = \tfrac{N}{2} \sin\vartheta \qquad \text{and} \qquad S_z = \tfrac{N}{2} \cos\vartheta \ , \tag{46.189}$$

and find from either the first or third equation,

$$\sin\vartheta = \frac{2\bar{\eta}_i}{N} \tag{46.190}$$

and consequently,

$$S_z = \frac{N}{2} \sqrt{1 - \left(\frac{2\eta_i}{Ng}\right)^2} \ . \tag{46.191}$$

The differential equations can be analytically solved for the initial condition $\mathbf{S} = \left(0, 0, -\frac{N}{2}\right)$. We find,

$$\begin{aligned} \dot{S}_x &= 2\kappa_c S_x S_z - 2\kappa_c \bar{\eta}_i S_z \\ \dot{S}_z &= -2\kappa_c S_x^2 + 2\kappa_c \bar{\eta}_i S_x \ . \end{aligned} \tag{46.192}$$

Substituting (46.189), the initial condition becomes $\vartheta = \pi$ and the differential equations simplify to,

$$\dot{\vartheta} = \kappa_c (N \sin\vartheta - 2\bar{\eta}_i) \ . \tag{46.193}$$

Let us have a look at the red curves in Figs. 46.21, which are obtained for low driving ($\Omega_\eta < \Omega_c$), and at the dash-dotted lines in Fig. 46.19. We see that higher spontaneous emission rate *increases* $\langle \hat{S}_z \rangle$. This is because (slow) individual decay spoils (fast) superradiant decay. This is illustrated in Fig. 46.20.

46.5.2 Driven-dissipative spin squeezing beyond mean field

In Sec. 46.4.2 we have seen that the XX-Heisenberg model predicts spin squeezing when the cavity is *detuned from the resonance*, $U_c \neq 0$, which is immediately clear by the presence of a non-linear term in the Hamiltonian (46.141), $\hat{H} \sim U_c \hat{S}_+ \hat{S}_-$. As in the XX-Heisenberg model no equilibrium is reached, specific Gaussian spin states (coherent or squeezed) must be generated by pulsed application of a (linear or non-linear) Hamiltonian interaction, which rotates or squeezes an initial ground state into any point of the superradiant Bloch sphere, where it stays forever as long as no dissipation nor driving occurs.

On resonance, $U_c = 0$, and the above non-linear term vanishes. However, the non-linearity survives in the dissipative part of the effective Hamiltonian (46.183),

$\hat{H}_{\text{eff}} \sim -\imath\kappa_{\text{c}}\hat{S}_+\hat{S}_-$. In the following we will show that, *induced by dissipation*, spin squeezing may also occur on resonance and that, *pumped on the mean field*, squeezed states even represent the steady state of the system in certain parameter regimes.

A necessary condition for spin squeezing is however, as we have seen in the previous section, that (i) the drive is weak enough not to overrule the self-determined dynamics resulting from an *equilibrium between drive and superradiance* and (ii) that this equilibrium is *not spoiled by spontaneous emission*. In the following we will concentrate on studying this equilibrium neglecting single atom decay.

46.5.2.1 Solution of the master equation without adiabatic elimination of the cavity field

Setting $\Delta_{\text{c}} = \Delta_{\text{a}} = \Gamma_1 = 0$, the full master equation (46.94) for the atom-cavity system becomes,

$$\begin{aligned}\dot{\hat{\rho}} &= \imath[\hat{\rho}, \hat{H}] + \mathfrak{L}_{\kappa,\hat{a}}\hat{\rho} \\ &= \imath g[\hat{\rho}, \hat{S}_+\hat{a} + \hat{a}^\dagger\hat{S}_-] + \eta[\hat{\rho}, \hat{a} - \hat{a}^\dagger] + \kappa(2\hat{a}\hat{\rho}\hat{a}^\dagger - \hat{a}^\dagger\hat{a}\hat{\rho} - \hat{\rho}\hat{a}^\dagger\hat{a}) \ .\end{aligned} \tag{46.194}$$

We now express the spin operators in a local reference frame anchored to the mean field spin vector on the meridian at $\varphi = 0$, as shown in Eq. (46.80),

$$\hat{S}_- = \hat{S}_x - \imath\hat{S}_y = \hat{S}_\vartheta \cos\vartheta + \hat{S}_\rho \sin\vartheta - \imath\hat{S}_y \simeq \sqrt{S}(\hat{x}\cos\vartheta + \imath\hat{p}) + S\sin\vartheta \ . \tag{46.195}$$

In the last step, we approximated the local spin operators by Holstein-Primakoff bosons, which holds for large enough atom numbers $N \to \infty$. With this we obtain for the first term,

$$\begin{aligned}&\imath g[\hat{\rho}, \hat{S}_+\hat{a} + \hat{a}^\dagger\hat{S}_-] \\ &\simeq \imath g\sqrt{S}\left([\hat{\rho}, (\hat{x}\cos\vartheta - \imath\hat{p} + \sqrt{S}\sin\vartheta)\hat{a}] + [\hat{\rho}, \hat{a}^\dagger(\hat{x}\cos\vartheta + \imath\hat{p} + \sqrt{S}\sin\vartheta)]\right) \\ &\simeq \imath g\sqrt{S}\left([\hat{\rho}, (\hat{x}\cos\vartheta - \imath\hat{p})\hat{a}] + [\hat{\rho}, \hat{a}^\dagger(\hat{x}\cos\vartheta + \imath\hat{p})]\right) \ .\end{aligned} \tag{46.196}$$

In steady state $\dot{\hat{\rho}} = 0$, *below the critical pump rate*, the system evolves towards a pure state that we will call $\hat{\rho} = |S,\alpha\rangle\langle S,\alpha|$,

$$\begin{aligned}0 = {}&\imath g\sqrt{S}|S,\alpha\rangle\langle S,\alpha|(\hat{x}\cos\vartheta - \imath\hat{p})\hat{a} - \imath g\sqrt{S}(\hat{x}\cos\vartheta - \imath\hat{p})\hat{a}|S,\alpha\rangle\langle S,\alpha| \\ &+ |S,\alpha\rangle\langle S,\alpha|\hat{a}^\dagger(\hat{x}\cos\vartheta + \imath\hat{p}) - |S,\alpha\rangle\langle S,\alpha|\hat{a}^\dagger(\hat{x}\cos\vartheta + \imath\hat{p}) \\ &+ 2\kappa\hat{a}|S,\alpha\rangle\langle S,\alpha|\hat{a}^\dagger - \kappa\hat{a}^\dagger\hat{a}|S,\alpha\rangle\langle S,\alpha| - \kappa|S,\alpha\rangle\langle S,\alpha|\hat{a}^\dagger\hat{a} \ .\end{aligned} \tag{46.197}$$

provided that

$$\boxed{\hat{a}|S,\alpha\rangle = (\hat{x}\cos\vartheta + \imath\hat{p})|S,\alpha\rangle = 0} \ . \tag{46.198}$$

This means, that the light field is then a vacuum state. With this, we obtain from Eq. (46.195),

$$\boxed{\hat{S}_-|S,\alpha\rangle = S\sin\vartheta|S,\alpha\rangle} \ , \tag{46.199}$$

which means that the states $|S,\alpha\rangle$ are *eigenstates of the spin-down operator* $\hat{S}_-$.

Furthermore, from the calculation

$$\begin{aligned} 0 &= \langle S,\alpha|(\hat{x}\cos\vartheta - \imath\hat{p})(\hat{x}\cos\vartheta + \imath\hat{p})|S,\alpha\rangle \\ &= \langle S,\alpha|\hat{x}^2\cos^2\vartheta + \hat{p}^2 + \imath[\hat{x},\hat{p}]\cos\vartheta|S,\alpha\rangle = \langle S,\alpha|2\hat{p}^2 - \cos\vartheta|S,\alpha\rangle \ , \end{aligned} \tag{46.200}$$

we derive,

$$\langle S,\alpha|\hat{S}_y^2|S,\alpha\rangle \simeq S\hat{p}^2 = \tfrac{S}{2}\cos\vartheta \ , \tag{46.201}$$

which means that the collective spin state is squeezed as compared to the coherent spin state (CSS) for which we derived in Excs. 46.1.8.5 and 46.1.8.18,

$$\langle\vartheta,0|^N\hat{S}_y^2|\vartheta,0\rangle^N = \tfrac{S}{2} \ . \tag{46.202}$$

46.5.2.2 Steady state solution of the master equation after adiabatic elimination of the cavity field

Let us again repeat the calculation of the previous section using the adiabatically simplified master equation and neglecting single atom spontaneous emission. Defining,

$$\tilde{S}_\pm \equiv \hat{S}_\pm \mp \frac{\imath\Omega}{4\kappa_c} \tag{46.203}$$

the master equation can be rewritten as,

$$\begin{aligned} \dot{\hat{\rho}} &= \imath[\hat{\rho},\hat{H}_{\rm ad}] + \mathfrak{L}_{\kappa_c,\hat{S}_-}\hat{\rho} \\ &= \imath\tfrac{\Omega}{2}[\hat{\rho},\hat{S}_+ + \hat{S}_-] + \kappa_c(2\hat{S}_-\hat{\rho}\hat{S}_+ - \hat{S}_+\hat{S}_-\hat{\rho} - \hat{\rho}\hat{S}_+\hat{S}_-) \\ &= \kappa_c(2\tilde{S}_-\hat{\rho}\tilde{S}_+ - \tilde{S}_+\tilde{S}_-\hat{\rho} - \hat{\rho}\tilde{S}_+\tilde{S}_-) \ . \end{aligned} \tag{46.204}$$

The steady state solution is simply,

$$\boxed{\hat{\rho}_{\rm ss} = C^{-1}\tilde{S}_-^{-1}\tilde{S}_+^{-1}} \ , \tag{46.205}$$

and can be used to numerically evaluate steady state values of the spin operator,

$$\langle\hat{\mathbf{S}}(\infty)\rangle = {\rm Tr}\,\hat{\rho}_{\rm ss}\hat{\mathbf{S}} = \sum_{M=-S}^{S}\langle S,M|\hat{\rho}_{\rm ss}\hat{\mathbf{S}}|S,M\rangle \ . \tag{46.206}$$

Example 337 (*Analytical steady state solution*): On the other hand, it is enlightening to derive analytical solutions. To do so, we expand [758, 156]

$$\tilde{S}_\pm^{-1} = \sqrt{\tfrac{1}{C}}\sum_{n=0}^{N}\left(\mp\frac{\imath\Omega}{4\kappa_c}\right)^{N-n}\hat{S}_\pm^n \tag{46.207}$$

with the normalization

$$C = \sum_{n=0}^{N}\sum_{m=0}^{n}\frac{(N-n+m)!n!}{(n-m)!(N-n)!}\left(\frac{\Omega}{4\kappa_c}\right)^{2(N-m)} \ , \tag{46.208}$$

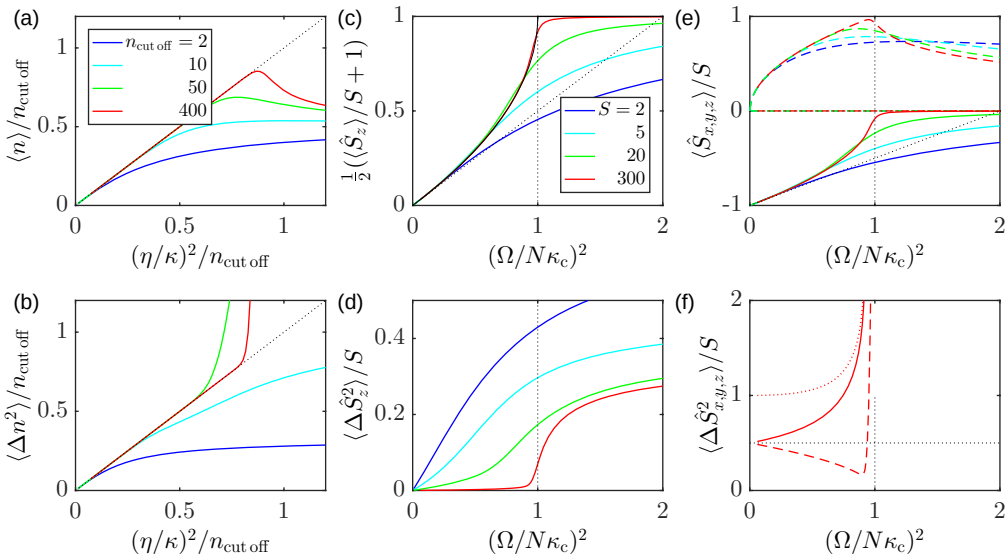

Figure 46.22: (code) Comparison between (a,b) cavity field and (c-f) collective spin. Note that the cut-off photon number in (a,b) is an artifact, while the total spin in (c-f) is limited by the available number of atoms. The panels (a,c,e) show expectation values, while (b,d,f) show uncertainties. The steady state inversion calculated for various atom numbers from the exact formulas (46.205) or (46.210) without mean field approximation, but also without spontaneous emission. The black solid line in panel (b) is obtained from $\hat{S}_z = S - \sqrt{N^2 - (\frac{\Omega}{\kappa_c})^2}$.

we can write the steady state solution as,

$$\hat{\rho}_{\text{ss}} = \tfrac{1}{C} \sum_{n,m=0}^{N} \imath^{n-m} \left(\frac{\Omega}{4\kappa_c} \right)^{2N-n-m} \hat{S}_-^n \hat{S}_+^m \ . \tag{46.209}$$

With this the steady state collective spin can be derived from,

$$\langle \hat{\mathbf{S}}(\infty) \rangle = \text{Tr}\, \hat{\rho}_{\text{ss}} \hat{S}_z = \sum_{M=-S}^{S} \langle S, M | \hat{\rho}_{\text{ss}} \hat{\mathbf{S}} | S, M \rangle \tag{46.210}$$

$$= \tfrac{1}{C} \sum_{M=-S}^{S} \sum_{n,m=0}^{N} (-\imath)^{n-m} \left(\frac{\Omega}{4\kappa_c} \right)^{2N-n-m} \langle S, M | \hat{S}_-^n \hat{S}_+^m \hat{\mathbf{S}} | S, M \rangle \ .$$

In particular we find,

$$\langle \hat{S}_z^n(\infty) \rangle = \text{Tr}\, \hat{S}_z^n(\infty) \hat{\rho}_{\text{ss}} \tag{46.211}$$

$$= \frac{1}{C} \sum_{p=0}^{2S} \sum_{k=0}^{p} (S-m)^n \frac{(2S-p+k)!p!}{(2S-p)!(p-k)!} \left(\frac{\Omega}{4\kappa_c} \right)^{2(2S-k)} \ .$$

Substituting $\hat{S}_\pm \to \langle \hat{S}_\pm \rangle = S e^{\imath\varphi} \cos\vartheta$ we find,

$$\hat{\rho}_{\text{ss}} \to \frac{1}{\left| S e^{\imath\varphi} \sin\vartheta + \frac{\imath\Omega}{4\kappa_c} \right|^2} \ . \tag{46.212}$$

Example 338 (*Comparison to bosonic field results*): The master equation (38.61) describing a light mode in a cavity as a harmonic oscillator and the master equation (46.204) describing a collective spin system are formally identical. The master equation for the light mode has been solved in Sec. 38.2.3, one of the findings being that, over time, any non-classical state evolves toward a Glauber state. Furthermore, the Holstein-Primakoff prescription allows to approximate the collective spin system as a harmonic oscillator. The question thus arises, whether non-coherent collective spin states possible at all.
Fig. 46.22 presents a comparison of the steady state behavior of both systems, a cavity mode with artificial photon number cut-off and a collective spin system in the bad cavity limit. Indeed, the systems behave quite similar. At weak driving both, the mean photon number and the spin inversion tend toward the pump rate,

$$\langle \hat{n} \rangle \overset{\eta \ll \kappa}{\to} \frac{\eta^2}{\kappa^2} \qquad \text{while} \qquad \langle \hat{S}_z/N \rangle + \tfrac{1}{2} \overset{\Omega \ll \kappa_c}{\to} \frac{\Omega^2}{N^2 \kappa_c^2} \ . \tag{46.213}$$

At strong driving both, the mean photon number and the spin inversion saturate; the intracavity photon number to the artificial cut-off and the spin system to $\langle \hat{S}_z \rangle = 0$. At intermediate driving both systems seem to feature a phase transition, which however, for the photon system is not real.
Comparing the real photon number dependence [dotted black line in panel (a)] with the spin system, we notice very different behaviors: The spin system reveals much richer features, than the bosonic mode, which implies that the Holstein-Primakoff approximation fails at intermediate or strong driving. Apparently, the different commutation relations holding for photonic operators and for collective spin operators induce different solutions for identical master equations.
It is also interesting to compare the uncertainties shown in panels (b,d). Compare to Exc. 46.1.8.5.

Projection onto the generalized Bloch sphere for coherent spin states restricting on $\varphi = \frac{\pi}{2}$,

$$\langle \hat{\mathbf{S}} \rangle = S \begin{pmatrix} \cos\varphi \sin\vartheta \\ \sin\varphi \sin\vartheta \\ \cos\vartheta \end{pmatrix} \overset{\varphi=\pi/2}{\longrightarrow} S \begin{pmatrix} 0 \\ \sin\vartheta \\ \cos\vartheta \end{pmatrix} \ . \tag{46.214}$$

Using the transformation (48.80), but now assuming $\varphi = \frac{\pi}{2}$, we find,

$$\hat{S}_\vartheta = \hat{S}_y \cos\vartheta - \hat{S}_z \sin\vartheta = \hat{S}_y \tfrac{\langle \hat{S}_z \rangle}{S} - \hat{S}_z \tfrac{\langle \hat{S}_y \rangle}{S} \ . \tag{46.215}$$

The uncertainties can now be expressed as $\langle \Delta S_x^2 \rangle$ and,

$$\langle \Delta \hat{S}_\vartheta^2 \rangle = \langle \hat{S}_\vartheta^2 \rangle - \langle \hat{S}_\vartheta \rangle^2 = \mathrm{Tr}\, \hat{\rho} \left(\hat{S}_y \tfrac{\langle \hat{S}_z \rangle}{S} - \hat{S}_z \tfrac{\langle \hat{S}_y \rangle}{S} \right)^2 - \left[\mathrm{Tr}\, \hat{\rho} \left(\hat{S}_y \tfrac{\langle \hat{S}_z \rangle}{S} - \hat{S}_z \tfrac{\langle \hat{S}_y \rangle}{S} \right) \right]^2 \tag{46.216}$$

$$= (\langle \hat{S}_x^2 \rangle - \langle \hat{S}_x \rangle^2) \cos^2\vartheta + (\langle \hat{S}_z^2 \rangle - \langle \hat{S}_z \rangle^2) \sin^2\vartheta - (\langle \hat{S}_x \hat{S}_z + \hat{S}_z \hat{S}_x \rangle - 2\langle \hat{S}_x \rangle \langle \hat{S}_z \rangle) \sin\vartheta \cos\vartheta$$

$$= \tfrac{1}{S^2} \left[\langle \Delta S_x^2 \rangle \langle \hat{S}_z \rangle^2 + \langle \Delta S_z^2 \rangle \langle \hat{S}_x \rangle^2 - (\langle \hat{S}_x S_z \rangle + \langle \hat{S}_z \hat{S}_x \rangle - 2\langle \hat{S}_x \rangle \langle \hat{S}_z \rangle) \langle \hat{S}_x \rangle \langle \hat{S}_z \rangle \right] \ .$$

The Heisenberg uncertainty is verified, since,

$$\langle \Delta \hat{S}_\vartheta^2 \rangle \langle \Delta \hat{S}_x^2 \rangle > \frac{S^2}{4} = \frac{N^2}{16} \ . \tag{46.217}$$

46.5.2.3 Solution using effective Hamiltonian

For an arbitrary Hamiltonian and Lindbladian we write the master equation,

$$\begin{aligned}\dot{\hat{\rho}} &= \imath[\hat{\rho}, \hat{H}_{\rm ad}] + \mathfrak{L}_{\kappa_c,\hat{S}_-}\hat{\rho} \\ &= \imath[\hat{\rho}, \hat{H}_{\rm ad}] + \kappa_{\rm c}(2\hat{S}_-\hat{\rho}\hat{S}_+ - \hat{S}_+\hat{S}_-\hat{\rho} - \hat{\rho}\hat{S}_+\hat{S}_-) \\ &= \imath(\hat{\rho}\hat{H}^\dagger_{\rm eff} - \hat{H}_{\rm eff}\hat{\rho}) + 2\kappa_{\rm c}\hat{S}_-\hat{\rho}\hat{S}_+ \\ &= \imath(|S,\alpha\rangle\langle S,\alpha|\hat{H}^\dagger_{\rm eff} - \hat{H}_{\rm eff}|S,\alpha\rangle\langle S,\alpha|) + 2\kappa_{\rm c}\hat{S}_-|S,\alpha\rangle\langle S,\alpha|\hat{S}_+ \ .\end{aligned} \tag{46.218}$$

where we introduced the effective Hamiltonian $\hat{H}_{\rm eff} \equiv \hat{H}_{\rm ad} - \imath\kappa_{\rm c}\hat{S}_+\hat{S}_-$ and expressed the density operator as a pure state $\hat{\rho} \equiv |S,\alpha\rangle\langle S,\alpha|$. Now, if and only if $\hat{S}_-$ and $\hat{H}_{\rm eff}$ have common eigenstates such that,

$$\hat{S}_-|S,\alpha\rangle = \alpha|S,\alpha\rangle \qquad \text{and} \qquad \hat{H}_{\rm eff}|S,\alpha\rangle = h_{\rm eff}|S,\alpha\rangle \tag{46.219}$$

with $h_{\rm eff} = \langle H_{\rm ad}\rangle - \imath\kappa_{\rm c}|\alpha|^2$, the density operator remains steady in a pure state [994],

$$\dot{\hat{\rho}} = [\imath(h^*_{\rm eff} - h_{\rm eff}) + 2\kappa_{\rm c}|\alpha|^2]\hat{\rho} = 0 \ . \tag{46.220}$$

For the spin operator we then find,

$$\begin{aligned}\langle S,\alpha|\hat{S}_x|S,\alpha\rangle &= \tfrac{1}{2}(\alpha + \alpha^*) \\ \langle S,\alpha|\hat{S}_y|S,\alpha\rangle &= \tfrac{\imath}{2}(\alpha - \alpha^*) \\ \langle S,\alpha|\hat{S}_z|S,\alpha\rangle &= 0 \\ \langle S,\alpha|\hat{S}_+\hat{S}_-|S,\alpha\rangle &= |\alpha|^2 \ .\end{aligned} \tag{46.221}$$

Hence, the uncertainty of the spin-down operator in the state $|S,\alpha\rangle$ is,

$$\langle S,\alpha|\Delta\hat{S}^2_-|S,\alpha\rangle = 0 \ , \tag{46.222}$$

while for a *coherent spin state* (CSS) we calculated in Exc. 46.1.8.5 [22],

$$\langle\vartheta,\varphi|^N\Delta\hat{S}^2_\pm|\vartheta,\varphi\rangle^N = -\tfrac{N}{4}e^{\pm 2\imath\varphi}\sin^2\vartheta \ . \tag{46.223}$$

Collective radiation $\hat{S}_-$ is stimulated by the cavity, unlike spontaneous emission $\hat{s}^-_j$. In the presence of spontaneous emission the theorem (46.219) looses its validity, which means that the state generated will not be the perfect CRSS any more [569].

Let us now consider the Hamiltonian (46.141) which with the abbreviation (46.170) delivers the effective Hamiltonian,

$$\begin{aligned}\hat{H}_{\rm eff} = \hat{H}_{\rm ad} - \imath\kappa_{\rm c}\hat{S}_+\hat{S}_- &= -2\mathfrak{Im}\,(\bar{\eta}U_\kappa)\hat{S}_x - 2\mathfrak{Re}\,(\bar{\eta}U_\kappa)\hat{S}_y - \Delta_{\rm a}\hat{S}_z + U_\kappa\hat{S}_+\hat{S}_- \\ &= \tfrac{\Omega}{2}\hat{S}_+ + \tfrac{\Omega^*}{2}\hat{S}_- - \Delta_{\rm a}\hat{S}_z + U_\kappa\hat{S}_+\hat{S}_- \ ,\end{aligned} \tag{46.224}$$

[22] Note that $\langle S,\alpha|\hat{S}_-|S,\alpha\rangle = \alpha$ does not necessarily imply $\hat{S}_-|S,\alpha\rangle = \alpha|S,\alpha\rangle$, since the error made on writing down this latter equation can be compensated by the projection on $\langle S,\alpha|$.

Its expectation value becomes,

$$\begin{aligned} h_{\text{eff}} = \langle S,\alpha|\hat{H}_{\text{eff}}|S,\alpha\rangle &= -\mathfrak{Im}\,(\bar{\eta}U_\kappa)(\alpha+\alpha^*) - \mathfrak{Re}\,(\bar{\eta}U_\kappa)\imath(\alpha-\alpha^*) + U_\kappa|\alpha|^2 \\ &= \tfrac{\Omega}{2}\alpha^* + \tfrac{\Omega^*}{2}\alpha + U_\kappa|\alpha|^2 \ . \end{aligned} \tag{46.225}$$

Since $\hat{S}_-$ is a constant of motion of the effective Hamiltonian $\hat{H}_{\text{eff}}$,

$$\begin{aligned} 0 = [\hat{S}_-,\hat{H}_{\text{eff}}] &= \tfrac{\Omega}{2}[\hat{S}_-,\hat{S}_+] - \Delta_{\text{a}}[\hat{S}_-,\hat{S}_z] + U_\kappa[\hat{S}_-,\hat{S}_+]\hat{S}_- \\ &= -\Omega\hat{S}_z - \Delta_{\text{a}}\hat{S}_- - 2U_\kappa\hat{S}_z\hat{S}_- \ . \end{aligned} \tag{46.226}$$

On resonance, $\Delta_{\text{a}} = 0$, we find,

$$\alpha = \langle S,\alpha|\hat{S}_-|S,\alpha\rangle = -\frac{\Omega}{2U_\kappa} = \imath\bar{\eta} \ . \tag{46.227}$$

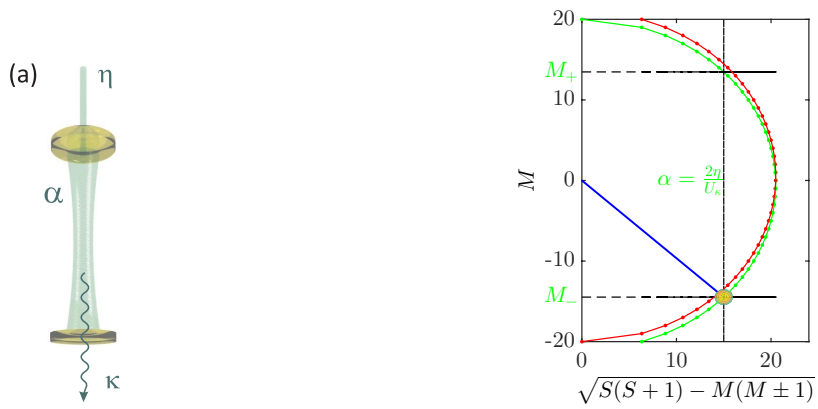

Figure 46.23: (code) (a) Driven-dissipative cavity. (b) Construction of a CRSS state with $N = 40$ atoms.

We thus found a new class of spin states apparently sharing features with Glauber states of light, as they can be represented in a two-dimensional plane. We will call them *coherently radiating spin states* (CRSS) [957, 865, 569]. The analogy between spin states and the harmonic oscillator has been worked out in Sec. 46.1.7. In particular, the action of the lowering operator on a number state is given by,

$$\hat{a}|n\rangle = \sqrt{n}|n-1\rangle \qquad \text{versus} \qquad \hat{S}_\pm|S,M\rangle = \sqrt{S(S+1)-M(M\pm 1)}|S,M-1\rangle \ . \tag{46.228}$$

The states $|n\rangle$ are highly non-classical, similarly to $|S,M\rangle$. Furthermore,

$$\hat{a}|\alpha\rangle = \alpha|\alpha\rangle \qquad \text{versus} \qquad \hat{S}_\pm|S,\vartheta,\varphi\rangle = Se^{\pm\imath\varphi}\sin\vartheta|S,\vartheta,\varphi\rangle \ . \tag{46.229}$$

These are not really eigenvalue equations, since α, respectively, $e^{\pm\imath\varphi}\sin\vartheta$ are complex numbers.

46.5.2.4 Construction of coherently radiating spin states

The problem with CRSSs is, however, more profound and related to the finiteness of the system. While Glauber states can be expanded into Poissonian distributions of Fock states to perfect approximation, there is no exact analytical expression for CRSSs.

Example 339 (*Eigenvalue of spin-down operator*): To see this, let us first have a quick look at Glauber states, $|\alpha\rangle = e^{-|\alpha|^2/2}\sum_{k=0}^{\infty}\frac{\alpha^n}{\sqrt{n!}}|n\rangle$, for which the expression $\hat{a}|\alpha\rangle = \alpha|\alpha\rangle$ is a very good approximation to an eigenvalue equation, but this is only because ∞ is big,

$$\hat{a}|\alpha\rangle \simeq \alpha|\alpha\rangle \quad \Longrightarrow \quad \sum_{n=0}^{\infty-1}\frac{\alpha^{n+1}}{\sqrt{n!}}|n\rangle \simeq \sum_{n=0}^{\infty}\frac{\alpha^{n+1}}{\sqrt{n!}}|n\rangle \ . \tag{46.230}$$

We may expect a similar behavior for spin states, provided the atom number N is large enough.

Let us suppose there is a state $|S,\alpha\rangle$ satisfying the eigenvalue equations (46.219) and expand it onto the Dicke state basis

$$|S,\alpha\rangle = \sum_{M=-S}^{S} a_M|S,M\rangle \ , \tag{46.231}$$

yielding,

$$\hat{S}_-|S,\alpha\rangle \simeq \alpha|S,\alpha\rangle \tag{46.232}$$

$$\Longrightarrow \sum_{M=-S}^{S-1} a_{M+1}\sqrt{S(S+1)-M(M+1)}|S,M\rangle \simeq \sum_{M=-S}^{S}\alpha a_M|S,M\rangle \ .$$

This formula is analogous to (46.230) with the difference that $S<\infty$. Consequently, we may expect the eigenvalue equation to be a good approximation only if the atom number is very large.

From (46.232) we obtain the recursion formula [865],

$$\begin{aligned} \alpha a_M &= 0 && \text{for} \quad M=S \\ \alpha a_M &= a_{M+1}\sqrt{S(S+1)-M(M+1)} && \text{for} \quad M=-S,...,S-1 \end{aligned} \tag{46.233}$$

Hence, if $\alpha>0$, then $a_S=0$ and all other coefficients are $a_M=0$ as well. In the non-trivial case $a_M\neq 0$ the operators $\hat{S}_\pm$ have only one eigenstate with eigenvalue $\alpha=0$. The state obtained is a coherent spin ground state.

Now, let us *postulate* the existence of an *approximate* eigenstate $|S,\alpha\rangle$ of the operator $\hat{S}_-$ with eigenvalue $\alpha>0$. One approach is the following. Guided by the observation that the highest and lowest states on the Dicke ladder are eigenstates, $\hat{S}_\pm|S,\pm S\rangle=0$, we write approximately,

$$\begin{aligned} \hat{S}_-|S,M_++1\rangle &= \sqrt{S(S+1)-M_+(M_++1)}|S,M_+\rangle \\ &\simeq \sqrt{S(S+1)-M_+(M_++1)}|S,M_++1\rangle = \alpha|S,M_++1\rangle \ , \end{aligned} \tag{46.234}$$

yielding,

$$\begin{aligned} M_\pm &= \pm\sqrt{S(S+1)-\alpha^2+\tfrac{1}{4}}-\tfrac{1}{2} && \text{for} \quad M=S \\ \alpha a_M &= a_{M+1}\sqrt{S(S+1)-M(M+1)} && \text{for} \quad M=-S,...,S-1 \end{aligned} \tag{46.235}$$

The other states follow from the same recursion formula as in (46.232)(ii). Thus, the CRSS state obeys,

$$\boxed{|S,\alpha\rangle = \sum_{M=-S}^{M_+} a_M |S,M\rangle} \,. \tag{46.236}$$

An intuitive justification for the truncation of the Dicke state expansion (46.236) might be that, differently from *rotations*, decay processes break the symmetry between $\hat{S}_\pm$, because only energetically lower states can be reached via superradiant emission. In Exc. 46.5.3.1 we will derive from the recursion formula (46.235) an approximate analytical expression for the coefficients a_M [865].

46.5.2.5 Characterization of coherently radiating spin states

The truncated Dicke state expansion (46.236) together with the recursion formulas (46.235) and the normalization condition allows us to discover some properties of CRSSs.

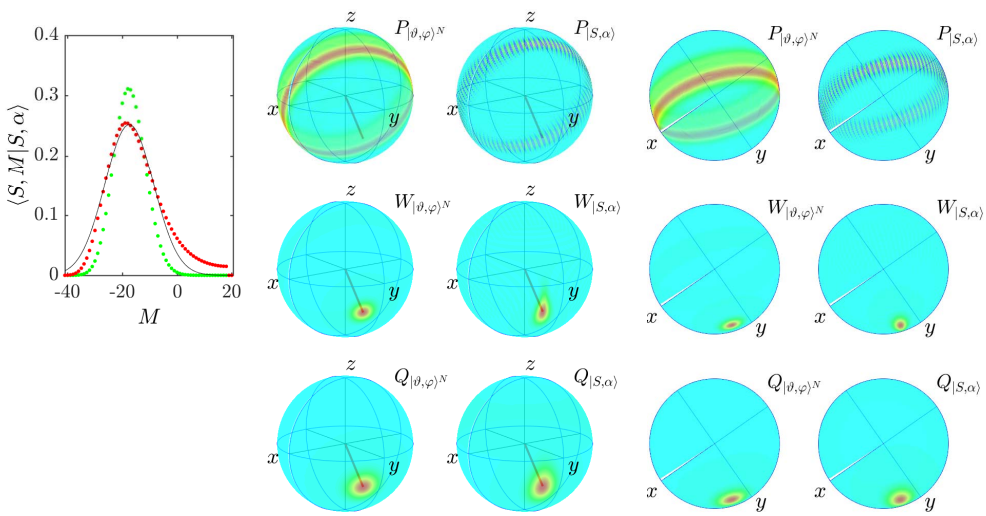

Figure 46.24: (code) (left) Excitation amplitudes for a CSS (green dots), for a CRSS (red dots), and for CRSS in the Gaussian approximation. (center) Quasi-probability distributions for a CSS and for a CRSS on the Bloch sphere. (right) Projections of the distributions onto the equator plane.

In Fig. 46.24(left) we plot the amplitudes a_M of the Dicke states for CSSs and CRSSs as well as their approximations by Gaussian formulas. Figs. 46.24(center and right) show the quasi-probability distributions P, W, and Q calculated for the same

states. Clearly visible in Wigner distribution (middle row) is spin squeezing for the CRSS state $|S,\alpha\rangle$, but not for the CSS state $|\vartheta,\varphi\rangle^N$. For the projection onto the equatorial plane it is just the opposite: The projection of the CSS is squeezed, but not of the CRSS [23].

To calculate the squeezing parameter we just need to evaluate the definition,

$$\boxed{\xi^2 \equiv \frac{2S}{|\langle\hat{\mathbf{S}}\rangle|^2}\min_\varphi \Delta\hat{S}_\perp^2(\varphi)} \ , \tag{46.237}$$

where

$$\Delta\hat{S}_\perp^2(\varphi) = \langle S,\alpha|\hat{S}_\perp(\varphi)^2|S,\alpha\rangle - \langle S,\alpha|\hat{S}_\perp(\varphi)|S,\alpha\rangle^2 \hat{S}_\perp(\varphi) \quad = \tfrac{1}{2}(e^{\imath\varphi}\hat{S}_- + e^{-\imath\varphi}\hat{S}_+)$$
$$\langle\hat{\mathbf{S}}\rangle = \sqrt{\langle\hat{S}_x\rangle^2 + \langle\hat{S}_y\rangle^2 + \langle\hat{S}_z\rangle^2} \ .$$

Fig. 46.25 demonstrates how spin-squeezing increases parameter with $r = S\sin\vartheta$ [865].

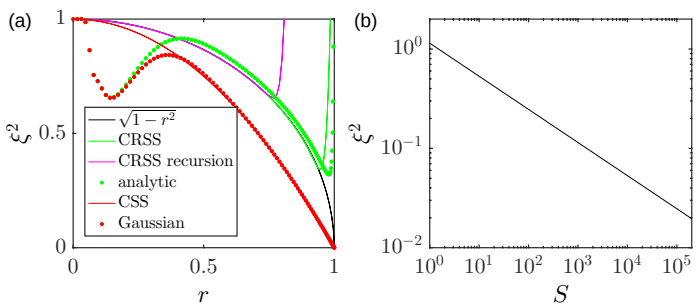

Figure 46.25: (code) Squeezing parameter as a function of (a) r and (b) S.

46.5.2.6 Light as spin squeezing witness

The cloud-cavity interaction is ruled by terms like $\hat{H} = g(\hat{a}^\dagger\hat{S}_- + \hat{S}_+\hat{a})$. The field emitted $\hat{a}(t) = \hat{a}_0(t) + G\hat{S}_-(t)$ is continuously measured, i.e. we constantly force it into an eigenstate. We may thus assume that the system is pumped into $|S,\alpha\rangle$ with [865],

$$\hat{S}_-(0)|S,\alpha(t)\rangle = \alpha(t)|S,\alpha(t)\rangle \ . \tag{46.238}$$

The evolution $e^{-\imath\hat{H}t}$ is the displacement operator of the field, generating a coherent light state out of an initial vacuum state,

$$\mathcal{U}(t) = e^{-\imath\hat{H}t} = e^{-\imath g(\hat{S}_+\hat{a}+\hat{a}^\dagger\hat{S}_-)t} = e^{-\imath g(\alpha^*\hat{a}+\alpha\hat{a}^\dagger)t} \ , \tag{46.239}$$

so that

$$\hat{a}(t) = \mathcal{U}^\dagger(t)\hat{a}(0)\mathcal{U}(t) = \hat{a}(0) - \imath g\alpha t \ , \tag{46.240}$$

[23] The projection of the observable $\hat{S}_x = \frac{1}{2}(\hat{S}_- + \hat{S}_+)$ onto a non-compatible basis represented by the operator $\hat{S}_-$ necessarily introduces projection noise, which overrules spin squeezing.

This coherent light state is an eigenstate of the operator $\hat{S}_-$ represented in the Glauber xy-plane,

$$\hat{a}_-|S,\alpha\rangle = \alpha|S,\alpha\rangle \qquad \text{with} \qquad \alpha = Sre^{-\imath\varphi} \qquad \text{where} \qquad r < 1 \ , \tag{46.241}$$

which by construction is a coherent state of light if $\hat{a}(0)|\psi(0)\rangle = 0$ is initially the vacuum state [24]. See also Exc. 46.5.3.2.

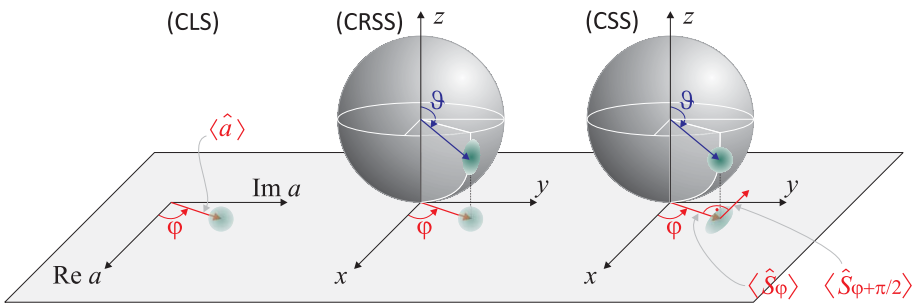

Figure 46.26: Illustration of the quadratures of a coherent state of light (CLS), and of a CRSS and a CSS on the generalized Bloch sphere.

Interesting signal are delivered by the photon emission rate [308],

$$\gamma(t) = \langle \hat{S}_+\hat{S}_-\rangle = \mathrm{Tr}\,[\hat{S}_+\hat{S}_-\hat{\rho}(t)] \tag{46.242}$$

and the correlation function,

$$g_N^{(2)}(t,t) = \frac{\langle \hat{S}_+\hat{S}_+\hat{S}_-\hat{S}_-\rangle_t}{\langle \hat{S}_+\hat{S}_-\rangle_t^2} = \frac{\mathrm{Tr}\,[\hat{S}_+\hat{S}_+\hat{S}_-\hat{S}_-\hat{\rho}(t)]}{\mathrm{Tr}\,[\hat{S}_+\hat{S}_-\hat{\rho}(t)]^2} \ . \tag{46.243}$$

Example 340 (*Equal-time correlation for CSS and CRSS*): Let us first calculate the correlation functions for a CRSS (see (46.221)),

$$\begin{aligned} \langle S,\alpha|\hat{S}_+\hat{S}_-|S,\alpha\rangle &\simeq |\alpha|^2 = S^2\sin^2\vartheta \\ \langle S,\alpha|\hat{S}_+\hat{S}_+\hat{S}_-\hat{S}_-|S,\alpha\rangle &\simeq |\alpha|^4 \ . \end{aligned} \tag{46.244}$$

Hence, $g^{(1)} = 1 = g^{(2)}$.
For the CSS, we found in Exc. 46.1.8.5,

$$\begin{aligned} \langle\vartheta,\varphi|^N\hat{S}_+\hat{S}_-|\vartheta,\varphi\rangle^N &= Np_+^2 + N^2p_+p_- \\ &= N\cos^4\tfrac{\vartheta}{2} + N^2\sin^2\tfrac{\vartheta}{2}\cos^2\tfrac{\vartheta}{2} = \tfrac{N}{4}(\cos\vartheta+1)^2 + \tfrac{N^2}{4}\sin^2\vartheta \ . \end{aligned} \tag{46.245}$$

Also,

$$\begin{aligned} &\langle\vartheta,\varphi|^N\hat{S}_+\hat{S}_+\hat{S}_-\hat{S}_-|\vartheta,\varphi\rangle^N \\ &\quad = N^4p_+^2p_-^2 + 2N^3p_+^2(3p_+-1)p_- + N^2p_+^2(11p_+^2-10p_++1) - 2Np_+^3(3p_+-2) \ . \end{aligned} \tag{46.246}$$

[24] Even if one manages to generate intracavity squeezed light, it is necessary to verify that the light transmitted through a cavity mirror is still squeezed and not spoiled by vacuum fluctuations. Then one might try to homodyne it with a local oscillator [596, 597, 634, 791].

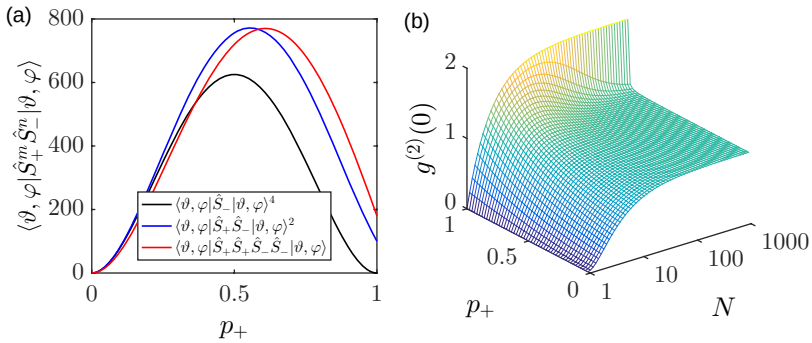

Figure 46.27: (code) (a) Correlation functions as a function of $p_+ = Sr = S\sin\theta$ for $N = 10$ atoms. (b) Second order coherence $g^{(2)}(0)$.

The time-dependent correlation functions can be evaluated using the quantum regression theorem exposed in (46.165).

Example 341 (*Equal-time correlation for the cavity field*): From (46.132) at resonance,

$$\dot{\hat{a}} = -\kappa\hat{a} - \imath g\hat{S}_- + \eta \ .$$

In steady state,

$$\hat{S}_- = \imath\tilde{\eta} + \imath\frac{\kappa}{g}\hat{a} \ .$$

Hence, the second order-correlation depends on

$$\begin{aligned}
&\langle\hat{S}_+\hat{S}_+\hat{S}_-\hat{S}_-\rangle \\
&= \tfrac{1}{g^4}\left(\kappa^4\langle\hat{a}^\dagger\hat{a}^\dagger\hat{a}\hat{a}\rangle - 2\imath\eta\kappa^3\langle\hat{a}^\dagger\hat{a}\hat{a} - \hat{a}^\dagger\hat{a}^\dagger\hat{a}\rangle - \eta^2\kappa^2\langle\hat{a}^\dagger\hat{a}^\dagger - 4\hat{a}^\dagger\hat{a} + \hat{a}\hat{a}\rangle + 2\imath\eta^3\kappa\langle\hat{a}^\dagger - \hat{a}\rangle + \eta^4\right) \\
&= \tfrac{1}{g^4}\left(\eta^2 + 2\eta\kappa\mathfrak{Im}\,\alpha + \kappa^2|\alpha|^2\right)^2 \ .
\end{aligned}$$

We will see in the following, how the interplay between coherent pumping η and collective decay κ_c leads to spin squeezing [569]. In Exc. 46.4.4.3 we study the mean field approximation of the equations (46.184) and derive analytical formulas for the steady state. The solutions, which will be discussed in the following, are exhibited in Figs. 46.19.

The stable branches are those with positive slope, leaving two accessible branches a lower and an upper one. The lower branch corresponds to weak intracavity power and hence small inversion. Here, the normal mode splitting is so large that it inhibits the penetration of pump light into the cavity. The upper branch is characterized by high intracavity power and hence strong saturation generating an inversion approaching 50%. According to [569] states located in the upper branch of the bistable regime are CRSSs, states located in the lower branch are CSSs. This can be understood in the light of Fig. 46.23: The state close to 50% inversion is exposed to strong superradiant decay, in contrast to the state close to 0% inversion dominated by spontaneous emission.

46.5.3 Exercises

46.5.3.1 Ex: Coherently radiating spin states (CRSS)

a. Search for general states satisfying,

$$\hat{S}_-|S,\alpha\rangle = \alpha|S,\alpha\rangle \qquad \text{with} \qquad \alpha \equiv Se^{-\imath\varphi}\sin\vartheta \ .$$

Proceed by inserting the ansatz

$$|S,\alpha\rangle_{\text{ans}} = \sum_{M=-S}^{M_+} a_M|S,M\rangle \ .$$

b. Compare with the CSS obtained by letting $M_+ \to S$.
c. Calculate the uncertainties for a CSS.
d. Calculate the uncertainties for a CRSS.

46.5.3.2 Ex: Light and spin squeezing in the CSS and the CRSS

a. Derive the Heisenberg uncertainty relations for the electric field operators $\hat{a}_\varphi$ and $\hat{a}_{\varphi-\pi/2}$ defined in Eq. (24.201) and for the collective spin operators $\hat{S}_\varphi$ and $\hat{S}_{\varphi-\pi/2}$ defined in Eq. (46.40).
b. Assuming that field and collective spin operators are connected via $\hat{a}(t) = \hat{a}_0(t) + G\hat{S}_+(t)$ where $G \in \mathbb{C}$, derive the condition for $\langle\hat{S}_z\rangle$ to obtain light squeezing.

46.6 Three-level atoms in a cavity

Inclusion of a third atomic level considerably enriches the possibilities of controlling the collective interaction of atoms and cavities, in particular, when the collective synchronization of atomic dipole moments is done on a different transition as the clock/interferometry transition. In this section, we study a collection of three-level atoms $|1\rangle$-$|2\rangle$-$|3\rangle$ in cascade configuration, as illustrated in Fig. 46.28(a). The atoms interact with a linear cavity tuned quasi-resonant to the upper $|2\rangle$-$|3\rangle$ transition. In certain regimes controlled by parameters of the upper transitions, we observe excitation blockade on the lower transition, similar to what is observed in dense clouds of Rydberg atoms. With respect to Rydberg blockade systems this has the advantage of generating uniform coupling between all atoms located in the mode volume of the cavity [992, 356, 658, 867, 455]. In other parameter regimes the dispersive interaction of the cavity field with the $|2\rangle$-$|3\rangle$ transition can induce quantum correlations such as spin-squeezing on the $|1\rangle$-$|2\rangle$ transition.

Based on the open Tavis-Cummings model for N three-level atoms, we set up in Sec. 46.6.1 the full master equation expanding the transition operators on the product state basis $|\psi\rangle = \bigotimes_{j=1}^{N}(a_j|1\rangle_j + b_j|2\rangle_j + c_j|3\rangle_j)$. In particular, we will numerically study a simple toy model with two atoms interacting via a cavity field, which predicts cavity-mediated blockade effects. Then we gradually simplify the model in order to obtain numerically tractable formulas. In Sec. 46.6.2 we adiabatically eliminate the excited state $|3\rangle$ and rewrite the equations of motion in a two-level spin notation. At the hand of the toy model, we will compare numerical simulations within the simplified

and the full model. In Sec. 46.6.3, supposing uniform coupling of the atoms to the light, we once more rewrite the equations of motion in a collective spin formalism suited for representing the coupled atom-cavity system expanding the spin operators on the Dicke state basis, $|\psi\rangle = |S, M\rangle$, which suits well for larger ensembles of up to 50 atoms. In particular, within the Dicke model we will discuss the occurrence of spin-squeezing. In Sec. 46.6.4 we adiabatically eliminate the cavity field and linearize the Heisenberg equations for small collective coupling. Finally, in Sec. 46.6.5 we neglect higher-order correlations for the case of many atoms to study one-axis twisting and the emergence of phases and instabilities using the mean-field approximation and calculating second-order moments [632, 234].

46.6.1 Open Tavis-Cummings model for the three-level system

The basic idea consists in a sequence of pulse radiation fields to the three-level system exhibited in Fig. 46.28(a) [25]. The lower transition $|1\rangle$-$|2\rangle$, assumed to be forbidden, is driven by $\pi/2$ classical light pulses. The upper transition $|2\rangle$-$|3\rangle$ is driven far from resonance by the light field stored in a laser-pumped optical cavity operated in the bad-cavity limit. As illustrated in Fig. 46.28(b), the pump laser frequency is tuned to the edge of the cavity's transmission profile. Now, only atoms which are excited from the ground state the state $|2\rangle$ will interact with the cavity, thus modifying its resonance frequency, and changing the effective pump rate. This in turn modifies the light shift of level $|2\rangle$ induced by the intra-cavity light and the effective Rabi frequency at which other atoms can be excited from the ground state. See Exc. 46.6.6.1.

In the following, we will show how this cavity-mediated feedback may lead to non-linear dynamics reminiscent to Rydberg blockade and to spin-squeezing.

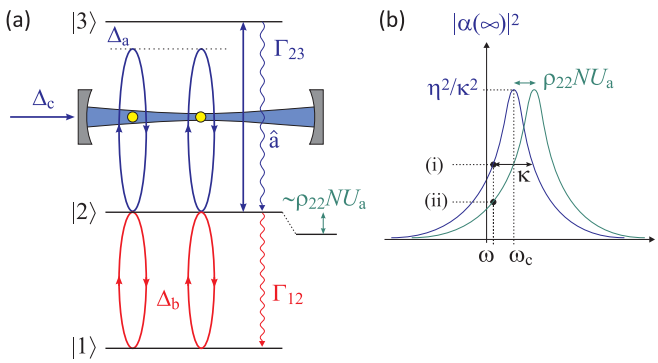

Figure 46.28: (a) Level scheme and driven transitions. For the sake of concreteness, one might consider the strontium level scheme $|1\rangle \equiv {}^1S_0$, $|2\rangle \equiv (5s5p)^3P_1$, and $|3\rangle \equiv (5s6s)^3S_1$ with the respective transition wavelength $\lambda_{12} = 689\,\text{nm}$ and $\lambda_{23} = 688\,\text{nm}$ and the decay widths $\Gamma_{12}/2\pi = 7.6\,\text{kHz}$ and $\Gamma_{23}/2\pi = 4\,\text{MHz}$. (b) Stationary cavity field intensity as a function of the population $\sum_j \text{Tr}\,\hat{\rho}\sigma_j^{22}$ of level $|2\rangle$.

The light field driving the lower transition is treated classically, i.e. $[\hat{a}, \hat{\rho}] = 0$,

[25] Alternatively, we may consider a V-shaped level configuration with two narrow transitions and $|2\rangle \equiv {}^1S_0$, $|1\rangle \equiv (5s5p)^3P_0$, and $|3\rangle \equiv (5s5p)^3P_1$. Since $\Gamma_{12} \simeq 0$ the energetic order of levels $|1\rangle$ and $|2\rangle$ doesn't matter.

while the cavity mode $\hat{a}$ is treated *either as classical or quantum.* The atoms are denoted by lower indices, their internal excitations by upper indices,

$$\begin{aligned} \hat{\sigma}_1^{mn} &\equiv |m\rangle\langle n| \otimes \mathbb{I}_3 \otimes \mathbb{I}_3 \otimes \dots \ , \\ \hat{\sigma}_2^{mn} &\equiv \mathbb{I}_3 \otimes |m\rangle\langle n| \otimes \mathbb{I}_3 \otimes \dots \ , \end{aligned} \tag{46.247}$$

etc.. Assuming a sufficiently dilute sample we may disregard dipole-dipole interactions. The Hamiltonian is then ($\hbar = 1$),

$$\boxed{\begin{aligned} \hat{H} &= \hat{H}_{\text{cav}} + \textstyle\sum_{j=1}^N \hat{H}_j \qquad \text{with} \\ \hat{H}_{\text{cav}} &= -\imath\eta(\hat{a} - \hat{a}^\dagger) - \Delta_{\text{c}}\hat{a}^\dagger\hat{a} \\ \hat{H}_j &= -\Delta_{\text{b}}\hat{\sigma}_j^{22} + \tfrac{\Omega_{\text{b}}}{2}(\hat{\sigma}_j^{12} + \hat{\sigma}_j^{21}) + g(z_j)(\hat{a}^\dagger\hat{\sigma}_j^{23} + \hat{\sigma}_j^{32}\hat{a}) - \Delta_{\text{a}}\hat{\sigma}_j^{33} \end{aligned}} \tag{46.248}$$

where Ω_{b} is the Rabi frequency on the lower transition $|1\rangle$-$|2\rangle$ and Δ_{b} the detuning from resonance of the laser driving this transition, Δ_{a} is the detuning of the laser driving the upper transition $|2\rangle$-$|3\rangle$, Δ_{c} the detuning of the latter laser from the resonance frequency of the cavity, η the pump rate of the cavity, and $g(\mathbf{r}_j) = g\cos kz_j$ (assuming for one-dimensionality for simplicity) the atom-cavity coupling strength or single-photon Rabi frequency generated on the upper transition, which depends on the atomic positions.

As indicated in (46.94), the time evolution is governed by a master equation for the density operator $\hat{\rho}$, or by Heisenberg equations for particular degrees of freedom $\hat{A}$, or by combinations of both. Incoherent processes are described by jump operators $\hat{L}$ and their corresponding rates γ. In our simulations we consider spontaneous emission occurring via the processes $\hat{L} = \hat{\sigma}_{12}$ and $\hat{L} = \hat{\sigma}_{23}$ with the respective decay rates $\gamma = \frac{1}{2}\Gamma_{12}$ and $\gamma = \frac{1}{2}\Gamma_{23}$. Assuming $\Gamma_{23} \gg \Gamma_{12} \gg \Gamma_{13} \simeq 0$, we may disregard the decay rate Γ_{13}. Incoherent optical pumping from lower to higher levels, for instance the one described by $\hat{L} = \hat{\sigma}_{31}$ occurring at a rate $\gamma = \xi_{31}$, may also be included. Finally, the cavity field decays as $\hat{L} = \hat{a}$ at a rate $\gamma = \kappa$. On the other hand, we disregard phase fluctuations of the cavity field and of the atomic dipole moments.

The dynamics ruled by the Hamiltonian (46.248) and the decay terms compiled using the expressions (46.94) is conveniently simulated using the QuantumOptics.jl framework for the JULIA language. To do so, we construct the density operator for the atoms only using the tensor products (46.247), which evolves according to a master equation, and derive a separate Heisenberg equation for the light field [517],

$$\boxed{\begin{aligned} \frac{d}{dt}\hat{a} &= \imath[\hat{H}, \hat{a}] + \mathfrak{L}_\kappa^\dagger\hat{a} = (\imath\Delta_{\text{c}} - \kappa)\hat{a} + \eta - \imath\sum_{j=1}^N g(z_j)\hat{\sigma}_j^{23} \\ \frac{d}{dt}\hat{\rho} &= \imath[\hat{\rho}, \hat{H}] + \mathfrak{L}_{\Gamma_{12}/2}\hat{\rho} + \mathfrak{L}_{\Gamma_{23}/2}\hat{\rho} + \mathfrak{L}_{\xi_{12}}\hat{\rho} + \mathfrak{L}_{\xi_{23}}\hat{\rho} \end{aligned}} \ . \tag{46.249}$$

$\hat{\rho}$ is the density operator for the internal atomic states and represented by a $3N \times 3N$ matrix,

$$\hat{\rho} = \sum_{m,n} |m\rangle\langle n| \otimes \sum_{m,n} |m\rangle\langle n| = \sum_{m,n} \hat{\sigma}_1^{mn} \sum_{m,n} \hat{\sigma}_2^{mn} \ . \tag{46.250}$$

46.6.1.1 Mean-field approximation

To simplify the code for the three-level equations of motion (46.249) when using the MATLAB software, we treat the light field as classical. That is, we take the expectation value of Eq. (46.249)(i),

$$\frac{d}{dt}\alpha = (\imath\Delta_{\rm c} - \kappa)\alpha + \eta - \imath\sum_{j=1}^{N} g(z_j)\mathrm{Tr}\,\hat{\rho}\hat{\sigma}_j^{23} \tag{46.251}$$

$$\begin{aligned}\frac{d}{dt}\hat{\rho} = &\sum_{j=1}^{N}\imath\Delta_{\rm b}[\hat{\sigma}_j^{22},\hat{\rho}] - \tfrac{\imath}{2}\Omega_{\rm b}[\hat{\sigma}_j^{12}+\hat{\sigma}_j^{21},\hat{\rho}] + \imath\Delta_{\rm a}[\hat{\sigma}_j^{33},\hat{\rho}] - \imath g(z_j)[\alpha^*\hat{\sigma}_j^{23}+\alpha\hat{\sigma}_j^{32},\hat{\rho}]\\ &+ \mathfrak{L}_{\Gamma_{12}/2}\hat{\rho} + \mathfrak{L}_{\Gamma_{23}/2}\hat{\rho}\ ,\end{aligned}$$

where we now disregard optical pumping terms $\mathfrak{L}_{\xi_{12}}\hat{\rho}$ and $\mathfrak{L}_{\xi_{23}}\hat{\rho}$. Initially, we may assume that both atoms are in their ground states, i.e.,

$$\hat{\rho}(0) = |1\rangle\langle 1|\otimes|1\rangle\langle 1| = \begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}\otimes\begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}\ , \tag{46.252}$$

and that the cavity field is that of a resonantly pumped empty cavity,

$$\alpha(0) = \frac{\eta}{\kappa}\ . \tag{46.253}$$

The populations of the atomic excitation states are extracted from $\hat{\rho}(t)$ via,

$$\rho_j^{nn}(t) = \mathrm{Tr}\ \hat{\rho}(t)\hat{\sigma}_j^{nn}\ , \tag{46.254}$$

using the operators defined in (46.247).

46.6.2 Adiabatic elimination of excited state

As already mentioned, we assume that the upper transition is driven far from resonance. This allows us to adiabatically eliminate the excited state from the description, which considerably simplifies the model,

$$|\Delta_{\rm a}| \gg \Gamma_{23}, |\alpha|g\ . \tag{46.255}$$

We also disregard optical pumping, $\xi_{mn} = 0$. Then, $\rho_{33} \simeq 0$, and we may adiabatically eliminate state $|3\rangle$. To this end, we derive the Heisenberg equation for $\hat{\sigma}_j^{23}$ from the Hamiltonian (46.248) and set,

$$\begin{aligned}0 \simeq \frac{d}{dt}\hat{\sigma}_j^{23} &= \imath[\hat{H},\hat{\sigma}_j^{23}] + \mathfrak{L}_{\Gamma_{23}/2,\hat{\sigma}_j^{23}}\hat{\sigma}_j^{23}\\ &= (\imath\Delta_{\rm a} - \imath\Delta_{\rm b} - \tfrac{\Gamma_{23}}{2})\hat{\sigma}_j^{23} + \tfrac{\imath\Omega_{\rm b}}{2}\hat{\sigma}_j^{13} + \imath g(\hat{\sigma}_j^{33}-\hat{\sigma}_j^{22})\hat{a}\\ &\simeq (\imath\Delta_{\rm a} - \imath\Delta_{\rm b} - \tfrac{\Gamma_{23}}{2})\hat{\sigma}_j^{23} - \imath g\hat{\sigma}_j^{22}\hat{a}\ ,\end{aligned} \tag{46.256}$$

where in the last step we neglected $\hat{\sigma}_j^{13} = 0 = \hat{\sigma}_j^{33}$. Hence,

$$\hat{\sigma}_j^{23} = \hat{\sigma}_j^{22}\frac{g\hat{a}}{\Delta_{\rm a} - \Delta_{\rm b} + \frac{\imath}{2}\Gamma_{23}}\ . \tag{46.257}$$

Inserting this in the Hamiltonian (46.248) we get,

$$\hat{H} = \hat{H}_{\rm cav} + \sum_{j=1}^{N} [\tfrac{\Omega_{\rm b}}{2}(\hat{\sigma}_j^{12} + \hat{\sigma}_j^{21}) + 2U_{\rm a}\hat{a}^\dagger\hat{\sigma}_j^{22}\hat{a} - \Delta_{\rm b}\hat{\sigma}_j^{22}] \tag{46.258}$$

with the abbreviation,

$$U_{\rm a} \equiv \frac{g^2(\Delta_{\rm a} - \Delta_{\rm b})}{(\Delta_{\rm a} - \Delta_{\rm b})^2 + \frac{1}{4}\Gamma_{23}^2} \simeq \frac{g^2}{\Delta_{\rm a}} \ , \tag{46.259}$$

where we assume $|\Delta_{\rm a}| \gg |\Delta_{\rm b}|$. As the excited state $|3\rangle$ does not appear in the Hamiltonian any more, we may as well use the spin notation,

$$\hat{H} = \hat{H}_{\rm cav} + \sum_{j=1}^{N} \left[\tfrac{\Omega_{\rm b}}{2}(\hat{s}_j^- + \hat{s}_j^+) + 2U_{\rm a}(z_j)\hat{a}^\dagger(\hat{s}_j^z + \tfrac{1}{2}\mathbb{I})\hat{a} - \Delta_{\rm b}(\hat{s}_j^z + \tfrac{1}{2}\mathbb{I})\right] \ . \tag{46.260}$$

From this Hamiltonian we can derive new approximate equations of motion for an effective two-level system,

$$\begin{aligned} \frac{d}{dt}\hat{a} &= \imath[\hat{H}, \hat{a}] - \kappa\hat{a} = (\imath\Delta_{\rm c} - \kappa)\hat{a} + \eta - 2\imath\sum_{j=1}^{N} U_{\rm a}(z_j)(\hat{s}_j^z + \tfrac{1}{2}\mathbb{I})\hat{a} \\ \frac{d}{dt}\hat{\rho} &= \imath[\hat{\rho}, \hat{H}] + \mathfrak{L}_{\Gamma_{12}/2}\hat{\rho} \end{aligned} \ . \tag{46.261}$$

The density operator $\hat{\rho}$ for the internal atomic states is now represented by a $2N \times 2N$ matrix.

46.6.2.1 Mean-field approximation

In analogy to the three-level case, to simplify the code for the two-level equations of motion (46.261) when using the MATLAB software, we treat the light field as classical. That is, we take the expectation value of Eq. (46.261)(i), and obtain,

$$\begin{aligned} \frac{d}{dt}\alpha &= (\imath\Delta_{\rm c} - \kappa)\alpha + \eta - 2\imath\sum_{j=1}^{N} U_{\rm a}(z_j)\alpha(\mathrm{Tr}\,\hat{\rho}\hat{s}_j^z + \tfrac{1}{2}) \\ \frac{d}{dt}\hat{\rho} &= \sum_{j=1}^{N} -\tfrac{\imath}{2}\Omega_{\rm b}[\hat{s}_j^- + \hat{s}_j^+, \hat{\rho}][\imath\Delta_{\rm b} - 2\imath|\alpha|^2 U_{\rm a}(z_j)][\hat{s}_j^z, \hat{\rho}] + \mathfrak{L}_{\Gamma_{12}/2}\hat{\rho} \ . \end{aligned} \tag{46.262}$$

Again, the populations of the atomic excitation states are extracted from $\hat{\rho}(t)$ as shown in Eq. (46.254).

46.6.2.2 Cavity at steady-state

The elimination of the dynamic variable $\hat{a}$ allows to convert the master equation (46.262)(ii) into a Liouville equation, which is much easier to solve. If κ dominates all time scales, $\dot{\alpha} \simeq 0$ and,

$$\alpha = \frac{\eta}{\imath\Delta_{\mathrm{c}} - \kappa + \eta - 2\imath \sum_{j=1}^{N} U_{\mathrm{a}}(z_j)\alpha(\mathrm{Tr}\,\hat{\rho}\hat{s}_j^z + \frac{1}{2})} \ . \tag{46.263}$$

Example 342 (*Two-atoms toy model, cavity blockade and anti-blockade*): We consider a toy model consisting of only two three-level atoms coupled to a single classical light mode, $\hat{a} \to \alpha$. We perform numerical simulations with the QuantumOptics.jl framework for the JULIA language or with the MATLAB software for (i) the full model (46.251) an compare the results with approximations consisting in (ii) the adiabatic elimination of the excited state [see (46.262)], and (iii) the adiabatic elimination of the cavity field [see (46.263)].
We choose a good parameter regime according to the following criteria. For the system illustrated in Fig. 46.28,

1. we choose $\Omega_{\mathrm{b}} \gg \Gamma_{12}$, in order not to be affected by spontaneous emission on the $|1\rangle$-$|2\rangle$ transition;
2. the cavity should adiabatically follow the internal dynamics, $\kappa \gg \Omega_{\mathrm{b}}$;
3. we avoid population of level $|3\rangle$ by choosing large detuning $|\Delta_{\mathrm{a}}| \gg \Gamma_{12}, \Gamma_{23}, \Omega_{\mathrm{b}}$;
4. to reach small signal behavior, we set the laser driving the cavity to the halfwidth of the cavity resonance $\Delta_{\mathrm{c}} = \pm\kappa$;
5. we aim at a reasonably but not too strong light shift due to the presence of a single atom, i.e.,
$$\frac{|\alpha|\,|U_{\mathrm{a}}|}{\kappa} = |\alpha|^2 \frac{g^2}{|\Delta_{\mathrm{a}}|\kappa} \lesssim 1 \ ,$$
which, together with the condition (2) implies, $g \gg \kappa$; and
6. in order to satisfy the last condition, we then need,
$$|\alpha|^2 \lesssim \frac{|\Delta_{\mathrm{a}}|\kappa}{g^2} \ ,$$
which we can achieve with $\eta = \kappa$;
7. the only free parameter left is the detuning of the laser on the lower transition, which we want to set to resonance to the Stark-shifted transition, such that the Rabi oscillations reach maximum amplitude, but without the light shift from the cavity,
$$\Delta_{\mathrm{b}} = \frac{\eta^2 U_{\mathrm{a}}}{2\kappa^2} = \frac{\eta^2 g^2}{2\kappa^2|\Delta_{\mathrm{a}}|} = \frac{25\kappa}{72} \ .$$

With these settings, we compare time evolutions simulated via (i) the set of equations (46.265) based on the full three-level Hamiltonian (46.248), (ii) the reduced Hamiltonian (46.259), and (iii) the Hamiltonian (46.269) where the cavity field has been eliminated. The operators appearing in the respective equations are generated by the prescriptions (46.247). For the chosen parameters all simulations are in perfect agreement, as seen in Fig. 46.29. Fig. 46.29

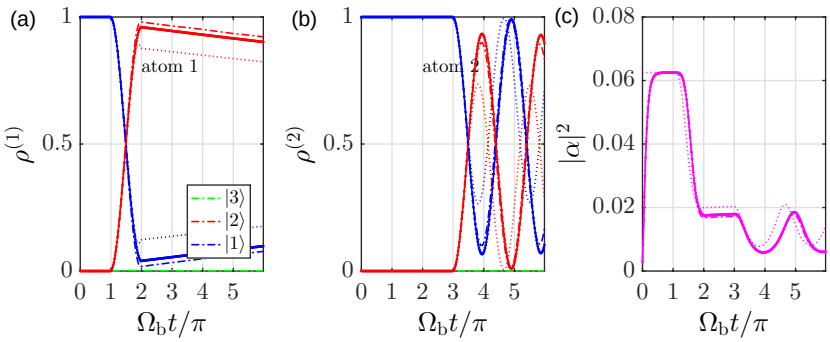

Figure 46.29: (code) Cavity blockade in a two-atom toy model. Panel (a) shows the populations of the first atom, panel (b) of the second atom and panel (c) of the cavity mode. Blue curves denote the population of level $|1\rangle$, red curves of level $|2\rangle$, and green curves of level $|3\rangle$. At time $\Omega_b t = \pi$ atom 1 is excited to level $|2\rangle$ via a π-pulse, and from time $\Omega_b t = 3\pi$ on, atom 2 is continuously excited. The parameters are scaled to Γ_{12} and $\zeta = 0.5$. Dash-dotted lines denote simulations based on Eqs. (46.251). Solid lines are obtained using Eqs. (46.262). Dashed lines are obtained using Eqs. (46.262), but with the cavity field assumed in steady-state according to Eq. (46.263). Dotted lines are obtained using Heisenberg equation derived from the Hamiltonian for (46.260) for α and $\rho_{mn} = \langle \hat{\sigma}^{mn} \rangle$.

shows an interesting behavior. Apparently, the excitation of a first atom to level $|2\rangle$ is able to influence the subsequent excitation of a second one, since the maximum inversion reached for the second atom is lower than 1. This behavior is reminiscent to the phenomenon of spin-blockade mostly studied in ensembles of Rydberg atoms. For much larger coupling strengths g the blockade becomes dramatic, as demonstrated in Fig. 46.29. However, the approximations start to fail, so that in Fig. 46.29 we only show a simulation based on the full equations (46.265).

Interestingly, a blockade may be observed even in the limit that the light field is treated as classical [26].

$$
\begin{aligned}
\Gamma_{12} &= (2\pi)\ 7.5\,\mathrm{kHz} & U_a &= g^2/\Delta_a = 1.7\kappa \\
\Gamma_{23} &= 50\Gamma_{12} & \Omega_a &= 22.5\Gamma_{23} \\
\kappa &= 750\Gamma_{12} & \zeta_0 &= 2\eta^2 U_a/\kappa^2 = 0.21\kappa \\
\eta &= 0.25\kappa & \zeta_1 &= 4\eta^2 U_a^3/\kappa^3 = 0.72\kappa \\
\Delta_c &= 0 & \Upsilon &= 4g^2/\kappa\Gamma_{12} \quad . \\
\Delta_b &= U_a\eta^2/\kappa^2 = 1.7\kappa \\
\Delta_a &= 15\kappa \\
g &= 5\kappa \\
\Omega_b &= 200\Gamma_{12}
\end{aligned}
$$

[26] Note that the parameters are not realistic, since,

$$g = \sqrt{\frac{6\Gamma_{23}\delta_{fsr}}{k^2 w^2}} = 5\kappa \Longrightarrow \delta_{fsr} = 825\,\mathrm{THz} \ .$$

On the other hand, with 10^5 atoms, $\delta_{fsr} = 8.25\,\mathrm{GHz}$.

46.6.3 Open Dicke model for the two-level system

For very few atoms the equations of motion derived for the open Tavis-Cummings model [908] Eqs. (46.249) or (46.261) can be solved numerically. However, for the simulation of more (several tens of) atoms, the model becomes increasingly impracticable, as the dimension of the Hilbert space scales with 3^N for a three-level system and 2^N for a two-level system. In this case, the Dicke model is useful as the Hilbert space only scales as $N+1$. The expression in terms of collective operators $\hat{S}_{mn}$ allows us to use the usual Dicke state formalism [256]. We just need to represent them in a Dicke basis. The downside of the Dicke model is, that the atoms *loose their individuality* with respect to the driving light field, i.e. they cannot be addressed one by one any more.

Neglecting $\hat{\sigma}_j^{33} = 0$ and assuming uniform coupling, $g(z_j) = g$, we may introduce collective spin operators,

$$\begin{aligned} \hat{S}_{m\neq n} &= \sum_j \hat{\sigma}_j^{m\neq n} \quad , \quad \hat{S}_{nn} = \tfrac{1}{2}\sum_j \hat{\sigma}_j^{nn} \\ \hat{S}_z &\equiv \hat{S}_{22} - \hat{S}_{11} \quad , \quad \tfrac{N}{2} = \hat{S}_{22} + \hat{S}_{11} \quad , \quad \hat{S}_- = \hat{S}_{12} \ , \end{aligned} \tag{46.264}$$

helping us to simplify the Hamiltonian (46.260),

$$\hat{H} = \hat{H}_{\text{cav}} + \Omega_{\text{b}}\hat{S}_x + 2U_{\text{a}}\hat{a}^\dagger(\hat{S}_z + \tfrac{N}{2}\mathbb{I})\hat{a} - \Delta_{\text{b}}(\hat{S}_z + \tfrac{N}{2}\mathbb{I}) \ . \tag{46.265}$$

From this Hamiltonian we can derive Heisenberg equations [517],

$$\frac{d}{dt}\hat{A} = -\imath[\hat{A}, \hat{H}] + \mathfrak{L}^\dagger_{\kappa,\hat{a}}\hat{A} + \mathfrak{L}^\dagger_{\Gamma_{12}/2,\hat{\sigma}_j^{12}}\hat{A} + \mathfrak{L}^\dagger_{\Gamma_{23}/2,\hat{\sigma}_j^{23}}\hat{A} \ , \tag{46.266}$$

for all observables $\hat{A} \equiv \hat{a}$ and $\hat{S}_{x,y,z}$,

$$\boxed{\begin{aligned} \left(\frac{d}{dt} + \kappa\right)\hat{a} &= \imath(\Delta_{\text{c}} - 2U_{\text{a}}\hat{S}_z - NU_{\text{a}})\hat{a} + \eta \\ \left(\frac{d}{dt} + \tfrac{1}{2}\Gamma_{12}\right)\hat{S}_x &= \Delta_{\text{b}}\hat{S}_y - 2U_{\text{a}}\hat{a}^\dagger\hat{S}_y\hat{a} \\ \left(\frac{d}{dt} + \tfrac{1}{2}\Gamma_{12}\right)\hat{S}_y &= -\Delta_{\text{b}}\hat{S}_x + 2U_{\text{a}}\hat{a}^\dagger\hat{S}_x\hat{a} - \Omega_{\text{b}}\hat{S}_z \\ \tfrac{N}{2}\Gamma_{12} + \left(\frac{d}{dt} + \Gamma_{12}\right)\hat{S}_z &= \Omega_{\text{b}}\hat{S}_y \end{aligned}} \ . \tag{46.267}$$

The quantity $(N + 2\hat{S}_z)U_{\text{a}}$ represents the frequency shift of the cavity resonance due to the refractive index change generated by presence in the mode volume of atoms in their internal state $|2\rangle$.

46.6.4 Cavity at steady-state and small signal approximation

Now, assuming that the cavity field quickly adjusts to the atomic dynamics we may eliminate the cavity field from the equations of motion. Assuming the cavity in

steady-state $\dot{\hat{a}} = 0$, we get from (46.267)(i),

$$\boxed{\hat{a} = (\kappa - \imath\Delta_{\rm c} + \imath N U_{\rm a} + 2\imath U_{\rm a}\hat{S}_z)^{-1}\eta} \ . \tag{46.268}$$

The equations (46.267)(i,iii) include non-linear terms $\hat{a}^\dagger \hat{S}_{x,y}\hat{a}$. Now, let us assume $\langle \hat{S}_z \rangle \simeq 0$ and expand the field operator (46.268) for *small deviations*,

$$\hat{a} \simeq \frac{1}{\kappa + \imath N U_{\rm a} - \imath\Delta_{\rm c}} + \frac{2U_{\rm a}}{(\kappa + \imath N U_{\rm a} - \imath\Delta_{\rm c})^2}\hat{S}_z + ... = \alpha + \delta\hat{a} \ . \tag{46.269}$$

With this we find up to first order,

$$\hat{a}^\dagger \hat{S}_{x,y}\hat{a} = \eta^2 \left(\kappa - \imath N U_{\rm a} + \imath\Delta_{\rm c} - 2\imath U_{\rm a}\hat{S}_z\right)^{-1} \hat{S}_{x,y} \left(\kappa + \imath N U_{\rm a} - \imath\Delta_{\rm c} + 2\imath U_{\rm a}\hat{S}_z\right)^{-1} \tag{46.270}$$

$$\simeq \frac{\eta^2 \hat{S}_{x,y}}{\kappa^2 + (NU_{\rm a} - \Delta_{\rm c})^2} + \frac{2\eta^2 U_{\rm a}}{\kappa^2 + (NU_{\rm a} - \Delta_{\rm c})^2}\left(\frac{\hat{S}_z\hat{S}_{x,y}}{\kappa - \imath N U_{\rm a} + \imath\Delta_{\rm c}} + \frac{\hat{S}_{x,y}\hat{S}_z}{\kappa + \imath N U_{\rm a} - \imath\Delta_{\rm c}}\right) \ .$$

Setting the cavity on the light-shifted resonance, $\Delta_{\rm c} = NU_{\rm a}$, we find,

$$2U_{\rm a}\hat{a}^\dagger \hat{S}_{x,y}\hat{a} \simeq \zeta_0 \hat{S}_{x,y} + \zeta_1\{\hat{S}_{x,y}, \hat{S}_z\} \ , \tag{46.271}$$

defining

$$\zeta_0 \equiv \frac{2\eta^2 U_{\rm a}}{\kappa^2} \qquad \text{and} \qquad \zeta_1 = \frac{4\eta^2 U_{\rm a}^2}{\kappa^3} \ , \tag{46.272}$$

where ζ_1 is called the squeezing parameter. Terms like (46.271) can be derived from a Hamiltonian, $\hat{H}_\zeta = \zeta_0\hat{S}_z + \zeta_1\hat{S}_z^2$. That is, the Hamiltonian where the cavity field is adiabatically eliminated is approximated by,

$$\hat{H} = \Omega_{\rm b}\hat{S}_x + (\zeta_0 - \Delta_{\rm b})\hat{S}_z + \zeta_1\hat{S}_z^2 \qquad \text{for} \qquad \Delta_{\rm c} = NU_{\rm a} \ . \tag{46.273}$$

with the corresponding equations of motion,

$$\boxed{\begin{aligned} \left(\frac{d}{dt} + \frac{\Gamma_{12}}{2}\right)\hat{S}_x &= (\Delta_{\rm b} - \zeta_0)\hat{S}_y - \zeta_1\{\hat{S}_y, \hat{S}_z\} \\ \left(\frac{d}{dt} + \frac{\Gamma_{12}}{2}\right)\hat{S}_y &= -(\Delta_{\rm b} - \zeta_0)\hat{S}_x + \zeta_1\{\hat{S}_x, \hat{S}_z\} - \Omega_{\rm b}\hat{S}_z \\ \tfrac{N}{2}\Gamma_{12} + \left(\frac{d}{dt} + \Gamma_{12}\right)\hat{S}_z &= \Omega_{\rm b}\hat{S}_y \end{aligned}} \ . \tag{46.274}$$

The quadratic term in the Hamiltonian (46.273) has been shown in Sec. 46.1.4 and Exc. 46.1.8.13 to induce one-axis twisting and spin-squeezing. It is also reminiscent to the Rydberg interaction Hamiltonian (46.128) [787, 877]. We may hence expect similar phenomena, such as the emergence of an excitation blockade.

Another interesting regime might be $\Delta_{\rm c} - NU_{\rm a} = \pm\kappa$. We derive the corresponding Hamiltonian in Exc. 46.6.6.2.

46.6.4.1 Mean-field approximation

Note, that if the light field were classical, the non-linear term $|\alpha|^2\hat{S}_{x,y}$ would not lead to quantum correlations, because the equations of motion could then be derived from a Hamiltonian, which is linear in the collective spin components. From (46.265) we get,

$$\sum_j \hat{H}_j = \Omega_\mathrm{b}\hat{S}_x + (2U_\mathrm{a}|\alpha|^2 - \Delta_\mathrm{b})(\hat{S}_z + \tfrac{N}{2}) \ . \tag{46.275}$$

In analogy,

$$\begin{aligned}
\frac{d}{dt}\alpha &= (\imath\Delta_\mathrm{c} - \kappa)\alpha + \eta - \imath N U_\mathrm{a} - 2\imath U_\mathrm{a}\alpha\,\mathrm{Tr}\,\hat{\rho}\hat{S}_z \\
\frac{d}{dt}\hat{S}_x &= (\Delta_\mathrm{b} - 2\imath|\alpha|^2 U_\mathrm{a})\hat{S}_y - \tfrac{\Gamma_{12}}{2}\hat{S}_x \\
\frac{d}{dt}\hat{S}_y &= -(\Delta_\mathrm{b} - 2\imath|\alpha|^2 U_\mathrm{a})\hat{S}_x - \Omega_\mathrm{b}\hat{S}_z - \tfrac{\Gamma_{12}}{2}\hat{S}_y \\
\frac{d}{dt}\hat{S}_z &= \Omega_\mathrm{b}\hat{S}_y - \Gamma_{12}\hat{S}_z - \tfrac{N}{2}\Gamma_{12}\hat{S}_z \ .
\end{aligned} \tag{46.276}$$

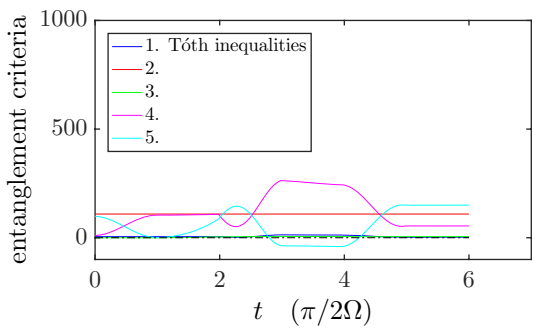

Figure 46.30: (code) Time evolution of the Tóth inequalities calculated from Heisenberg equations directly derived from the Hamiltonian Eq.(46.273).

Hence, for the adiabatically approximated two-level system, treating the light classically, we may set $\dot{\alpha} = 0$ in Eq. (46.267)(i) and obtain,

$$\alpha = \frac{\eta}{\kappa - \imath\Delta_\mathrm{c} + \imath N U_\mathrm{a} + 2\imath U_\mathrm{a}\mathrm{Tr}\,\hat{\rho}\hat{S}_z} \ . \tag{46.277}$$

This expression can replace Eq. (46.276)(i) in numerical simulations. For small deviations around $\Delta_\mathrm{c} = \pm\kappa$, we may linearize the steady-state solution by expanding $|\alpha|^2$ in $U_\mathrm{a}\mathrm{Tr}\,\hat{\rho}\hat{S}_{22}$,

$$|\alpha|^2 = \frac{\eta^2}{\kappa^2 + (\Delta_\mathrm{c} - U_\mathrm{a}\mathrm{Tr}\,\hat{\rho}\hat{S}_{22})^2} \simeq \frac{\eta^2}{\kappa^2 + \Delta_\mathrm{c}^2} + \frac{2\eta^2\Delta_\mathrm{c}}{(\kappa^2 + \Delta_\mathrm{c}^2)^2}U_\mathrm{a}\mathrm{Tr}\,\hat{\rho}\hat{S}_{22} \ , \tag{46.278}$$

and on resonance,

$$|\alpha|^2 = \frac{\eta^2}{2\kappa^2} \pm \frac{\eta^2}{2\kappa^3}U_\mathrm{a}\mathrm{Tr}\,\hat{\rho}\hat{S}_{22} = \frac{\eta_0}{4} \pm \frac{\eta_1}{8}U_\mathrm{a}\mathrm{Tr}\,\hat{\rho}\hat{S}_{22} \ . \tag{46.279}$$

With this the Hamiltonian (46.275) reads,

$$\sum_j \hat{H}_j = \Omega_\mathrm{b}\hat{S}_x + \left(\tfrac{\eta^2 U_\mathrm{a}}{2\kappa^2} - \Delta_\mathrm{b}\right)\hat{S}_{22} \pm \tfrac{\eta}{2}\hat{S}_{22}\mathrm{Tr}\,\hat{\rho}\hat{S}_{22}\ . \tag{46.280}$$

46.6.5 Cumulant expansion for many atoms, the role of cooperativity

To handle the case of many atoms (we have in mind $N = 10000$) under the premises of uniform coupling $[g(z_j) = g]$ we derive the equations of motion for the light field and all populations and coherences of the three-level system and treat them as c-numbers, which obviously discards the possibility of individual manipulations of the atoms. From the collective Hamiltonian for three levels,

$$\begin{aligned}\hat{H} &= \imath\eta(\hat{a} - \hat{a}^\dagger) - \Delta_\mathrm{c}\hat{a}^\dagger\hat{a} + \tfrac{\Omega_\mathrm{b}}{2}(\hat{S}_{12} + \hat{S}_{21}) - \Delta_\mathrm{b}\hat{S}_{22} \\ &\quad + g(\hat{a}^\dagger\hat{S}_{23} + \hat{S}_{32}\hat{a}) - \Delta_\mathrm{a}\hat{S}_{33}\end{aligned}\ , \tag{46.281}$$

as shown in Exc. 46.6.6.3, we derive the equations of motion from the Heisenberg equation,

$$\boxed{\begin{aligned}\frac{d}{dt}\hat{a} &= \imath[\hat{H}, \hat{a}] + \mathfrak{L}_\kappa^\dagger\hat{a} \\ \frac{d}{dt}\hat{S}_{mn} &= \imath[\hat{H}, \hat{S}_{mn}] + \mathfrak{L}_\Gamma^\dagger\hat{S}_{mn} + \mathfrak{L}_\gamma^\dagger\hat{\sigma}_j^{mn}\end{aligned}}\ . \tag{46.282}$$

The collective decay terms, if they existed would be given by,

$$\mathfrak{L}_\Gamma^\dagger\hat{S}_{mn} = \sum_\Gamma \Gamma\left(\hat{L}_\Gamma^\dagger[\hat{S}_{mn}, \hat{L}_\Gamma] + [\hat{L}_\Gamma^\dagger, \hat{S}_{mn}]\hat{L}_\Gamma\right)\ , \tag{46.283}$$

where Γ are possible collective decay channels and $\hat{L}_\Gamma$ the operators describing the decay. For example, the operator $\hat{L}_{\Gamma_{12}} \equiv \hat{S}_{12}$ describes collective spontaneous emission from $|2\rangle$ to $|1\rangle$. However, in the absence interatomic interaction, we do not expect collective spontaneous emission, so that we may set $\Gamma_{mn} = 0$. On the other hand, spontaneous emission leads to decay of individual atoms, here denoted by γ_{mn}. That is, we assume the decay rates are the same for all atoms and there is no interatomic correlation (that is, no super- or subradiance). The Lindblad expression for the decay terms is,

$$\mathfrak{L}_\gamma^\dagger\hat{\sigma}_j^{mn} = \sum_\gamma \gamma\left(\hat{L}_\gamma^\dagger[\hat{\sigma}_j^{mn}, \hat{L}_\gamma] + [\hat{L}_\gamma^\dagger, \hat{\sigma}_j^{mn}]\hat{L}_\gamma\right)\ . \tag{46.284}$$

46.6.5.1 Mean-field approximation

In lowest order we neglect all correlations and obtain for the expectation values,

$$\begin{aligned}\frac{d}{dt}\alpha &= (\imath\Delta_\mathrm{c} - \kappa)\alpha - \imath g\mathrm{Tr}\,\hat{\rho}\hat{S}_{23} - \eta \\ \frac{d}{dt}\vec{\rho} &= \mathcal{M}\vec{\rho}\ ,\end{aligned} \tag{46.285}$$

where $\vec{\rho}$ is Bloch vector of the three-level system and $\mathcal{M}$ the Liouvillean explicitly derived in Exc. 46.6.6.3.

Fig. 46.31 illustrates the spin blockade effect. When the atom number in linearly increased, under the influence of a constant excitation of the lower transition, the fraction of excited atoms first increases linearly, as well. But beyond a critical population of the level $|22\rangle$, the excitation remains constant. (Well, this is what I hoped to see, but it seems not that simple.)

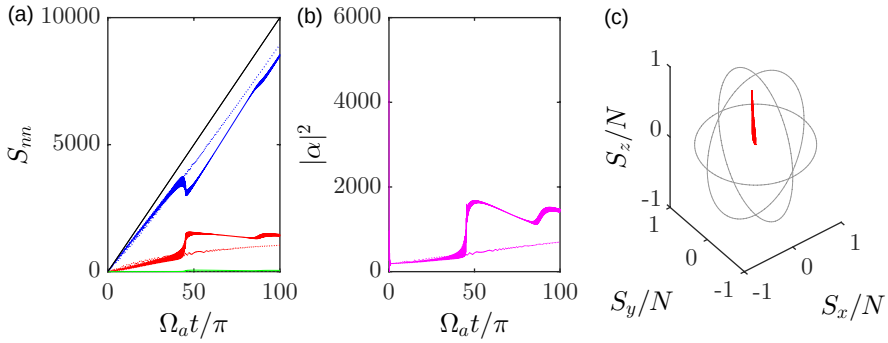

Figure 46.31: (code) Spin blockade in a large ensemble of three-level atoms. To illustrate the effect, the atom number is linearly increased from $N = 0$ to 10000. Panel (a) shows the time evolution of the populations $\langle S_{11}\rangle$ (blue), $\langle S_{22}\rangle$ (red) , and $\langle S_{33}\rangle$ (green) and panel (b) of the cavity field $|\alpha|^2$. Panel (c) visualizes the Bloch vector of the lower transition, $\left(\mathfrak{Re}\,\hat{S}_{12}\ ,\ \mathfrak{Im}\,\hat{S}_{12}\ ,\ \hat{S}_{22}-\hat{S}_{11}\right)$, in configuration space. Solid lines refer to full simulation of Eqs. (46.283), for the dotted lines the light field was assumed in steady state. Same parameters as in Fig. 46.29 except for $\Omega_{\rm b}/2\pi = 1\,$MHz, $g = 0.5\kappa$, $\eta = 70\kappa$, and $\Delta_{\rm c} = 5\kappa$.

46.6.5.2 One-axis twisting

Far from resonance, $|\Delta_{\rm a}| \gg U_{\rm a}$, the spin-spin interaction strength of (46.269) is approximated by,

$$\begin{aligned}\frac{\zeta}{\kappa} &= \frac{\eta^2}{\kappa^4}\frac{g^4\Delta_a^2}{(\Delta_{\rm a}^2+\gamma_{23}^2)^2} \simeq \frac{\eta^2}{\kappa^4}\frac{g^4\Delta_{\rm a}^2}{(\Delta_{\rm a}^2+\gamma_{23}^2)^2} \\ &< \frac{\eta^2}{\kappa^4}\frac{g^4}{4\gamma_{23}^2} = \frac{|\alpha_\infty|^2}{4}\Upsilon^2\ .\end{aligned} \tag{46.286}$$

Requesting that the cooperative cavity Lamb shift,

$$U_{\rm c} \equiv \frac{g^2\Delta_{\rm c}}{\Delta_c^2+\kappa^2}\ , \tag{46.287}$$

be larger than the decay rate γ_{23} of the driven atomic transition implies,

$$1 < \frac{NU_{\rm c}}{\gamma_{23}} = \frac{1}{\gamma_{23}}\frac{Ng^2\Delta_{\rm c}}{\Delta_{\rm c}^2+\kappa^2} < \frac{Ng^2}{2\kappa\gamma_{23}} = \frac{N\Upsilon}{2}\ . \tag{46.288}$$

That is, for this condition to be fulfilled is is sufficient to have strong 'collective' cooperativity,

$$\Upsilon_N \equiv N\Upsilon \ . \tag{46.289}$$

Let us now consider $N = 10^4$, which is the number of atoms we typically load into our ring cavity [779]. We call,

$$\gamma_{\rm c} \equiv \frac{g^2\kappa}{\Delta_{\rm c}^2 + \kappa^2} \tag{46.290}$$

the Purcell-enhanced atomic decay rate [422, 424].

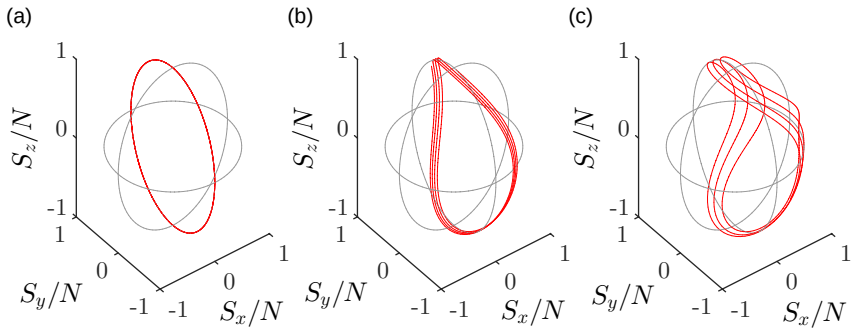

Figure 46.32: (code) One-axis twisting (inversion-dependent frequency shift) according to Eq. (??) with $N = 10000$ atoms and $\Omega_b/2\pi = 1\,\text{MHz}$ and $\Delta_{\rm b} = 0$. The squeezing parameter is (a) $N\zeta = 0$, (b) $N\zeta = 2\Omega_{\rm b}$, and (c) $N\zeta = 4\Omega_{\rm b}$.

46.6.6 Exercises

46.6.6.1 Ex: Two non-interacting three-level atoms in free space

Extend the two two-level atoms toy model of example 327 to two non-interacting three level atoms $|1\rangle$-$|2\rangle$-$|3\rangle$ in cascade configuration.
a. Write down the total Hamiltonian and its matrix representation chosing an appropriate basis.
b. Write down the Lindbladian and numerically solve the master equation.

46.6.6.2 Ex: Spin-squeezing Hamiltonian

Simplifying the expression (46.270) for $\Delta_{\rm c} - NU_{\rm a} = \pm\kappa$ derive the Hamiltonian and, if necessary the Lindbladian, generating the equations of motion (46.267).

46.6.6.3 Ex: Collective spin description for three levels

Derive a collective spin description for the three-level system interacting with a cavity.

Chapter 47

Quantum information science

47.1 Quantum correlations and entanglement

The concept of *entanglement* arose in quantum mechanics by Einstein, Podolski and Rosen's famous Gedankenexperiment, today called the *EPR paradox* [290]. In his Gedankenexperiment, Einstein tried to prove the necessity of hidden variables for quantum mechanics to be a complete theory. Consequently, we begin this chapter by introducing the notion of entangled particles and recapitulating the discussion of the EPR paradox.

Since Feynman discovered the utility of entangled states for quantum computation [721, 179], this area of research exploded with thousands of theoretical researchers, but few experiments, due to the enormous technical difficulties of creating and controlling these states. On the other side, states of entangled photons already play an important role in *quantum cryptography* [79]. And in the context of metrology, *spin-squeezed* correlated quantum states offer the possibility of quantum noise reduction in frequency standards [974].

Among the various systems proposed for the realization of entangled states and quantum computing gates we will only discuss one idea, which is based on the mutual coupling of atoms through a Jaynes-Cummings-like interaction mediated by an optical mode.

47.1.1 The EPR paradox and GHZ states

Let us imagine two maximally correlated particles produced by a suitable source, which fly freely without interaction in opposite directions along the y-axis toward two detectors a and b. The particles have an internal degree of freedom (spin) $|\pm\rangle_{a,b}$, which can be measured in various directions, for example, z or x by operators $\hat{\sigma}_z^{a,b}$ or $\hat{\sigma}_x^{a,b}$. Since the particles are completely entangled, the result of a measurement on the first particle $\hat{\sigma}_z^a$ allows the prediction of the result of another measurement $\hat{\sigma}_z^b$ performed on the second particle, and similarly for $\hat{\sigma}_x^a$ and $\hat{\sigma}_x^b$. Why is that?

The theory of *hidden variables* proposed by Einstein, Podolsky and Rosen [290] postulates, that the total state describing the two particles contains all information about the way, how the particles should behave at the detectors. The information was imprinted on each one of the two particle's when they were created in the source,

i.e. the total state must be of the type,

$$|\psi\rangle = \begin{pmatrix} \pm_z^a & \pm_z^b \\ \pm_x^a & \pm_x^b \end{pmatrix} , \tag{47.1}$$

where the notation should be read as a decision table.

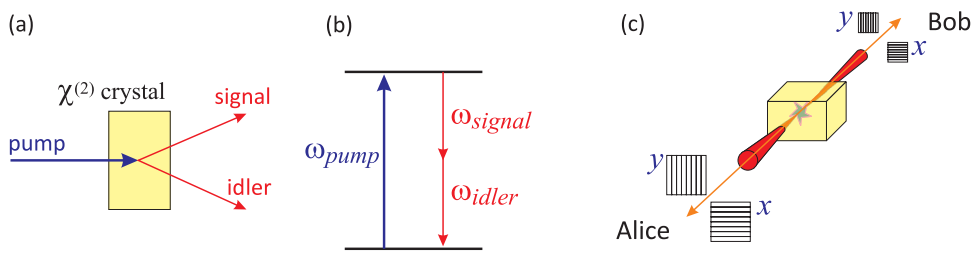

Figure 47.1: (a) Generation of entangled photon via parametric down-conversion. (b) Energy conservation upon parametric down-conversion. (c) Illustration of the EPR paradox.

On the other hand, quantum mechanics postulates that the reduction of the wavepacket describing the particle at detector a decides *spontaneously* on the result of the measurement at detector b. This decision *has no physical cause*. If the particles move with the speed of light, this decision is not restricted by *local causality* [425]. The state, also called *Bell state*, can be given in the form,

$$|\psi\rangle = |+_a \ +_b\rangle + |-_a \ -_b\rangle \ . \tag{47.2}$$

In Exc. 47.1.3.1 we check that this state cannot be expressed as a product state. Let us have a closer look at the EPR state (47.2) and imagine that particle 'a' (the one that will later be analyzed by detector a) is embarked with Alice on a starship, while particle 'b' flies with Bob in opposite direction.

We introduce a basis choosing z as the quantization axis, that is, the basis vectors

$$|+\rangle_z = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad , \quad |-\rangle_z = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \tag{47.3}$$

are eigenvectors of the Pauli matrix $\hat{\sigma}_z$. On the other hand,

$$|+\rangle_x = \tfrac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ 1 \end{pmatrix} \quad , \quad |-\rangle_x = \tfrac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ -1 \end{pmatrix} \tag{47.4}$$

are eigenvectors of the Pauli matrix $\hat{\sigma}_x$. Quantum mechanics now tells us that, before any measurement, the wavefunction is in a superposition of states $|+\rangle$ and $|-\rangle$. That is, in the z-basis, using the tensor notation, we may write the entangled state (47.2) as,

$$\boxed{|\psi\rangle = \tfrac{1}{\sqrt{2}} \left(|+\rangle_z \otimes |+\rangle_z + |-\rangle_z \otimes |-\rangle_z \right)} \ . \tag{47.5}$$

But we can also express it in the x-basis,

$$\begin{aligned}|\psi\rangle &= \tfrac{1}{\sqrt{2}}\left(\tfrac{|+\rangle_x+|-\rangle_x}{\sqrt{2}}\otimes\tfrac{|+\rangle_x+|-\rangle_x}{\sqrt{2}}+\tfrac{|+\rangle_x-|-\rangle_x}{\sqrt{2}}\otimes\tfrac{|+\rangle_x-|-\rangle_x}{\sqrt{2}}\right) \\ &= \tfrac{1}{2\sqrt{2}}\left(\begin{array}{c}|+\rangle_x\otimes|+\rangle_x+|+\rangle_x\otimes|-\rangle_x+|-\rangle_x\otimes|+\rangle_x+|-\rangle_x\otimes|-\rangle_x \\ +|+\rangle_x\otimes|+\rangle_x-|+\rangle_x\otimes|-\rangle_x-|-\rangle_x\otimes|+\rangle_x+|-\rangle_x\otimes|-\rangle_x\end{array}\right) \\ &= \tfrac{1}{\sqrt{2}}\left(|+\rangle_x\otimes|+\rangle_x+|-\rangle_x\otimes|-\rangle_x\right)\ .\end{aligned} \tag{47.6}$$

A generalization of this calculation to arbitrary rotations of the detector will be studied in Exc. 47.1.3.2.

After some time, Alice measures her spin in z-direction, i.e. performs a measurement of $\hat{\sigma}_z$. Her measurement not only collapses the wavefunction of Alice's spin a in either one of the states $|\pm\rangle_z$, but it instantaneously also collapses the wavefunction of Bob's spin along the z-direction,

$$|\psi\rangle \curvearrowright \begin{cases}|+\rangle_z\otimes|+\rangle_z = |+\rangle_z\otimes\frac{|+\rangle_x+|-\rangle_x}{\sqrt{2}} \\ |-\rangle_z\otimes|-\rangle_z = |+\rangle_z\otimes\frac{|+\rangle_x-|-\rangle_x}{\sqrt{2}}\end{cases} \tag{47.7}$$

Hence, if Bob measures along the z-axis, his measurement will be predefined by Alice's measurement. On the other hand, if tries to measure along the x-axis, he will find a random result with a probability of $\frac{1}{2}$ for each outcome [1]. That is, the direction of measurement in Alice's experiment fixes the quantization axis for Bob's experiment.

Two hypotheses have been put forward: The first one is that Alice's experiment sends information to Bob's experiment. Alice's particle told Bob's particle which spin state he should be in. But this hypothesis violates the locality requirement of special relativity claiming that information cannot travel faster than light. Einstein called it 'spooky action at a distance'. The second hypothesis is to assume that quantum mechanics does not violate locality, but that the particles carry with them 'local hidden variables' [2] (like a proper DNA) whose values would be set right from the moment of the separation of the particles and which would determine the outcomes of any future spin measurement. Then, quantum mechanics would not be a complete theory, because it has nothing to say about these hidden variables.

47.1.1.1 Bell's inequality

In 1964 John S. Bell suggested an experimental test for the EPR paradox [73]. He proposed a theorem formulated as an inequality, the famous *Bell's inequality*, stating that *if the local hidden variables hypothesis proposed by Einstein is correct, then the inequality must be satisfied by experiment.*

There are many versions of Bell's inequality, all of them are equivalent. Let us follow Bell's argumentation and assume Alice and Bob to use Stern-Gerlach magnets

[1] Due to Bob's measurement along the x-axis Alice's wavefunction should collapse along the x-axis, as well. But according to quantum mechanics, Alice should be unable to know the spin value in x-direction, since she already knows the spin the z-direction, which is not allowed by the commutation rules,

$$[\hat{\sigma}_z^a,\hat{\sigma}_x^a] = \imath\hbar\hat{\sigma}_y^a \qquad , \qquad [\hat{\sigma}_z^b,\hat{\sigma}_x^b] = \imath\hbar\hat{\sigma}_y^b\ .$$

[2] Note the difference to *non-local hidden variables* assumed by de Broglie and David Bohm in their formulation of quantum mechanics.

oriented in arbitrary directions $\mathbf{a} \equiv \hat{\mathbf{e}}_{\vartheta,\varphi}$, respectively, $\mathbf{b} \equiv \hat{\mathbf{e}}_{\vartheta',\varphi'}$ to measure the expectation values,

$$\langle\psi|\hat{\vec{\sigma}} \cdot \mathbf{a} \otimes \mathbb{I}|\psi\rangle \qquad \text{and} \qquad \langle\psi|\mathbb{I} \otimes \hat{\vec{\sigma}} \cdot \mathbf{b}|\psi\rangle \tag{47.8}$$

respectively, on an anti-symmetric entangled two-spin state [3],

$$\boxed{|\psi\rangle = \tfrac{1}{\sqrt{2}}(|+\rangle_z \otimes |-\rangle_z - |+\rangle_z \otimes |-\rangle_z)} \ . \tag{47.9}$$

Let us first do the quantum calculation. Using the rules for Pauli matrices and the anti-symmetry of the entangled state,

$$\hat{\sigma}_x|\pm\rangle_z = |\mp\rangle_z \quad , \quad \hat{\sigma}_y|\pm\rangle_z = \pm\imath|\mp\rangle_z \quad , \quad \hat{\sigma}_z|\pm\rangle_z = \pm|\pm\rangle_z \ , \tag{47.10}$$

we derive in Excs. 47.1.3.3 and 47.1.3.4 the general relationship,

$$\langle\psi|\hat{\vec{\sigma}} \cdot \mathbf{a} \otimes \hat{\vec{\sigma}} \cdot \mathbf{b}|\psi\rangle = -\mathbf{a} \cdot \mathbf{b} \ , \tag{47.11}$$

which is the quantum mechanical correlation function for a joined measurement of Alice and Bob.

On the other hand, if local hidden variables exist, Alice's measurement is determined by the orientation $\mathbf{a}$ of her magnets and a (set of) hidden variable(s) λ, which are also available to Bob, whose measurement is determined by the orientation $\mathbf{b}$ of his magnets,

$$A(\mathbf{a},\lambda) \equiv \langle\psi|\hat{\vec{\sigma}} \cdot \mathbf{a} \otimes \mathbb{I}|\psi\rangle = \pm 1 \qquad \text{and} \qquad B(\mathbf{b},\lambda) \equiv \langle\psi|\mathbb{I} \otimes \hat{\vec{\sigma}} \cdot \mathbf{b}|\psi\rangle = \pm 1 \ , \tag{47.12}$$

with the crucial assumption that A does not depend on $\mathbf{b}$ and B not $\mathbf{a}$. Let us assume a probability distribution $\rho(\lambda)$ for the hidden variable satisfying $\int \rho(\lambda)d\lambda = 1$. Then the joint probability distribution $P(\mathbf{a},\mathbf{b})$ should coincide with the quantum mechanical correlation function,

$$P(\mathbf{a},\mathbf{b}) = \int A(\mathbf{a},\lambda)B(\mathbf{b},\lambda)\rho(\lambda)d\lambda = \langle\psi|\hat{\vec{\sigma}} \cdot \mathbf{a} \otimes \hat{\vec{\sigma}} \cdot \mathbf{b}|\psi\rangle \geq -1 \ . \tag{47.13}$$

For example, let the hidden variable now be unit vector $\vec{\lambda}$ with uniform probability distribution over all directions, such that,

$$A(\mathbf{a},\lambda) = \text{sign}(\mathbf{a} \cdot \vec{\lambda}) \qquad \text{and} \qquad B(\mathbf{b},\lambda) = -\text{sign}(\mathbf{b} \cdot \vec{\lambda}) \ . \tag{47.14}$$

Then,

$$\begin{aligned} P(\mathbf{a},\mathbf{b}) &= -\int \text{sign}(\cos\vartheta_{a\lambda})\text{sign}(\cos\vartheta_{b\lambda})\rho(\vartheta_\lambda)d\vartheta_\lambda \\ &= -\int_{\vartheta_a}^{\vartheta_b} \text{sign}(\cos\vartheta_\lambda)d\vartheta_\lambda = -1 + \tfrac{2}{\pi}\angle(\mathbf{a},\mathbf{b}) \ . \end{aligned} \tag{47.15}$$

This probability distribution clearly deviates from the quantum prediction, in particular at angles $\angle(\mathbf{a},\mathbf{b}) = \frac{\pi}{2}$, as seen in Fig. 47.2(a).

[3] The anti-symmetric state is chosen here for symmetry reasons facilitating the quantum calculation, but the arguments hold for any entangled state.

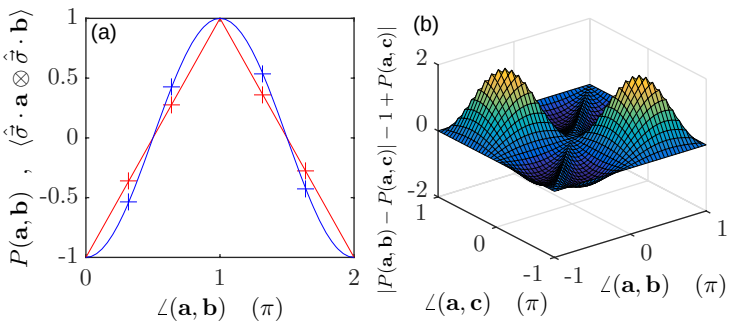

Figure 47.2: (code) (a) Joint probability distribution $P(\mathbf{a},\mathbf{b})$ in local hidden variables theory (red) and correlation function $\langle\psi|\vec{\sigma}\cdot\mathbf{a}\otimes\vec{\sigma}\cdot\mathbf{b}|\psi\rangle$ in quantum mechanics (blue). (b) Verification of Bell's inequality.

Let us finally derive Bell's inequality. Because of (47.12) for the anti-symmetric state we have the relation $B(\mathbf{b},\lambda) = -A(\mathbf{b},\lambda)$ and $A(\mathbf{a},\lambda) = A(\mathbf{a},\lambda)^{-1}$ allowing us to derive,

$$\begin{aligned} P(\mathbf{a},\mathbf{b}) - P(\mathbf{a},\mathbf{c}) &= -\int \left[A(\mathbf{a},\lambda)A(\mathbf{b},\lambda) - A(\mathbf{a},\lambda)A(\mathbf{c},\lambda)\right]\rho(\lambda)d\lambda \\ &= \int A(\mathbf{a},\lambda)A(\mathbf{b},\lambda)\left[A(\mathbf{b},\lambda)A(\mathbf{c},\lambda) - 1\right]\rho(\lambda)d\lambda \ , \end{aligned} \tag{47.16}$$

and

$$\begin{aligned} |P(\mathbf{a},\mathbf{b}) - P(\mathbf{a},\mathbf{c})| &\leq \int |A(\mathbf{a},\lambda)A(\mathbf{b},\lambda)\left[A(\mathbf{b},\lambda)A(\mathbf{c},\lambda) - 1\right]|\rho(\lambda)d\lambda \\ &\leq \int [1 - A(\mathbf{b},\lambda)A(\mathbf{c},\lambda)]\rho(\lambda)d\lambda \\ &= \int \rho(\lambda)d\lambda + \int A(\mathbf{b},\lambda)B(\mathbf{c},\lambda)\rho(\lambda)d\lambda = 1 + P(\mathbf{b},\mathbf{c}) \ . \end{aligned} \tag{47.17}$$

This inequality derived from the local hidden variables assumption is violated by quantum mechanics, since,

$$\begin{aligned} |\langle\hat{\vec{\sigma}}\cdot\mathbf{a}\otimes\hat{\vec{\sigma}}\cdot\mathbf{b}\rangle - \langle\hat{\vec{\sigma}}\cdot\mathbf{a}\otimes\hat{\vec{\sigma}}\cdot\mathbf{c}\rangle| &= |-\mathbf{a}\cdot\mathbf{b} + \mathbf{a}\cdot\mathbf{c}| \\ &\leq 1 - \mathbf{b}\cdot\mathbf{c} = 1 + \langle\hat{\vec{\sigma}}\cdot\mathbf{b}\otimes\hat{\vec{\sigma}}\cdot c\rangle \end{aligned} \tag{47.18}$$

is not satisfied for arbitrary choices of $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$. To see this we plot in Fig. 47.2(b),

$$1 - \cos\angle(\mathbf{b},\mathbf{c}) - |\cos\angle(\mathbf{a},\mathbf{b}) - \cos\angle(\mathbf{a},\mathbf{c})| \ , \tag{47.19}$$

finding that this quantity becomes negative for some choices of the projection vectors.

Example 343 (*EPR paradox using GHZ states*): Here, we show a modified version of the EPR experiment proposed by Greenberger, Horne and Zeilinger (GHZ) based on the *GHZ state* [378]. They imagined a source creating three correlated non-interacting spin $\frac{1}{2}$ particles labeled a, b, and c flying toward

three Stern-Gerlach type magnetic detectors, which measure the spins in x or in y-direction. The correct state is either quantum,

$$|\psi\rangle = |\,+_a \quad +_b \quad +_c\rangle_z - |\,-_a \quad -_b \quad -_c\rangle_z \ , \tag{47.20}$$

or

$$\boxed{|\psi\rangle = |+\rangle_z \otimes |+\rangle_z \otimes |+\rangle_z - |-\rangle_z \otimes |-\rangle_z \otimes |-\rangle_z} \ , \tag{47.21}$$

in tensor notation, or it contains hidden variables, that is, instructions telling the detectors which measurement result to exhibit upon arrival of a particle,

$$|\psi\rangle = \begin{pmatrix} \pm_x^a \ \pm_x^b \ \pm_x^c \\ \pm_y^a \ \pm_y^b \ \pm_y^c \end{pmatrix} . \tag{47.22}$$

Now, using the quantum mechanical rules (47.10), we obtain,

$$\hat{\sigma}_x \otimes \hat{\sigma}_x \otimes \hat{\sigma}_x |\psi\rangle \equiv \hat{\sigma}_x^a \hat{\sigma}_x^b \hat{\sigma}_x^c |\psi\rangle = -|\psi\rangle \ , \tag{47.23}$$

but also,

$$\hat{\sigma}_x^a \hat{\sigma}_y^b \hat{\sigma}_y^c |\psi\rangle = \hat{\sigma}_y^a \hat{\sigma}_x^b \hat{\sigma}_y^c |\psi\rangle = \hat{\sigma}_y^a \hat{\sigma}_y^b \hat{\sigma}_x^c |\psi\rangle = |\psi\rangle \ . \tag{47.24}$$

Hidden variables in a state $|\psi\rangle$ that *is not a coherent superposition* should at

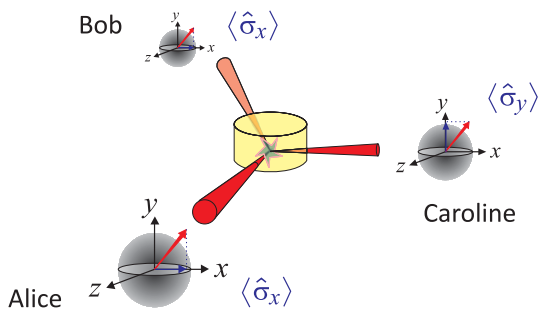

Figure 47.3: Scheme of the EPR experiment proposed by Greenberger, Horne and Zeilinger.

least be able to predict how each particle will behave in its respective detector, when we measure each one of the two spin components. From all possible combination only eight combinations can satisfy the requirement (47.24) written as,

$$\langle\hat{\sigma}_x^a\rangle\langle\hat{\sigma}_y^b\rangle\langle\hat{\sigma}_y^c\rangle = \langle\hat{\sigma}_y^a\rangle\langle\hat{\sigma}_x^b\rangle\langle\hat{\sigma}_y^c\rangle = \langle\hat{\sigma}_y^a\rangle\langle\hat{\sigma}_y^b\rangle\langle\hat{\sigma}_x^c\rangle = 1 \ . \tag{47.25}$$

These are,

$$\begin{pmatrix} \langle\sigma_x^a\rangle & \langle\sigma_x^b\rangle & \langle\sigma_x^c\rangle \\ \langle\sigma_y^a\rangle & \langle\sigma_y^b\rangle & \langle\sigma_y^c\rangle \end{pmatrix} = \tag{47.26}$$

$$\begin{pmatrix} + + + \\ + + + \end{pmatrix} \begin{pmatrix} + - - \\ + - - \end{pmatrix} \begin{pmatrix} - + - \\ - + - \end{pmatrix} \begin{pmatrix} - - + \\ - - + \end{pmatrix} \begin{pmatrix} + + + \\ - - - \end{pmatrix} \begin{pmatrix} + - - \\ - + + \end{pmatrix} \begin{pmatrix} - + - \\ + - + \end{pmatrix}$$

but none of them satisfies (47.23) written as,

$$\langle\hat{\sigma}_x^a\rangle\langle\hat{\sigma}_x^b\rangle\langle\hat{\sigma}_x^c\rangle = -1 \ . \tag{47.27}$$

Therefore, the local hidden variables assumption is incompatible with quantum mechanics, and the EPR critique of quantum mechanics regarding its incompleteness must be refuted [4].

Which one of the two pictures is correct, the local hidden variables assumption or quantum mechanics, can actually be tested by Wheeler's *delayed choice* experiment. It consists of using pairs of correlated photons emitted in different directions, where they are expected by photodetectors. Polarizers located in front of the detectors fix the quantization axis to $\hat{\mathbf{e}}_x$ or $\hat{\mathbf{e}}_y$, but the choice of the axis is made only after the photons were created by the source, in order to avoid possible backactions of the polarizers on the source [5]. Bell's inequality condition [73] predicts a statistics for the results of repeated measurements where the orientation of the polarizers is randomly varied. The experiment run by Aspect [36, 35] showed that the assumption of local hidden variables violates *local realism* and thus confirmed quantum mechanics as being a complete theory.

47.1.2 Information entropy

According to von Neumann, we can define the *von Neumann entropy*, also called quantum *information entropy* as,

$$\boxed{S \equiv -\langle \log_2 \hat{\rho} \rangle = \mathrm{Tr}\,(\hat{\rho}\log_2 \hat{\rho}) = -\sum_n \hat{\rho}_n \log_2 \hat{\rho}_n} \;, \tag{47.28}$$

where $\rho_n \equiv \langle n|\hat{\rho}|n\rangle$. For statistically independent systems the density operator is $\hat{\rho} = \hat{\rho}_1 \otimes \hat{\rho}_2$ and the entropy is additive $S = S_1 + S_2$. The entropy is observable, that is, independent of the basis and invariant with respect to unitary transformations. Therefore, $\hat{\rho}$ can be diagonalized and can be assumed diagonal in the following examples. For N independent qubits the density operator $\hat{\rho}^{(N)}$ and the entropy $S^{(N)}$ are:

$$\begin{aligned}
&\hat{\rho}^{(0)} = |+\rangle\langle+| &&, \quad S^{(0)} = 0 \text{ bit} \\
&\hat{\rho}^{(1)} = \tfrac{1}{2}(|+\rangle\langle+| + |-\rangle\langle-|) &&, \quad S^{(1)} = 1 \text{ bits} \\
&\hat{\rho}^{(2)} = \tfrac{1}{4}(|++\rangle\langle++| + |+-\rangle\langle+-| + |-+\rangle\langle-+| + |--\rangle\langle--|) &&, \quad S^{(2)} = 2 \text{ bits} \\
&\hat{\rho}^{(N)} = \tfrac{1}{2^N}(|++...\rangle\langle++...| + ...) &&, \quad S^{(N)} = N \text{ bits} .
\end{aligned} \tag{47.29}$$

The set is canonical and the entropy maximal. On the other hand, if the states are entangled, the entropy is always less than $S^{(N)} = N$ bits. For the state of maximally entangled spins, we have,

$$\rho^{(N)}_{\mathrm{corr}} = \tfrac{1}{2^N}(|++...+\rangle\langle++...+| + |--...-\rangle\langle--...-|) \quad , \quad S^{(N)}_{\mathrm{corr}} = 1 \text{ bit} . \tag{47.30}$$

[4] Note that the coupling of different degrees of freedom *is not* an entanglement, but it is the *condition* for being able to generate entanglement.

[5] We note that first attempts to demonstrate wave-particle duality with single photons in dilute laser beams are not really conclusive, because the attenuation of a coherent state does NOT result in a single photon states (non-classical Fock state). Even if on average only less than one photon is in the interferometer, this may still be a Glauber state. Nonetheless, real single photon experiments involving the deexcitation of individual atoms by emission of two photons, produced the same result.

Entropy is a measure for the degree of entanglement of a system. For a Dicke state $|J, M\rangle$ the entropy is,

$$S_{JM} = -\log_2 \binom{2J}{J+M} \ . \tag{47.31}$$

For beam splitters, the information entropy is calculated as follows: A Fock state $|N\rangle = |+\rangle^N$ divided by a beam splitter is described by,

$$\begin{aligned} 2^{-N/2}(|+\rangle + |-\rangle)^N &= \tfrac{1}{2^{N/2}} \sum_{n=0}^{N} \binom{N}{n} |+\rangle^{N-n} |-\rangle^n \\ \rho^{(N)}_{\text{split}} &= \tfrac{1}{2^N} \sum_{n,m=0}^{N} \binom{N}{n}\binom{N}{m} |+\rangle^{N-n} |-\rangle^n \langle+|^{N-m} \langle-|^m \\ \rho^{(N)}_{\text{split}} &= \tfrac{1}{2^N} \sum_{n=0}^{N} \binom{N}{n}\binom{N}{n} |+\rangle^{N-n} |-\rangle^n \langle+|^{N-n} \langle-|^n \ . \end{aligned} \tag{47.32}$$

For the information entropy, we obtain,

$$S^{(N)}_{\text{split}} = N + \tfrac{1}{2^N} \sum_{n=0}^{N} \binom{N}{n} \log_2 \binom{N}{n} \ . \tag{47.33}$$

The division of a beam is an incoherent process in the sense that it increases the entropy. The process is *irreversible*. The divided beams can not be recombined by a coherent process. For example, an interferometer always has two output ports. However, the phase is preserved.

The *quantum information content* is defined by the deviation from maximum entropy,

$$Q = S_{\text{mx}} - S_{\text{actual}} \ . \tag{47.34}$$

If the system is in a mixed state, the entropy measures deviations from a pure state behavior [65].

47.1.2.1 Separability and entanglement

Separable states are defined by,

$$\hat{\rho}_{\text{sep}} = \sum_m \hat{\rho}^{(1)}_m \otimes ... \otimes \hat{\rho}^{(N)}_m \ , \tag{47.35}$$

where $\hat{\rho}^{(n)}_m$ are single-particle pure states. Separable states are essentially states that can be created without an inter-particle interaction, just by mixing product states [923]. States that are not separable are called *entangled*.

47.1.3 Exercises

47.1.3.1 Ex: Bell states

Show that the Bell states cannot be written as products of two states.

47.1.3.2 Ex: Behavior of entanglement upon rotation of the quantization axis

Show that the anti-symmetric entangle Bell state remains entangled upon rotation of the quantization axis, that is,

$$|+\rangle_{\vartheta,\varphi} \otimes |-\rangle_{\vartheta,\varphi} - |-\rangle_{\vartheta,\varphi} \otimes |+\rangle_{\vartheta,\varphi} \;\propto\; |+\rangle_z \otimes |-\rangle_z - |-\rangle_z \otimes |+\rangle_z \;,$$

where $|\pm\rangle_{\vartheta,\varphi}$ are the eigenstates of the Pauli spin operator $\hat{\vec{\sigma}}$.

47.1.3.3 Ex: Rotations with Pauli matrices

a. Verify,

$$e^{-\imath(\pi/4)\hat{\sigma}_k}\hat{\sigma}_m e^{\imath(\pi/4)\hat{\sigma}_k} = \epsilon_{kmn}\hat{\sigma}_n + \delta_{km}\hat{\sigma}_k \qquad \text{with} \qquad (kmn) = (xyz) \;.$$

b. Prove,

$$|\vartheta,\varphi\rangle = e^{-\imath\varphi(\hat{\sigma}_z - I)/2}e^{-\imath\vartheta\hat{\sigma}_y/2}|0,0\rangle = e^{\imath\varphi/2}e^{-\imath\varphi\hat{\sigma}_z/2}e^{-\imath\vartheta\hat{\sigma}_y/2}|+\rangle \;.$$

c. Solve the eigenvalue equations,

$$\hat{\vec{\sigma}}\cdot\hat{\mathbf{e}}_z|\vartheta,\varphi\rangle = m|\vartheta,\varphi\rangle \qquad \text{and} \qquad \hat{\vec{\sigma}}\cdot\hat{\mathbf{e}}_\rho|\vartheta,\varphi\rangle = m|\vartheta,\varphi\rangle \;,$$

with $\hat{\mathbf{e}}_\rho \equiv \hat{\mathbf{e}}_x\cos\phi + \hat{\mathbf{e}}_y\sin\phi$.

47.1.3.4 Ex: Projections of single-atom spins and their correlations

a. Calculate explicitly $\langle\vartheta,\varphi|\hat{\vec{\sigma}}|\vartheta,\varphi\rangle$ and $\langle\vartheta',\varphi'|\hat{\vec{\sigma}}\cdot\hat{\mathbf{e}}_{\vartheta,\varphi}|\vartheta',\varphi'\rangle$, where $|\vartheta,\varphi\rangle$ are the states defined in (46.10), using the basis ${}_z\langle+| = (1\;0)$ and ${}_z\langle-| = (0\;1)$.
b. For the anti-symmetric entangled two-atom spin state defined in (47.9) calculate the spin projection correlations $\langle\psi|\hat{\vec{\sigma}}\cdot\hat{\mathbf{e}}_{\vartheta,\varphi}\otimes\hat{\vec{\sigma}}\cdot\hat{\mathbf{e}}'_{\vartheta,\varphi}|\psi\rangle$.

47.1.3.5 Ex: No cloning theorem

Based upon the superposition principle of quantum mechanics, prove the *no-cloning theorem* which states that a quantum state $|\psi\rangle$ cannot evolve into two separable (non-entangled) copies described by the tensor product state $|\psi\rangle|\psi\rangle$.

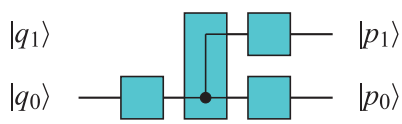

Figure 47.4: Illustration of the 'no-cloning theorem'. The transformation must be reversible, but from the state $|q_1, q_0\rangle$ we cannot infer the state $|p_1, p_0\rangle$.

47.1.3.6 Ex: Entanglement

Upon detecting the polarization of one photon in an entangled photon pair the polarization of the other photon gets determined. Does this lead to a faster than light communication? Justify your answer. How would you demonstrate the *no-cloning theorem* from the assumption that relativistic causality should prevail.

47.1.3.7 Ex: Entanglement

Three photon are prepared in the GHZ state defined as,

$$|\psi\rangle = \frac{1}{\sqrt{3}}\left(|h\rangle_1|h\rangle_2|h\rangle_3 + |v\rangle_1|v\rangle_2|v\rangle_3\right) \ .$$

Show that, when the components of polarization are measured along the axes that have an angle of 45° with respect to the original axes, corresponding to the states,

$$|h'\rangle = \frac{1}{\sqrt{2}}(|h\rangle + |v\rangle) \qquad \text{and} \qquad |v'\rangle = \frac{1}{\sqrt{2}}(|h\rangle - |v\rangle) \ ,$$

one gets necessarily an even number of photons with vertical polarization v'.

47.1.3.8 Ex: NOON state

A *NOON state* is a quantum-mechanical many-body entangled state:

$$|\psi_{\text{NOON}}\rangle = \frac{|N\rangle_a|0\rangle_b + e^{\imath N\theta}|0\rangle_a|N\rangle_b}{\sqrt{2}} \ , \tag{47.36}$$

which represents a superposition of N particles in mode a with zero particles in mode b, and vice versa. Usually, the particles are photons, but in principle any bosonic field can support NOON states.
Two-photon NOON states, where $N = 2$, can be created deterministically from two identical photons and a 50:50 beam splitter. This is called the *Hong-Ou-Mandel effect* in quantum optics. Three- and four-photon NOON states cannot be created deterministically from single-photon states, but they have been created probabilistically via post-selection using spontaneous parametric down-conversion.

47.2 Creating quantum correlations

Since the experimental verification of *Bell's inequality* [37] numerous ideas were proposed for the creation and application of correlated states in distant particles. Realistic proposals on how to create such states are often based on a Jaynes-Cummings type coupling between states of atomic excitation and the degrees of freedom of a harmonic oscillator. The Jaynes-Cummings dynamics has been extensively studied in micromasers, where the non-resonant interaction of an atomic transition with the TEM_{00} mode of a stored radiation field generates quantum coherences. In very high finesse cavities, light field states with sub-Poissonian photon statistics can be generated and stored for macroscopic times, and schemes for the creation of Fock states and Schrödinger cat states were proposed and tested. Furthermore, the electronic excitation states of atoms successively traversing a micromaser can be correlated under suitable conditions. The availability of fundamental techniques motivated proposals for the investigation of phenomena such as EPR correlations, quantum teleportation, and quantum switching [270]. On the other hand, quantum coherences are very fragile to dissipation and rapidly decay when exposed to perturbations.

Jaynes-Cummings type dynamics can also be realized with a single ion stored in a Paul trap, where the interaction of its mechanical motion with an electronic transition [103] can induce very stable quantum coherences in the vibrational degrees of freedom.

Schrödinger cat states have already been demonstrated in this system [630], as well as fundamental parts of a quantum computer, the quantum *controlled not gate* [630] and the quantum *phase gate* [930]. In Sec. 47.2.1 we present a possible extension of these ideas to several atoms in a collective Jaynes-Cummings type interaction (also called Tavis-Cummings model) with a single harmonic oscillator mode.

In order to correlate particles, they must be able to exchange information, that is, they must interact in some way. One method uses ions trapped in a linear Paul trap, where they form a straight chain, individually driven by laser beams and coupled to each other via their vibrational degrees of freedom mediated through Coulomb repulsion [179]. We present this idea in Sec. 47.2.2. Such scenarios have been implemented to create the first quantum computers. Another way consists in trapping neutral atoms in a dual optical lattice and let them undergo *controlled collisions* [474], as will be discussed in Sec. 47.2.3.

Alternative approaches to realizing quantum gates use dipole-dipole interactions [128], conditional Raman adiabatic passages by laser-induced excitation of interatomic dipole-dipole interactions [598], or interactions between permanent dipoles of atoms in Rydberg states [475] [6]

47.2.1 Correlating atoms in the Jaynes-Cummings model

In Sec. 40.2 we showed already that the Jaynes-Cummings model is able to perform coherent operations on a two-level system –which from now on we will call *qubit*–, such as the *population inversion* (`NOT`-gate) and the controlled dephasing of an excited dipole moment (phase gate). These operations are fundamental for applications in quantum information, however, we still lack essential ingredients allowing us to entangle states of two, three or more qubits in order to perform a *quantum register* of *qubits*. Once these register are realized, we must define coherent quantum operations called *quantum gates*.

47.2.1.1 Tavis-Cummings model for 2 atoms

In Sec. 40.2 we showed, how a Jaynes-Cummings interaction between an atom and a radiation field can exchange quantum correlations. It is reasonable to expect that, when we have two (or more) atoms interacting with the same radiation field, we can exchange correlations between atoms via the field. This would allow the implementation of entanglement protocols and quantum gates. We will disregard spontaneous processes, such that all couplings are then coherent and the processes reversible.

In Sec. 23.5.8 we learned, how to span a Hilbert space of various particles. We will now apply these notions in the scope of generalizing the Jaynes-Cummings model to *two atoms interacting with the same optical mode*, without spontaneous decay processes considered. The system is often referred to as the *Tavis-Cummings model*. The Hamiltonian of the system, which consists of two non-interacting atoms, both coupled in the same optical mode, is,

$$\boxed{\hat{H} = \omega \hat{a}^\dagger \hat{a} + \sum_{i=1,2} \omega_{ai}(\hat{\sigma}_i^+ \hat{\sigma}_i^- - \tfrac{1}{2}) + \sum_{i=1,2} \tfrac{1}{2} g_i(t)(\hat{a}\hat{\sigma}_i^+ + \hat{a}^+ \hat{\sigma}_i^-)} \,. \tag{47.37}$$

[6] A system to create quantum correlations is the *optical parametric oscillator* (OPO).

The suffix denotes the individual atoms. Note that the coupling constant $g_i(t)$ can be considered as time dependent, which may be useful for modeling radiation pulse envelopes. In matrix representation the Hamiltonian acting on the subspace of n photons is,

$$|\psi\rangle = \sum_n \begin{pmatrix} c_{11\ n+1} \\ c_{12\ n} \\ c_{21\ n} \\ c_{22\ n-1} \end{pmatrix} |n\rangle \qquad \text{where} \qquad c_{ij} \equiv_1 \langle j|_2\langle i|\langle n|\psi\rangle \tag{47.38}$$

for example, $\langle n| \otimes \langle 1| \otimes \langle 1| = \langle n|(1\ 0\ 0\ 0)$, $\langle n| \otimes \langle 2| \otimes \langle 1| = \langle n|(0\ 1\ 0\ 0)$, and so on. The atomic transition operators are generalized to,

$$\hat{\sigma}_1^- = \sum_n |n\rangle \hat{\sigma}^- \otimes \mathbb{I} \langle n| = \sum_n |n\rangle \begin{pmatrix} & & 1 & \\ & & & 1 \\ 0 & & & \\ & 0 & & \end{pmatrix} \langle n| \tag{47.39}$$

$$\hat{\sigma}_2^- = \sum_n |n\rangle \mathbb{I} \otimes \hat{\sigma}^- \langle n| = \sum_n |n\rangle \begin{pmatrix} & 1 & & \\ 0 & & & \\ & & & 1 \\ & & 0 & \end{pmatrix} \langle n| \qquad \text{, etc. .}$$

The Hamiltonian is, on this basis,

$$\hat{H} = \sum_n |n\rangle \begin{pmatrix} n\omega - \frac{\omega_{a1}}{2} - \frac{\omega_{a2}}{2} & & & \\ & n\omega - \frac{\omega_{a1}}{2} + \frac{\omega_{a2}}{2} & & \\ & & n\omega + \frac{\omega_{a1}}{2} - \frac{\omega_{a2}}{2} & \\ & & & n\omega + \frac{\omega_{a1}}{2} + \frac{\omega_{a2}}{2} \end{pmatrix} \langle n|$$
$$+ \sum_n |n-1\rangle \sqrt{n} \begin{pmatrix} 0 & & & \\ g_2 & & & \\ g_1 & & & \\ 0 & g_1 & g_2 & 0 \end{pmatrix} \langle n| + \sum_n |n+1\rangle \sqrt{n+1} \begin{pmatrix} 0 & g_2 & g_1 & 0 \\ & & & g_1 \\ & & & g_2 \\ & & & 0 \end{pmatrix} \langle n| \ . \tag{47.40}$$

Now, we can rearrange the subspaces and finally get,

$$\hat{H} = \sum_n |n\rangle \begin{pmatrix} (n+1)\omega - \frac{\omega_{a1}}{2} - \frac{\omega_{a2}}{2} & g_1\sqrt{n} & g_2\sqrt{n} & \\ g_1\sqrt{n} & n\omega + \frac{\omega_{a1}}{2} - \frac{\omega_{a2}}{2} & & g_2\sqrt{n+1} \\ g_2\sqrt{n} & & n\omega - \frac{\omega_{a1}}{2} + \frac{\omega_{a2}}{2} & g_1\sqrt{n+1} \\ & g_2\sqrt{n+1} & g_1\sqrt{n+1} & (n-1)\omega + \frac{\omega_{a1}}{2} + \frac{\omega_{a2}}{2} \end{pmatrix} \langle n| \ . \tag{47.41}$$

The density operator for the subspace is,

$$\hat{\rho} = \begin{pmatrix} |n+1\rangle|1\rangle_1|1\rangle_2\ {}_1\langle 1|_2\langle 1|\langle n+1| & |n+1\rangle|1\rangle_1|1\rangle_2\ {}_1\langle 1|_2\langle 2|\langle n| & \ldots \\ |n\rangle|1\rangle_2|1\rangle_2\ {}_1\langle 1|_2\langle 1|\langle n+1| & \ldots & \\ |n\rangle|2\rangle_1|2\rangle_2\ {}_1\langle 1|_2\langle 1|\langle n+1| & \ldots & \\ |n-1\rangle|2\rangle_1|2\rangle_2\ {}_1\langle 1|_2\langle 1|\langle n+1| & \ldots & \end{pmatrix} , \tag{47.42}$$

if the basis is again defined by equation (47.39).

47.2.1.2 Resonant excitation

To discuss the case of resonant excitation, $\Delta_1 = \Delta_2 = 0$, let us assume identical atoms, $\omega_{a1} = \omega_{a2} \equiv \omega_0$, and equal Rabi frequencies, $g_1 = g_2 \equiv g$. Assuming dipolarly forbidden strongly saturated transition, $n = \alpha^2$ for all n, the Hamiltonian simplifies considerably,

$$\hat{H}_n = \begin{pmatrix} n\omega & g\sqrt{n} & g\sqrt{n} & \\ g\sqrt{n} & n\omega & & g\sqrt{n} \\ g\sqrt{n} & & n\omega & g\sqrt{n} \\ & g\sqrt{n} & g\sqrt{n} & n\omega \end{pmatrix} ,$$

the eigenvalues can be calculated and the time evolution matrix becomes, using the abbreviation $\varphi \equiv gt\sqrt{n}$,

$$\boxed{e^{-\imath\hat{H}_n t} = e^{-\imath\hat{H}_n^{A1} t} e^{-\imath\hat{H}_n^{A2} t} = \begin{pmatrix} \cos^2\varphi & \imath\sin\varphi\cos\varphi & \imath\sin\varphi\cos\varphi & -\sin^2\varphi \\ \imath\sin\varphi\cos\varphi & \cos^2\varphi & -\sin^2\varphi & \imath\sin\varphi\cos\varphi \\ \imath\sin\varphi\cos\varphi & -\sin^2\varphi & \cos^2\varphi & \imath\sin\varphi\cos\varphi \\ -\sin^2\varphi & \imath\sin\varphi\cos\varphi & \imath\sin\varphi\cos\varphi & \cos^2\varphi \end{pmatrix}} . \tag{47.43}$$

For a π-pulse, we get,

$$e^{-\imath\hat{H}_n t} \xrightarrow{\pi/2} \frac{1}{2} \begin{pmatrix} 1 & \imath & \imath & -1 \\ \imath & 1 & -1 & \imath \\ \imath & -1 & 1 & \imath \\ -1 & \imath & \imath & 1 \end{pmatrix} . \tag{47.44}$$

It is interesting to note that some superposition states completely separate from the optical mode,

$$e^{-\imath\hat{H}_n t} \begin{pmatrix} 0 \\ 1 \\ -1 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \\ -1 \\ 0 \end{pmatrix} \quad \text{and} \quad e^{-\imath\hat{H}_n t} \begin{pmatrix} 1 \\ 0 \\ 0 \\ -1 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ 0 \\ -1 \end{pmatrix} . \tag{47.45}$$

47.2.1.3 Dispersive excitation

In the dispersive limit, $\Delta_i \gg n^{1/2} g_i$, the dynamic evolution can be evaluated from a first order perturbative approach, analogous to the one already made for the standard JCM model. In this approach, the off-diagonal matrix elements (47.41) generate a light-shift of the energy levels appearing on the diagonal of the approximated matrix. Using the abbreviation $\Lambda_i \equiv g_i^2/\Delta_i$, the temporal evolution matrix $e^{-\imath\hat{H}_n t}$ can now be evaluated from,

$$\begin{aligned} \hat{H}_n = & -\frac{\Delta_1 + \Delta_2}{2} \mathbb{I}_4 \\ & + \begin{pmatrix} n\Lambda_1 + n\Lambda_2 & & & \\ & -n\Lambda_1 + (n+1)\Lambda_2 & & \\ & & (n+1)\Lambda_1 - n\Lambda_2 & \\ & & & -(n+1)\Lambda_1 - (n+1)\Lambda_2 \end{pmatrix} . \end{aligned} \tag{47.46}$$

We now assume that the light field only interacts with the upper level, as in the case of the dual resonance configuration studied in Exc. 40.2.5.4. This can be taken into account, neglecting those terms in the matrix (47.45) rotating with a positive Rabi frequency. Letting, moreover, $\Delta_1 = \Delta_2$ and $\Omega_1 = \Omega_2$, we obtain,

$$\hat{H}_n^{(1)} = \begin{pmatrix} 0 & & & \\ & -n\Lambda & & \\ & & -n\Lambda & \\ & & & -2(n+1)\Lambda \end{pmatrix} . \tag{47.47}$$

Thus, the temporal evolution is,

$$\boxed{e^{-\imath \hat{H}_n t} = \begin{pmatrix} 1 & & & \\ & e^{-n\Lambda} & & \\ & & e^{-n\Lambda} & \\ & & & e^{-2(n+1)\Lambda} \end{pmatrix}} . \tag{47.48}$$

For $\Lambda = \pi$,

$$e^{-\imath \hat{H}_n t} \xrightarrow{\pi} \begin{pmatrix} 1 & & & \\ & -1 & & \\ & & -1 & \\ & & & 1 \end{pmatrix} . \tag{47.49}$$

47.2.1.4 Bloch vector and the Q-function in the JC model with 2 atoms

Despite the more complex structure of the Hilbert space, the Bloch vectors of the individual atoms and the Q-function can be evaluated in analogy to Sec. 40.2.2. The Bloch vector is,

$$\vec{\rho}_{A1} = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}\, \mathfrak{Re}\, \rho_{12(A1)} \\ \sqrt{2}\, \mathfrak{Im}\, \rho_{12(A1)} \\ \rho_{22(A1)} - \rho_{11(A1)} \end{pmatrix} \qquad \text{where} \qquad \rho_{ij(A1)} = \mathrm{Tr}\, |i\rangle_1 \langle j|\psi\rangle\langle\psi| . \tag{47.50}$$

In particular we have,

$$\begin{aligned} \rho_{22(A1)} &= \sum_{i,j,n} {}_2\langle j|_1\langle i|\langle n|1\rangle_1\langle 2|\psi\rangle\langle\psi|n\rangle|i\rangle_1|j\rangle_2 \\ &= \sum_{j,n} {}_2\langle j|_1\langle 2|\langle n|\psi\rangle\langle\psi|n\rangle|1\rangle_1|j\rangle_2 \\ &= \sum_{n,m,m'} \langle n| \left(c_{2,1,m}|m\rangle\langle m'+1|c^*_{1,1,m'+1} + c_{2,2,m}|m'-1\rangle\langle m'|c^*_{1,2,m'}\rangle \right) |n\rangle \\ &= \sum_n (c^*_{1,1,n}c_{2,1,n} + c^*_{1,2,n}c_{2,2,n}) . \end{aligned} \tag{47.51}$$

Summarizing,

$$\begin{array}{lcl} \rho_{12(Ai\neq Aj)} & = & \sum_n (c^*_{1,1,n}c_{j,i,n} + c^*_{i,j,n}c_{2,2,n}) \\ \rho_{11(Ai\neq Aj)} & = & \sum_n (|c_{1,1,n}|^2 + |c_{i,j,n}|^2) \\ \rho_{22(Ai\neq Aj)} & = & \sum_n (|c_{j,i,n}|^2 + |c_{2,2,n}|^2) \end{array} . \tag{47.52}$$

The function $Q(\alpha)$ for the JC dynamics of 2 atoms is,

$$\begin{aligned} Q(\alpha) &= \tfrac{1}{\pi}\langle\alpha|\hat{\rho}_{field}|\alpha\rangle = \tfrac{1}{\pi}\langle\alpha|\sum_{i,j} {}_2\langle j|_1\langle i|\psi\rangle\langle\psi|i\rangle_1|j\rangle_2|\alpha\rangle \\ &= \tfrac{1}{\pi}\langle\alpha|\sum_{m,n}(c^*_{2,2,m-1}c_{2,2,n-1}|n-1\rangle\langle m-1| + c^*_{1,2,m}c_{1,2,n}|n\rangle\langle m| \\ &+ c^*_{2,1,m}c_{2,1,n}|n\rangle\langle m| + c^*_{1,1,m+1}c_{1,1,n+1}|n+1\rangle\langle m+1|\rangle)|n\rangle|\alpha\rangle \\ &= e^{-|\alpha|^2}\left[\left|\sum_n c_{2,2,n-1}\frac{\alpha^n}{\sqrt{n!}}\right|^2 + \left|\sum_n c_{1,2,n}\frac{\alpha^n}{\sqrt{n!}}\right|^2 + \left|\sum_n c_{2,1,n}\frac{\alpha^n}{\sqrt{n!}}\right|^2 + \left|\sum_n c_{2,2,n+1}\frac{\alpha^n}{\sqrt{n!}}\right|^2\right] . \end{aligned} \tag{47.53}$$

47.2.1.5 Correlating 2 atoms in the JC model

The investigations of the last section can be applied to describe the transfer of quantum coherence from one atom to another. The size of our system is now increased by the additional degrees of freedom, provided by internal states of the second atom. A suitable basis was defined in equation (23.223). Now, we imagine the following Gedankenexperiment: Starting from the initial condition that two adjacent atoms are in their respective electronic ground states, we assume a microwave $\pi/2$-pulse to create *simultaneously, but independently* on both atoms, a superposition of the HFS levels. Then, a non-resonant optical π-pulse interacts with the upper HFS level of the first atom $|1\rangle_{A1}$, and afterward the second atom $|2\rangle_{A2}$. Instead of reducing the atomic states and preparing a Schrödinger cat state in the optical field, (as we did in Sec. 40.2), we now project the field state onto the coherent state $|\beta\rangle$ and leave the atoms in a correlated state. The total procedure can be resumed by tracing the evolution of the whole state in the following suggestive way [43, 356]:

$$\begin{pmatrix}|\beta\rangle\\0\\0\\0\end{pmatrix} \overset{\pi/2\text{ microwave}}{\curvearrowright} \tfrac{1}{4}\begin{pmatrix}1\\\imath\\\imath\\-1\end{pmatrix}|\beta\rangle \overset{\pi\text{ opt+atom1}}{\curvearrowright} \tfrac{1}{4}\begin{pmatrix}|\beta\rangle\\-\imath|-\beta\rangle\\\imath|\beta\rangle\\|-\beta\rangle\end{pmatrix} \overset{\pi\text{ opt+atom2}}{\curvearrowright} \tfrac{1}{4}\begin{pmatrix}|\beta\rangle\\-\imath|-\beta\rangle\\-\imath|-\beta\rangle\\-|\beta\rangle\end{pmatrix}$$

$$\overset{\pi/2\text{ microwave}}{\curvearrowright} \tfrac{1}{4}\begin{pmatrix}1\\0\\0\\1\end{pmatrix}|\beta\rangle + \frac{1}{4}\begin{pmatrix}1\\0\\0\\-1\end{pmatrix}|-\beta\rangle \overset{\text{reduction}}{\curvearrowright} \tfrac{1}{2}\begin{pmatrix}1\\0\\0\\-1\end{pmatrix}|\beta\rangle\ . \tag{47.54}$$

If this procedure is extended to an arbitrary number of atoms, obviously all atoms being excited by the same optical mode before its projection in a coherent state $|\beta\rangle$ are included in the entangled state,

$$|\psi\rangle = \tfrac{1}{4}\begin{pmatrix}1\\\vdots\\1\end{pmatrix}|\beta\rangle + \tfrac{1}{4}\begin{pmatrix}1\\\vdots\\-1\end{pmatrix}|-\beta\rangle\ . \tag{47.55}$$

Finally, the correlation of the spin orientation of the atoms must be probed with additional laser light fields, which are selectively irradiated onto the atoms and resonantly tuned to a rapidly decaying optical transition. The states correlated in this

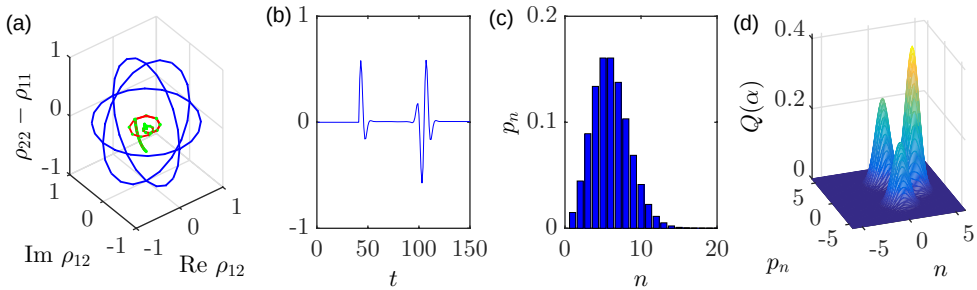

Figure 47.5: (code) Evolution of the state during a Jaynes-Cummings interaction with 2 atoms: (a) Bloch vector for the two atoms, (b) time evolution of the coherence ρ_{12} showing the phenomenon of collapse and revival, (c) distribution of photons, and (d) $Q(\alpha)$-function.

way show a relatively low order entanglement, the von Neumann information entropy only being $S' = -\langle \log_2 \rho \rangle = N - 1$.

In a matricial notation the entangling gate can be expressed defining the state,

$$\begin{aligned} \langle \psi | &= \begin{pmatrix} c_{+\beta 11} & c_{+\beta 12} & c_{+\beta 21} & c_{+\beta 22} & c_{-\beta 11} & c_{-\beta 12} & c_{-\beta 21} & c_{-\beta 22} \end{pmatrix} \\ &= \langle \beta | \otimes \langle \text{atom}_1 | \otimes \langle \text{atom}_2 | \ . \end{aligned} \tag{47.56}$$

In this basis, the dispersive π-pulse is represented by,

$$\mathcal{U}_{\text{disp}} \equiv \begin{pmatrix} 1 & & & & & & & \\ & & & & & -1 & & \\ & & & & & & -1 & \\ & & & 1 & & & & \\ & & & & 1 & & & \\ & -1 & & & & & & \\ & & -1 & & & & & \\ & & & & & & & 1 \end{pmatrix} . \tag{47.57}$$

A resonant $\pi/2$-pulse acting on the *both atoms simultaneously* does,

$$\mathcal{U}_{\text{reson}} \equiv \mathbb{I} \otimes \mathcal{U}^{(2)}_{\pi/2} \otimes \mathbb{I} = \tfrac{1}{\sqrt{2}} \begin{pmatrix} 1 & \imath & \imath & -1 & & & & \\ \imath & 1 & -1 & \imath & & & & \\ \imath & -1 & 1 & \imath & & & & \\ -1 & \imath & \imath & 1 & & & & \\ & & & & 1 & \imath & \imath & -1 \\ & & & & \imath & 1 & -1 & \imath \\ & & & & \imath & -1 & 1 & \imath \\ & & & & -1 & \imath & \imath & 1 \end{pmatrix} . \tag{47.58}$$

Now, concatenating and projecting on the Glauber state $|\beta\rangle$ we obtain, a posteriori,

a unitary entangling gate,

$$\mathcal{U}_{\text{entangl}} \equiv \text{Tr}_\beta\ |\beta\rangle\langle\beta|\mathcal{U}_{\text{reson}}\mathcal{U}_{\text{disp}}\mathcal{U}_{\text{reson}}|\beta\rangle\langle\beta| = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 0 & 0 & -1 \\ 0 & -1 & -1 & 0 \\ 0 & -1 & -1 & 0 \\ -1 & 0 & 0 & 1 \end{pmatrix} \tag{47.59}$$

$$\text{such that} \quad \begin{pmatrix} 1 \\ 0 \\ 0 \\ -1 \end{pmatrix} = \mathcal{U}_{\text{entangl}} \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix} .$$

47.2.2 Phononic quantum gate

The normal mode coupling can be used to create *quantum entanglement*. A suggested procedure to correlate two atoms '1' and '2' is shown in Fig. 47.6 [180, 429]. The atoms are regarded as qubits with the possible states of excitation $|g\rangle$ and $|e\rangle$. Additionally, the atoms are trapped (either they are ions in a linear ion trap or atoms in standing light wave sustained by a ring cavity). The are assumed to be cooled to the vibrational ground state $|0\rangle$, from which they can be coherently excited to the second collective vibrational mode $|1\rangle$ by means of a Raman transition, as illustrated in Fig. 47.6.

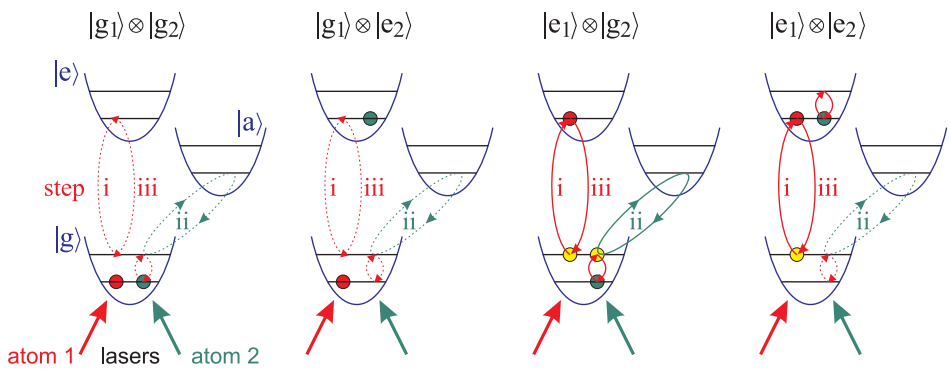

Figure 47.6: Scheme for an XOR-gate in an ion trap or a ring-cavity (see text for explanation). The four possible initial collective states respond differently to a predefined laser pulse sequence. Possible transitions are represented by solid lines, impossible transitions by dashed lines. $|a\rangle$ is an auxiliary excited level.

The sequence reads,

$$\begin{array}{c} |g_1\rangle|g_2\rangle|0\rangle \\ |g_1\rangle|e_2\rangle|0\rangle \\ |e_1\rangle|g_2\rangle|0\rangle \\ |e_1\rangle|e_2\rangle|0\rangle \end{array} \overset{\text{step 1}}{\curvearrowright} \begin{array}{r} |g_1\rangle|g_2\rangle|0\rangle \\ |g_1\rangle|e_2\rangle|0\rangle \\ -\imath|g_1\rangle|g_2\rangle|1\rangle \\ -\imath|g_1\rangle|e_2\rangle|1\rangle \end{array} \overset{\text{step 2}}{\curvearrowright} \begin{array}{r} |g_1\rangle|g_2\rangle|0\rangle \\ |g_1\rangle|e_2\rangle|0\rangle \\ +\imath|g_1\rangle|g_2\rangle|1\rangle \\ -\imath|g_1\rangle|e_2\rangle|1\rangle \end{array} \overset{\text{step 3}}{\curvearrowright} \begin{array}{r} |g_1\rangle|g_2\rangle|0\rangle \\ |g_1\rangle|e_2\rangle|0\rangle \\ |e_1\rangle|g_2\rangle|0\rangle \\ -|e_1\rangle|e_2\rangle|0\rangle \end{array} . \tag{47.60}$$

Using the tensor notation $|\psi\rangle \otimes |\psi\rangle \equiv |\psi_1\rangle|\psi_2\rangle$ and introducing a matrix notation by

defining a basis as,

$$|g\rangle \otimes |g\rangle = \begin{pmatrix}1\\0\\0\\0\end{pmatrix} \ , \ |g\rangle \otimes |e\rangle = \begin{pmatrix}0\\1\\0\\0\end{pmatrix} \ , \ |e\rangle \otimes |g\rangle = \begin{pmatrix}0\\0\\1\\0\end{pmatrix} \ , \ |e\rangle \otimes |e\rangle = \begin{pmatrix}0\\0\\0\\1\end{pmatrix} \ , \tag{47.61}$$

we can set up the truth table for this gate, also known as Cirac-Zoller gate, as,

$\lvert\psi\rangle$	$\lvert\psi\rangle$	$\lvert\psi\rangle \otimes \lvert\psi\rangle$	
$\lvert g\rangle$	$\lvert g\rangle$	$\lvert g\rangle \otimes \lvert g\rangle$	1
$\lvert g\rangle$	$\lvert e\rangle$	$\lvert g\rangle \otimes \lvert e\rangle$	1
$\lvert e\rangle$	$\lvert g\rangle$	$\lvert e\rangle \otimes \lvert g\rangle$	1
$\lvert e\rangle$	$\lvert e\rangle$	$-\lvert e\rangle \otimes \lvert e\rangle$	-1

$$\Longrightarrow \qquad U_{\text{CiZo}} = \begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&1&0\\0&0&0&-1\end{pmatrix} \ . \tag{47.62}$$

We now define a new basis for the second atom only via $|a_2\rangle = \frac{1}{\sqrt{2}}(|g_2\rangle + |e_2\rangle)$ and $|b_2\rangle = \frac{1}{\sqrt{2}}(|g_2\rangle - |e_2\rangle)$. The basis transform corresponds to,

$$\begin{pmatrix}|g\rangle \otimes |a\rangle\\|g\rangle \otimes |b\rangle\\|g\rangle \otimes |a\rangle\\|g\rangle \otimes |b\rangle\end{pmatrix} = \tfrac{1}{\sqrt{2}}\mathbb{I}\otimes H \begin{pmatrix}|g\rangle \otimes |g\rangle\\|g\rangle \otimes |e\rangle\\|g\rangle \otimes |g\rangle\\|g\rangle \otimes |e\rangle\end{pmatrix} \quad \text{where} \quad \mathbb{I}\otimes H = \tfrac{1}{\sqrt{2}}\begin{pmatrix}1&1&0&0\\1&-1&0&0\\0&0&1&1\\0&0&1&-1\end{pmatrix} \tag{47.63}$$

is the Hadamard gate applied to the second qubit. Finally, we obtain the *controlled NOT* gate,

$$\mathcal{U}_{\texttt{XOR}} = (\mathbb{I} \otimes H)\mathcal{U}_{\text{CiZo}}(\mathbb{I} \otimes H)^{-1} = \begin{pmatrix}1&0&0&0\\0&1&0&0\\0&0&0&1\\0&0&1&0\end{pmatrix} \ . \tag{47.64}$$

In particular, if $|\psi_1\rangle$ is initially in a superposition state, the states $|\psi_1\rangle$ and $|\psi_2\rangle$ end up entangled,

$$\mathcal{U}_{\texttt{XOR}}(|g\rangle + |e\rangle) \otimes \mathbb{I} = \tfrac{1}{\sqrt{2}}(|g\rangle \otimes |g\rangle + |e\rangle \otimes |e\rangle) \ . \tag{47.65}$$

47.2.3 Quantum gates via controlled collisions

The proposed conditional quantum operation is based on a conditional collisional phase shift, the condition being that the atoms are in a particular state of excitation. In a suggestive notation for the Bloch vector of a particle subject to a resonant radiation pulse, the interaction is described by,

$$|\downarrow\rangle \xrightarrow{\pi/2} |\downarrow\rangle + \imath|\uparrow\rangle \xrightarrow{\pi/2} |\uparrow\rangle \xrightarrow{\pi/2} |\downarrow\rangle - \imath|\uparrow\rangle \xrightarrow{\pi/2} |\downarrow\rangle \ . \tag{47.66}$$

Jaksch demonstrated the following *phase gate*,

$$\begin{matrix}\downarrow\downarrow\\\uparrow\downarrow\\\downarrow\uparrow\\\uparrow\uparrow\end{matrix} \longrightarrow \begin{matrix}\downarrow\downarrow\\-\downarrow\uparrow\\\uparrow\downarrow\\\uparrow\uparrow\end{matrix} \ . \tag{47.67}$$

This gate is equivalent to the *XOR* port for the qubits defined by $\downarrow$ and $\downarrow \pm \uparrow$, since,

$$\begin{matrix} \downarrow (\downarrow \pm \uparrow) \\ \uparrow (\downarrow \pm \uparrow) \end{matrix} \longrightarrow \begin{matrix} \downarrow (\downarrow \mp \uparrow) \\ \uparrow (\downarrow \pm \uparrow) \end{matrix} . \tag{47.68}$$

47.2.4 Exercises

47.2.4.1 Ex: Generating a Bell state

Show that the operation $\overset{c}{X}_{01}(H \otimes \mathbb{I})$, where H is the Hadamard gate acting on the first qu-bit and $\overset{c}{X}_{01}$ the controlled NOT acting on the second qubit, applied to the 2-qubit ground state generates *Bell* type entanglement.

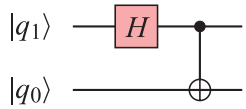

Figure 47.7: Quantum circuit generating Bell type entanglement.

47.3 Quantum gates

In *quantum information* we use the notions introduced in the preceding sections and formalize the calculation. In this section, we present a brief formal introduction to the field of *quantum computation with qubit matrices*. The formalism is abstract, but we may keep in mind a chain of entangled ions confined in a linear Paul trap. We will show how the electronic states of the ions are correlated to form a single collective state, and how quantum gates can be realized on such correlated particles. With three ions, an arbitrary quantum gate can be implemented, which includes and generalizes the three-bit Toffoli gate.

To construct a quantum gate, we need at least two qubits spanning a 4-dimensional Hilbert space, since $\mathbb{H}^2 \otimes \mathbb{H}^2$ and $\mathbb{H}^1 \otimes \mathbb{H}^4$ are isomorph, that is,

$$\begin{aligned} |\varepsilon\rangle_0|\mu\rangle_1 &= (|0\rangle_0 + \imath|1\rangle_0)(|0\rangle_1 + \imath|1\rangle_1) &&= \begin{pmatrix} |0\rangle_0|0\rangle_1 \\ \imath|0\rangle_0|1\rangle_1 \\ \imath|1\rangle_0|0\rangle_1 \\ -|1\rangle_0|1\rangle_1 \end{pmatrix} \\ \triangleq \quad |0\rangle_0|\varepsilon\mu\rangle_1 &= |00\rangle_1 + \imath|01\rangle_1 + \imath|10\rangle_1 - |11\rangle_1 &&= \begin{pmatrix} |00\rangle_1 \\ \imath|01\rangle_1 \\ \imath|10\rangle_1 \\ -|11\rangle_1 \end{pmatrix} . \end{aligned} \tag{47.69}$$

A presentation on the subject is available at (watch talk). See also the websites IBM Circuit Composer, Qiskit, Cirq, and Pennylane.

47.3.1 The qubit

The general state of a qubit is a quantum superposition in the Hilbert space $\mathbb{H}^2$,

$$|\varepsilon\rangle = \alpha|0\rangle + \imath\beta|1\rangle = \begin{pmatrix} \alpha \\ \imath\beta \end{pmatrix} . \tag{47.70}$$

and can be represented by a point on the Bloch sphere.

The possible outcomes of a *measurement* of its state are represented by a classical truth table,

$$\begin{array}{c} |q_0\rangle \\ \hline |0\rangle \\ |1\rangle \end{array} \quad , \qquad \text{for example} \qquad |1\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} . \tag{47.71}$$

While the possible values of a measurement are restricted to the binaries 0 or 1, but the probability with which one of the two results is encountered depends on the position of the Bloch vector at the time the measurement was performed.

As we have seen earlier, the two principle ways a light mode acts on a two-level system are the resonant interaction and the dispersive interaction. From the Jaynes-Cummings model (40.35) and (40.42),

$$\begin{aligned} R(\tau) &\equiv \begin{pmatrix} \cos\frac{\pi}{2}\tau & \imath\sin\frac{\pi}{2}\tau \\ \imath\sin\frac{\pi}{2}\tau & \cos\frac{\pi}{2}\tau \end{pmatrix} \xrightarrow{\tau\to 1} \begin{pmatrix} & \imath \\ \imath & \end{pmatrix} , \\ D(\tau) &\equiv \begin{pmatrix} e^{\imath\pi\tau} & 0 \\ 0 & 1 \end{pmatrix} \xrightarrow{\tau\to 1} \begin{pmatrix} -1 & \\ & 1 \end{pmatrix} . \end{aligned} \tag{47.72}$$

Both interactions lead to unitary evolutions of the qubit's state.

The two gates (47.72) are particular cases of the most fundamental single qubit quantum gate, which can be written as,

$$\boxed{\mathcal{U}_3(\vartheta,\varphi,\lambda) = \begin{pmatrix} \cos\frac{\vartheta}{2} & -e^{\imath\lambda}\sin\frac{\vartheta}{2} \\ e^{\imath\varphi}\sin\frac{\vartheta}{2} & e^{\imath\lambda+\imath\varphi}\cos\frac{\vartheta}{2} \end{pmatrix}} , \tag{47.73}$$

which is a unitary operation since $\det\mathcal{U}_3(\vartheta,\varphi,\lambda) = e^{\imath(\lambda+\varphi)}$. Special cases are the *Hadamard gate*,

$$H \equiv \mathcal{U}_3(\tfrac{\pi}{2},0,\pi) = \tfrac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} , \tag{47.74}$$

and the *phase gate*,

$$\mathcal{U}_1(\varphi) \equiv \mathcal{U}_3(0,\varphi,0) = \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\varphi} \end{pmatrix} . \tag{47.75}$$

Phase rotations about particular angles receive specific names. For example,

$$\boxed{Z \equiv -\hat{\sigma}_z = \mathcal{U}_1(\pi)} = |-q_0\rangle\langle q_0| , \tag{47.76}$$

is simply the negative Pauli z-matrix defined in (23.154). The *negation* in the Hilbert space $\mathbb{H}^2$,

$$\boxed{X \equiv \hat{\sigma}_x = \mathcal{U}_3(\pi, 0, \pi) = |\bar{q}_0\rangle\langle q_0|}\ , \tag{47.77}$$

is simply the Pauli x-matrix.

Analogously to classical logic circuits, which can be represented by concatenated symbols, quantum circuits can be composed by concatenations of unitary operations. Fig. 47.8(b) lists fundamental quantum logic gates together with their classical counterparts shown in Fig. 47.8(a).

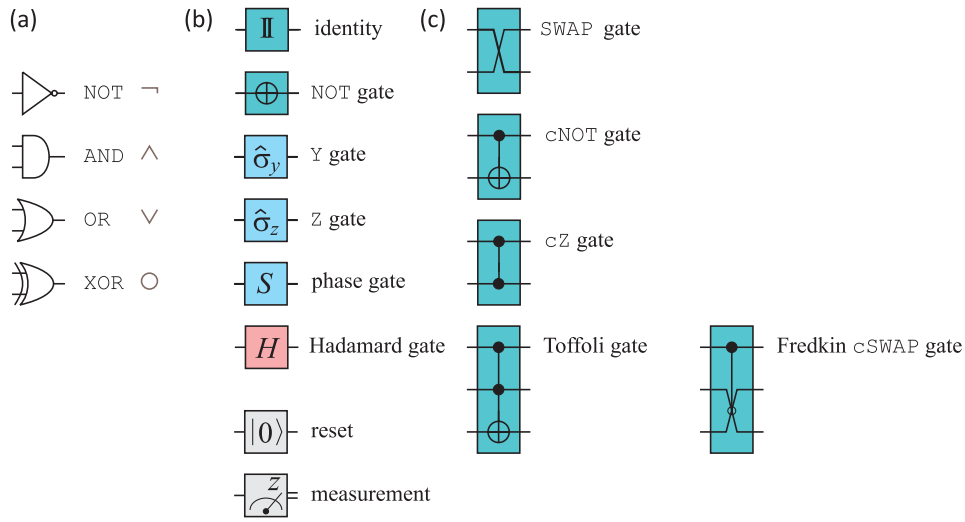

Figure 47.8: (a) Common symbols for fundamental classical gates, (b) for single qubit quantum gates, and (c) for three qubit quantum gates.

47.3.2 Quantum gates of 2 qubits

We can generalize the single-qubit algebra to arbitrary registers using the *direct* sum and the *external product* defined in (23.223) and (23.225),

$$\begin{array}{c} |q_1, q_0\rangle \\ \hline |0,0\rangle \\ |0,1\rangle \\ |1,0\rangle \\ |1,1\rangle \end{array}\ , \qquad \text{for example} \qquad |0,1\rangle = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}\ . \tag{47.78}$$

47.3.2.1 Single qubit gates in $\mathbb{H}^4$

Single qubit gates can be embedded in multi-qubit registers. For example, the *negation* of 'NOT' gate in $\mathbb{H}^4$ can be applied either to the first or the second qubit [7],

$$\boxed{\begin{aligned} X_0 &\hat{=} \mathbb{I} \otimes \hat{X} = |q_1, \bar{q}_0\rangle\langle q_1, q_0| \\ X_1 &\hat{=} \hat{X} \otimes \mathbb{I} = |\bar{q}_1, q_0\rangle\langle q_1, q_0| \end{aligned}} \ . \tag{47.79}$$

Example 344 (*Negation gates*): The classical truth table for the negation of qubit q_1 reads,

$$\begin{array}{ccc} |q_1, q_0\rangle & \curvearrowright & |\bar{q}_1, q_0\rangle \\ \hline |0,0\rangle & & |0,1\rangle \\ |0,1\rangle & & |0,0\rangle \\ |1,0\rangle & & |1,1\rangle \\ |1,1\rangle & & |1,0\rangle \end{array} \tag{47.80}$$

In the quantum language the relations (47.79) are executed by multiplying the unitary transform describing the negation gate with the truth table representation (47.78) of the input state $|q_1, q_0\rangle$,

$$X \otimes \mathbb{I}|q_1, q_0\rangle = \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 1 \end{pmatrix} = |\bar{q}_1, q_0\rangle \ . \tag{47.81}$$

Analogously, Hadamard and other rotation gates $\mathcal{U}$ are applied to specific qubits of a register via $\mathbb{I} \otimes ... \otimes \mathcal{U} \otimes ... \otimes \mathbb{I}$.

47.3.2.2 Parallel and serial operations

In order to execute unitary operations U_k on different qubits q_k of a quantum register in parallel, the complete Hilbert space must be spanned first before the individual operation can be described by matrix multiplication,

$$U = U_1 \otimes U_0 = (U_1 \otimes \mathbb{I}) \ (\mathbb{I} \otimes U_0) \ . \tag{47.82}$$

Consecutive operations U, V on the quantum register can be concatenated, $U \ V$.

47.3.2.3 The controlled NOT gate

The most interesting two-qubit quantum gate is the 'controlled NOT' gate or *antivalence*, which we will now discuss in detail. This gate is originally defined on $\mathbb{H}^2 \otimes \mathbb{H}^2$. The quantum operation is implemented by first going to the Hilbert space $\mathbb{H}^1 \otimes \mathbb{H}^4$, applying the unitary transform,

$$\mathbb{I} \triangleright X = \begin{pmatrix} \mathbb{I}_2 & \\ & X \end{pmatrix} \ , \tag{47.83}$$

[7] Note that we call 'first' the rightmost qubit.

where X has been defined in Eq. (47.77), and finally returning to $\mathbb{H}^2 \otimes \mathbb{H}^2$:

$$
\begin{aligned}
|\varepsilon\rangle_0|\mu\rangle_1 &\triangleq |0\rangle_0|\varepsilon\mu\rangle_1 \xrightarrow{\hat{N}} \delta_{\varepsilon=0}|\varepsilon\rangle_0|\mu\rangle_1 + \delta_{\varepsilon=1}|\varepsilon\rangle_1 \begin{pmatrix} 1 & \imath \\ \imath & 1 \end{pmatrix}^2 |\mu\rangle_1 \triangleq |\varepsilon\rangle_0|\varepsilon \oplus \mu\rangle_1 \\
\begin{pmatrix} |0\rangle_0|0\rangle_1 \\ \imath|0\rangle_0|1\rangle_1 \\ \imath|1\rangle_0|0\rangle_1 \\ -|1\rangle_0|1\rangle_1 \end{pmatrix} &\triangleq \begin{pmatrix} |00\rangle_1 \\ \imath|01\rangle_1 \\ \imath|10\rangle_1 \\ -|11\rangle_1 \end{pmatrix} \xrightarrow{\hat{N}} \begin{pmatrix} |00\rangle_1 \\ \imath|01\rangle_1 \\ \imath|11\rangle_1 \\ -|10\rangle_1 \end{pmatrix} \triangleq \begin{pmatrix} |0\rangle_0|0\rangle_1 \\ \imath|0\rangle_0|1\rangle_1 \\ \imath|1\rangle_0|0\rangle_1 \\ -|1\rangle_0|1\rangle_1 \end{pmatrix} .
\end{aligned}
\tag{47.84}
$$

The short-hand notation of the 'controlled `NOT`' operation on $\mathbb{H}^4$ can be written as,

$$
\boxed{
\begin{aligned}
\overset{c}{X}_{10} &\hat{=} \mathbb{I} \triangleright X &&= |q_1, q_1 \oplus q_0\rangle\langle q_1, q_0| \\
\overset{c}{X}_{01} &\hat{=} X \triangleleft \mathbb{I} = \mathbb{S}(\mathbb{I} \triangleright X)\mathbb{S} &&= |q_0 \oplus q_1, q_0\rangle\langle q_1, q_0|
\end{aligned}
}
\quad . \tag{47.85}
$$

where the '`SWAP`' operator $\mathbb{S}$ has been defined in (23.229). When the qubits addressed by a gate are not identified from their position in the tensor product, an index at the gate symbol indicates which qubits are involved. For example, X_0 inverts the first qubit q_0, and $\overset{c}{X}_{0\to 1} = \overset{c}{X}_{01}$ controls the state of the second qubit q_1 by the first one.

Example 345 (*Controlled `NOT` gates*): We can easily verify,

$$
\begin{aligned}
\overset{c}{X}_{10} &= |0\rangle\langle 0| \otimes \mathbb{I} + |1\rangle\langle 1| \otimes X \\
&= \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \otimes \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} \mathbb{I} & 0 \\ 0 & X \end{pmatrix} ,
\end{aligned}
\tag{47.86}
$$

and

$$
\begin{aligned}
\overset{c}{X}_{01} &= \mathbb{I}| \otimes |0\rangle\langle 0| + X \otimes |1\rangle\langle 1| \\
&= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \otimes \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \otimes \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} = \mathbb{S}\overset{c}{X}_{10}\mathbb{S} .
\end{aligned}
\tag{47.87}
$$

The `SWAP` gate itself can be generated from `cNOT` gates, as will be shown in Exc. 47.3.7.1. Do the Excs. 47.3.7.2 to 47.3.7.3.

47.3.3 Boolean versus linear algebra

It is now time to work out the fundamental difference between classical and quantum computing. The mathematical formalism underlying *classical computing* is the *Boolean algebra*, while the formalism underlying *quantum computing* is the *linear algebra*.

Example 346 (*Controlled `NOT` gates*): We illustrate the difference between classical and quantum computing at the example of the `XOR` gate represented by

the classical truth table,

$$\begin{array}{cc} |q_1, q_0\rangle \curvearrowright & |q_1, q_1 \oplus q_0\rangle \\ \hline |0,0\rangle & |0,0\rangle \\ |0,1\rangle & |0,1\rangle \\ |1,0\rangle & |1,1\rangle \\ |1,1\rangle & |1,0\rangle \end{array} \tag{47.88}$$

The operation can be realized via unitary transform,

$$\mathbb{I}\triangleright X|q_1, q_0\rangle = \texttt{XOR}_1|q_1, q_0\rangle = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} 0 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \\ 1 & 1 \\ 1 & 0 \end{pmatrix} = |q_1, q_1 \oplus q_0\rangle \ . \tag{47.89}$$

The unitary transform allows not only to propagate specific states $|q_1, q_0\rangle$ of the basis through the circuit, but also linear combinations, such as for example the state $|0,0\rangle + |1,0\rangle$.

Quantum superpositions are not permitted in classical computing, which is to say that the only permitted input states are the eigenstates of the product basis. Consequently, gate operations inducing superpositions, such as the Hadamard gate are not allowed. Only gate operations transforming an eigenstate into another eigenstate are possible, such as the `NOT` or the `NAND` gate.

It is important to stress that *everything you can do on a classical computer, you can do on a quantum computer, and vice versa.* The question is simply whether you can do it in due time. The first part of the statement is obvious by the fact that quantum computing is described by unitary transformations on a large but discrete and finite Hilbert space. The transformations are represented by matrices, which can be processed on a classical computer. The second part of the statement is a bit more tricky, because the fundamental gates of classical computing are `AND` and `OR` operations, which are not unitary. So see this, we set up the classical truth table for the `AND` gate,

$$\begin{array}{cc} |q_1, q_0\rangle \curvearrowright & |q_1, q_1 \wedge q_0\rangle \\ \hline |0,0\rangle & |0,0\rangle \\ |0,1\rangle & |0,0\rangle \\ |1,0\rangle & |1,0\rangle \\ |1,1\rangle & |1,1\rangle \end{array} \tag{47.90}$$

and the corresponding transform,

$$\texttt{AND}_1|q_1, q_0\rangle = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 0 & 0 \\ 0 & 1 \\ 1 & 0 \\ 1 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 1 & 1 \end{pmatrix} = |q_1, q_1 \wedge q_0\rangle \ . \tag{47.91}$$

Hence, the fundamental gates of classical computing cannot be constructed only from unitary `XOR` and `NOT` gates. Another way to see this is by noticing that the result $|0,0\rangle$ of the truth table (47.90) can be obtained from two different input states, which

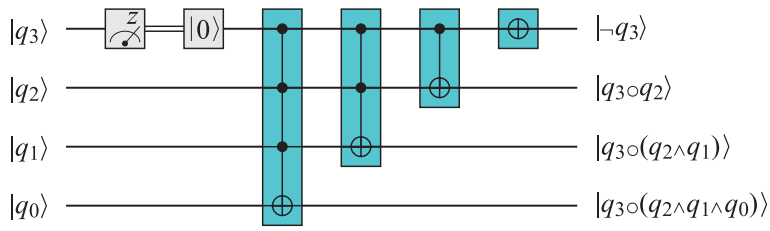

Figure 47.9: Quantum circuit realizing logical gates. While the `NOT` and `XOR` gates can be made reversible, the `AND` and `OR` gates require projection of some qubits.

means that the classical operation is not reversible. Do the Excs. 47.3.7.4 to 47.3.7.5.

In Exc. 47.3.7.10 we will show how to embed `AND` and `OR` into more general three-bit quantum gates, which then can be projected into non-unitary `AND` and `OR` gates.

47.3.4 Fundamental and universal quantum gates of 3 qubits and more

We now consider three qubits in $\mathbb{H}^8 \equiv \mathbb{H}^2 \otimes \mathbb{H}^2 \otimes \mathbb{H}^2$. The *truth table* has the shape,

$$\begin{array}{c} |q_2, q_1, q_0\rangle \\ \hline |0,0,0\rangle \\ |0,0,1\rangle \\ |0,1,0\rangle \\ |0,1,1\rangle \\ |1,0,0\rangle \\ |1,0,1\rangle \\ |1,1,0\rangle \\ |1,1,1\rangle \end{array} \quad , \quad \text{for example} \quad |0,1,0\rangle = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} . \tag{47.92}$$

We choose $\mathbb{I}_8$ as the basis of $\mathbb{H}^8$. We assume that the number represented by the state $|q_2, q_1, q_0\rangle$ is $[q_2 q_1 q_0]_{binary} = [2^2 q_2 + 2^1 q_1 + 2^0 q_0]_{decimal}$.

The unitary transform implemented by a quantum gate can be understood as a permutation of the basis vectors in the truth table. We can generalize the permutation rules (23.229) to 3D Hilbert spaces $\mathbb{H}^2 \otimes \mathbb{H}^2 \otimes \mathbb{H}^2$, where $M \otimes N \otimes R = \mathbb{S}_{01}(N \otimes M \otimes R)\mathbb{S}_{01} = \mathbb{S}_{12}(M \otimes R \otimes N)\mathbb{S}_{12} = \mathbb{S}_{01}(R \otimes N \otimes M)\mathbb{S}_{02}$, with the transformation matrices,

$$\mathbb{S}_{01} = \mathbb{I} \otimes \mathbb{S} \quad , \quad \mathbb{S}_{12} = \mathbb{S} \otimes \mathbb{I} \quad , \quad \mathbb{S}_{02} = \mathbb{S}_{01}\mathbb{S}_{12}\mathbb{S}_{01} \ , \tag{47.93}$$

where the operator $\mathbb{S}$ has again been taken from (23.229). In Exc. 47.3.7.7 we derive the explicit matricial forms of $\mathbb{S}_{ij}$.

Examples of fundamental three-qubits gates are, in short notation, the *negation* in $\mathbb{H}^8$,

$$\begin{aligned} X_0 &\hat{=} \mathbb{I} \otimes \mathbb{I} \otimes X = |q_2, q_1, \bar{q_0}\rangle\langle q_2, q_1, q_0| \\ X_1 &\hat{=} \mathbb{I} \otimes X \otimes \mathbb{I} = |q_2, \bar{q_1}, q_0\rangle\langle q_2, q_1, q_0| \\ X_2 &\hat{=} X \otimes \mathbb{I} \otimes \mathbb{I} = |\bar{q_2}, q_1, q_0\rangle\langle q_2, q_1, q_0| \ , \end{aligned} \tag{47.94}$$

the *antivalence*,

$$\begin{aligned}
\overset{c}{X}_{10} &\equiv \mathbb{I}\otimes(\mathbb{I}\rhd X) &&= |q_2,q_1,q_1\oplus q_0\rangle\langle q_2,q_1,q_0| \\
\overset{c}{X}_{01} &\equiv \mathbb{S}_{01}\overset{c}{X}_{10}\mathbb{S}_{01} &&= |q_2,q_0\oplus q_1,q_0\rangle\langle q_2,q_1,q_0| \\
\overset{c}{X}_{02} &\equiv \mathbb{S}_{12}\overset{c}{X}_{01}\mathbb{S}_{12} &&= |q_0\oplus q_2,q_1,q_0\rangle\langle q_2,q_1,q_0| \\
\overset{c}{X}_{20} &\equiv \mathbb{S}_{02}\overset{c}{X}_{02}\mathbb{S}_{02} &&= |q_2,q_1,q_2\oplus q_0\rangle\langle q_2,q_1,q_0| \\
\overset{c}{X}_{21} &\equiv \mathbb{S}_{02}\overset{c}{X}_{01}\mathbb{S}_{02} &&= |q_2,q_2\oplus q_1,q_0\rangle\langle q_2,q_1,q_0| \\
\overset{c}{X}_{12} &\equiv \mathbb{S}_{12}\overset{c}{X}_{21}\mathbb{S}_{12} &&= |q_1\oplus q_2,q_1,q_0\rangle\langle q_2,q_1,q_0| \ ,
\end{aligned} \tag{47.95}$$

from which we get explicitly, as verified in Exc. 47.3.7.8,

$$\overset{c}{X}_{10} = \begin{pmatrix} \mathbb{I} & & & \\ & X & & \\ & & \mathbb{I} & \\ & & & X \end{pmatrix} \ , \quad \overset{c}{X}_{20} = \begin{pmatrix} \mathbb{I} & & & \\ & \mathbb{I} & & \\ & & X & \\ & & & X \end{pmatrix} \ , \quad \overset{c}{X}_{21} = \begin{pmatrix} \mathbb{I} & & \\ & \mathbb{I} & \\ & & X\otimes\mathbb{I} \end{pmatrix} \ . \tag{47.96}$$

It is possible to show that all quantum logic gates can be reduced to a universal so-called *Toffoli gate* [62],

$$\begin{aligned}
\mathbb{H}^8 &\xrightarrow{\mathcal{U}} \mathbb{H}^8 \\
|q_2,q_1,q_0\rangle &\xrightarrow{\mathcal{U}} |q_2,q_1,(q_2\wedge q_1)\oplus q_0\rangle \\
\mathbb{I}_8 &\xrightarrow{\mathcal{U}} \mathcal{U} \ ,
\end{aligned} \tag{47.97}$$

or in short-hand notation,

$$\boxed{\overset{cc}{X}_{210} = \mathbb{I}\rhd\mathbb{I}\rhd X = |q_2,q_1,(q_2\wedge q_1)\oplus q_0\rangle\langle q_2,q_1,q_0| = \begin{pmatrix} \mathbb{I}_6 & \\ & \hat{\sigma}_x \end{pmatrix}} \ , \tag{47.98}$$

as will be shown in Exc. 47.3.7.9 and 47.3.7.10.

Obviously, to perform quantum calculations, we need at least two qubits and operations acting simultaneous on both. Do the Excs. 47.3.7.11 to 47.3.7.12.

The extension of the formalism to more than three qubits is straightforward, and the implementation of a quantum algorithm on a classical computer is quite simple, the difficulty mainly being the size of the Hilbert space, which rapidly explodes with increasing numbers of qubits.

In practice, the task often consists in breaking down a problem into a sequence of operations on a binary quantum register. As we have shown in Sec. 47.3.3 every irreversible classical algorithm can be mapped to a corresponding reversible quantum algorithm. This brute force 'quantization' is, however, very inefficient since it uses as many (and even more) qubits than the classical algorithm.

Until now, we restricted to pure states $|\psi_f\rangle = \bigotimes_k[\alpha_k|0\rangle_k + \beta_k|1\rangle_k]$ generated from an initial eigenstate $|\psi_i\rangle = \bigotimes_k |0\rangle_k$ by reversible quantum computing. The density

Table 47.1: Symbols and definitions of common quantum gates.

gate	symbol	matrix
identity	$\mathbb{I}$	$\mathcal{U}_3(0,0,0)$
inversion	$X = \texttt{NOT}$	$\hat{\sigma}_x = \mathcal{U}_3(\pi,0,\pi)$
Pauli Y	Y	$\hat{\sigma}_y = \mathcal{U}_3(\pi,\frac{\pi}{2},\frac{\pi}{2})$
Pauli Z	Z	$\hat{\sigma}_z = \mathcal{U}_1(\pi)$
S gate	S	$\hat{\sigma}_z = \mathcal{U}_1(\frac{\pi}{2})$
T gate	T	$\hat{\sigma}_z = \mathcal{U}_1(\frac{\pi}{4})$
Hadamard gate	H	$\mathcal{U}_3(\frac{\pi}{2},0,\pi)$
swap gate	$\mathbb{S} = \texttt{SWAP}$	$\begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$
controlled X	$\overset{c}{X} = \texttt{cX}$	$\mathbb{I} \triangleright \hat{\sigma}_x = \begin{pmatrix} \mathbb{I}_2 & 0 \\ 0 & \hat{\sigma}_x \end{pmatrix}$
controlled Z	$\overset{c}{Z} = \texttt{cZ}$	$\mathbb{I} \triangleright \hat{\sigma}_z = \begin{pmatrix} \mathbb{I}_2 & 0 \\ 0 & \hat{\sigma}_z \end{pmatrix}$
controlled H	$\overset{c}{H} = \texttt{cH}$	$\mathbb{I} \triangleright H = \begin{pmatrix} \mathbb{I}_2 & 0 \\ 0 & H \end{pmatrix}$
Toffoli	$\overset{cc}{X} = \texttt{ccX}$	$\mathbb{I} \triangleright \mathbb{I} \triangleright \hat{\sigma}_x = \begin{pmatrix} \mathbb{I}_6 & \\ & \hat{\sigma}_x \end{pmatrix}$

operator can then be written,

$$\boxed{\hat{\rho} = |\psi_f\rangle\langle\psi_f| = \mathcal{U}|\psi_i\rangle\langle\psi_i|\mathcal{U}^\dagger} \,. \tag{47.99}$$

In the next section, following up on Sec. 37.2.3, we will discuss how projective measurements introduce irreversibility into the evolution of the density operator.

47.3.5 State propagation and projective measurements

The measurement of a qubit projects the Hilbert space on its two possible outcomes. For example, measuring the first out of three qubits means,

$$\mathbb{H} \otimes \mathbb{H} \otimes \mathbb{H} \xrightarrow{measure} \begin{cases} |0\rangle \otimes \mathbb{H} \otimes \mathbb{H} \\ |1\rangle \otimes \mathbb{H} \otimes \mathbb{H} \end{cases} . \tag{47.100}$$

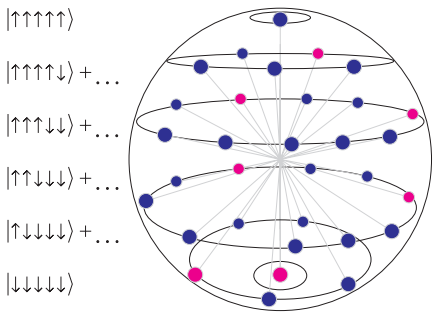

Figure 47.10: Illustration of the possible states of a 5-qubit system.

We consider a density matrix $\hat{\rho}$ operating on the entire Hilbert space and define projectors,

$$\hat{P}_j^{(n)} = \mathbb{I} \otimes ... \otimes |n\rangle_j \langle n| \otimes ... \otimes \mathbb{I} \qquad \text{with} \qquad n = 0, 1 \ . \tag{47.101}$$

that, applied to a specific qubit q_j, project its state onto the eigenstate $|0\rangle$ or $|1\rangle$, respectively. A projective measurement of the j-th qubit with two possible outcomes $|q_j\rangle = |0\rangle, |1\rangle$ with the respective probabilities $p_j^{(0)}, p_j^{(1)}$, generates the mixed states reduced density operator,

$$\boxed{\hat{\rho}_j^{\text{red}} = \sum_{n=0,1} p_j^{(n)} \frac{\hat{P}_j^{(n)} \hat{\rho} \hat{P}_j^{(n)}}{\text{Tr } \hat{\rho} \hat{P}_j^{(n)}}} \ . \tag{47.102}$$

Note that, a priori, $\hat{\rho}_j^{\text{red}}$ has the same rank as $\hat{\rho}$, but a more diagonal structure, since some coherences have been traced out.

47.3.5.1 Quantum state tomography

Any density operator of a pure or mixed state of an individual qubit can be expanded as,

$$\hat{\rho}_j = \tfrac{1}{2} \left(\mathbb{I} + a_j \hat{\sigma}_j^x + b_j \hat{\sigma}_j^y + c_j \hat{\sigma}_j^z \right) = \tfrac{1}{2} \begin{pmatrix} 1 + c_j & a_j - \imath b_j \\ a_j + \imath b_j & 1 - c_j \end{pmatrix} \ , \tag{47.103}$$

where,

$$\hat{\sigma}_j^k = \mathbb{I} \otimes ... \otimes \hat{\sigma}^k \otimes ... \otimes \mathbb{I} \ , \tag{47.104}$$

and $\hat{\sigma}^k$ are the Pauli matrices. The parameters a_j, b_j, and c_j can be determined by measurements,

$$\boxed{\langle \hat{\vec{\sigma}}_j \rangle = \text{Tr } \hat{\rho} \hat{\vec{\sigma}}_j = \begin{pmatrix} a_j \\ b_j \\ c_j \end{pmatrix}} \ , \tag{47.105}$$

where $\hat{\rho}$ is the density matrix of the whole system.

47.3.5.2 Measurements on a single qubit

A single qubit $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$, normalized as $|\alpha|^2 + |\beta|^2 = 1$, is described by the density operator,

$$\hat{\rho} = \begin{pmatrix} \rho_{00} & \rho_{01} \\ \rho_{10} & \rho_{11} \end{pmatrix} = |\psi\rangle\langle\psi| = \begin{pmatrix} |\alpha|^2 & \alpha\beta^* \\ \alpha^*\beta & |\beta|^2 \end{pmatrix} . \tag{47.106}$$

A projective measurement of the qubit with two possible outcomes, $|q\rangle = |0\rangle, |1\rangle$ with the respective probabilities $p^{(0)} = |\alpha|^2$ and $p^{(1)} = |\beta|^2$, generates the mixed states reduced density operator,

$$\hat{\rho}^{\text{red}} = p^{(0)} \frac{|0\rangle\langle 0|\hat{\rho}|0\rangle\langle 0|}{\text{Tr } \hat{\rho}|0\rangle\langle 0|} + p^{(1)} \frac{|1\rangle\langle 1|\hat{\rho}|1\rangle\langle 1|}{\text{Tr } \hat{\rho}|1\rangle\langle 1|} = |\alpha|^2|0\rangle\langle 0| + |\beta|^2|1\rangle\langle 1| . \tag{47.107}$$

Some physical processes may not only project the density operator onto a specific basis, but onto a particular eigenstate,

$$\hat{\rho} \longrightarrow \hat{\rho}^{\text{prj}} = |0\rangle\langle 0|\hat{\rho}|0\rangle\langle 0| . \tag{47.108}$$

Example 347 (*Quantum Zeno effect on a single qubit*): As an example, let us express the quantum Zeno effect in quantum computing language. Starting from a two-level system in its ground state,

$$\hat{\rho}^{in} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \quad , \quad \mathcal{U}_3(\vartheta, 0, 0) = \begin{pmatrix} \cos\vartheta & -\sin\vartheta \\ \sin\vartheta & \cos\vartheta \end{pmatrix} ,$$

we perform small rotations,

$$\hat{\rho}^{rot} = \mathcal{U}_3(\vartheta, 0, 0)\hat{\rho}^{in}\mathcal{U}_3(\vartheta, 0, 0)^\dagger = \begin{pmatrix} \cos^2\vartheta & \cos\vartheta\sin\vartheta \\ \cos\vartheta\sin\vartheta & \sin^2\vartheta \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} ,$$

before measuring the system,

$$\hat{\rho}^{\text{red}} = \cos^2\vartheta \frac{|0\rangle\langle 0|\hat{\rho}^{rot}|0\rangle\langle 0|}{\text{Tr } \hat{\rho}^{rot}|0\rangle\langle 0|} + \sin^2\vartheta \frac{|1\rangle\langle 1|\hat{\rho}^{rot}|1\rangle\langle 1|}{\text{Tr } \hat{\rho}^{rot}|1\rangle\langle 1|} = \begin{pmatrix} \cos^2\vartheta & 0 \\ 0 & \sin^2\vartheta \end{pmatrix} .$$

Discarding the possibility that the system be excited, we project it system onto the ground state,

$$\hat{\rho}^{fin} = |0\rangle\langle 0|\hat{\rho}^{\text{red}}|0\rangle\langle 0| = |0\rangle\langle 0|\mathcal{U}_3(\vartheta, 0, 0)\hat{\rho}^{in}\mathcal{U}_3(\vartheta, 0, 0)^\dagger|0\rangle\langle 0| = \begin{pmatrix} \cos^2\vartheta & 0 \\ 0 & 0 \end{pmatrix} .$$

On the other hand, repeating the procedure n times with $\vartheta = \frac{\pi}{2n}$ and $n \to \infty$, we find,

$$\hat{\rho}^{fin} = \lim_{n\to\infty} \left(|0\rangle\langle 0|\mathcal{U}_3(\tfrac{\pi}{2n}, 0, 0)\hat{\rho}^{in}\mathcal{U}_3(\tfrac{\pi}{2n}, 0, 0)^\dagger|0\rangle\langle 0|\right)^n = \begin{pmatrix} \lim_{n\to\infty}\cos^{2n}\frac{\pi}{2n} & 0 \\ 0 & 0 \end{pmatrix} = \hat{\rho}^{in} .$$

That is, the evolution of the system is frozen by too many measurements.

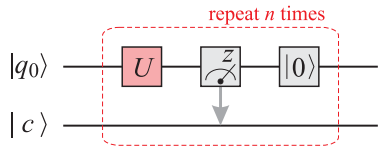

Figure 47.11: Quantum Zeno effect on a single qubit.

47.3.5.3 Measurements in two qubit systems

Let us now consider a two-qubit system $q_1 \otimes q_0$ described by the initial density matrix,

$$\hat{\rho} = \hat{\rho}_1 \otimes \hat{\rho}_0 = \begin{pmatrix} |\alpha_1|^2 & \alpha_1\beta_1^* \\ \alpha_1^*\beta_1 & |\beta_1|^2 \end{pmatrix} \otimes \begin{pmatrix} |\alpha_0|^2 & \alpha_0\beta_0^* \\ \alpha_0^*\beta_0 & |\beta_0|^2 \end{pmatrix} \tag{47.109}$$

$$= \begin{pmatrix} (\rho_1)_{00} & (\rho_1)_{01} \\ (\rho_1)_{10} & (\rho_1)_1 \end{pmatrix} \otimes \begin{pmatrix} (\rho_0)_{00} & (\rho_0)_{01} \\ (\rho_0)_{10} & (\rho_0)_1 \end{pmatrix} = \begin{pmatrix} \rho_{00\otimes 00} & \rho_{00\otimes 01} & \rho_{10\otimes 00} & \rho_{01\otimes 01} \\ \rho_{00\otimes 10} & \rho_{00\otimes 11} & \rho_{01\otimes 10} & \rho_{01\otimes 11} \\ \rho_{10\otimes 00} & \rho_{10\otimes 01} & \rho_{11\otimes 00} & \rho_{11\otimes 01} \\ \rho_{10\otimes 10} & \rho_{10\otimes 11} & \rho_{11\otimes 10} & \rho_{11\otimes 11} \end{pmatrix} ,$$

where we defined $\rho_{kl\otimes mn} \equiv (\rho_1)_{kl}(\rho_0)_{mn}$. Projective measurements of qubit q_1 with two possible outcomes, $|q_1\rangle = |0\rangle, |1\rangle$, with the respective probabilities $p^{(0)} = |\alpha_1|^2$ and $p^{(1)} = |\beta_1|^2$, yields the reduced density operator,

$$\hat{\rho}_1^{\text{red}} = p^{(0)} \frac{[|0\rangle\langle 0| \otimes \mathbb{I}]\hat{\rho}[|0\rangle\langle 0| \otimes \mathbb{I}]}{\text{Tr } \hat{\rho}[|0\rangle\langle 0| \otimes \mathbb{I}]} + p^{(1)} \frac{[|1\rangle\langle 1| \otimes \mathbb{I}]\hat{\rho}[|1\rangle\langle 1| \otimes \mathbb{I}]}{\text{Tr } \hat{\rho}[|1\rangle\langle 1| \otimes \mathbb{I}]} \tag{47.110}$$

$$= \frac{|\alpha_1|^2}{\rho_{00\otimes 00} + \rho_{01\otimes 01}} \begin{pmatrix} \rho_{00\otimes 00} & \rho_{00\otimes 01} & 0 & 0 \\ \rho_{01\otimes 00} & \rho_{01\otimes 01} & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} + \frac{|\beta_1|^2}{\rho_{10,10} + \rho_{11,11}} \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \rho_{10\otimes 10} & \rho_{10\otimes 11} \\ 0 & 0 & \rho_{11\otimes 10} & \rho_{11\otimes 11} \end{pmatrix} .$$

The inversion of qubit q_1 is,

$$\langle \hat{\sigma}_1^z \rangle = \text{Tr } \hat{\rho}\,[\hat{\sigma}^z \otimes \mathbb{I}] = \rho_{00,00} + \rho_{01,01} - \rho_{10,10} - \rho_{11,11} \ . \tag{47.111}$$

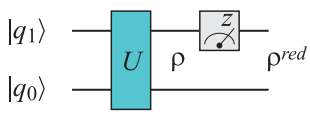

Figure 47.12: Projective measurement. After an operation U, two qubits remain in an entangled state $\hat{\rho}$. Measurement of qubit q_1 reduces the state to $\hat{\rho}^{\text{red}}$, while transferring the information to a classical channel c.

Example 348 (*Measurements on disentangled qubits*): As a particular case, let us first consider two disentangled qubits $|\psi\rangle = |q_1\rangle \otimes |q_0\rangle = [\alpha_1|0\rangle +$

$\beta_1|1\rangle] \otimes [\alpha_0|0\rangle + \beta_0|1\rangle]$, such that,

$$\hat{\rho} = \begin{pmatrix} \alpha_1\alpha_0 \\ \alpha_1\beta_0 \\ \beta_1\alpha_0 \\ \beta_1\beta_0 \end{pmatrix} \begin{pmatrix} \alpha_1^*\alpha_0^* & \alpha_1^*\beta_0^* & \beta_1^*\alpha_0^* & \beta_1^*\beta_0^* \end{pmatrix} \tag{47.112}$$

$$= \begin{pmatrix} |\alpha_1|^2|\alpha_0|^2 & |\alpha_1|\alpha_0^*\beta_0^* & \alpha_1\beta_1^*|\alpha_0|^2 & \alpha_1\beta_1^*\alpha_0\beta_0^* \\ |\alpha_1|^2\alpha_0^*\beta_0 & |\alpha_1|^2|\beta_0|^2 & \alpha_1\beta_1^*\alpha_0^*\beta_0 & \alpha_1\beta_1^*|\beta_0|^2 \\ \alpha_1^*\beta_1|\alpha_0|^2 & \beta_1\alpha_1^*\alpha_0\beta_0^* & |\beta_1|^2|\alpha_0|^2 & |\beta_1|^2\alpha_0\beta_0^* \\ \alpha_1^*\beta_1\alpha_0^*\beta_0 & \alpha_1^*\beta_1|\beta_0|^2 & |\beta_1|^2\alpha_0^*\beta_0 & |\beta_1|^2|\beta_0|^2 \end{pmatrix} .$$

A projective measurements of qubit q_1 with two possible outcomes, $|q_1\rangle = |0\rangle_1, |1\rangle_1$ with the respective probabilities $p_0 = |\alpha_1|^2$ and $p_1 = |\beta_1|^2$, yields the reduced density operator,

$$\hat{\rho}_1^{\text{red}} = p^{(0)} \frac{[|0\rangle\langle 0| \otimes \mathbb{I}]\hat{\rho}[|0\rangle\langle 0| \otimes \mathbb{I}]}{\text{Tr } \hat{\rho}[|0\rangle\langle 0| \otimes \mathbb{I}]} + p^{(1)} \frac{[|1\rangle\langle 1| \otimes \mathbb{I}]\hat{\rho}[|1\rangle\langle 1| \otimes \mathbb{I}]}{\text{Tr } \hat{\rho}[|1\rangle\langle 1| \otimes \mathbb{I}]} \tag{47.113}$$

$$= |\alpha_1|^2 \begin{pmatrix} |\alpha_0|^2 & \alpha_0\beta_0^* & 0 & 0 \\ \alpha_0^*\beta_0 & |\beta_0|^2 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} + |\beta_1|^2 \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & |\alpha_0|^2 & \alpha_0\beta_0^* \\ 0 & 0 & \alpha_0^*\beta_0 & |\beta_0|^2 \end{pmatrix}$$

$$= [|\alpha_1|^2|0\rangle\langle 0| + |\beta_1|^2|1\rangle\langle 1|] \otimes \hat{\rho}_0 .$$

The inversion of qubit q_1 is,

$$\langle \hat{\sigma}_1^z \rangle = |\alpha_1|^2 - |\beta_1|^2 . \tag{47.114}$$

That is, we are left with a mixture of two product states, $|0\rangle \otimes [\alpha_0|0\rangle + \beta_0|1\rangle]$ or $|1\rangle \otimes [\alpha_0|0\rangle + \beta_0|1\rangle]$. Analogically, a projective measurements of qubit q_0 yields,

$$\hat{\rho}_0^{\text{red}} = |\alpha_0|^2\hat{\rho}_1 \otimes |0\rangle\langle 0| + |\beta_0|^2\hat{\rho}_1 \otimes |1\rangle\langle 1| \tag{47.115}$$

$$\text{and} \qquad \langle \hat{\sigma}_0^z \rangle = |\alpha_0|^2 - |\beta_0|^2 .$$

Example 349 (*Measurements on entangled qubits*): Now, we consider two entangled qubits $|\psi\rangle = \alpha[|0\rangle \otimes |0\rangle] + \beta[|1\rangle \otimes |1\rangle]$, with $|\alpha|^2 + |\beta|^2 = 1$, such that,

$$\hat{\rho} = \begin{pmatrix} \alpha \\ 0 \\ 0 \\ \beta \end{pmatrix} \begin{pmatrix} \alpha^* & 0 & 0 & \beta^* \end{pmatrix} = \begin{pmatrix} |\alpha|^2 & 0 & 0 & \alpha\beta^* \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \alpha^*\beta & 0 & 0 & |\beta|^2 \end{pmatrix} . \tag{47.116}$$

Projective measurements of qubit q_1 with two possible outcomes yields in both of the two cases, $|q_1\rangle = |0\rangle, |1\rangle$, the reduced density operator,

$$\hat{\rho}_1^{\text{red}} = p^{(0)} \frac{[|0\rangle\langle 0| \otimes \mathbb{I}]\,\hat{\rho}[|0\rangle\langle 0| \otimes \mathbb{I}]}{\text{Tr } \hat{\rho}[|0\rangle\langle 0| \otimes \mathbb{I}]} + p_1 \frac{[|1\rangle\langle 1| \otimes \mathbb{I}]\hat{\rho}[|1\rangle\langle 1| \otimes \mathbb{I}]}{\text{Tr } \hat{\rho}[|1\rangle\langle 1| \otimes \mathbb{I}]} \tag{47.117}$$

$$= \begin{pmatrix} |\alpha|^2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & |\beta|^2 \end{pmatrix} = |\alpha|^2[|0\rangle\langle 0| \otimes |0\rangle\langle 0|] + |\beta|^2[|1\rangle\langle 1| \otimes |1\rangle\langle 1|] .$$

A projective measurements of qubit q_1 would yield exactly the same result.

47.3.6 The field of quantum information

The possibility to experimentally control, manipulate and read out individual qubits gave birth to a new field of physics in the past two decades now called *quantum information*. This fields includes the more specific areas of *quantum processing* (which itself splits into the subareas of *quantum computing* and *quantum simulation*), *quantum communication*, and *quantum sensing* (see Sec. 47.4).

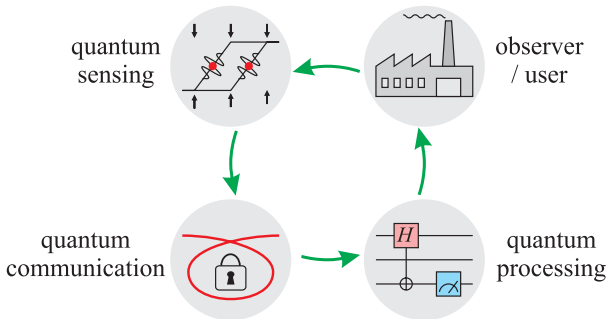

Figure 47.13: Key technologies of the second quantum revolution.

The fundamental epitomic systems on which the quantum information technologies are based are listed in the table below. Although the correspondence is oversimplified, it gives a coarse idea of the involved areas of quantum mechanics. Technological revolutions have often been triggered by paradigmatic 'paradoxes' which, in fact, were mostly dramatized juxtapositions of classical and innovative concepts and stop being paradoxical, once they have been resolved by a more complete theory. The table also lists the cornerstone paradoxes of quantum information technologies.

area	quantum computing	communication	sensing
system	two-level atom / spin	harmonic oscillator	propagation of free atom
device	qubit	photon	interferometer
phenomenon	quantum entanglement		superposition & measurement
paradox	EPR paradox		Schrödinger cat

47.3.6.1 Physical implementation of quantum computers

Quantum entanglement and information processing protocols for quantum computing have been implemented with various technologies (see table below for a non-exhaustive list), some of them pursued by private companies. Every approach has its advantages and disadvantages, the main figures of merit being the *qubit number*, the *qubit connectivity*, and the *gate fidelity*. Other important factors are *scalability*, *qubit homogeneity*, and *ease of fabrication and use*.

physical system	description	companies	publications
ions	trapped ion array	IonQ, AQT	[663, 612]
neutral atoms	optical lattice	-	[20]
transmons	superconducting JJ arrays	IBM, Google, ...	[31]
molecules	NMR on bonds in molecules	-	[990]
NV centers	color centers in diamond	-	[730]
quantum dots	quantum dots arrays	diraq	[588]
photons	polarization or timing	-	[891]

Example 350 (*Quantum volume of perfect processor*): The *quantum volume* of an N-qubit quantum processor is a metric invented by IBM that characterizes the largest random quantum circuit that the device can efficiently simulate. The formula for quantum volume is given by:

$$\text{quantum volume} = N^2 \times \text{maximal depth} \ . \tag{47.118}$$

In the case of a perfect N-qubit processor, the maximal depth is equal to N since each gate can be applied in parallel on all qubits, and there are N such layers. Therefore, the quantum volume of a perfect N-qubit processor is quantum volume $= N^3$. This means that a perfect N-qubit quantum processor can efficiently simulate random quantum circuits of up to N^3 gates. However, in reality, quantum processors suffer from errors due to various sources such as decoherence and imperfect gate operations, and as a result, their quantum volume is typically much lower than this theoretical limit.

47.3.6.2 Quantum sensing 2.0

Many sensors are based on interferometry, as explained in Sec. 47.4.2. The circuit exhibited in Fig. 47.14 visualizes the basic principle of an interferometer. The two Hadamard gates correspond to Ramsey pulses, and the controlled U gate realizes the interaction, which transfers information from the U gate to the sensing qubit.

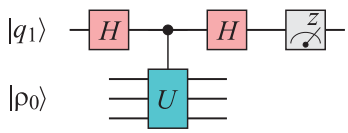

Figure 47.14: Quantum interferometry.

As mentioned in Sec. 41.2.2 and in Sec. 46.1.4, the sensitivity of interferometers can be enhanced when correlated particles are used. In Exc. 47.3.7.16 we show how the interferometer of Fig. 47.14 can be modified in order to benefit from correlated particles.

47.3.6.3 Continuous variable quantum information

Continuous variable quantum information is the area of quantum information science that makes use of physical observables with continuous spectra, like the strength of an electromagnetic field. Continuous-variable quantum computation is performed on infinite-dimensional Hilbert spaces and may be called 'analog', while qubit quantum

computation is performed on finite-dimensional Hilbert spaces (2^N with N the number of qubits) and may be called 'digital'.

Bosonic modes are examples of systems being studied for the implementation of continuous-variable quantum information. By modeling each mode of the electromagnetic field as a quantum harmonic oscillator with its associated field operators, one defines a canonically conjugate pair of variables for each mode, the so-called *quadratures*, which span a phase space on which Wigner quasi-probability distributions can be defined. Quantum measurements on such a system can be performed using homodyne and heterodyne detectors. Interestingly, qubits can be encoded into a continuous variable [374]. The procedure is easily understood at the example of a two-level atom dispersively interacting with a cavity mode studied within the Jaynes-Cummings model in Sec. 40.2.2 and in the Exc. 40.2.5.6. See also Sec. 47.2.1.

In all approaches to quantum computing, it is important to know whether a task under consideration can be carried out efficiently by a classical computer. An algorithm might be described in the language of quantum mechanics, but upon closer analysis, reveals to be implementable using only classical resources [373], even if making use of quantum entanglement. When the Wigner quasi-probability representations of all the quantities (states, time evolutions and measurements) involved in a computation are non-negative, then they can be interpreted as ordinary probability distributions, indicating that the computation can be modeled as an essentially classical one [637].

47.3.6.4 Quantum Fourier transform

The *quantum Fourier transform* (QFT) is a linear transformation on qubits and the quantum analogue of the inverse discrete Fourier transform. The quantum Fourier transform is a part of many quantum algorithms, notably Shor's algorithm for factoring and computing the discrete logarithm or the quantum phase estimation algorithm for estimating the eigenvalues of a unitary operator.

The quantum Fourier transform can be performed efficiently on a quantum computer, with a particular decomposition into a product of simpler unitary matrices. Using a simple decomposition, the discrete Fourier transform on 2^n amplitudes can be implemented as a quantum circuit consisting of only $O(n^2)$ Hadamard gates and controlled phase shift gates, where n is the number of qubits. This can be compared with the classical discrete Fourier transform, which takes $O(2^n)$ gates, which is exponentially more than in the classical case. However, the quantum Fourier transform acts on a quantum state, whereas the classical Fourier transform acts on a vector, so not every task that uses the classical Fourier transform can take advantage of this exponential speedup.

The quantum Fourier transform is the classical discrete Fourier transform applied to the vector of amplitudes of a quantum state, where we usually consider vectors of length $N = 2^n$. The classical Fourier transform acts on a vector $(x_0, x_1, \ldots, x_{N-1}) \in \mathbb{C}^N$ and maps it to the vector $(y_0, y_1, \ldots, y_{N-1}) \in \mathbb{C}^N$ according to the formula:

$$\boxed{y_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} x_n \omega_N^{\mp kn} \ ,} \tag{47.119}$$

where $k = 0, 1, \ldots, N-1$ and $\omega_N = e^{2\pi\imath/N}$ and ω_N^n is an Nth root of unity. The lower sign holds for the *inverse* FT.

Similarly, the quantum Fourier transform acts on a quantum state $|x\rangle = \sum_{i=0}^{N-1} x_i|i\rangle$ and maps it to a quantum state $\sum_{i=0}^{N-1} y_i|i\rangle$ according to the same formula (47.119). In case that $|x\rangle$ is a basis state, the quantum Fourier Transform can also be expressed as the map,

$$|x\rangle \mapsto \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} \omega_n^{xk}|k\rangle \ . \tag{47.120}$$

Equivalently, the quantum Fourier transform can be viewed as a unitary matrix (or a quantum gate, similar to a Boolean logic gate for classical computers) acting on quantum state vectors, where the unitary matrix is given by,

$$F_N = \frac{1}{\sqrt{N}} \begin{pmatrix} 1 & 1 & 1 & 1 & \cdots & 1 \\ 1 & \omega & \omega^2 & \omega^3 & \cdots & \omega^{N-1} \\ 1 & \omega^2 & \omega^4 & \omega^6 & \cdots & \omega^{2(N-1)} \\ 1 & \omega^3 & \omega^6 & \omega^9 & \cdots & \omega^{3(N-1)} \\ \vdots & \vdots & \vdots & \vdots & & \vdots \\ 1 & \omega^{N-1} & \omega^{2(N-1)} & \omega^{3(N-1)} & \cdots & \omega^{(N-1)(N-1)} \end{pmatrix} \tag{47.121}$$

where $\omega = \omega_N$. Do the Excs. 47.3.7.13 and 47.3.7.14.

The QFT is unitary,

$$\boxed{FF^\dagger = \mathbb{I}\ ,} \tag{47.122}$$

and can be efficiently performed on a quantum computer. The quantum gates used in the circuit are the Hadamard gate and the controlled phase gate R_m,

$$H = \tfrac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \qquad \text{and} \qquad R_m = \begin{pmatrix} 1 & 0 \\ 0 & e^{2\pi\imath/2^m} \end{pmatrix}\ , \tag{47.123}$$

with $e^{2\pi\imath/2^m} = \omega_{(2^m)}$ the primitive 2^m-th root of unity. The circuit is composed of H gates and the controlled version of R_m.

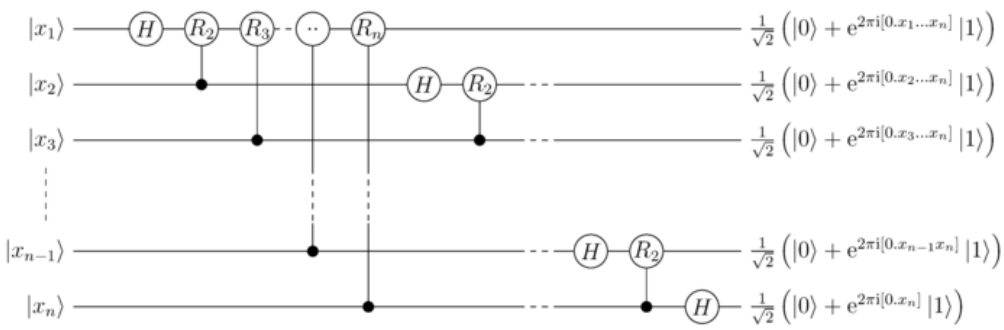

Figure 47.15: Quantum circuit for QFT with n qubits (without rearranging the order of output states).

All quantum operations must be linear, so it suffices to describe the function on each one of the basis states and let the mixed states be defined by linearity. This is in contrast to how Fourier transforms are usually described. We normally describe Fourier transforms in terms of how the components of the results are calculated on an arbitrary input. This is how you would calculate the path integral or show BQP is in PP. But it is much simpler here (and in many cases) to just explain what happens to a specific arbitrary basis state, and the total result can be found by linearity.

The quantum Fourier transform can be approximately implemented for any N; however, the implementation for the case where N is a power of 2 is much simpler. As already stated, we assume $N = 2^n$. We have the orthonormal basis consisting of the vectors $|0\rangle, \ldots, |2^n - 1\rangle$. The basis states enumerate all the possible states of the qubits, $|x\rangle = |x_1 x_2 \ldots x_n\rangle = |x_1\rangle \otimes |x_2\rangle \otimes \cdots \otimes |x_n\rangle$, where $|x_j\rangle$ indicates that qubit j is in state x_j, with x_j either 0 or 1. By convention, the basis state index x orders the possible states of the qubits lexicographically, i.e. by converting from binary to decimal in this way:

$$x = x_1 2^{n-1} + x_2 2^{n-2} + \cdots + x_n 2^0 \ . \tag{47.124}$$

It is also useful to borrow fractional binary notation:

$$[0.x_1 \ldots x_m] = \sum_{k=1}^{m} x_k 2^{-k} \ . \tag{47.125}$$

For instance, $[0.x_1] = \frac{x_1}{2}$ and $[0.x_1 x_2] = \frac{x_1}{2} + \frac{x_2}{2^2}$. With this notation, the action of the quantum Fourier transform can be expressed in a compact manner:

$$\begin{aligned} \mathrm{QFT}(|x_1 x_2 \ldots x_n\rangle) = \frac{1}{\sqrt{N}} \Big(|0\rangle + e^{2\pi\imath\ [0.x_n]}|1\rangle\Big) \otimes \Big(|0\rangle + e^{2\pi\imath\ [0.x_{n-1}x_n]}|1\rangle\Big) \otimes \cdots \\ \otimes \Big(|0\rangle + e^{2\pi\imath\ [0.x_1 x_2 \ldots x_n]}|1\rangle\Big) \ , \end{aligned} \tag{47.126}$$

where we have used $[0.x_1 x_2 ... x_m] = [x_1 x_2 ... x_n]/2^m$. This can be seen by rewriting the formula for the Fourier transform in the binary expansion:

$$\mathrm{QFT}(|x\rangle) = \frac{1}{\sqrt{N}} \sum_{k=0}^{2^n-1} \omega_n^{xk} |k\rangle = ... = \frac{1}{\sqrt{N}} \bigotimes_{j=1}^{n} \Big(|0\rangle + \omega_n^{x2^{n-j}}|1\rangle\Big) \ . \tag{47.127}$$

Now, we have $\omega_n^{x2^{n-j}} = e^{\frac{2\pi\imath}{2^n} x 2^{n-j}} = e^{2\pi\imath(x2^{-j})}$. Let,

$$\begin{aligned} f(j) = x2^{-j} = 2^{-j} \sum_{r=1}^{n} x_r 2^{n-r} &= \sum_{r=1}^{n} x_r 2^{n-j-r} \\ &= \sum_{r=1}^{n-j} x_r 2^{n-j-r} + \sum_{r=n-j+1}^{n} x_r 2^{n-j-r} = a(j) + b(j) \ . \end{aligned} \tag{47.128}$$

then $a(j) \in \mathbb{N}_0$, because $2^{n-j-r} \geq 0$, for $n-j-r \geq 0$, and $b(j) = 0.x_{n-j+1} x_{n-j+2} \ldots x_n$, thus the (2) becomes:

$$e^{2\pi\imath f(j)} = e^{2\pi\imath(a(j)+b(j))} = e^{2\pi\imath a(j)} \cdot e^{2\pi\imath b(j)} = e^{2\pi\imath[0.x_{n-j+1}x_{n-j+2}\cdots x_n]} \ , \tag{47.129}$$

since $e^{2\pi\imath a(j)} = 1$ for all j. Then we can write:

$$\mathrm{QFT}(|x_1 x_2 \ldots x_n\rangle) = \frac{1}{\sqrt{N}} \bigotimes_{j=1}^{n} \left(|0\rangle + \omega_n^{x 2^{n-j}} |1\rangle\right) \tag{47.130}$$

$$= \frac{1}{\sqrt{N}} \bigotimes_{j=1}^{n} \left(|0\rangle + e^{2\pi\imath[0.x_{n-j+1}x_{n-j+2}\ldots x_n]}|1\rangle\right)$$

$$= \frac{1}{\sqrt{N}} \left(|0\rangle + e^{2\pi\imath[0.x_n]}|1\rangle\right) \otimes \left(|0\rangle + e^{2\pi\imath[0.x_{n-1}x_n]}|1\rangle\right) \otimes \cdots \otimes \left(|0\rangle + e^{2\pi\imath[0.x_1 x_2 \ldots x_n]}|1\rangle\right) \ .$$

To obtain this state from the circuit depicted above, a swap operations of the qubits must be performed to reverse their order. After the reversal, the n-th output qubit will be in a superposition state of $|0\rangle$ and $e^{2\pi\imath\ [0.x_1\ldots x_n]}|1\rangle$, and similarly the other qubits before that (take a second look at the sketch of the circuit above).

In other words, the discrete Fourier transform, an operation on n qubits, can be factored into the tensor product of n single-qubit operations, suggesting it is easily represented as a quantum circuit (up to an order reversal of the output). In fact, each of those single-qubit operations can be implemented efficiently using a Hadamard gate and controlled phase gates. The first term requires one Hadamard gate and $(n-1)$ controlled phase gates, the next one requires a Hadamard gate and $(n-2)$ controlled phase gate, and each following term requires one fewer controlled phase gate. Summing up the number of gates, excluding the ones needed for the output reversal, gives $n + (n-1) + \cdots + 1 = n(n+1)/2 = O(n^2)$ gates, which is quadratic polynomial in the number of qubits.

The QFT is useful in the simulation of Hamiltonian evolution governed by conjugate variables,

$$e^{-\hat{H}t/\hbar} \qquad \text{where} \qquad \hat{H} = \frac{\hat{p}}{2m} + \frac{m}{2}\omega^2 \hat{x}^2 \ , \tag{47.131}$$

where, similar to the *time-splitting spectral algorithm*, we may replace differential operators,

$$\hat{p} = F^{-1}\ \hat{x}\ F \ . \tag{47.132}$$

47.3.7 Exercises

47.3.7.1 Ex: Two-bit `SWAP` gate

Represent the two-qubit `SWAP` gate by a succession of three `CNOT` gates.

47.3.7.2 Ex: Quantum computing code for spin-squeezing

Express spin-squeezing of 2, respectively, 3 qubits by a quantum circuit. See also Exc. 46.1.8.11!

47.3.7.3 Ex: Controlled `Z`-gate

Check that the Cirac-Zoller `cZ` gate is invariant under spin exchange. This fact justifies the symmetry of the symbol with respect to the two coupled qubits.

47.3.7.4 Ex: Boolean logic

Write an algorithm encoding a decimal integer A_0 into a binary,

$$D = \sum_{k=0}^{k_{\max}} 2^k a_k \ .$$

47.3.7.5 Ex: Boolean logic

a. Design a classical logic circuit only based on `NAND` gates for the increment by 1 of a number encoded in a n-bit register.
b. Design a classical logic circuit only based on `NAND` gates for the addition of two numbers.

47.3.7.6 Ex: Fredkin cSWAP gate

a. Write down the truth table for the *Fredkin gate* defined by the protocol that the qubits q_1 and q_0 are swapped only if the state of qubit q_2 is 1.
b. Write down the matrix realizing the Fredkin gate.
c. Check that the quantum circuit sketched in Fig. 47.16, which only envolves two-qubit quantum gates, realizes a Fredkin gate.

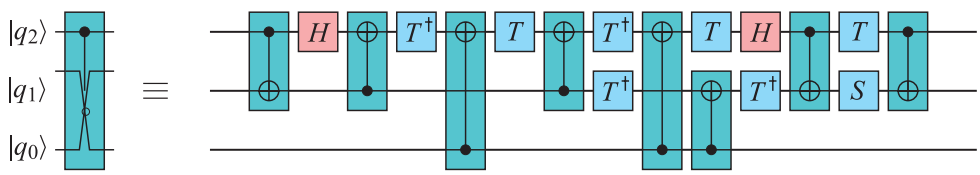

Figure 47.16: Quantum circuit realizing a Fredkin gate $\overset{cc}{X}_{012}$.

47.3.7.7 Ex: Three-bit SWAP gate

a. Convince yourself that the SWAP gates defined by (47.93) have the explicit matrix form,

$$\mathbb{S}_{ij}(k, k_{ij}) \equiv 1 \qquad \text{where} \qquad \begin{cases} k = [0, ..., 7] \\ k_{12} = [0, 1, 4, 5, 2, 3, 6, 7] \\ k_{01} = [0, 2, 1, 3, 4, 6, 5, 7] \\ k_{02} = [0, 4, 2, 6, 1, 5, 3, 7] \end{cases} ,$$

the index k indicating the column and k_{ij} the row where the matrix has an entry.
b. Verify,

$$\mathbb{S}^{-1} = \mathbb{S} \quad , \quad \mathbb{S}_{ij}^{-1} = \mathbb{S}_{ij} \ .$$

47.3.7.8 Ex: Quantum gates

Verify the formulae (47.95).

47.3.7.9 Ex: Toffoli gate

a. Write down the truth table for the *Toffoli gate*.
b. Write down the matrix realizing the Toffoli gate.
c. Check that the quantum circuit sketched in Fig. 47.17, which only envolves two-qubit quantum gates realizes a *Toffoli gate*.

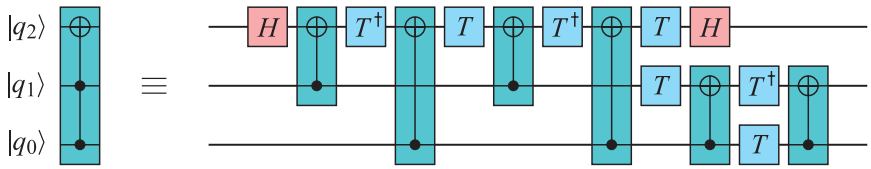

Figure 47.17: Quantum circuit realizing a Toffoli gate $\overset{cc}{X}_{012}$.

47.3.7.10 Ex: Classical and quantum logic

a. Verify $\neg(A \vee B) = \neg A \wedge \neg B$ and $A \oplus B = (\neg A \wedge B) \vee (A \wedge \neg B)$.
b. How would you realize the classical logical operations `AND`, `OR`, and `XOR` on a quantum computer?

47.3.7.11 Ex: Quantum composer

Show that the following diagrams describe identical unitary operations:

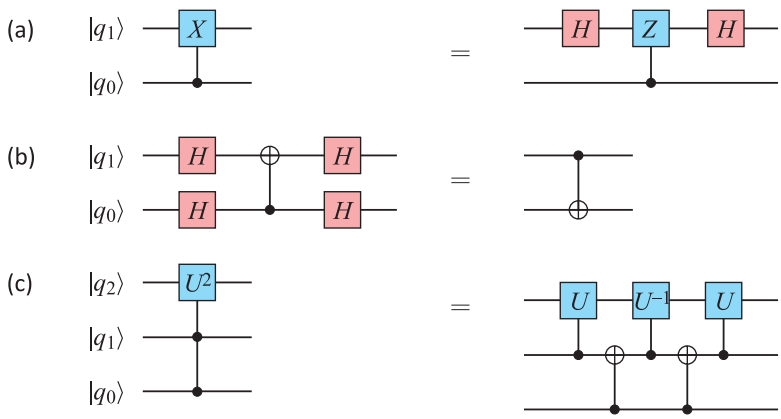

Figure 47.18: Quantum composer.

47.3.7.12 Ex: Classical addition of two qubits

Design a quantum algorithm for the classical addition of up to 8 qubits.

47.3.7.13 Ex: CARL simulation on a quantum computer

Try to recast the so-called CARL Hamiltonian,

$$\hat{H} = U_0(\hat{a}_+^\dagger \hat{a}_- e^{-\imath k\hat{r}} + \hat{a}_+ \hat{a}_-^\dagger e^{\imath k\hat{r}})$$

such that it can be simulated by a sequence of quantum gates.

47.3.7.14 Ex: Quantum Fourier transform on a quantum computer

Write down the QF transformation matrix for the case of $N = 4 = 2^2$ and phase $\omega = \imath$.

47.3.7.15 Ex: Three entangled qubits

a. Imagine a three-qubit quantum gate or a sequence of gates generating from the ground state the three partite states [282]:

$$|\mathrm{GHZ}\rangle \equiv \tfrac{1}{\sqrt{2}}(|000\rangle + |111\rangle \qquad \text{and} \qquad |\mathrm{W}\rangle \equiv \tfrac{1}{\sqrt{3}}(|001\rangle + |010\rangle + |100\rangle) \ .$$

b. Show how the procedure for the generation of the $|\mathrm{GHZ}\rangle$ state can be easily extended to N entangled particles.

47.3.7.16 Ex: Scattering circuit

a. Consider the controlled $\mathcal{U}$ gate given by,

$$\overset{c}{\mathcal{U}}_{10} = |0\rangle\langle 0| \otimes \mathbb{I} + |1\rangle\langle 1| \otimes \mathcal{U} \ ,$$

where U is an arbitrary unitary operation, and the quantum circuit given by,

$$M = [H \otimes \mathbb{I}]\overset{c}{\mathcal{U}}_{10}[H \otimes \mathbb{I}]$$

and depicted in Fig. 47.14. Starting from an initial state $|0\rangle\langle 0| \otimes \hat{\rho}_0$, show, that a measurement of the first qubit $|q_1\rangle$ of the final state,

$$\hat{\rho}_f = M[|0\rangle\langle 0| \otimes \hat{\rho}_0]M^\dagger$$

yields,

$$\langle \hat{\sigma}_1^z \rangle = \mathfrak{Re}\,[\mathrm{Tr}_0\ \hat{\rho}_0 \mathcal{U}] \qquad \text{and} \qquad \langle \hat{\sigma}_1^y \rangle = \mathfrak{Im}\,[\mathrm{Tr}_0\ \hat{\rho}_0 \mathcal{U}] \ .$$

b. Calculate $\langle \vec{\hat{\sigma}}_1 \rangle$ for the case that $\mathcal{U}$ is a one-qubit phase gate given by (47.75).
c. Calculate $\langle \vec{\hat{\sigma}}_1 \rangle$ for the case that $\mathcal{U} = X$ is a one-qubit `NOT` gate given by (47.77).

47.3.7.17 Ex: Heisenberg-limited quantum sensing

This exercise aims at showing that entangled qubits allow for phase measurements beyond the standard quantum limit. Proceed as follows:
a. Express standard Ramsey interferometry for a single qubit as a sequence of quantum gates and calculate the uncertainty of the final Bloch vector component $\Delta\hat{S}_z/||\hat{S}_z||$.
b. Repeat (a) with a product state of two qubits.
c. Plot the relative uncertainty of the inversion $(\Delta\hat{S}_z^2/\langle\hat{S}_z^2\rangle)^{1/2}$ after the Ramsey cycle as a function of the precession phase for the cases (a) and (b), as well as the spin squeezing parameter $\sqrt{N}\langle\Delta\hat{S}_y\rangle/|\langle\hat{S}_z\rangle|$ [974, 236].
d. Repeat (b) with two entangled qubits and interpret your observations.

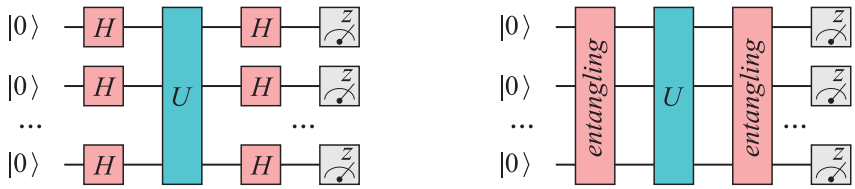

Figure 47.19: Scheme for Heisenberg-limited quantum sensing.

47.4 Metrology and quantum sensing

We have seen at the end of the last section how to perform projective measurements in entangled systems. In the following we will now show that such systems have the potential of improving the sensitivity of measurements. The field of research dealing with this, called *quantum sensing*, represents an extension of the field of metrology into the quantum regime. Before discussing the stakes of quantum information science in metrology, let us review in a comprehensible way what metrology and sensing is about.

47.4.1 Atomic clocks

Metrology is the art of sensing, and sensing is simply the activity of measuring a physical quantity as accurately as possible. The most fundamental quantities to measure are time and space. However, *absolute space and time do not exist*. According to the restricted and the general theory of relativity they are interconnected by velocity and additionally depend on the presence of masses exerting gravitational forces.

Hence, before talking about clocks, we need to spend a few words on the physical quantity they are supposed to measure: *time*. In the same way as it is meaningless to talk about space with nothing in it, time is only there, because things are happening. Space is the distance between things and time is nothing else than the distance between events.

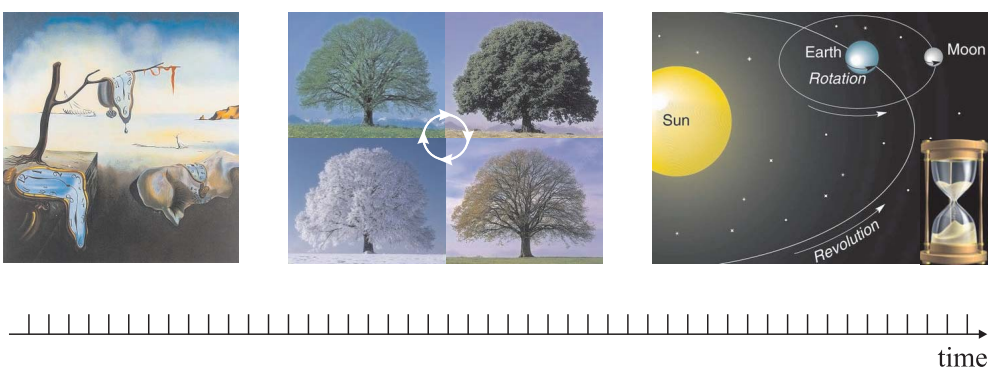

Figure 47.20: (left) 'Time persistence' by Salvatore Dali. (center) Recurrent events. (right) Periodic astronomical cycles.

In our current physical understanding of the universe the most elementary events

are collisions between (real or virtual) particles. Obviously, our universe is full of time. In order to bring any succession of such events into a logical and causal order, a reference time line is needed. It allows for historical book keeping of sequences of events, that we may call *histories*. And in order to facilitate a comparison between different histories, this reference time line should follow a simple deterministic rule, e.g. be periodic or exponentially decaying. In fact, both types of processes are currently used for time measurements. E.g. exponential processes, such as radioactive decay is commonly used in radioactive dating.

The most common practical approach to the measurement of time, however, is based on the observation of recurrent phenomena that we think of being periodic, such as a day on Earth, the dripping of a water pipe, or the oscillation of a pendulum or of an atomic excitation. Assuming the time intervals separating the recurrent phenomena as being all the same, we build a ruler for time which we call *clock*.

But now comes a tricky question: How do we know whether a clock is really periodic? In fact, we never know for sure whether the time intervals are really all the same. We only know that some clocks deserve a greater degree of confidence based on the fact that *more care has been taken in their design and construction*, or based on the observation that clocks built in a certain manner tend to deviate less from each other than clocks built in a different manner. The other approach would be to compare several totally *independent* clocks and to give preference to those who deviate less from each other.

An important criterion for a useful clock concerns its duty cycle. The shorter the cycling time, the faster we can extract information from the clock, and the higher is the accuracy we can reach in a given integration time. Ancient time standards had been link to the periodic motion of celestial bodies, e.g. the revolution time of the Earth around the sun. Therefore, clocks with smaller duty cycles have been engineered, such as the clepsydra or the hour glass. But their calibration to periodical astronomical cycles remained tedious and slow. Historically, the development of ever precise clocks has been motivated by navigation. Indeed, 1 minute of inaccuracy in the clock generates an uncertainty of 28 km in global positioning. And this motivation still prevails nowadays, although, meanwhile, atomic clocks are reaching uncertainties of below 10^{-18} and extremely short duty cycles on the order of femto-seconds.

The left part of Fig. 47.21 shows the basic idea of any human-made clock, which consists in locking an oscillating mechanism, whose time constant can be manipulated, for instance a pendulum or a laser, by a very precise periodic process, that we call *resonance*. This resonance can be an astronomic period or the transition of an atomic between two states of excitation. Expressing the stability of a clock that can be obtained in a given integration time as,

$$\sigma = \frac{\Gamma_{\rm nat} + \Gamma_{\rm pert}}{\omega} \frac{1}{S/N_{\rm noise}} \ , \tag{47.133}$$

we see that we better look for oscillators and resonances operating at high frequencies ω, having very narrow widths $\Gamma_{\rm nat}$, being subject to very weak perturbations and line broadenings $\Gamma_{\rm pert}$, and delivering a good signal-to-noise ratio. The right part of Fig. 47.21 shows the concept of a cesium beam *atomic clock*. A microwave oscillator operating at $\omega/2\pi = 9.1\,\mathrm{GHz}$ excites cesium atoms passing through a microwave cavity thus generating in a detector a frequency-dependent error signal which can be

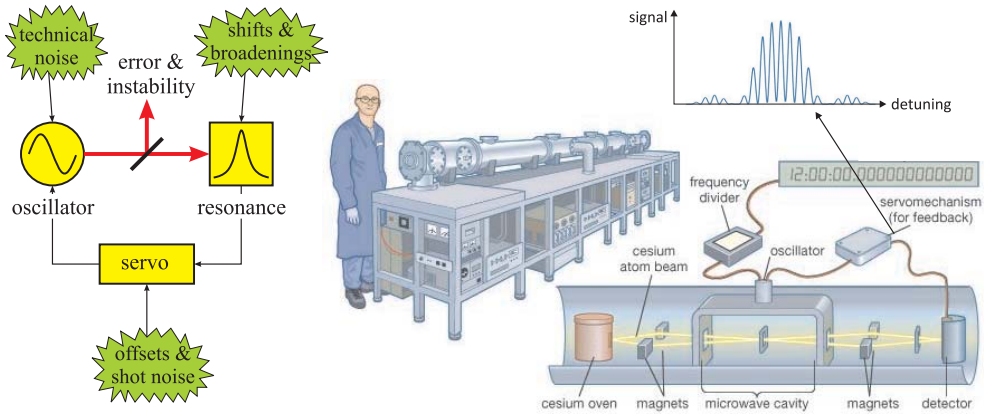

Figure 47.21: (left) Principle of any clock and possible perturbations. (right) Cesium beam atomic clock and Ramsey interference fringes.

used to correct the oscillator frequency.

47.4.1.1 Gravitational red-shift

Clocks and gravimeters are intrinsically related the gravitational redshift. The *gravitational red-shift* is that phenomenon in which electromagnetic waves or photons traveling out of a gravitational well (seem to) lose energy. This loss of energy corresponds to a decrease in the wave frequency and increase in the wavelength. Gravitational redshift can be interpreted (i) as a consequence of the *equivalence principle* stating that gravity and acceleration are equivalent and the redshift is caused by the Doppler effect. It can also be understood (ii) as a consequence of the mass-energy equivalence stating that 'falling' photons gain energy (though there are numerous subtleties that complicate a rigorous derivation). Finally, it can be understood (iii) in terms of gravitational time dilation at the source of the radiation: an oscillator (producing electromagnetic radiation) will seem to 'tick' faster when exposed to a stronger gravitational potential.

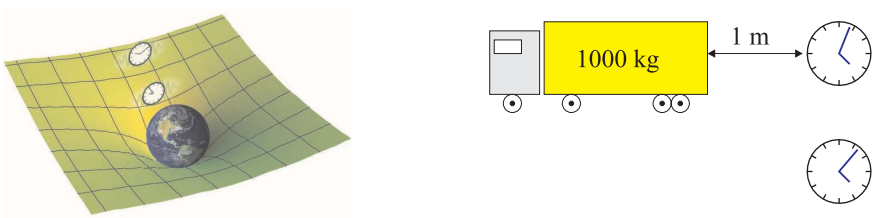

Figure 47.22: Gravitational redshift is due to the dilation of time near heavy masses.

To first approximation, the gravitational redshift is proportional to the difference in gravitational potential. In a homogeneous field (see Sec. 6.3.3),

$$\frac{\Delta\nu}{\nu} = \frac{\Delta\lambda}{\lambda} \simeq \frac{g\Delta z}{c^2} \ , \tag{47.134}$$

where Δz is the change in height. Accounting for the accompanying gravitational time dilation affecting the atomic clock in the satellite is crucially important for accurate navigation. For this reason, *metrology* of time and *gravimetry* are closely interrelated. Do the Exc. 47.4.6.1.

Example 351 (*Prediction by the equivalence principle and general relativity for a uniform gravitational field or acceleration*): Einstein's theory of general relativity incorporates the equivalence principle, which can be stated in various different ways. One such statement is that gravitational effects are locally undetectable for a free-falling observer. Therefore, in a laboratory experiment at the surface of the earth, all gravitational effects should be equivalent to the effects that would have been observed if the laboratory had been accelerating through outer space at g. One consequence is a gravitational Doppler effect. If a light pulse is emitted at the floor of the laboratory, then a free-falling observer says that by the time it reaches the ceiling, the ceiling has accelerated away from it, and therefore when observed by a detector fixed to the ceiling, it will be observed to have been Doppler shifted toward the red end of the spectrum. This shift, which the free-falling observer considers to be a kinematic Doppler shift, is thought of by the laboratory observer as a gravitational redshift. Such an effect was verified in the 1959 Pound-Rebka experiment. Since this prediction arises directly from the equivalence principle, it does not require any of the mathematical apparatus of general relativity, and its verification does not specifically support general relativity over any other theory that incorporates the equivalence principle.

47.4.2 Quantum sensing

Let us first define what we mean by a *sensor* in general before discussing what quantum mechanics has to do with it. A *sensor* is a device, module, machine, or subsystem whose purpose is to detect events or changes in its environment and send the information to other electronics, frequently a computer processor. Progress in engineering, science, medicine, and other disciplines is unavoidably conditioned to sensing: What you cannot measure, you cannot improve! In many areas of applications, however, conventional sensing techniques have met fundamental limitations, and novel disruptive approaches are required in order to reach higher sensitivity and precision.

In many cases, limitations are imposed by the macroscopic, i.e. *classical*, nature of the sensor, and much can be gained by using microscopic sensors. These however, follow different rules of physics given by *quantum mechanics*. Nuclear magnetic resonance spectroscopy (NMR), magnetic resonance imaging, and the development of transistors, LEDs, solar panels, and lasers are examples of technologies developed during the first so-called quantum revolution in the 20th century, which was based on the exploitation of the particle-wave duality. However, the full potential of quantum mechanics goes much further. Today *quantum sensing* is, together with quantum computation and quantum communication (see Sec. 47.3.6), one of the key technologies anticipated to drive the quantum revolution 2.0. However, unlike quantum sensing with light, which is on the verge of turning into mature 2.0 technologies, with applications e.g. in quantum imaging, quantum sensing applications with matter waves are nowadays exclusively on the 1.0 level.

Let us discuss the disruptive role of quantum mechanics at the example of an *atom*, which is a paradigmatic example for a sensor subject to quantum laws. The reasons for this are numerous: (i) Because all atoms of a given species are strictly identical (that is, indistinguishable in the quantum statistical sense) they can be used in different sensing devices, places and countries. We do not need to duplicate reference standards, such as the Original Meter or the Original Kilogram safely kept in Paris. We simply recommend to people wishing to construct their own clock standard to gather cesium atoms (wherever you can find them) and try to excite the 9.1 GHz hyperfine transition (with whatever technique you prefer). In the end, you just need to prove that your clock is sufficiently good. (ii) Some atomic species have ultra-narrow transitions outperforming any imaginable artificial device by many orders of magnitude, which makes them ideal candidates for clock resonances. (iii) Atoms can easily be moved in space with extremely high precision, which makes them suitable for matter wave interferometers, which are useful for the measurement of distances and the sensing of forces.

The main reason, however, for the superiority of atoms (and other quantum devices, such as SQUIDs, quantum dots or nitrogen-vacancy (NV) centers in diamond) with respect to classical objects in sensing applications is, that they can exist in superposition states (of their internal excitation or of their center-of-mass motion) whose evolution delicately depends on external parameters, such as forces. We can now define a *quantum sensor* as a measurement device exploiting quantum correlations in order to enhance sensitivity and resolution, f.ex. quantum superpositions or entanglement [236]. Typically its core is a single atomic two-level system (or any other kind of qubit), whose superposition states (i) are sensitive to some environment parameter, (ii) can be manipulated in a controlled way, and (iii) can be read out.

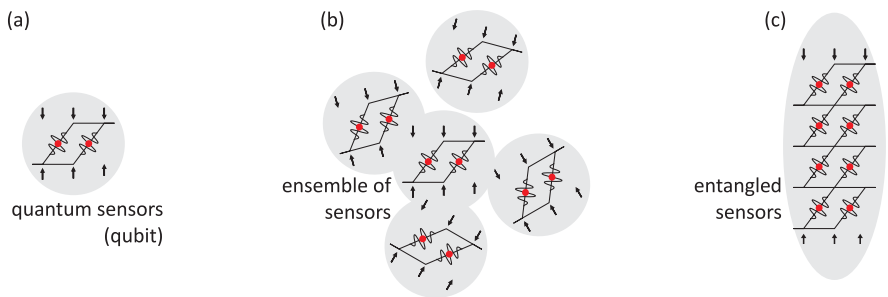

Figure 47.23: (left) Single qu-bit. (center) Larger signals can be observed using ensemble of qu-bits. (right) Collective manipulations on entangled qu-bits allow precisions beyond the standard quantum limit.

In fact, quantum sensors already exist since the invention of atomic clocks and matter wave interferometers, which build on the control and detection of quantum states in individual qubits, even though in practice, most of these device are operated with large incoherent ensembles of qubits. Even if perturbations related to uncontrolled inter-qubit interactions (collisions, thermal excitations, etc.) can be avoided, the sensitivity that can be reached with such ensembles is bound to the standard quantum limit imposed by quantum projection noise (see Secs. 41.2.2 and 46.1.4).

Novel approaches investigate the possibilities of overcoming these limits via the creation of strong interparticle correlations via entanglement, spin-squeezing [974], or superradiant lasing [719]. Such correlations have been created with atoms, which therefore qualify as building blocks of quantum computers or sensing devices capable of overruling the standard quantum limit.

Example 352 (*'Quantumness' of atomic quantum sensors*): The question we want to address here is: What is actually 'quantum' in an atomic quantum sensors?
A possible answer could be: Not much!
OK, atoms have discrete energy levels. But a coin also does and shows the same projection noise features as atoms!
Then, one can point out the role of coherence: Atoms can be in a superposition of two states. But Ramsey fringes can be obtained with classical light beams. The fact that Ramsey fringes can be observed with atoms is simply due to the fact that electrons behave like waves (matter) waves, which is indeed a quantum 1.0 feature. On the other hand, an atom can be described as a classical spinning top and its interaction with light as a torque exerted on the rotor.
The good news is that you do things with atoms that are difficult to do with coins. Atoms are strictly identical and can be sensitive to electric or magnetic fields and gravity in a very reproducible way. Another very important feature is that atoms can be entangled, which you can't do with atoms. But here we are going beyond 1.0 technology.
Important for gravimeter: use neutral particle matter waves, e.g. atoms, not electronic excitation states!

47.4.2.1 Working principle of a quantum sensor

As mentioned above, in order to measure a weak force it is not sufficient to sense it, one also has to read the result. In the field of atom optics, this can conveniently be done with light fields taking the information from an atom isolated in a vacuum chamber to the macroscopic world. In order not to loose information already at the level of the light-atom interaction, one generally tries to avoid dissipation and keep the interaction coherent [8].

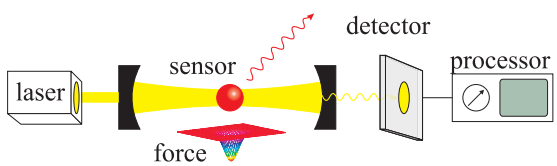

Figure 47.24: Taking information from the sensor to the detector.

A typical quantum sensor can be described by the generic Hamiltonian [236],

$$\hat{H}(t) = \hat{H}_{\text{qbit}} + \hat{H}_{\text{cntrl}}(t) + \hat{H}_{\text{int}}(t) \ , \tag{47.135}$$

[8] E.g. by using two-level systems not subject to motion, collisions, spontaneous emission, etc.. Sometimes spontaneous emission can be controlled by confining both, the atom and the interrogating light field, in a cavity.

composed of a (known) internal Hamiltonian $\hat{H}_{\rm qbit}$, a control Hamiltonian $\hat{H}_{\rm cntrl}$ allowing to manipulate or tune the sensor, and a signal Hamiltonian $\hat{H}_{\rm int}$ allowing to pass information about the state of the system to the outside world.

Typically, the internal Hamiltonian is static and defines the energy eigenstates $|0\rangle$ and $|1\rangle$,

$$\hat{H}_{\rm qbit} = E_0|0\rangle\langle 0| + E_1|1\rangle\langle 1| \ . \tag{47.136}$$

The qubit internal Hamiltonian may contain additional interactions, such as couplings to other qubits or time-dependent stochastic terms due to interactions with an environment.

Many quantum sensing protocols require to manipulate the qubit either before, during, or after the sensing process. This is achieved via a control Hamiltonian, which allows implementing a sequence of appropriate quantum gates, such as the Hadamard gate or Pauli X and Y gates. These gates are nothing else than what, in the language of atom interferometry is known as $\pi/2$ or π-pulses around different axes. Advanced sensing schemes employing more than one sensor qubit may further require conditional gates, especially controlled-NOT gates to generate entanglement, swap gates to exploit memory qubits, and controlled phase shifts in quantum phase estimation (see Sec. 47.3). Finally, the control Hamiltonian can include control fields for systematically tuning the transition frequency $\hbar\omega_0 = E_1 - E_2$.

Finally, the signal Hamiltonian represents the coupling between the sensor qubit and a signal $V(t)$ to be measured. When the signal is weak (which is assumed here) $\hat{H}_{\rm int}$ adds a small perturbation to the internal Hamiltonian. The signal Hamiltonian can then be separated into two qualitatively different contributions,

$$\hat{H}_{\rm int} = \hat{H}_{\rm int,\parallel} + \hat{H}_{\rm int,\perp} \ , \tag{47.137}$$

where $\hat{H}_{\rm int,\parallel}$ is the parallel (commuting) and $\hat{H}_{\rm int,\perp}$ the transverse (non-commuting) components, respectively. The two components can quite generally be captured by,

$$\begin{aligned} \hat{H}_{\rm int,\parallel} &= \tfrac{\gamma}{2} V_\parallel(t)[|1\rangle\langle 1| - |0\rangle\langle 0|] \\ \hat{H}_{\rm int,\perp} &= \tfrac{\gamma}{2}[V_\perp(t)|1\rangle\langle 0| + V_\perp^\dagger(t)|0\rangle\langle 1|] \ , \end{aligned} \tag{47.138}$$

where γ is the coupling or transduction parameter of the qubit to the signal $V(t)$. We verify,

$$\begin{aligned} [\hat{H}_{\rm qbit}, \hat{H}_{\rm int,\parallel}] &= 0 \\ [\hat{H}_{\rm qbit}, \hat{H}_{\rm int,\perp}] &= \tfrac{\gamma}{2} V_\perp(E_0 - E_1)(|0\rangle\langle 1| - |1\rangle\langle 0) \ . \end{aligned} \tag{47.139}$$

Examples of coupling parameters include the Zeeman shift parameter or the Stark shift parameter of electric dipoles in an electric field. The parallel and transverse components of a signal have distinctly different effects on the quantum sensor. A commuting perturbation $\hat{H}_{\rm int,\parallel}$ leads to shifts of the energy levels and an associated change of the transition frequency ω_0. A non-commuting perturbation $\hat{H}_{\rm int,\perp}$, by contrast, can induce transitions between levels, manifesting through an increased transition rate. Most often, this requires the signal to be time-dependent (resonant with the transition) in order to have an appreciable effect on the quantum sensor.

An important class of signals are vector signal $\mathbf{V}(t)$, in particular, those provided by electric or magnetic fields. The interaction between a vector signal and a qubit can be described by the signal Hamiltonian,

$$\hat{H}_{\rm int} = \gamma \mathbf{V}(t) \cdot \hat{\vec{\sigma}} \ , \tag{47.140}$$

where $\hat{\vec{\sigma}}$ is the vector of Pauli matrices (23.153). For a vector signal, the two signal functions $V_\parallel(t)$ and $V_\perp(t)$ are,

$$\begin{aligned} V_\parallel(t) &= V_z(t) \\ V_\perp(t) &= V_x(t) + \imath V_y(t) \ , \end{aligned} \tag{47.141}$$

where the z-direction is defined by the qubit's quantization axis. The corresponding signal Hamiltonian,

$$\hat{H}_V(t) = \gamma \hat{\sigma}_x \mathfrak{Re}\, V_\perp(t) + \gamma \hat{\sigma}_y \mathfrak{Im}\, V_\perp(t) + \gamma \hat{\sigma}_z V_\parallel(t) \ , \tag{47.142}$$

is just the one of the Rabi model extensively discussed in Sec. 39.3.

47.4.2.2 Sensing forces by matter wave interferometry

Matter wave interferometry is ideal for sensing weak forces or sensing strong forces with high precision. Many interferometers employ the Ramsey scheme, which consists in sandwiching the sensing Hamiltonian between two $\pi/2$-control Hamiltonian pulses $\hat{H}_{\rm cntrl}$ preparing and reading out the atomic coherence. Between the pulses (or interaction zones), the atomic coherence is influenced by the parallel part of the sensing Hamiltonian $\hat{H}_{{\rm int},\parallel}$.

The basic idea is the following: One takes a matter wave and lets it fall in the Earth's gravitational field. But before that, apply a laser pulse separating the matter wave into two parts taking different paths. Thus, the Broglie waves of the two parts will accumulate different phases, which results in an interference pattern when the waves are superimposed again. As illustrated in Fig. 47.25, the matter wave interferometry works similarly to the Ramsey method used in atomic clocks with the difference that in the former the trajectories of the atomic center-of-mass motion must be separated in real space as much as possible (see Sec. 39.3.6 on Ramsey pulses and NMR, Sec. 24.1.3 on gravity with Excs. 23.7.6.2 and 23.7.6.3, Sec. 52.2.2 on Bragg interferometry and photon echos with Excs. 52.2.4.1) [9].

A particularly smart way to do matter wave interferometry is via the observation of Bloch oscillations of matter waves in a periodic lattice (see Sec. 26.2.2). The Bloch oscillations can be understood in the following picture: A resting atom has infinite de Broglie wavelength. Being constantly accelerated by gravity, the matter wave reduces its de Broglie wavelength from ∞ to a value, where it becomes commensurate with the periodicity of the standing light wave potential. At this moment Bragg scattering comes into play, reflecting the atomic motion back into upward direction, and the process starts over again. The atoms evolve like jumping on a trampoline with a frequency given,

$$\nu_{\rm blo} = \frac{mg}{2\hbar k_{\rm lat}} \ . \tag{47.143}$$

[9] See also Sec. 55.5 and 56.5 on interferometric and spectroscopic techniques.

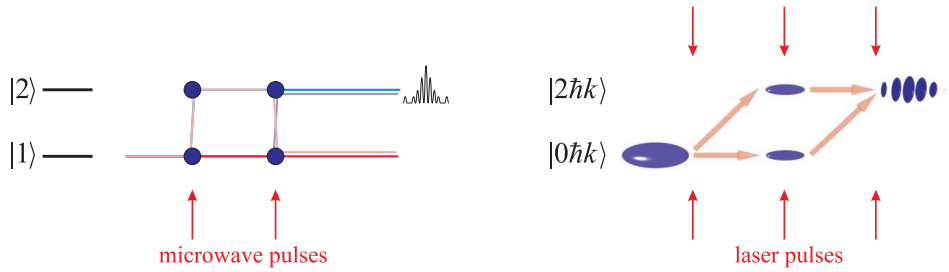

Figure 47.25: Difference between clocks and interferometers. (left) Ramsey-type clock. (right) Ramsey-Bordé interferometer. A movie can be seen at (watch movie).

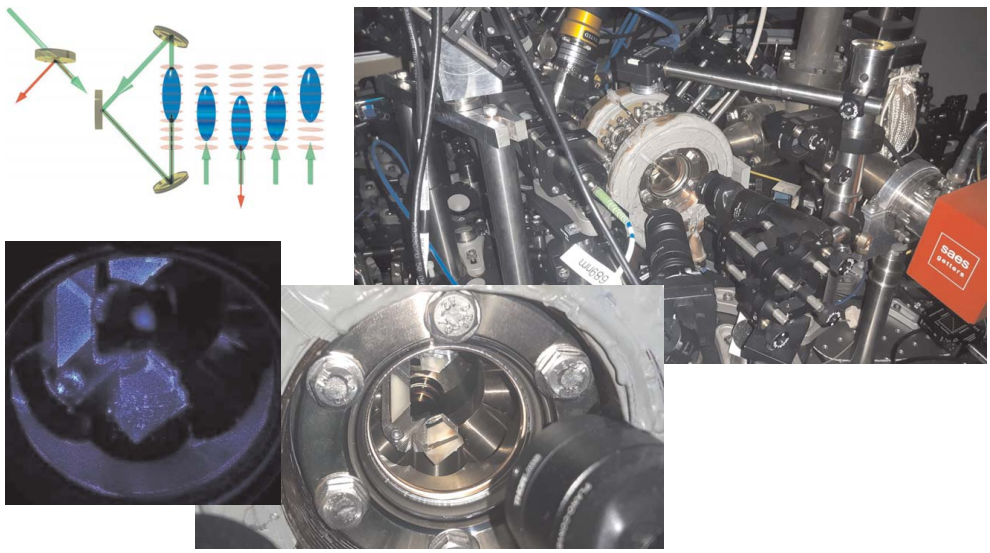

Figure 47.26: Working principle and pictures of the Sr Bloch oscillation interferometer constructed at the IFSC, USP.

47.4.3 Parameter estimation from measurements

The purpose of metrology is the design of technical devices capable of measuring physical quantities with high precision. This obviously necessitates a high degree of correlation between the physical parameter on which we want to obtain information and the observable that is really measured by the device. This is not always easy to achieve and depends on the engineer's skills and inventiveness. A paradigmatic example is Ramsey's idea to sense phase shifts in atom interferometers by measuring atomic internal state populations.

Finding the most likely value for a parameter by measurement is relatively straightforward. It is, however, as important to evaluate the precision of a measurement, and this can be much more complicated. Technically, we may get an idea of the precision by comparing measurements produced by different devices. But it is also interesting to be able to evaluate the precision upfront, before the device has been constructed,

as this may serve as a guidance for the design of the best possible device, at least for idealized conditions.

In practice, the experimentalist will design an apparatus aiming at measuring the dependence (or independence) on a particular observable, say $\hat{M}$, from a parameter, say θ [10]. To increase the confidence in the measurement outcome, the experimentalist will repeat the measurement many times. As any measurement is subject to technical (classical) noise and intrinsic (quantum) noise, the repetitions will generate a distribution of results, which are commonly represented as a histogram. The relevant question in any such measurement is now, how much the outcome probability distribution $P(\theta)$ depends on the experimental parameter θ. We purpose of this section is to introduce quantities, such as the *fidelity* and the *Fisher information*, quantifying this dependency. The greater these figures of merit are, the greater the dependency of $P(\theta)$ on θ and the higher the sensitivity of the measurement apparatus.

47.4.3.1 Repeated measurements

Let us call $p(\mu|\theta)$ the conditional probability of measuring a result μ given that the experimental control parameter is θ. The combined probability to observe the sequence of results $\vec{\mu} = \{\mu_1, .., \mu_N\}$ in N independent measurements is then,

$$P(\vec{\mu}|\theta) = \prod_{i=1}^{N} p(\mu_i|\theta) \ . \tag{47.144}$$

The statistical mean value and variance are,

$$\boxed{1 = \sum_{\vec{\mu}} P(\vec{\mu}|\theta) \quad , \quad \bar{\theta} = \sum_{\vec{\mu}} P(\vec{\mu}|\theta)\theta \quad , \quad (\Delta\theta)^2 = \sum_{\vec{\mu}} P(\vec{\mu}|\theta)(\theta - \bar{\theta})^2} \tag{47.145}$$

the sum extending over all possible sequences of N measurement results.

Example 353 (*Bernoulli trial*): As a first simple example, let us consider the experiment of tossing a coin (also called *Bernoulli trial*) with faces called $\pm$. At the end of the flight we grab the coin, read the upper face, and acknowledge one of two possible results, $\mu = \pm$. The experimental control parameter θ could be related to the symmetry of the coin: If it is evenly distributed, the coin will be unbiased, and we expect the probability of finding the $+$-side to be

$$p(\mu|\theta) = p(+|\theta) = \tfrac{1}{2} \ . \tag{47.146}$$

When we repeat the experiment N times, there are 2^N possible combinations $\vec{\mu}$, such that,

$$p(\mu_i|\theta) = p(\pm|\theta) = \tfrac{1}{2} \quad \Rightarrow \quad P(\vec{\mu}|\theta) = \tfrac{1}{2^N} \quad \Rightarrow \quad \sum_{\vec{\mu}} P(\vec{\mu}|\theta) = 1 \ . \tag{47.147}$$

Solve Exc. 47.4.6.2.

[10] Sometimes we will be interested in the dependence of several observables $\hat{\mathbf{A}}$ from a set of various parameters $\vec{\theta}$.

Example 354 (*Ramsey interferometer*): Another example where the value of the control parameter influences the result of the measurement is the Ramsey experiment with a two-level system (see Excs. 39.3.7.6 and 39.3.7.7). Reading out the population of the upper state $\mu = +$ we find,

$$p(+|\theta) = \cos^2 \tfrac{\theta}{2} = \tfrac{1}{2} + \tfrac{1}{2}\cos\Delta\tau \qquad \text{and} \qquad p(-|\theta) = \sin^2 \tfrac{\theta}{2} \ . \tag{47.148}$$

The precision of the estimation of a parameter ϑ from a measurement of an observable $\hat{A}$ which depends on that parameter is obtained from error propagation [923],

$$(\Delta\vartheta)^2 = \frac{\langle \Delta\hat{A}\rangle^2}{|\partial_\vartheta \langle \hat{A}\rangle|^2} = \frac{\langle \hat{A}^2\rangle - \langle \hat{A}\rangle^2}{|\partial_\vartheta \langle \hat{A}\rangle|^2} \ . \tag{47.149}$$

At the example of the Rabi experiment illustrated in Fig. 47.27, it simply means

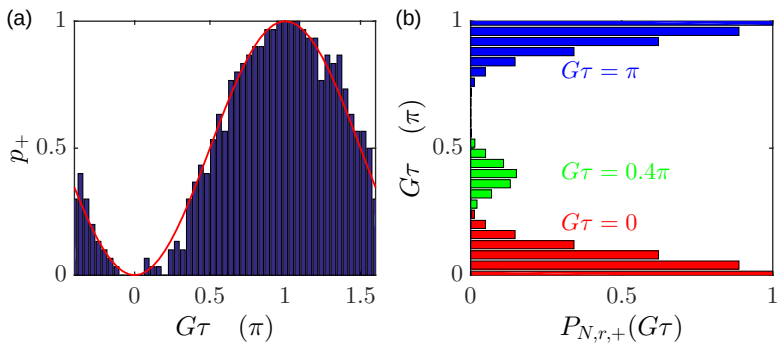

Figure 47.27: (code) (a) Simulation of a Rabi experiment where the pulse area is varied. At each value of the pulse area $N = 30$ excitation trials are done and the ratio of successful trials p_+/N is plotted. Obviously, the precision with which a specific pulse area can be measured increases with the number of trials. (b) Histogram of measurement results obtained for three different pulse areas. The question here is, given an excitation is observed, how likely is it due to the parameter being tuned to exactly the right position.

that an experimental parameter (here, the pulse area) can be determined with lower imprecision $\Delta\vartheta$ when the slope of the error signal $|\partial_\vartheta \langle \hat{A}\rangle|$ is steep (here, at mid height of the Rabi fringe). Additionally, the noise of the measured variable $\Delta\hat{A}$ should be small (here, at the top and bottom of the Rabi fringe). Interestingly, in Exc. 46.1.8.21 we show that $\Delta\vartheta_z^2 = \frac{\langle \Delta\hat{S}_z\rangle^2}{|\partial_\vartheta \langle \hat{S}_z\rangle|^2} = \frac{1}{N}$ does not dependent on the parameter.

47.4.3.2 Classical Fisher information

Let us assume two distributions $P(\vec{\mu}|\theta)$ and $P(\vec{\mu}|\theta')$ differing from each other by the fact that they belong to slightly different parameters θ and $\theta' = \theta + \vartheta$. The fidelity between two distributions can be defined as [583],

$$d_{\mathrm{f}}(\theta,\theta') = \left(\sum_{\vec{\mu}} \sqrt{P(\vec{\mu}|\theta)P(\vec{\mu}|\theta')}\right)^2 \xrightarrow{\theta=\theta'} 1 \ . \tag{47.150}$$

With the boundary conditions,

$$1 = \sum_{\vec{\mu}'} P(\vec{\mu}'|\theta+\vartheta) \qquad \text{and therefore} \qquad 0 = \sum_{\vec{\mu}} \partial_\vartheta P(\vec{\mu}|\theta+\vartheta)\ , \tag{47.151}$$

we may derive the *Fisher information* [125, 300],

$$\begin{aligned}
F_{\mathrm{c}}(\theta) &= -4\ \frac{\partial^2 d_{\mathrm{f}}(\theta,\theta+\vartheta)}{\partial\vartheta^2}\bigg|_{\vartheta=0} \qquad (47.152)\\
&= -4\ \frac{\partial}{\partial\vartheta}\left(\sum_{\vec{\mu}'}\sqrt{P(\vec{\mu}'|\theta)P(\vec{\mu}'|\theta+\vartheta)}\sum_{\vec{\mu}}\frac{\sqrt{P(\vec{\mu}|\theta)}}{2\sqrt{P(\vec{\mu}|\theta+\vartheta)}}\frac{\partial P(\vec{\mu}|\theta+\vartheta)}{\partial\vartheta}\right)\bigg|_{\vartheta=0}\\
&= -4\cancelto{0}{\sum_{\vec{\mu}'}\frac{\partial\sqrt{P(\vec{\mu}'|\theta)P(\vec{\mu}'|\theta+\vartheta)}}{\partial\vartheta}}\ \cancelto{0}{\sum_{\vec{\mu}}\frac{\sqrt{P(\vec{\mu}|\theta)}}{2\sqrt{P(\vec{\mu}|\theta+\vartheta)}}\frac{\partial P(\vec{\mu}|\theta+\vartheta)}{\partial\vartheta}}\ -\\
&\quad -4\cancelto{1}{\textstyle\sum_{\vec{\mu}'}\sqrt{P(\vec{\mu}'|\theta)P(\vec{\mu}'|\theta+\vartheta)}}\sum_{\vec{\mu}}\frac{\partial}{\partial\vartheta}\left(\frac{\sqrt{P(\vec{\mu}|\theta)}}{2\sqrt{P(\vec{\mu}|\theta+\vartheta)}}\frac{\partial P(\vec{\mu}|\theta+\vartheta)}{\partial\vartheta}\right)\bigg|_{\vartheta=0}\\
&= -4\sum_{\vec{\mu}}\frac{\partial P(\vec{\mu}|\theta+\vartheta)}{\partial\vartheta}\frac{\partial}{\partial\vartheta}\frac{\sqrt{P(\vec{\mu}|\theta)}}{2\sqrt{P(\vec{\mu}|\theta+\vartheta)}}\\
&= \sum_{\vec{\mu}}\frac{1}{P(\vec{\mu}|\theta)}\left(\frac{\partial P(\vec{\mu}|\theta)}{\partial\vartheta}\right)^2 .
\end{aligned}$$

Hence, the (classical) Fisher information can be calculated from,

$$\boxed{F_{\mathrm{c}}(\theta) = \sum_{\vec{\mu}}\frac{1}{P(\vec{\mu}|\theta)}\left(\frac{\partial P(\vec{\mu}|\theta)}{\partial\theta}\right)^2} = \sum_{\vec{\mu}} P(\vec{\mu}|\theta)\left(\frac{\partial \ln P(\vec{\mu}|\theta)}{\partial\theta}\right)^2 . \tag{47.153}$$

The *Cramér-Rao* bound gives a lower bound for the variance,

$$\boxed{\Delta\theta \geq \Delta\theta_{\mathrm{CR}} \equiv \frac{1}{\sqrt{F(\theta)}}}\ . \tag{47.154}$$

Example 355 (*Meaning of the Fisher information*): The formulation of the Fisher information in terms of the second derivative of the fidelity lends itself to an intuitive graphical interpretation. The Fisher information measures how fast a probability or quasi-probability distribution changes towards a recognizably different distribution when a particular parameter is modified. Let us for example consider a harmonic oscillator in a coherent state $|\beta\rangle = |re^{\imath\varphi}\rangle$ represented by the Husimi distribution $Q_{|\beta\rangle}(\alpha)$, as plotted in Fig. 37.2. The question is, how much do we have to change the amplitude r, or the phase φ, or a quadrature component $r\cos\varphi$ or $r\sin\varphi$ in order to get a noticeably different Husimi distribution, and how does this change depend on the photon number $n = |\alpha|$? This change is what is called Fisher information.
The width of the Husimi distribution of a coherent in the Glauber plane is independent on its amplitude, that is, the states $|r_1 e^{\imath\varphi_1}\rangle$ and $|r_2 e^{\imath\varphi_2}\rangle$ both have the same width [see Fig. 24.14 or 47.28(a)], since,

$$\Delta\hat{x} = \langle(\hat{a}+\hat{a}^\dagger)^2\rangle - \langle\hat{a}+\hat{a}^\dagger\rangle^2 = 1 \tag{47.155}$$

$$\Delta\hat{p} = \langle(\imath\hat{a}-\imath\hat{a}^\dagger)^2\rangle - \langle\imath\hat{a}-\imath\hat{a}^\dagger\rangle^2 = 1\ . \tag{47.156}$$

Now, assuming $r_1 = r_2 \equiv r$, the distance of the two states is approximately the arc between them, $a = r(\varphi_2 - \varphi_1)$. Hence, the phase difference is inversely proportional to the amplitude $r = |\alpha| = \sqrt{n}$,

$$\Delta\varphi \propto \frac{1}{\sqrt{n}} \,. \tag{47.157}$$

While the Husimi distribution works well for coherent states, it fails to represent non-classical features, such as quantum interferences. These are better viewed in the Wigner distribution, where they appear as very narrow structures, whose widths rapidly decrease with the amplitude of the harmonic oscillation. Obviously, quantum interferences are extremely sensitive to parameter changes, provided the change occurs in a direction perpendicular to the fringes. Fig. 47.28 illustrates this at the example of a Schrödinger cat state. The distribution obviously changes much faster upon shifts along the p_α than along the $_\alpha$ direction.

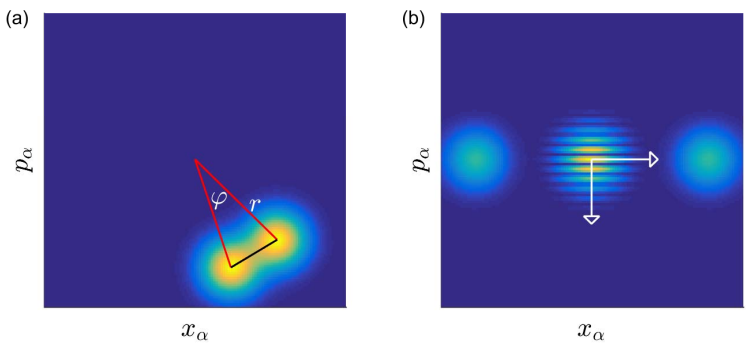

Figure 47.28: (code) (a) Wigner distribution of two coherent states separated by a small angle φ. (b) Wigner distribution of a cat state exhibiting quantum interferences.

47.4.4 Quantum Fisher information

The previously introduced quantifiers for parameter estimation can be extended to quantum mechanics with the definition of a *quantum Fisher information* and a *quantum Cramér-Rao bound*. Quantum parameter estimation aims at measuring the value of a continuous parameter θ that is encoded in the state of a quantum system characterized by the density operator $\hat{\rho}_\theta$, via its interaction with the external force that we want to characterize. The estimation process consists of two steps: in the first step, the state of the system (i.e. the measurement apparatus) $\hat{\rho}_\theta$ is measured; in the second step, the estimate of θ is determined by data processing the measurement outcomes.

In quantum mechanics $\vec{\mu}$ is just the eigenvalue spectrum. The big advantage in using quantum systems is, that the exigency that the measurements be independent can be overcome, via the use of entangled atoms. In the best case this can lead to a more favorable scaling of the Cramér-Rao bound like $1/N$, leading to a considerable *metrological gain*. The following sections are devoted to developing the notions of quantum parameter estimation.

The quantum Fisher information can be regarded as a generalization of the variance concept. Via the Cramér-Rao bound, it gives similar information but it can be extended to several parameters, in which case it corresponds to the covariance matrix, and to mixed states.

47.4.4.1 Quantum Fisher information for a pure state depending on a single parameter

As a first example, we will study the sensitivity of a pure state on changes of a single parameter. Let us consider a small deviation of a parameter θ by ϑ and expand the wavefunction [641],

$$|\psi(\theta+\vartheta)\rangle = |\psi(\theta)\rangle + \vartheta\tfrac{\partial}{\partial\vartheta}|\psi(\theta)\rangle \equiv |\psi\rangle + \vartheta\partial_\vartheta|\psi\rangle \ , \tag{47.158}$$

where in the last expression we drop the argument θ for readability. The fidelity is given by,

$$\begin{aligned} |\langle\psi(\theta)|\psi(\theta+\vartheta)\rangle|^2 &= |1+\vartheta\langle\psi|\partial_\vartheta\psi\rangle|^2 \\ &= 1+\vartheta\langle\psi|\partial_\vartheta\psi\rangle + \vartheta\langle\partial_\vartheta\psi|\psi\rangle + \vartheta^2\langle\partial_\vartheta\psi|\psi\rangle\langle\psi|\partial_\vartheta\psi\rangle \ . \end{aligned} \tag{47.159}$$

On the other hand,

$$\begin{aligned} 1 &= \langle\psi(\theta+\vartheta)|\psi(\theta+\vartheta)\rangle \\ &= 1+\vartheta\langle\psi|\partial_\vartheta\psi\rangle + \vartheta\langle\partial_\vartheta\psi|\psi\rangle + \vartheta^2\langle\partial_\vartheta\psi|\partial_\vartheta\psi\rangle \ . \end{aligned} \tag{47.160}$$

Substituting this result into the fidelity, we get,

$$|\langle\psi(\theta)|\psi(\theta+\vartheta)\rangle|^2 = 1-\vartheta^2\langle\partial_\vartheta\psi|\partial_\vartheta\psi\rangle + \vartheta^2\langle\partial_\vartheta\psi|\psi\rangle\langle\psi|\partial_\vartheta\psi\rangle \ . \tag{47.161}$$

The so called *Bures distance* is defined as,

$$d_{\mathrm{f}}(\theta,\theta') \equiv 2-2|\langle\psi(\theta)|\psi(\theta')\rangle|^2 \ , \tag{47.162}$$

where the factor 2 is just convention and serves to meet the classical formulas. Hence,

$$\begin{aligned} d_{\mathrm{f}}(\theta,\theta+\vartheta) &\equiv 2-2|\langle\psi(\theta)|\psi(\theta+\vartheta)\rangle|^2 \\ &= 2\vartheta^2\langle\partial_\vartheta\psi|\partial_\vartheta\psi\rangle - 2\vartheta^2\langle\partial_\vartheta\psi|\psi\rangle\langle\psi|\partial_\vartheta\psi\rangle \ . \end{aligned} \tag{47.163}$$

The *Fisher information* is defined as,

$$F_{\mathrm{q}}(\theta) \equiv \frac{\partial^2}{\partial\vartheta^2} d_{\mathrm{f}}(\theta,\theta+\vartheta)\bigg|_{\vartheta=0} \ , \tag{47.164}$$

so that we finally get,

$$\boxed{F_{\mathrm{q}}(\theta) = 4\left(\langle\partial_\vartheta\psi|\partial_\vartheta\psi\rangle - \langle\partial_\vartheta\psi|\psi\rangle\langle\psi|\partial_\vartheta\psi\rangle\right) \ .} \tag{47.165}$$

In Exc. 47.4.6.5 we derive the quantum Fisher information for separable states.

Example 356 (*Generalization to multi-parameter metrology*): The quantum Fisher information can be generalized to several parameters. Let us consider a small deviation of a set of parameters $\vec{\theta}$ by $\vec{\vartheta}$ and expand the wavefunction [641],

$$|\psi(\vec{\theta}+\vec{\vartheta})\rangle = |\psi(\vec{\theta})\rangle + \sum_\alpha \tfrac{\partial}{\partial\vartheta_\alpha}\psi(\vec{\theta}+\vec{\vartheta})\rangle\Big|_{\vec{\vartheta}=0}\vartheta_\alpha \equiv |\psi\rangle + \sum_\alpha \vartheta_\alpha|\partial_\alpha\psi\rangle \ , \quad (47.166)$$

where in the last expression we drop the argument $\vec{\theta}$ for readability. The *fidelity* is given by,

$$\begin{aligned}|\langle\psi(\vec{\theta})|\psi(\vec{\theta}+\vec{\vartheta})\rangle|^2 &= |1+\sum_\alpha \vartheta_\alpha\langle\psi|\partial_\alpha\psi\rangle|^2 \qquad (47.167)\\ &= 1+\sum_\alpha \vartheta_\alpha\langle\psi|\partial_\alpha\psi\rangle + \sum_\beta \vartheta_\beta\langle\partial_\beta\psi|\psi\rangle + \sum_{\mu,\nu}\vartheta_\alpha\vartheta_\beta\langle\partial_\alpha\psi|\psi\rangle\langle\psi|\partial_\beta\psi\rangle \ .\end{aligned}$$

On the other hand,

$$\begin{aligned}1 = \langle\psi(\vec{\theta}+\vec{\vartheta})|\psi(\vec{\theta}+\vec{\vartheta})\rangle &= \left(\langle\psi| + \sum_\alpha \vartheta_\alpha\langle\partial_\alpha\psi|\right)\left(|\psi\rangle + \sum_\alpha \vartheta_\alpha|\partial_\alpha\psi\rangle\right) \qquad (47.168)\\ &= 1+\sum_\alpha \vartheta_\alpha\langle\psi|\partial_\alpha\psi\rangle + \sum_\alpha \vartheta_\alpha\langle\partial_\alpha\psi|\psi\rangle + \sum_{\alpha,\beta}\vartheta_\alpha\vartheta_\beta\langle\partial_\alpha\psi|\partial_\beta\psi\rangle \ .\end{aligned}$$

Substituting this result into the fidelity, we get,

$$|\langle\psi(\vec{\theta})|\psi(\vec{\theta}+\vec{\vartheta})\rangle|^2 = 1 - \sum_{\alpha,\beta}\vartheta_\alpha\vartheta_\beta\langle\partial_\alpha\psi|\partial_\beta\psi\rangle + \sum_{i,j}\vartheta_\alpha\vartheta_\beta\langle\partial_\alpha\psi|\psi\rangle\langle\psi|\partial_\beta\psi\rangle \ . \quad (47.169)$$

The so called Bures distance is defined as,

$$d_{\rm f}(\vec{\theta},\vec{\theta}') \equiv 2 - 2|\langle\psi(\vec{\theta})|\psi(\vec{\theta}')\rangle|^2 \ . \quad (47.170)$$

Hence,

$$\begin{aligned}d_{\rm f}(\vec{\theta},\vec{\theta}+\vec{\vartheta}) &= 2 - 2|\langle\psi(\vec{\theta})|\psi(\vec{\theta}+\vec{\vartheta})\rangle|^2 \qquad (47.171)\\ &= 2\sum_{\alpha,\beta}\vartheta_\alpha\vartheta_\beta\langle\partial_\alpha\psi|\partial_\beta\psi\rangle - 2\sum_{\alpha,\beta}\vartheta_\alpha\vartheta_\beta\langle\partial_\alpha\psi|\psi\rangle\langle\psi|\partial_\beta\psi\rangle \ .\end{aligned}$$

The Fisher information is now a matrix,

$$\begin{aligned}F_{\rm q}^{(\mu\nu)}(\vec{\theta}) &= \frac{\partial^2}{\partial\vartheta_\mu\partial\vartheta_\nu}d_{\rm f}(\vec{\theta},\vec{\theta}+\vec{\vartheta})\Big|_{\vec{\vartheta}=0} \qquad (47.172)\\ &= 2\frac{\partial}{\partial\vartheta_\mu}\sum_{\alpha,\beta}\frac{\partial\vartheta_\alpha\vartheta_\beta}{\partial\vartheta_\nu}\left(\langle\partial_\alpha\psi|\partial_\beta\psi\rangle - \langle\partial_\alpha\psi|\psi\rangle\langle\psi|\partial_\beta\psi\rangle\right)\\ &= 2\frac{\partial}{\partial\vartheta_\mu}\sum_\alpha\left(\vartheta_\alpha\langle\partial_\alpha\psi|\partial_\nu\psi\rangle - \langle\partial_\alpha\psi|\psi\rangle\langle\psi|\partial_\nu\psi\rangle + \vartheta_\alpha\langle\partial_\nu\psi|\partial_\alpha\psi\rangle - \langle\partial_\nu\psi|\psi\rangle\langle\psi|\partial_\alpha\psi\rangle\right)\\ &= 2\left(\langle\partial_\mu\psi|\partial_\nu\psi\rangle - \langle\partial_\mu\psi|\psi\rangle\langle\psi|\partial_\nu\psi\rangle + \langle\partial_\nu\psi|\partial_\mu\psi\rangle - \langle\partial_\nu\psi|\psi\rangle\langle\psi|\partial_\mu\psi\rangle\right) \ .\end{aligned}$$

We finally get [11],

$$\boxed{F_{\rm q}^{(\mu\nu)}(\vec{\theta}) = 4\mathfrak{Re}\left(\langle\partial_\mu\psi|\partial_\nu\psi\rangle - \langle\partial_\mu\psi|\psi\rangle\langle\psi|\partial_\nu\psi\rangle\right)\ .} \tag{47.173}$$

47.4.4.2 Quantum Fisher information via generators

In Eq. (47.165) we calculated the Fisher information from derivatives of wavefunctions. The derivatives represent operations, for instance angular momentum, $\hat{G}_\varphi \equiv \hat{S}_z \propto \partial_\varphi$, called *generators*. With these operations the dependence of pure states on parameters can be formulated as Heisenberg-type equations,

$$\frac{\partial\hat{\rho}_\theta}{\partial\theta} \equiv \imath(\hat{\rho}_\theta\hat{G}_\theta - \hat{G}_\theta\hat{\rho}_\theta) \qquad \text{with the solution} \qquad \hat{\rho}_\theta = e^{-\imath\theta\hat{G}_\theta}\hat{\rho}_0 e^{\imath\theta\hat{G}_\theta}\ . \tag{47.174}$$

Interestingly, those equations can always be rewritten as,

$$\frac{\partial\hat{\rho}_\theta}{\partial\theta} \equiv \tfrac{1}{2}(\hat{L}_\theta\hat{\rho}_\theta + \hat{\rho}_\theta\hat{L}_\theta)\ , \tag{47.175}$$

where we defined the *symmetric logarithmic derivative*,

$$\boxed{\hat{L}_\theta = 2\imath(\hat{\rho}_\theta\hat{G}_\theta - \hat{G}_\theta\hat{\rho}_\theta)\ .} \tag{47.176}$$

The equivalence of (47.174) and (47.175) is easy to check substituting $\hat{L}_\theta$ and using the pure state condition, $\hat{\rho}_\theta^2 = \hat{\rho}_\theta = |\psi_\theta\rangle\langle\psi_\theta|$. The advantage of expression (47.187) is that, without using the pure state condition, the quantum Fisher information can now we written as,

$$\begin{aligned} F_{\rm q}(\theta) &= \mathrm{Tr}\,\hat{\rho}_\theta\hat{L}_\theta^2 &&= 4\mathrm{Tr}\,\hat{\rho}_\theta(\hat{G}_\theta^2 - \hat{G}_\theta\hat{\rho}_\theta\hat{G}_\theta) \\ &= \langle\psi_\theta|\hat{L}_\theta^2|\psi_\theta\rangle &&= 4(\langle\hat{G}_\theta\psi_\theta|\hat{G}_\theta\psi_\theta\rangle - \langle\hat{G}_\theta\psi_\theta|\psi_\theta\rangle\langle\psi_\theta|\hat{G}_\theta\psi_\theta\rangle) \end{aligned} \tag{47.177}$$

which coincides with (47.165) when we set the generator $\hat{G}_\theta \equiv \partial_\theta$.

47.4.4.3 Quantum Fisher information for pure light states

Common systems for quantum sensing are light fields or ensembles of atoms on which we will focus in the following. The procedure will be (i) to identify the parameters θ for which we want to calculate the Fisher information, (ii) to formulate the corresponding generators $\hat{G}_\theta$ and the symmetric logarithmic derivatives, and (iii) evaluate the Fisher information by tracing in the Fock or Dicke basis.

[11] Note that for pure states, the quantum Fisher information is deeply connected to the symmetric *covariance matrix*, which for a set of operators $\hat{G}_\mu$ is defined as,

$$\mathbf{C} = \mathrm{cov}[\hat{G}_\mu, \hat{G}_\nu] = \langle(\hat{G}_\mu - \langle\hat{G}_\mu\rangle)(\hat{G}_\nu - \langle\hat{G}_\nu\rangle)\rangle = \tfrac{1}{2}\langle\hat{G}_\mu\hat{G}_\nu + \hat{G}_\nu\hat{G}_\mu\rangle - \langle\hat{G}_\mu\rangle\langle\hat{G}_\nu\rangle\ .$$

The most basic operations we may perform with states of light are displacements and rotations in the Glauber plane applying the unitary transformations for harmonic oscillator states (24.120), respectively, (24.130), which we may write as,

$$\mathcal{D}(r) = e^{\imath r(\imath e^{-\imath\varphi}\hat{a} - \imath e^{\imath\varphi}\hat{a}^\dagger)} \qquad \text{and} \qquad \mathcal{R}(\varphi) = e^{\imath\varphi\hat{a}^\dagger\hat{a}} \ . \tag{47.178}$$

Indeed, fixing the angle φ, the free parameter will be $\theta \equiv r$, and the operator $\mathcal{D}(r)$ describes radial displacement by an amount r,

$$|\alpha\rangle \equiv |\alpha_0 + \beta\rangle = \mathcal{D}(r)|\alpha_0\rangle = e^{\beta\hat{a}^\dagger - \beta^*\hat{a}}|\alpha_0\rangle \tag{47.179}$$

where we have set $\beta \equiv re^{\imath\varphi}$. We may now write the density operator for Glauber states,

$$\hat{\rho}_r = |\alpha\rangle\langle\alpha| = \mathcal{D}(\beta)|\alpha_0\rangle\langle\alpha_0|\mathcal{D}^\dagger(\beta) = e^{-\imath r\hat{G}_r}|\alpha_0\rangle\langle\alpha_0|e^{\imath r\hat{G}_r} \ , \tag{47.180}$$

introducing the displacement generating operator,

$$\boxed{\hat{G}_r \equiv \imath e^{\imath\varphi}\hat{a}^\dagger - \imath e^{-\imath\varphi}\hat{a}} \ . \tag{47.181}$$

Hence, the radial quantum Fisher information (47.177) is equal to the variance of the rotated quadrature field components, $F_{\mathrm{q}}(r) = 4\langle\hat{n}^2\rangle - 4\langle\hat{n}\rangle^2$.

On the other hand, fixing the radius r, the free parameter will be $\theta \equiv \varphi$, and the operator $\mathcal{R}$ describes rotation by an amount φ,

$$|\alpha\rangle \equiv |e^{\imath\varphi}\alpha_0\rangle = \mathcal{R}(\varphi)|\alpha_0\rangle = e^{\imath\varphi\hat{a}^\dagger\hat{a}}|\alpha_0\rangle \ . \tag{47.182}$$

We may now write the density operator for Glauber states,

$$\hat{\rho}_\varphi = |\alpha\rangle\langle\alpha| = \mathcal{R}(\varphi)|\alpha_0\rangle\langle\alpha_0|\mathcal{R}^\dagger(\varphi) = e^{-\imath\varphi\hat{G}_\varphi}|\alpha_0\rangle\langle\alpha_0|e^{\imath\varphi\hat{G}_\varphi} \ , \tag{47.183}$$

introducing the rotation (or phase shift) generating operator,

$$\boxed{\hat{G}_\varphi \equiv -\hat{a}^\dagger\hat{a}} \ . \tag{47.184}$$

Hence, the azimuthal quantum Fisher information is equal to the photon number variance, $F_{\mathrm{q}}(\varphi) = 4\langle\hat{n}^2\rangle - 4\langle\hat{n}\rangle^2$.

The expectation values of these generating operators $\langle\psi_\theta|\hat{G}_\theta|\psi_\theta\rangle$ and $\langle\psi_\theta|\hat{G}_\theta^2|\psi_\theta\rangle$ with $\theta \equiv r, \varphi$ permit us now calculate the quantum Fisher information for specific pure states of light $|\psi_\theta\rangle$. In Exc. 47.4.6.6 we calculate the quantum Fisher information for some paradigmatic single mode light fields. The results are summarized in Tab. 47.2.

It is interesting to discuss the results in the light of Figs. 37.2. The quantum Fisher information is always largest along the degree of freedom, at which the Wigner function exhibits the finest structure. For example, it is large for coherent states for rotations in the Glauber plane, for Fock states for radial displacements, and for squeezed states along the quadratures.

It seems that, while some of the considered states may have quantum Fisher information exceeding the classical *shot noise* limit, none of them exhibits Heisenberg scaling. Of course the hottest candidate, which would be the squeezed coherent state, was not considered, yet.

Table 47.2: Quantum Fisher information for various light states.

state	basis	Fisher information	Fisher information
Glauber	$\|\alpha\rangle$	$F_{\rm q}^{(\varphi)} = 4\|\alpha\|^2$	$F_{\rm q}^{(r)} = 4$
Fock	$\|n\rangle$	$F_{\rm q}^{(\varphi)} = 0$	$F_{\rm q}^{(r)} = 4 + 8n$
squeezed vacuum	$\|0,\xi\rangle$	$F_{\rm q}^{(\varphi)} = 2\sinh^2 2\|\xi\|^2$	$F_{\rm q}^{(r)} = 0$
cat	$\|\alpha\rangle + \|-\alpha\rangle$	$F_{\rm q}^{(x)} = 4(1+e^{-2\|\alpha\|^2})$	$F_{\rm q}^{(y)} = 4(1+4\alpha^2)(1+e^{-2\|\alpha\|^2})$
thermal	$\sum_n \frac{\bar{n}^n \|n\rangle\langle n\|}{(1+\bar{n})^{1+n}}$	$F_{\rm q}^{(\varphi)} = 0$	$F_{\rm q}^{(r)} = \sum_{k,m} \frac{2(\lambda_k-\lambda_m)^2}{\lambda_k+\lambda_m} \|\langle k\|\hat{G}_r\|m\rangle\|^2$

47.4.4.4 Quantum Fisher information for pure collective spin states

The most basic operations we may perform with collective atomic spin states are rotations about different axis on the Bloch sphere. We consider two cases, rotations about the y-axis by an angle ϑ and rotations about the z-axis by an φ described by the expression (46.38),

$$R_y(\vartheta)\hat{\mathbf{S}} = e^{\imath\vartheta\hat{S}_y}\hat{\mathbf{S}}e^{-\imath\vartheta\hat{S}_y} \qquad \text{and} \qquad R_z(\varphi)\hat{\mathbf{S}} = e^{\imath\varphi\hat{S}_z}\hat{\mathbf{S}}e^{-\imath\varphi\hat{S}_z} \ . \tag{47.185}$$

The collective spin states transform like,

$$|\psi\rangle = e^{-\imath\vartheta\hat{S}_y}|\psi_0\rangle \qquad \text{and} \qquad |\psi\rangle = e^{-\imath\varphi\hat{S}_z}|\psi_0\rangle \ . \tag{47.186}$$

We may now write the density operators,

$$\hat{\rho}_\vartheta = |\psi\rangle\langle\psi| = e^{-\imath\vartheta\hat{S}_y}|\psi_0\rangle\langle\psi_0|e^{\imath\vartheta\hat{S}_y} \qquad \text{and} \qquad \hat{\rho}_\varphi = |\psi\rangle\langle\psi| = e^{-\imath\varphi\hat{S}_z}|\psi_0\rangle\langle\psi_0|e^{\imath\varphi\hat{S}_z} \ , \tag{47.187}$$

introducing the generating operations

$$\boxed{\hat{G}_\vartheta = \hat{S}_y = \tfrac{1}{2\imath}(\hat{S}_- - \hat{S}_+) \qquad \text{and} \qquad \hat{G}_\varphi = \hat{S}_z \ .} \tag{47.188}$$

Again, the expectation values of these generating operators $\langle\psi_\theta|\hat{G}_\theta|\psi_\theta\rangle$ and $\langle\psi_\theta|\hat{G}_\theta^2|\psi_\theta\rangle$ with $\theta \equiv \vartheta, \varphi$ permit us now calculate the quantum Fisher information for specific pure collective spin $|\psi_\theta\rangle$. In Exc. 47.4.6.7 we calculate the quantum Fisher information for some paradigmatic collective spin states introduced in Sec. 46.1. The results are summarized in Tab. 47.3.

It is interesting to discuss the results in the light of Figs. 46.7. Apparently, *coherent spin states* are bounded by the *standard quantum limit*. The sensitivity is highest for rotations along great circles around the Bloch sphere.

Any *Fock spin state* is azimuthally symmetric, which explains $F_{\rm q}(\varphi) = 0$. We also note,

$$F_{{\rm q},|S,0\rangle}(\vartheta) = \tfrac{N^2}{2} + N \qquad \text{and} \qquad F_{{\rm q},|S,\pm S\rangle}(\vartheta) = N \ , \tag{47.189}$$

which means, that Fock states are sensitive to rotations within sagittal planes. While near the poles the quantum Fisher information scales linearly with the particle number, close to the equatorial plane it approaches the Heisenberg limit [120].

Table 47.3: Quantum Fisher information for various collective spin states.

state	basis	Fisher information	Fisher information
coherent	$\lvert\vartheta,\varphi\rangle^{\otimes N}$	$F_{\mathrm{q}}^{(\vartheta)} = N\sin\vartheta$	$F_{\mathrm{q}}^{(\varphi)} = N$
Fock	$\lvert S,M\rangle$	$F_{\mathrm{q}}^{(\vartheta)} = \frac{N^2}{2} + N - 2M^2$	$F_{\mathrm{q}}^{(\varphi)} = 0$
W	$\lvert S,S-1\rangle$	$F_{\mathrm{q}}^{(\vartheta)} = 3N - 2$	$F_{\mathrm{q}}^{(\varphi)} = 0$
cat	$\cos\frac{\vartheta}{2}\lvert S,S\rangle + e^{\imath\varphi}\sin\frac{\vartheta}{2}\lvert S,-S\rangle$	$F_{\mathrm{q}}^{(\vartheta)} = N$	$F_{\mathrm{q}}^{(\varphi)} = N^2(1-\cos\vartheta)$
GHZ	$\frac{1}{\sqrt{2}}(\lvert S,S\rangle + \lvert S,-S\rangle)$	$F_{\mathrm{q}}^{(\vartheta)} = N$	$F_{\mathrm{q}}^{(\varphi)} = N^2$
NOON	$\frac{1}{\sqrt{2}}(\lvert S,S\rangle + e^{\imath 2S\vartheta}\lvert S,-S\rangle)$	$F_{\mathrm{q}}^{(\vartheta)} = N$	$F_{\mathrm{q}}^{(\varphi)} = N^2$
squeezed	$e^{-\imath\zeta\hat{S}_z^2/2}\lvert\frac{\pi}{2},0\rangle^N$	$\simeq \frac{N^2}{2}(1-2\cos^{2N-2}\zeta + \ldots)$	

In contrast, *cat states* allow for Heisenberg-scaling only for rotations in the equatorial plane. For rotations within sagittal planes the quantum Fisher information scales linearly with N. Hence, differently from Fock states, cat states permit azimuthal sensing without Ramsey sequence. Particular cat states are the NOON and the GHZ states.

Cat states are extremely difficult to generate and to preserve from decoherence. They cannot be generated from Glauber states via unitary transforms. *Spin-squeezed states* are much more robust and better suited for Heisenberg-limited sensing.

Fig. 46.7 illustrates that the uncertainty distribution depends on the type of collective states. This is obviously interesting for metrological applications based on interferometric phase measurements, as discussed in Sec. 41.2.2. A *metrological gain* in the signal-to-noise ratio beyond the *standard quantum limit* depends on the type of entanglement generated.

47.4.4.5 Quantum Fisher information for mixed states

The advantage of the symmetric logarithmic derivative formulation is, that it can be generalized to mixed states. We express the density matrix expanded in an eigenstate basis as [923],

$$\hat{\rho}_\theta = \sum_k \lambda_k |k\rangle\langle k| \qquad \text{with} \qquad \mathbb{I} = \sum_k |k\rangle\langle k| \ . \tag{47.190}$$

In this case, a comparison between the expressions (47.174) and (47.175) yields,

$$\begin{aligned} &\hat{L}_\theta \sum_k \lambda_k |k\rangle\langle k| + \sum_k \lambda_k |k\rangle\langle k|\hat{L}_\theta = 2\imath \sum_k \lambda_k |k\rangle\langle k|\hat{G}_\theta - 2\imath\hat{G}_\theta \sum_k \lambda_k |k\rangle\langle k| \\ \Leftrightarrow \quad &\sum_{k,m}(\lambda_k+\lambda_m)|k\rangle\langle k|\hat{L}_\theta|m\rangle\langle m| = 2\imath\sum_{k,m}(\lambda_k-\lambda_m)|k\rangle\langle k|\hat{G}_\theta|m\rangle\langle m| \\ \Leftrightarrow \quad &(\lambda_k+\lambda_m)\langle k|\hat{L}_\theta|m\rangle = 2\imath(\lambda_k-\lambda_m)\langle k|\hat{G}_\theta|m\rangle \qquad \forall k,m \ . \end{aligned} \tag{47.191}$$

Hence,

$$\boxed{\hat{L}_\theta = 2\imath \sum_{k,m} \frac{\lambda_k - \lambda_m}{\lambda_k + \lambda_m} |k\rangle\langle k|\hat{G}_\theta|m\rangle\langle m| \ .} \tag{47.192}$$

Note that the pure state symmetric logarithmic derivative [Eq. (47.187) with $\hat{\rho}_\theta = |\psi\rangle\langle\psi| = |k\rangle\langle k|$] is recovered by setting $\lambda_k = \delta_{k,\psi}$ and $\lambda_m = \delta_{m,\psi}$.

The quantum Fisher information is now,

$$F_{\rm q}(\theta) = {\rm Tr}\,(\hat{\rho}_\theta \hat{L}_\theta^2) = \sum_n \langle n|\hat{\rho}_\theta \hat{L}_\theta^2|n\rangle \ . \tag{47.193}$$

Inserting the expressions (47.190) and (47.192), we get,

$$\begin{aligned} F_{\rm q}(\theta) &= \sum_n \langle n| \left(\sum_{n'} \lambda_{n'}|n'\rangle\langle n'|\right) \left(2\imath \sum_{k,m} \frac{\lambda_k - \lambda_m}{\lambda_k + \lambda_m}|k\rangle\langle k|\hat{G}_\theta|m\rangle\langle m|\right) \times \\ &\qquad \times \left(2\imath \sum_{k',m'} \frac{\lambda_{k'} - \lambda_{m'}}{\lambda_{k'} + \lambda_{m'}}|k'\rangle\langle k'|\hat{G}_\theta|m'\rangle\langle m'|\right)|n\rangle \\ &= 4\sum_{k,m} \frac{(\lambda_k - \lambda_m)^2}{\lambda_k + \lambda_m} \frac{\lambda_k}{\lambda_m + \lambda_k} |\langle k|\hat{G}_\theta|m\rangle|^2 \ . \end{aligned} \tag{47.194}$$

Hence,

$$\boxed{F_{\rm q}(\theta) = 2\sum_{k,m} \frac{(\lambda_k - \lambda_m)^2}{\lambda_k + \lambda_m} |\langle k|\hat{G}_\theta|m\rangle|^2 \ .} \tag{47.195}$$

An alternative expression for the quantum Fisher information can be derived as follows,

$$F_{\rm q}(\theta) = 2\sum_{k,m} \frac{(\lambda_k - \lambda_m)^2}{\lambda_k + \lambda_m} |\langle k|\hat{G}_\theta|m\rangle|^2 = 2\sum_{k,m} \frac{(\lambda_k + \lambda_m)^2 - 4\lambda_k\lambda_m}{\lambda_k + \lambda_m} |\langle k|\hat{G}_\theta|m\rangle|^2 \tag{47.196}$$

$$\begin{aligned} &= 4\sum_{k,m} \lambda_k |\langle k|\hat{G}_\theta|m\rangle|^2 - \sum_{k,m} \frac{8\lambda_k\lambda_m}{\lambda_k + \lambda_m} |\langle k|\hat{G}_\theta|m\rangle|^2 \\ &= 4\sum_{k,m} \lambda_k \langle k|\hat{G}_\theta|m\rangle\langle m|\hat{G}_\theta|k\rangle - \sum_{k,m} \frac{8\lambda_k\lambda_m}{\lambda_k + \lambda_m} |\langle k|\hat{G}_\theta|m\rangle|^2 \\ &= 4{\rm Tr}\,\hat{\rho}\hat{G}_\theta^2 - \sum_{k,m} \frac{8\lambda_k\lambda_m}{\lambda_k + \lambda_m} |\langle k|\hat{G}_\theta|m\rangle|^2 \ . \end{aligned}$$

In Exc. 47.4.6.6(e) we calculate the quantum Fisher information for a thermal state of light.

The Cramér-Rao bound defines the achievable largest precision of parameter estimation, however, it is not clear what has to be measured to reach this precision bound. An optimal measurement can be carried out if we measure in the eigenbasis of the $\hat{L}_\theta$ [125, 126]. This operator is defined such that it can be used to describe the quantum dynamics of the system with the equation [923].

47.4.4.6 Quantum Fisher information for multi-parameter metrology

For a mixed state

$$\hat{\rho}_\theta = \sum_i \lambda_i |\lambda_i\rangle\langle\lambda_i| \tag{47.197}$$

the quantum Fisher information becomes [583, 584],

$$F_{\mathrm{q}}^{(\mu\nu)}(\vec{\theta}) = \sum_{\substack{i,j \\ \lambda_i \neq -\lambda_j}} \frac{\mathfrak{Re}\left(\langle\lambda_i|\partial_\mu\hat{\rho}_\theta|\lambda_j\rangle\langle\lambda_j|\partial_\nu\hat{\rho}_\theta|\lambda_i\rangle\right)}{\lambda_i+\lambda_j} \tag{47.198}$$

$$= \sum_{\substack{i \\ \lambda_i \neq 0}} \frac{(\partial_\mu\lambda_i)(\partial_\nu\lambda_i)}{\lambda_i} + 4\lambda_i\mathfrak{Re}\,\langle\partial_\mu|\lambda_i|\partial_\nu\lambda_i\rangle - \sum_{\substack{i,j \\ \lambda_i \neq -\lambda_j}} \frac{8\lambda_i\lambda_j}{\lambda_i+\lambda_j}\mathfrak{Re}\left(\langle\partial_\mu\lambda_i|\lambda_j\rangle\langle\lambda_j|\partial_\nu\lambda_i\rangle\right) .$$

Using the symmetric logarithmic derivative (47.174) the Fisher information can also be written [772],

$$F_{\mathrm{q}}^{(\mu\nu)}(\vec{\theta}) = \sum_{\substack{i,j \\ \lambda_i \neq -\lambda_j}} \frac{2\mathfrak{Re}\left(\langle\lambda_i|[\hat{G}_\mu,\hat{\rho}_\theta]|\lambda_j\rangle\langle\lambda_j|[\hat{\rho}_\theta,\hat{G}_\nu]|\lambda_i\rangle\right)}{\lambda_i+\lambda_j} . \tag{47.199}$$

Example 357 (*Fisher information on the Bloch sphere*): As an example we may consider the Fisher information matrix whose components are calculated with the collective spin components $\hat{S}_{x,y,z}$ as generators,

$$F_{\mathrm{q}}^{(\mu\nu)}(\vec{\theta}) = \sum_{\substack{i,j \\ \lambda_i \neq -\lambda_j}} \frac{2\mathfrak{Re}\left(\langle\lambda_i|[\hat{S}_\mu,\hat{\rho}_\theta]|\lambda_j\rangle\langle\lambda_j|[\hat{\rho}_\theta,\hat{S}_\nu]|\lambda_i\rangle\right)}{\lambda_i+\lambda_j} . \tag{47.200}$$

Its eigenvalues are nothing else than the quantum Fisher informations with respect to particular generators already calculated in Tab. 47.3. Setting up the complete matrix facilitates the identification of optimal squeezing protocols [772].

47.4.5 Quantum Fisher information for coupled systems

We have seen that it is quite straightforward to calculate the quantum Fisher information for single mode systems in pure states. In quantum systems where different degrees of freedom are coupled a measurement is generally performed only one of them. As shown in the context of the Jaynes-Cummings model in Sec. 40.2.3, the partial measurement leaves the system in a mixed states, which makes the calculation of the quantum Fisher information more involved. In the following, we will calculate for the Jaynes-Cummings model the evolution of the quantum Fisher information during quantum collapse and revival and for the Dicke model the dependence of the quantum Fisher information on the atom-field coupling strength [957].

47.4.5.1 Quantum Fisher information in the Jaynes-Cummings model

In the Jaynes-Cummings model the quantum Fisher information can be calculated analytically. As we are interested not only in quantum superpositions of the atomic

excitation state, but also in quantum correlations (such as squeezing) in the light mode, we need to expand the field mode in a Fock basis,

$$\hat{\rho} = \sum_{n,j} |n\rangle\langle n| \otimes |j\rangle\langle j| \ , \tag{47.201}$$

which considerably increases the dimension of the Hilbert space. The time dependence of the system is obtained from the propagator (40.30), leading to (40.46),

$$|\psi(t)\rangle = e^{-\imath \hat{H}_n t}|\psi(0)\rangle = \sum_n (c_{1,n}|1,n\rangle + c_{2,n-1}|2,n-1\rangle) \ . \tag{47.202}$$

Starting from the total density matrix $\hat{\rho}(t) = |\psi\rangle\langle\psi|$, tracing over the field mode as done in (40.55) allows us to calculate the Fisher information for the atomic degrees of freedom,

$$\hat{\rho}_{\rm at} = {\rm Tr}_{\rm li}\, \hat{\rho} = \sum_{j=1,2} \langle j|\hat{\rho}|j\rangle = \sum_n (c_{1,n}|1\rangle + c_{2,n}|2\rangle)(c^*_{1,n}\langle 1| + c^*_{2,n}\langle 2|) \tag{47.203}$$

$$F_{\rm q,at}(\theta) = 4{\rm Tr}\, \hat{\rho}_{\rm at}(\hat{G}^2_{\theta,{\rm at}} - \hat{G}_{\theta,{\rm at}}\hat{\rho}_{\rm at}\hat{G}_{\theta,{\rm at}}) \ ,$$

where

$$\hat{G}_{y,{\rm at}} = \tfrac{1}{2}\hat{\sigma}_y \qquad \text{and} \qquad \hat{G}_{z,{\rm at}} = \tfrac{1}{2}\hat{\sigma}_z \ . \tag{47.204}$$

are the relevant generators (47.181) and (47.184) for the light field. Tracing over the atomic degrees of freedom as done in (40.54) allows us to calculate the Fisher information for the field mode,

$$\hat{\rho}_{\rm li} = {\rm Tr}_{\rm at}\, \hat{\rho} = \sum_{n=0}^{\infty} \langle n|\hat{\rho}|n\rangle = \sum_{n,m} (c^*_{1,m}c_{1,n}|n\rangle\langle m| + c^*_{2,m-1}c_{2,n-1}|n-1\rangle\langle m-1|) \tag{47.205}$$

$$F_{q,{\rm li}}(\theta) = 4{\rm Tr}\, \hat{\rho}_{\rm li}(\hat{G}^2_{\theta,{\rm li}} - \hat{G}_{\theta,{\rm li}}\hat{\rho}_{\rm li}\hat{G}_{\theta,{\rm li}}) \ ,$$

where

$$\hat{G}_{\varphi,{\rm li}} = -\hat{a}^\dagger\hat{a} \qquad \text{and} \qquad \hat{G}_{r,{\rm li}} = \imath(e^{\imath\varphi}\hat{a}^\dagger - e^{-\imath\varphi}\hat{a}) \tag{47.206}$$

are the relevant generators (47.188) for the atom.

The time evolution of the quantum Fisher information, calculated in Exc. 47.4.6.9 and plotted in Fig. 47.29, has a simple interpretation. The atomic Fisher informations stay below the classical limit of 1, because there is only a single atom. The nutational information $F_{\rm q,at}(y)$ depends on the orientation of the atomic coherence while it rotates in the equatorial plane, and it vanishes during the quantum collapse period. The precessional information $F_{\rm q,at}(z)$ drops to 0 only during the Ramsey pulses at the beginning and end of the evolution. In contrast, the light field Fisher informations can exceed the classical limit of 1. The azimuthal information $F_{\rm q,at}(\varphi)$ is largest during quantum collapse, when the coherence is stored in the light fields, which is due to the fact that the light field is then in a Schrödinger cat state. The radial information $F_{\rm q,at}(r)$ oscillates with the relative phase shift between the two coherent states composing the Schrödinger cat.

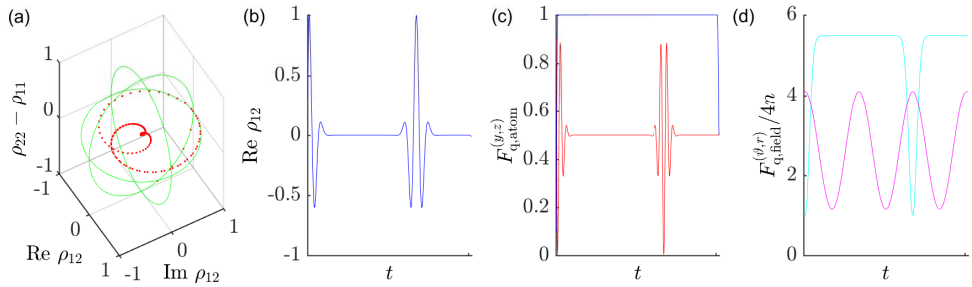

Figure 47.29: (code) (a) Evolution of the atomic state represented on the Bloch sphere. Evolutions of (b) the atomic coherence, (c) the quantum Fisher informations for the atom (red) $F_{\mathrm{q,at}}(y)$ and (blue) $F_{\mathrm{q,at}}(z)$, and (d) for the field mode (cyan) $F_{\mathrm{q,at}}(\varphi)$ and (magenta) $F_{\mathrm{q,at}}(r)$.

47.4.5.2 Scaling with particle number

The Jaynes-Cummings model discussed above considers an arbitrary number of photons, but only a single atom, which limited the Fisher information to below 1.

We found that in the 'classical' cases the quantum Fisher information is bounded by the numbers of (quasi-)particles, $F_{\mathrm{q},|\alpha\rangle} \leq 4n$, respectively, $F_{\mathrm{q},|\vartheta,\varphi\rangle^{\otimes N}} \leq N$. For other 'non-classical' states, however, this limitation can be surpassed. Quantum advantage is reached when $N^2 > F_{\mathrm{q}}/N > 1$, that is, the Cramér-Rao bound scales with $1/N$ called Heisenberg limit rather than $1/\sqrt{N}$ called shot-noise limit.

The quantum Fisher information is always larger than the classical Fisher information,

$$F_{\mathrm{c}}(\theta) \leq F_{\mathrm{q}}(\theta) \ . \tag{47.207}$$

If $F_{\mathrm{c}}(\theta) = F_{\mathrm{q}}(\theta)$ locally optimal at θ,

$$\mathrm{Var}[\hat{\theta}] \geq \frac{1}{NF_{\mathrm{c}}(\theta)} \geq \frac{1}{NF_{\mathrm{q}}(\theta)} \ . \tag{47.208}$$

Let us now turn our attention to the case of several atoms.

47.4.5.3 Quantum Fisher information in the Dicke model

The calculation of the quantum Fisher information for a single mode light field coupling to *several atoms* is even more complicated, as the dimension of the Hilbert space increases with the number of atoms. Nevertheless, it remains feasible within the Dicke model [957] treating the atomic cloud as a collective spin state, while the field mode is still expanded in a Fock basis,

$$\hat{\rho} = \sum_{n,M} |n\rangle\langle n| \otimes |S,M\rangle\langle S,M| \ , \tag{47.209}$$

with the Hamiltonian,

$$\hat{H} = \Delta_{\mathrm{c}}\hat{a}^\dagger\hat{a} + \Delta_{\mathrm{a}}\hat{S}_z + (\hat{a}^\dagger + \hat{a})(\hat{S}_+ + \hat{S}_-) \ . \tag{47.210}$$

Apart from the different basis used to describe the atomic state, the procedure is the same as for the Jaynes-Cummings model. Again, the system is described by a density operator $\hat{\rho} = \hat{\rho}_{\rm at} \otimes \hat{\rho}_{\rm li}$, such that the density operators of the subsystems $\hat{\rho}_{\rm at} = {\rm Tr}_{\rm li}\hat{\rho}$ and $\hat{\rho}_{\rm li} = {\rm Tr}_{\rm at}\hat{\rho}$ are necessarily mixed,

$$\hat{\rho}_{\rm li} = {\rm Tr}_{\rm at}\,\hat{\rho} = \sum_{M=-S}^{S} \langle S, M|\hat{\rho}|S, M\rangle \quad , \quad \hat{\rho}_{\rm at} = {\rm Tr}_{\rm li}\,\hat{\rho} = \sum_{n=0}^{\infty} \langle n|\hat{\rho}|n\rangle \ , \tag{47.211}$$

and the relevant generators for the atomic cloud must now be formulated with the collective spin operators,

$$\hat{G}_{y,{\rm at}} = \hat{S}_y \quad \text{and} \quad \hat{G}_{z,{\rm at}} = \hat{S}_z \ . \tag{47.212}$$

The Fisher informations are again calculated from the formulas (47.204) and (47.205), respectively.

Here, we are particularly interested in analyzing beyond mean field solutions in steady state [957].

47.4.5.4 Saturability of the quantum Cramér-Rao bound in multi-parameter systems

The saturability of the quantum Cramér-Rao bound in collective measurements, i.e. joint measurements over many copies of the quantum state, can be measured via strong commutativity $[L_i, L_j] = 0$ or weak commutativity $\langle [L_i, L_j]\rangle = 0$ [696].

47.4.6 Exercises

47.4.6.1 Ex: Red-shift of sun light and on Earth

a. Calculate the gravitational redshift of light escaping from the sun.
b. Calculate the blue-shift of navigational signals from GPS satellites orbiting at 20000 km altitude with respect to the surface of Earth. Compare it to the Doppler shift resulting from their orbital velocity.
c. In astronomy, the magnitude of a gravitational redshift is often expressed as the velocity that would create an equivalent shift through the relativistic Doppler effect. Calculate the sunlight redshift and the GPS signal blue-shift in terms of this velocity.

47.4.6.2 Ex: Scaling with the number of measurements

Imagine you have a coin which you suspect to be manipulated so that, when tossed, it doesn't provide a 50% chance to show the face side. Assuming that all flip trials are independent, how many trials are necessary to prove that the probability for 'face' is 60%? How many for 51%? What would be necessary to obtain a more favorable scaling with the number of trials?

47.4.6.3 Ex: Fisher information and Cramér-Rao bound for a Gaussian distribution

Calculate the Fisher information and Cramér-Rao bound for a Gaussian distribution in a Ramsey experiment.

47.4.6.4 Ex: Superresolution for two incoherent light sources

In this exercise we review the classical and quantum theory of *superresolution* for incoherent point sources of light [929, 928]. The goal is to determine from the intensity distribution in the image plane $\Lambda(x)$ the unknown positions X_s with $s = 1, 2$ of the point sources in the object plane.
a. Express $\Lambda(x)$ assuming Gaussian or pinhole point-spread functions $\langle x|\psi_s\rangle = \langle x - X_s|\psi\rangle$.
b. Generalize the classical Fisher information for continuous variables and multi-parameter systems and express it for the intensity distribution $\Lambda(x)$ choosing the parameters,

$$\theta_\mu = \tfrac{1}{2}(X_1 + X_2) \qquad \text{and} \qquad \theta_\nu = X_2 - X_1 \ . \tag{47.213}$$

47.4.6.5 Ex: Quantum Fisher information for separable states

Show that for a pure separable N-particle state depending on a single parameter the quantum Fisher information (47.165) scales as $F_{\rm q} \propto N$.

47.4.6.6 Ex: Fisher information for common light states

a. Using the expression (47.173) calculate the quantum Fisher information for a Glauber state.
b. Now, use the expression (47.177) to calculate the quantum Fisher information for a Glauber state,
c. a Fock state,
d. a squeezed state, and
e. a cat state.
f. Using the expression (47.195) calculate the quantum Fisher information for a thermal state of light with respect to amplitude and phase [957].

47.4.6.7 Ex: Fisher information for common collective spin states

a. Using the expression (47.173) calculate the quantum Fisher information for coherent spin states with respect to variations of the polar and azimuthal angles ϑ and φ.
b. Calculate the logarithmic derivatives for a coherent spin state with respect to variations of the polar and azimuthal angles and use the expression (47.188) to calculate the quantum Fisher information.
c. Calculate the quantum Fisher information for the collective spin states $|\text{Fock}\rangle$ and $|\text{W}\rangle$, as well as for
d. the states $|\text{cat}\rangle$, $|\text{GHZ}\rangle$, and $|\text{NOON}\rangle$, and finally for
e. a spin-squeezed state $|\text{squeezed}\rangle$.

47.4.6.8 Ex: Symmetric logarithmic derivative in a Ramsey experiment

a. For a single two-level atom initially in its ground state $\hat{\rho}_0 = |0\rangle\langle 0|$ determine the state $\hat{\rho}_1$ reached by a rotation by 90° about the y-axis [581, 923].
b. Show that for this state holds, $\imath(\hat{\rho}_1\hat{\sigma}_z - \hat{\sigma}_z\hat{\rho}_1) = \hat{\rho}_1\hat{\sigma}_y + \hat{\sigma}_y\hat{\rho}_1$.
c. Generalize to collective spin states for many atoms.
d. Expand $\hat{\rho}_1$ for small precessions.
e. Determine the logarithmic derivative and the quantum Fisher information for the precession.

47.4.6.9 Ex: Quantum Fisher information in the Jaynes-Cummings model

Calculate for the Jaynes-Cummings model the quantum Fisher information for the atomic and light degrees of freedom with respect to the relevant generators.

47.4.6.10 Ex: Transmission estimation

A common task in quantum sensing is the estimation of the intensity transmission of light through a lossy device (absorber or beam splitter) [981]. Here, we estimate the quantum Cramér-Rao bound for such a measurement for different (quantum) states of light.

Chapter 48

Atomic motion in optical cavities

In the preceding chapter we concentrated on the dynamics of the field modes of laser-pumped cavities. We devoted a particular attention to the role of scatterers, e.g. atoms, located in the mode volume and coupling the dynamics of counterpropagating modes. We assumed the atoms to be fixed in space, or at most subject to an external force constraining their motion. We have also seen that the coupling of counterpropagating modes critically depends on the position of the atom. Now, the cavity fields are expected to exert light forces on the atoms eventually leading to their displacement. As we will see in the following, this fact can have enormous impact on the coupling dynamics and even induce macroscopic instabilities.

We devote Sec. 48.1 to the derivation of the complete equations of motion for the case of a single atom, allowing for all degrees of freedom to be treated as quantized: the atomic excitation, the motion of its center of mass, and the radiation field in the cavity. We will provide a simple recipe for finding the suitable equations of motion depending on which degree of freedom s to be treated as quantized and which dissipation process to be taken into account. We will also show how and under which circumstances the atomic excitation may be adiabatically eliminated.

In Sec. 48.2 we generalize the equations of motion of many atoms, but treating all degrees of freedom as classical. This leads us to the paradigmatic Collective Atomic Recoil Laser (CARL), a self-organization phenomenon whose relationship to other such instabilities will be discussed in Sec. 48.3.

Finally, in Secs. 48.4 and 48.5 we will treat the light field, respectively, the atomic motion quantum mechanically and show in which sense the obtained dynamics are different.

48.1 Cavity interacting with a single atom

Here, we consider atoms interacting with the modes of an optical cavity pumped by lasers. As we saw in the previous chapter, the density of the modes in a cavity is concentrated around the optical axis, such that a scatterer located within the mode emits preferentially within the cavity, where the light is recycled. Therefore, we can in many situations treat the system as one-dimensional.

In free space, as discussed in Chp. 43, the force of light has two components: the radiation pressure, which scatters photons isotropically into space, and the dipole

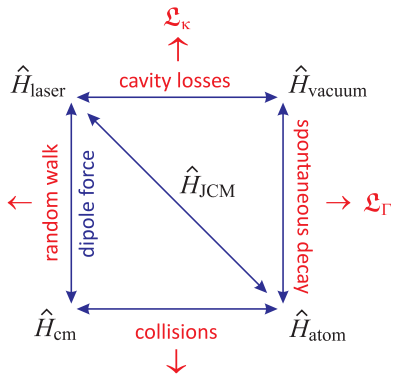

Figure 48.1: Hamiltonian in quantum optics.

force, which can be interpreted in terms of a redistribution of photons between light modes. In cavities, where the isotropic scattering is much reduced, radiative pressure can often be neglected. In contrast, if light is tuned away from atomic resonances, the atom will feel a dipole force originating from the backscattering of photons between counterpropagating modes.

48.1.1 Linear and ring cavities

We must distinguish two types of cavities with very different behaviors: The linear cavity or (*Fabry-Pérot etalon*), where counterpropagating modes form a single mode, and the ring cavity, where counterpropagating modes have independent photon budgets.

For a *linear cavity*, boundary conditions imposed by the surfaces of the cavity mirrors determine the possible spatial mode functions, which are necessarily standing waves. The amplitudes of the electric field are in second quantization (37.8),

$$\hat{\mathcal{E}}(z,t) = \hat{\mathcal{E}}^+(z,t)e^{-\imath\omega t} + \hat{\mathcal{E}}^-(z,t)e^{\imath\omega t} \qquad (48.1)$$
$$\text{with} \qquad \hat{\mathcal{E}}^+(z,t) = \hat{\mathcal{E}}_1\hat{a}(t)e^{\imath kz} = (\hat{\mathcal{E}}^-(z,t))^\dagger \ .$$

with $[\hat{a},\hat{a}^\dagger] = 1$. With this we obtain, for a single atom coupled to the mode of the cavity pumped by a laser, within the dipolar approximation and the RWA [1], the following relevant contributions to the Hamiltonian ($\hbar = 1$),

$$\begin{aligned}
\hat{H}_{\rm atom} &= -\Delta_a\hat{\sigma}^+\hat{\sigma}^- + \tfrac{\hat{p}^2}{2m} \qquad (48.2)\\
\hat{H}_{\rm cav} &= -\Delta_c\hat{a}^\dagger\hat{a}\\
\hat{H}_{\rm atom:cav} &= g\hat{a}^\dagger\hat{\sigma}^- e^{-\imath k\hat{z}} + h.c.\\
\hat{H}_{\rm laser:cav} &= \imath\eta\hat{a}^\dagger + h.c. \ ,
\end{aligned}$$

neglecting the dynamics of the pump field, which is supposed to be classical, $\eta = \delta_{fsr}\langle\hat{a}_{in}^\dagger\rangle$. Note that the propagator $e^{-\imath\hat{H}_{\rm laser:cav}t}$ corresponds to a coherent state

[1] For the transformation into the rotating frame see the derivation of Sec. 39.3.1.

displacement operator. Δ_a is the detuning between the light and the atomic resonance, Δ_c between the light and cavity resonance and g is the light-atom coupling force, also called the single-photon Rabi frequency. Neglecting the kinetic energy term $\hat{p}^2/2m$, the photonic recoil $e^{-\imath kv\hat{z}}$, and the pumping η we recover the *Jaynes-Cummings model*. Do the Excs. 48.1.7.1 and 48.1.7.2.

For a *ring cavity*, we must distinguish the counterpropagating modes $\hat{a}_\pm$,

$$\hat{\mathcal{E}}^+(z,t) = \hat{\mathcal{E}}_1 \hat{a}_+(t) e^{\imath kz} + \hat{\mathcal{E}}_1 \hat{a}_-(t) e^{-\imath kz} = (\hat{\mathcal{E}}^-(z,t))^\dagger \ . \tag{48.3}$$

such that the total Hamiltonian $\hat{H}$ consists of the following parts [2],

$$\boxed{\begin{aligned} \hat{H}_{\text{atom}} &= \hat{H}_{\text{electron}} + \hat{H}_{\text{motion}} = -\Delta_a \hat{\sigma}^+\hat{\sigma}^- + \frac{\hat{p}^2}{2m} \\ \hat{H}_{\text{cav}} &= -\Delta_c \hat{a}_+^\dagger \hat{a}_+ - \Delta_c \hat{a}_-^\dagger \hat{a}_- \\ \hat{H}_{\text{atom:cav}} &= g\hat{a}_+^\dagger \hat{\sigma}^- e^{-\imath k\hat{z}} + h.c. + g\hat{a}_-^\dagger \hat{\sigma}^- e^{\imath k\hat{z}} + h.c. \\ \hat{H}_{\text{laser:cav}} &= -\imath\eta_+(\hat{a}_+ - \hat{a}_+^\dagger) - \imath\eta_-(\hat{a}_- - \hat{a}_-^\dagger) \end{aligned}} \ . \tag{48.4}$$

We identify the degrees of freedom of the system through the quantum observables appearing in the Hamiltonian: the counterpropagating modes of light with the amplitudes ($\hat{a}_\pm$), the internal degrees of freedom ($\hat{\sigma}^z, \hat{\sigma}^\pm$), and the spatial coordinates of the atom ($\hat{z}, \hat{p}$).

In contrast to linear cavities, ring cavities have the following particularities: 1. The phase of the standing wave is free to move; 2. the counterpropagating modes of the cavity have independent photon budgets, each backscattering event conserves momentum; 3. the backscattering acts on the phase of the standing wave. Atoms can be trapped by the dipole force within the cavity mode volume. The dipole force corresponds to a backscattering of photons between modes.

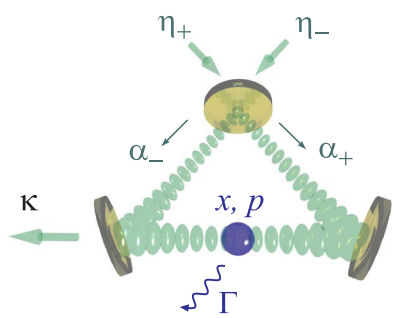

Figure 48.2: Scheme of an atom interacting with a ring cavity showing the relevant degrees of freedom ($\hat{x}$, $\hat{p}$, $\hat{a}_\pm$) and the possible decay processes (κ, Γ) for the derivation of the field equations.

[2]Throughout this chapter we will sometimes emphasize the motional degree of freedom in green color, photonic states in blue, electronic excitation states in pink.

48.1.2 Eliminating spontaneous emission and cavity decay

In fact, there are more degrees of freedom involved in the dynamics of atoms moving in a laser-pumped ring cavity, because of the atoms may scatter light into directions other than the cavity modes by spontaneous emission, and the cavity modes may decay by transmission through the mirrors. Therefore, we need to treat the respective vacuum field modes receiving the photons, $\hat{a}_{\mathbf{k}}$ and $\hat{a}_\omega$, quantum mechanically and include the respective Hamiltonians,

$$\begin{aligned}\hat{H}_{\text{atom:vacuum}} &= \sum_{\mathbf{k}} g_{\text{atom:vacuum}} \hat{a}^\dagger_{\mathbf{k}} \hat{\sigma}^- e^{-\imath \mathbf{k}\cdot\hat{\mathbf{r}}} + h.c. \\ \hat{H}_{\text{cav:bath}} &= \sum_{\omega} g_{\text{cav:bath}} \hat{a}^\dagger_\omega \hat{a}_+ + g_{\text{cav:bath}} \hat{a}^\dagger_\omega \hat{a}_- + h.c.\ ,\end{aligned} \tag{48.5}$$

in the description of the coupled dynamics. Here, $g_{\text{atom:vacuum}}$ denotes the vacuum Rabi frequency, that is, the coupling strength between the atomic dipole and the electromagnetic vacuum into which spontaneously emitted photons may escape. On the other hand, $g_{\text{cav:bath}}$ denotes the coupling strength between the cavity mode and the spectrum of electromagnetic modes into which cavity photons can escape and which we will from now on call *heat bath* to facilitate its semantic distinction from the spontaneous vacuum. The total density operator, the Hamiltonian and the equation of motion are, consequently,

$$\begin{aligned}\bar{\rho} &= \hat{\rho}_{\text{atom}} \otimes \hat{\rho}_{\text{electron}} \otimes \hat{\rho}_{\text{cav}} \otimes \hat{\rho}_{\text{vacuum}} \otimes \hat{\rho}_{\text{bath}} \\ \bar{H} &= \hat{H}_{\text{motion}} + \hat{H}_{\text{electron}} + \hat{H}_{\text{cav}} + \hat{H}_{\text{atom:cav}} + \hat{H}_{\text{laser:cav}} + \hat{H}_{\text{atom:vacuum}} + \hat{H}_{\text{cav:bath}} \\ \dot{\bar{\rho}} &= -\imath[\bar{H}, \bar{\rho}]\ .\end{aligned} \tag{48.6}$$

With the inclusion of the vacuum field modes $\hat{a}_\omega$ and $\hat{a}_{\mathbf{k}}$ the number of degrees of freedom to be treated literally explodes, and we have to find a way to eliminate them from the equation of motion. We do this by partially tracing the density operator over the vacuum field modes using the Weisskopf-Wigner theory,

$$\tilde{\rho} \equiv \text{Tr}_{\text{vacuum}}\ \text{Tr}_{\text{bath}}\ \bar{\rho} = \hat{\rho}_{\text{atom}} \otimes \hat{\rho}_{\text{electron}} \otimes \hat{\rho}_{\text{cav}}\ . \tag{48.7}$$

This allows us to reduce the Hamiltonian $\hat{H} = \bar{H} - \hat{H}_{\text{atom:vacuum}} - \hat{H}_{\text{cav:bath}}$. The price to pay is, that the equation of motion for this receives dissipative terms: The Liouville equation turns into a *master equation* with the following form,

$$\boxed{\begin{aligned}\dot{\hat{\rho}} = -\imath[\hat{H}, \hat{\rho}] \quad &+ \quad \mathcal{L}_{\text{atom:vacuum}} + \mathcal{L}_{\text{cav:vacuum,+}} + \mathcal{L}_{\text{cav:vacuum,-}} \\ \mathcal{L}_{\text{atom:vacuum}}\hat{\rho}(t) \quad &= \quad -\gamma\{\hat{\sigma}^+\hat{\sigma}^-\hat{\rho}(t) - 2\hat{\sigma}^-\hat{\rho}(t)\hat{\sigma}^+ + \hat{\rho}(t)\hat{\sigma}^+\hat{\sigma}^-\} \\ \mathcal{L}_{\text{cav:bath},\pm}\hat{\rho}(t) \quad &= \quad -\kappa\{\hat{a}^\dagger_\pm\hat{a}_\pm\hat{\rho}(t) - 2\hat{a}_\pm\hat{\rho}(t)\hat{a}^\dagger_\pm + \hat{\rho}(t)\hat{a}^\dagger_\pm\hat{a}_\pm\}\end{aligned}} \ , \tag{48.8}$$

where $\hat{H}$ is the Hamiltonian from (48.4). We see that each degree of freedom has its own loss mechanism. κ for the finite transmission of the resonator mirrors [190, 340] [3], Γ for the spontaneous emission, and γ_{frc}, when we exert a frictional force on the atoms.

[3] Here, we only consider cavity decay into a zero temperature reservoir without quantum phase fluctuations.

48.1.2.1 The problem with spontaneous emission in cavities

The above treatment still is incomplete, if we regard $\hat{\rho}$ as the atomic Bloch vector. The reason is that we know what the dissipative Lindblad terms $\mathcal{L}_{\text{vacuum}}\tilde{\rho}$ generated by spontaneous emission look like for the atomic excitation $\hat{\rho}_{\text{atom}}$, but the Hamiltonian $\hat{H}_{\text{atom:vacuum}}$ also *contains the motional degree of freedom* $e^{-\imath \mathbf{k}\cdot\hat{\mathbf{r}}}$, which is intrinsically three-dimensional. That is, the dissipative terms also need to describe, how the motion diffuses in momentum space.

The inclusion of dissipative terms, however, is difficult, because unavoidable photonic recoil violates the supposed one-dimensionality of the atomic motion along the optical axis. Omnidirectional photonic recoil is also incompatible with the assumption that the momentum is quantized in multiples of $2\hbar k$ in the direction of the optical axis. And finally, if we consider degenerate matter waves, photonic recoil will eject atoms from a BEC. Even if, neglecting the emission process, we only consider absorption, we would need a quantization in multiples of $1\hbar k$ instead of $2\hbar k$. In the following, in order to keep the problem 1D, we will neglect momentum diffusion, i.e. we consider the simplified Hamiltonian $\tilde{H}$ and discard motional terms from the term $\mathcal{L}_{\text{vacuum}}\hat{\rho}$.

48.1.2.2 Quantum derivation of the CARL equations

To obtain the equations of motion we insert the Hamiltonian (48.4) into the equations for the field operators, for which the following commutation rules hold, $[\hat{a}_\pm, \hat{a}_\pm^\dagger] = 1$ and $[\hat{a}_\pm, \hat{a}_\mp^\dagger] = 0 = [\hat{a}_\pm, \hat{a}_\pm]$,

$$\begin{aligned}\dot{\hat{a}}_+ &= \imath[\hat{H}, \hat{a}_+] - \kappa\hat{a}_+ \\ &= -\imath\Delta_c[\hat{a}_+^\dagger\hat{a}_+, \hat{a}_+] + \imath g e^{-\imath k\hat{z}}\hat{\sigma}^-[\hat{a}_+^\dagger, \hat{a}_+] + \imath g e^{\imath k\hat{z}}\hat{\sigma}^+[\hat{a}_+, \hat{a}_+] + \eta_+[\hat{a}_+ - \hat{a}_+^\dagger, \hat{a}_+] - \kappa\hat{a}_+ \\ &= (-\kappa + \imath\Delta_c)\hat{a}_+ - \imath g\hat{\sigma}^- e^{-\imath kx} + \eta_+ \ ,\end{aligned} \tag{48.9}$$

and similarly for $\hat{a}_-$. For the Pauli deexcitation matrix, using the usual commutation rules for the *Pauli spin matrices* (23.154), that is $[\hat{\sigma}^+, \hat{\sigma}^-] = \hat{\sigma}_z$, $\hat{\sigma}_z\hat{\sigma}^\pm = \pm\hat{\sigma}^\pm$, and $[\hat{\sigma}^-, \hat{\sigma}^-] = 0$, we calculate,

$$\begin{aligned}\dot{\hat{\sigma}}^- &= \imath[\hat{H}, \hat{\sigma}^-] - \gamma\hat{\sigma}^- \\ &= -\imath\Delta_a[\hat{\sigma}^+\hat{\sigma}^-, \hat{\sigma}^-] + \imath g e^{\imath k\hat{z}}\hat{a}_+[\hat{\sigma}^+, \sigma^-] + \imath g e^{-\imath k\hat{z}}\hat{a}_-[\hat{\sigma}^+, \sigma^-] - \gamma\hat{\sigma}^- \\ &= (-\gamma + \imath\Delta_a)\hat{\sigma}^- + \imath g e^{\imath k\hat{z}}\hat{a}_+\hat{\sigma}_z + \imath g e^{-\imath k\hat{z}}\hat{a}_-\hat{\sigma}_z \ .\end{aligned} \tag{48.10}$$

For the Pauli inversion matrix, using the following commutation rules, $[\hat{\sigma}_z, \hat{\sigma}^+\hat{\sigma}^+] = 0$ and $[\hat{\sigma}_z, \hat{\sigma}^\pm] = \pm 2\hat{\sigma}^\pm$, we calculate,

$$\begin{aligned}\dot{\hat{\sigma}}_z &= \imath[\hat{H}, \hat{\sigma}_z] - 2\gamma - 2\gamma\hat{\sigma}_z \\ &= \imath g e^{-\imath k\hat{z}}\hat{a}_+^\dagger[\hat{\sigma}^-, \hat{\sigma}_z] + \imath g e^{\imath k\hat{z}}\hat{a}_-^\dagger[\hat{\sigma}^-, \hat{\sigma}_z] + \imath g e^{\imath k\hat{z}}\hat{a}_+[\hat{\sigma}^+, \hat{\sigma}_z] + \imath g e^{-\imath k\hat{z}}\hat{a}_-[\hat{\sigma}^+, \hat{\sigma}_z] - 2\gamma\hat{\sigma}_z \\ &= -2\gamma - 2\gamma\hat{\sigma}_z + 2\imath g e^{-\imath k\hat{z}}\hat{a}_+^\dagger\hat{\sigma}^- + 2\imath g e^{\imath k\hat{z}}\hat{a}_-^\dagger\hat{\sigma}^- - 2\imath g e^{\imath k\hat{z}}\hat{a}_+\hat{\sigma}^+ - 2\imath g e^{-\imath k\hat{z}}\hat{a}_-\hat{\sigma}^+ \ .\end{aligned} \tag{48.11}$$

Finally, we need to derive the equations governing the motion of atoms. For the position we obtain,

$$\dot{\hat{z}} = \imath[\hat{H}, \hat{z}] = \imath[\tfrac{\hat{p}^2}{2m}, \hat{z}] = \tfrac{1}{m}\hat{p} \ . \tag{48.12}$$

In order to calculate the momentum, we need to do a small auxiliary calculation. With the commutator $[\hat{z},\hat{p}] = \imath$ we derive,

$$[\hat{z}^n,\hat{p}] = \imath\frac{\delta\hat{z}^n}{\delta\hat{z}} = \imath n\hat{z}^{n-1} \tag{48.13}$$
$$[e^{\imath k\hat{z}},\hat{p}] = \sum_{n=0}^{\infty}\frac{(\imath k)^n}{n!}[\hat{z}^n,\hat{p}] = -k\sum_{n=0}^{\infty}\frac{(\imath k)^{n-1}}{(n-1)!}\hat{z}^{n-1} = -ke^{\imath k\hat{z}} \ ,$$

and with this result,

$$\begin{aligned}\dot{\hat{p}} &= \imath[\hat{H},\hat{p}] \\ &= \imath g\hat{a}_+^\dagger\hat{\sigma}^-[e^{-\imath k\hat{z}},\hat{p}] + c.c. + \imath g\hat{a}_-^\dagger\hat{\sigma}^-[e^{\imath k\hat{z}},\hat{p}] + c.c. \\ &= -\imath gk\hat{a}_+^\dagger\hat{\sigma}^-e^{-\imath k\hat{z}} + c.c. + \imath gk\hat{a}_-^\dagger\hat{\sigma}^-e^{\imath k\hat{z}} + c.c. \ .\end{aligned} \tag{48.14}$$

The *quantum Langevin equations* [190] describing the dynamics of the internal and external degrees of freedom of the atom and the field are coupled,

$$\boxed{\begin{aligned}\dot{\hat{a}}_\pm &= (-\kappa + \imath\Delta_c)\hat{a}_\pm - \imath g\hat{\sigma}^-e^{\mp\imath k\hat{z}} + \eta_\pm \\ \dot{\hat{\sigma}}^- &= (-\gamma + \imath\Delta_a)\hat{\sigma}^- + \imath g(e^{\imath k\hat{z}}\hat{a}_+ + e^{-\imath kz}\hat{a}_-)\hat{\sigma}_z \\ \dot{\hat{\sigma}}_z &= -2\gamma\hat{\sigma}_z + 2\imath g(e^{-\imath k\hat{z}}\hat{a}_+^\dagger + e^{\imath k\hat{z}}\hat{a}_-^\dagger)\hat{\sigma}^- - 2\imath g(e^{\imath k\hat{z}}\hat{a}_+ + e^{-\imath k\hat{z}}\hat{a}_-)\hat{\sigma}^+ \\ \dot{\hat{z}} &= \hat{p}/m \\ \dot{\hat{p}} &= \imath g\hbar k\hat{\sigma}^-(\hat{a}_+^\dagger e^{-\imath k\hat{z}} - \hat{a}_-^\dagger e^{\imath k\hat{z}}) + c.c.\end{aligned}} \ . \tag{48.15}$$

We may also verify,

$$\begin{aligned}\dot{\hat{n}}_+ &= \imath[\hat{H},\hat{n}_+] \\ &= \imath[-\Delta_c\hat{a}_+^\dagger\hat{a}_+ + g\hat{a}_+^\dagger\hat{\sigma}^-e^{-\imath k\hat{z}} + g\hat{a}_+\hat{\sigma}^+e^{\imath k\hat{z}} - \imath\eta_+(\hat{a}_+ - \hat{a}_+^\dagger),\hat{a}_+^\dagger\hat{a}_+] \\ &= (\eta_+ - \imath ge^{-\imath k\hat{z}}\hat{\sigma}^-)\hat{a}_+^\dagger + (\eta_+ + \imath g\hat{\sigma}^+e^{\imath k\hat{z}})\hat{a}_+ \ ,\end{aligned} \tag{48.16}$$

and hence conservation of momentum,

$$[\hat{H},\hbar k(\hat{n}_+ - \hat{n}_-) - \hat{p}] = \hbar k\eta_+(\hat{a}_+^\dagger + \hat{a}_+) - \hbar k\eta_-(\hat{a}_-^\dagger + \hat{a}_-) \ , \tag{48.17}$$

in the absence of pumping, $\eta_+ = 0 = \eta_-$.

48.1.3 Adiabatic elimination of the excited state

Under certain conditions, however, the internal and external dynamics occur at very different time scales, which allows a decoupling of the differential equations [4]. When the light fields are very detuned from atomic resonances, $\Delta_a \gg \Gamma$, the internal dynamics of the atoms is very fast, that is, the internal state adapts very rapidly to the boundary conditions defined by the external state and the state of the light field.

[4] In good cavity the limit the degrees of freedom of atomic excitation $\hat{\sigma}^\pm$ drop out of the dynamics, in the bad cavity limit, the fields $\hat{a}^\pm$ drop out of the dynamics.

Therefore, the internal state has no separate dynamics of its own, and we can adiabatically eliminate the internal degrees of freedom. Thus, we can neglect correlations between degrees of freedom, $\langle \hat{a}_\pm \hat{\sigma}^\pm \rangle = \langle \hat{a}_\pm \rangle \langle \hat{\sigma}^\pm \rangle$ etc. [726, 336]. The adiabatic elimination of the excited state comes down to treating the atom as a classical antenna.

We obtain the stationary solutions for $t \to \infty$ in the same way as for the optical Bloch equations [see Eq. (39.151)], assuming in Eq. (48.15),

$$\dot{\hat{\sigma}}^- = 0 = \dot{\hat{\sigma}}_z \tag{48.18}$$

where $\langle \hat{\sigma}^- \rangle = \rho_{21}$. Introducing the position-dependent Rabi frequency of the atom in the standing wave [5],

$$\hat{\Omega}(z) = 2g(e^{\imath k \hat{z}} \hat{a}_+ + e^{-\imath k \hat{z}} \hat{a}_-) \ , \tag{48.19}$$

we write,

$$\begin{aligned} 0 &= (-\gamma + \imath \Delta_a)\hat{\sigma}^- + \tfrac{1}{2}\imath \hat{\Omega} \hat{\sigma}_z \\ 0 &= -2\gamma - 2\gamma \hat{\sigma}_z + \imath \hat{\Omega}^\dagger \hat{\sigma}^- - \imath \hat{\Omega} \hat{\sigma}^+ \ . \end{aligned} \tag{48.20}$$

These equations are solved by,

$$\begin{aligned} \hat{\sigma}_z(\infty) &= \frac{-2(\gamma^2 + \Delta_a^2)}{2(\gamma^2 + \Delta_a^2) + \hat{\Omega}^\dagger \hat{\Omega}} \\ \text{and} \quad \hat{\sigma}^-(\infty) &= \frac{-\imath(\gamma + \imath \Delta_a)\hat{\Omega}}{2(\gamma^2 + \Delta_a^2) + \hat{\Omega}^\dagger \hat{\Omega}} \simeq \frac{-\imath(\gamma + \imath \Delta_a)}{2\Delta_a^2} \hat{\Omega} \ . \end{aligned} \tag{48.21}$$

Inserting the approximated expression for $\hat{\sigma}^-(\infty)$ into the equation of motion (48.15) for the light modes,

$$\begin{aligned} \dot{\hat{a}}_\pm &= (-\kappa + \imath \Delta_c)\hat{a}_\pm - \imath g \hat{\sigma}^-(\infty) e^{\mp \imath k \hat{z}} + \eta_\pm \\ &= \left(-\kappa + \imath \Delta_c - \frac{g^2 \gamma}{\Delta_a^2} - \frac{\imath g^2}{\Delta_a} \right) \hat{a}_\pm - \left(\frac{g^2 \gamma}{\Delta_a^2} + \frac{\imath g^2}{\Delta_a} \right) e^{\mp 2\imath k \hat{z}} \hat{a}_\mp + \eta_\pm \ , \end{aligned} \tag{48.22}$$

and for the atomic momentum,

$$\begin{aligned} \dot{\hat{p}} &= \imath g \hbar k \hat{\sigma}^-(\infty)(\hat{a}_+^\dagger e^{-\imath k \hat{z}} - \hat{a}_-^\dagger e^{\imath k \hat{z}}) - \imath g \hbar k \hat{\sigma}^+(\infty)(\hat{a}_+ e^{\imath k \hat{z}} - \hat{a}_- e^{-\imath k \hat{z}}) \\ &= \frac{2\hbar k \gamma g^2}{\Delta_a^2}(\hat{a}_+^\dagger \hat{a}_+ - \hat{a}_-^\dagger \hat{a}_-) - \frac{2\imath \hbar k g^2}{\Delta_a}(e^{2\imath k \hat{z}} \hat{a}_+ \hat{a}_-^\dagger - e^{-2\imath k \hat{z}} \hat{a}_+^\dagger \hat{a}_-) \ . \end{aligned} \tag{48.23}$$

Defining the light-shift U_0 caused by only one photon and the scattering rate γ_0 by,

$$U_0 \equiv \frac{g^2}{\Delta_a} \qquad \text{and} \qquad \gamma_0 \equiv \frac{\Gamma g^2}{\Delta_a^2} \ , \tag{48.24}$$

with $\Gamma = 2\gamma$, we finally get a set of equations, where the internal degree of freedom of the atom has been eliminated,

$$\boxed{\begin{aligned} \dot{\hat{a}}_\pm &= (-\kappa - \gamma_0 + \imath \Delta_c - \imath U_0)\hat{a}_\pm - (\gamma_0 + \imath U_0) e^{\mp 2\imath k \hat{z}} \hat{a}_\mp + \eta_\pm \\ \dot{\hat{p}} &= 2\hbar k \gamma_0 (\hat{a}_+^\dagger \hat{a}_+ - \hat{a}_-^\dagger \hat{a}_-) + 2\imath \hbar k U_0 (e^{-2\imath k \hat{z}} \hat{a}_+^\dagger \hat{a}_- - e^{2\imath k \hat{z}} \hat{a}_+ \hat{a}_-^\dagger) \end{aligned}} \ . \tag{48.25}$$

[5] Note that the factor of 2 ensure consistency with previous definitions of the Rabi frequency, such as in (40.21). Note also, that $[\hat{\Omega}, \hat{\Omega}^\dagger] = 8g^2 \neq 0$, but this is negligible when the fields are large enough to be considered as classical. On the other hand the quadratic terms $\Omega^\dagger \Omega$ are negligible when they are small compared to γ^2 or Δ_a^2.

48.1.3.1 Radiation pressure and the adiabatically approximated Hamiltonian

The impact of radiation pressure should be considered when the pumping laser is close to a resonance. Then $\gamma_0 \ll U_0$ is no longer satisfied [336], and we get one more term from the equation for the atomic force: $\propto \hbar\gamma_0(|\alpha_+|^2 - |\alpha_-|^2)$.

For the adiabatically approximated Hamiltonian we get immediately from (48.4) [634],

$$\boxed{\begin{aligned}\hat{H} = \frac{\hat{p}^2}{2m} \quad &+ \quad \sum_{\pm}(U_0 - \Delta_c)\hat{a}_{\pm}^{\dagger}\hat{a}_{\pm} \\ &+ \quad U_0(e^{-2\imath k\hat{z}}\hat{a}_{+}^{\dagger}\hat{a}_{-} + e^{2\imath k\hat{z}}\hat{a}_{+}\hat{a}_{-}^{\dagger}) - \imath\sum_{\pm}\eta_{\pm}(\hat{a}_{\pm} - \hat{a}_{\pm}^{\dagger})\end{aligned}} \quad , \tag{48.26}$$

as shown in Exc. 48.1.7.3. Note that dissipative terms are (naturally) absent from this Hamiltonian, so that it shall not be used for the description of radiation pressure. On the other hand, all coherent terms of the equations of motion can be derived from this Hamiltonian (48.26), and we can verify momentum conservation (48.17) and deduce transformation properties. Solve the Exc. 48.1.7.4.

These equations, which we will call CARL equations for reasons that we will become clear in Sec. 48.2, describe the coupled dynamics of atoms being accelerated by the *kick* $e^{\imath k\hat{z}}$ imparted by the photonic recoil received upon scattering a photon from one mode into the counterpropagating one. In the same time, the backscattering *annihilates* a photon $\hat{a}_{\pm}$ in one mode and *creates* a photon $\hat{a}_{\mp}^{\dagger}$ in the counterpropagating mode. From now on we will exclusively use the CARL equations.

Finally, let us summarize, how the operators act on states and observables of the coupled system, noting that the same transformation rules as for free and trapped atoms (24.143) also hold for the optical lattice,

$$\boxed{\begin{array}{rclcrcl} e^{\imath k\hat{z}}|z\rangle &=& |z\rangle & , & e^{-\imath k\hat{z}}\hat{z}e^{\imath k\hat{z}} &=& \hat{z} \\ e^{\imath k\hat{z}}|p\rangle &=& |p+\hbar k\rangle & , & e^{-\imath k\hat{z}}\hat{p}e^{\imath k\hat{z}} &=& \hat{p}+\hbar k \\ \hat{a}_{\pm}|n\rangle &=& \sqrt{n}|n-1\rangle & , & e^{-\imath k\hat{z}}\hat{H}(\hat{z},\hat{p})e^{\imath k\hat{z}} &=& \hat{H}(\hat{z},\hat{p}-\hbar k) \\ \hat{a}_{\pm}^{\dagger}|n\rangle &=& \sqrt{n+1}|n+1\rangle & , & e^{\imath a\hat{p}/\hbar}\hat{H}(\hat{z},\hat{p})e^{-\imath a\hat{p}/\hbar} &=& \hat{H}(\hat{z}-a,\hat{p}) \end{array}} \quad . \tag{48.27}$$

For $ka = \pi$ the phase shift vanishes: $[e^{\imath\pi\hat{p}/\hbar k}, \hat{H}(\hat{z},\hat{p})] = 0$.

The dynamics is given by the time evolutions,

$$e^{-(\imath/\hbar)\hat{H}t}\hat{z}(0)e^{(\imath/\hbar)\hat{H}t} \quad , \quad e^{-(\imath/\hbar)\hat{H}t}\hat{p}(0)e^{(\imath/\hbar)\hat{H}t} \quad , \quad e^{-(\imath/\hbar)\hat{H}t}\hat{n}(0)e^{(\imath/\hbar)\hat{H}t} \quad . \tag{48.28}$$

In Exc. 48.1.7.5 we calculate the photon number superposition state resulting from a kick $e^{\imath k_{kck}\hat{z}}$.

48.1.4 Adiabatic elimination of the cavity modes

We have seen in Sec. 48.1.3 how to eliminate the internal atomic degrees of freedom, once the condition $|\Delta_a| \gg \Gamma$ is satisfied. We may try an analogous treatment accounting for the limit $|\Delta_c| \gg \kappa$. In this case, the cavity fields evolve on a fast time

scale, adiabatically following the evolution of the other degrees of freedom. Hence, we set,

$$\dot{\hat{a}}_\pm = 0 \ , \tag{48.29}$$

and obtain from the first Heisenberg equation (48.15),

$$\hat{a}_\pm(\infty) = \frac{\imath g \hat{\sigma}^- e^{\mp \imath k \hat{z}} - \eta_\pm}{-\kappa + \imath \Delta_c} \ . \tag{48.30}$$

Defining,

$$U_c \equiv \frac{g^2 \Delta_c}{\kappa^2 + \Delta_c^2} \qquad \text{and} \qquad \kappa_c \equiv \frac{g^2 \kappa}{\kappa^2 + \Delta_c^2} \ , \tag{48.31}$$

we can write the position-dependent Rabi frequency (48.19) as,

$$\begin{aligned} \Omega(z) = 2g(e^{\imath k \hat{z}} \hat{a}_+ + e^{-\imath k \hat{z}} \hat{a}_-) \quad &= 2(\kappa_c + \imath U_c) \left(\frac{\eta_+ e^{\imath k \hat{z}} + \eta_- e^{-\imath k \hat{z}}}{g} - 2\imath \hat{\sigma}^- \right) \\ \stackrel{\eta_\pm = 0}{\longrightarrow} -4\imath(\kappa_c + \imath U_c)\hat{\sigma}^- \ , \end{aligned} \tag{48.32}$$

in the limit of no pumping $\eta_\pm = 0$. Inserting this into the other Heisenberg equations (48.15), we immediately get,

$$\dot{\hat{\sigma}}^- = (-\gamma + \imath \Delta_a)\hat{\sigma}^- + \tfrac{\imath}{2}\Omega(z)\hat{\sigma}_z \stackrel{\eta_\pm = 0}{\longrightarrow} (-\gamma + \imath \Delta_a)\hat{\sigma}^- + 2(\kappa_c + \imath U_c)\hat{\sigma}^- \hat{\sigma}_z \ , \tag{48.33}$$

and

$$\dot{\hat{\sigma}}_z = -2\gamma \hat{\sigma}_z + \imath \Omega^\dagger(z)\hat{\sigma}^- - \imath \hat{\sigma}^+ \Omega(z) \stackrel{\eta_\pm = 0}{\longrightarrow} -2\gamma \hat{\sigma}_z - 4\kappa_c \hat{\mathbb{I}} \ , \tag{48.34}$$

as well as, $\dot{\hat{z}} = \hat{p}/m$ and

$$\dot{\hat{p}} = \imath g \hbar k \hat{\sigma}^- (e^{-\imath k \hat{z}} \hat{a}_+^\dagger - e^{\imath k \hat{z}} \hat{a}_-^\dagger) - \imath g \hbar k \hat{\sigma}^+ (e^{\imath k \hat{z}} \hat{a}_+ - e^{-\imath k \hat{z}} \hat{a}_-) \stackrel{\eta_\pm = 0}{\longrightarrow} 0 \ . \tag{48.35}$$

That is, in summary,

$$\boxed{\begin{aligned} \dot{\hat{\sigma}}^- &= (-\gamma - 2\kappa_c + \imath \Delta_a - 2\imath U_c)\hat{\sigma}^- \\ \dot{\hat{\sigma}}_z &= -2\gamma \hat{\sigma}_z - 4\kappa_c \hat{\mathbb{I}} \\ \dot{\hat{p}} &= 0 \end{aligned}} \ . \tag{48.36}$$

Alternatively, the coherent part of these equations can be derived by insert $\hat{a}_\pm(\infty)$ directly in the Hamiltonian (48.4). This will be done in Exc. 48.1.7.6. The equations (48.36) tell us that, in the absence of cavity decay and spontaneous emission, the atomic population will not undergo nutation, but the dipole moment will rotate with a velocity which depends on the inversion. The dynamics becomes interesting in the presence of several atoms, as studied in 46.4.2.

48.1.5 General rules for deriving equations of motion

We have, in the previous sections, derived Heisenberg equations (48.15), respectively (48.25) which, together with the Schrödinger equation for the system's state $|\psi(t)\rangle$ or the master equation for the density operator $\hat{\rho}(t)$ form an *over-complete* set. This

section aims at providing a general recipe for choosing the right set of equations depending on two basic criteria for the nature of the degrees of freedom involved in the dynamics: (i) Do judge it necessary to treat the degree of freedom as quantum or may a classical description be sufficient; and (ii) Is the degree of freedom subject to dissipation (e.g. spontaneous emission of the electronic excitation, cavity decay of the field mode, or collisions messing up the center-of-mass motion), or not. The procedure, which will be applied throughout the remaining part of this chapter, leads to very different descriptions of the system depending on the specific parameter regime.

1. The procedure is generally applicable to coupled systems: We first need to *identify all relevant degrees of freedom and set up the Hamiltonian*, possibly eliminating irrelevant degrees of freedom, e.g. via adiabatic elimination or by tracing over them, if they contribute to dissipation. In the context of atoms coupled to a ring cavity, we assume our system to be in some state [6],

$$|\psi(t)\rangle = |\mathbf{r}\rangle \otimes |\alpha_+\rangle \otimes |\alpha_-\rangle \otimes |i\rangle \ , \tag{48.37}$$

   coupling the atomic motion, the light fields and the electronic excitation, although the electronic excitation $|i\rangle$ is often eliminated adiabatically. The dissipative degrees of freedom related to vacuum modes leading to spontaneous emission and cavity decay, as well as collisions between moving atoms are traced away, but may be considered in the master equation for the density operator and in the Heisenberg equations, where the corresponding decay rates are added phenomenologically.

   This first item has already been solved in the previous sections and led us to the Hamiltonian (48.4) and the corresponding Heisenberg equations (48.15), or the adiabatically approximated Hamiltonian (48.26) and the corresponding Heisenberg equations (48.25).

2. Now, we must decide which degrees of freedom B can be treated as *classical*. Typically, those are highly excited degrees of freedom (e.g. fast velocities of many photons in a mode). The corresponding operators can be substituted by their expectation value. Purely classical energy terms in the Hamiltonian can be ignored and removed. For the degrees of freedom $\hat{A}$ we want to treat as *quantum*, we chose an appropriate common basis, which can be discrete $\{|m\rangle\}$ where m is a complete set of quantum numbers. It can also be continuous $\{|\mathbf{r}\rangle\}$ or a combination of both $\{|\mathbf{r}, m\rangle\}$. Now, we need to expand all operators on the chosen basis.

3. For the quantized degrees of freedom must now decide, whether they all evolve coherently or whether they are subject to dissipation. In the first case, perform steps A4 to A7, in the second case, perform steps B4 to B7.

A4. In the case of coherent dynamics, we *expand the state* of the system $|\psi(t)\rangle$ on the whole basis. For example, expanded on a partially continuous basis, the

[6] Throughout this chapter we will denote momentum states by the Greek letters $|\mu\rangle$ or $\nu\rangle$. Photonic states will be labeled by the Latin letters $|n\rangle$ or $|m\rangle$. Electronic excitation states will be labeled by the Latin letters $|i\rangle$ or $|j\rangle$. Finally, expansion coefficients c_{ν,i,n_+,n_-} of the state or of the density matrix elements will sometimes be emphasized in red.

coupled atom-ring cavity state may read,

$$|\psi(t)\rangle = \sum_{n_+,n_-,i} \int d^3r \; c_{n_+,n_-,i}(\mathbf{r},t)|\mathbf{r}\rangle \otimes |n_+\rangle \otimes |n_-\rangle \otimes |i\rangle \; , \tag{48.38}$$

where $\langle \mathbf{r}, \alpha_+, \alpha_-, i|\psi(t)\rangle = c_{n_+,n_-,i}(\mathbf{r},t)$ are the expansion coefficients depending on photon numbers $n_\pm$ in the counterpropagating light modes, the electronic excitation state i, and the atomic position $\mathbf{r}$ treated in terms of a continuous wavefunction in space [7]. When we want to treat the atomic motion as being quantized in discrete momentum states labeled by some integer number μ, we adopt the notation,

$$|\psi(t)\rangle = \sum_{\nu,n_+,n_-,i} c_{\nu,n_+,n_-,i}(t)|\nu\rangle \otimes |n_+\rangle \otimes |n_-\rangle \otimes |i\rangle \; , \tag{48.39}$$

where $\langle \nu, \alpha_+, \alpha_-, i|\psi(t)\rangle = c_{\nu,n_+,n_-,i}(t)$ are the new expansion coefficients.

A5. Next, we write down the *Schrödinger equation* for the state $|\psi(t)\rangle$, insert the expansion on the basis, and we derive a linear set of equation of motion for the expansion coefficients $\dot{c}_{\{m\}}(\mathbf{r})$. This set governs the dynamics of the quantum degrees of freedom.

A6. The dynamics of the classical degrees of freedom B is obtained by taking the expectation values of the *Heisenberg equations*. Here, we need to take care that the quantum degrees of freedom appearing in the Heisenberg equations are expressed by their expansions.

A7. The coupled set of equations for the expectation values of projectors of the system into a particular state, that is, $\dot{c}_{\{m\}}$ (respectively, $\dot{c}_{\{m\}}(\mathbf{r})$), and of observables B really represents all we need to describe the system dynamics and to simulate it numerically. Hack everything into your PC, pronto!

B4. In the case of dissipative dynamics, derive the master equation obeying commutation rules for all quantized degrees of freedom including the Lindbladt terms and expand every quantized degrees of freedom on the common basis, we do the same expansions, but,

$$\hat{\rho}(t) = |\psi(t)\rangle\langle\psi(t)| \; . \tag{48.40}$$

B5. Derive the linear set of equation of motion for the matrix elements $\dot{\rho}_{\{m\},\{n\}}$.

B6. Take the expectation values Tr $\hat{\rho}\hat{B}$ of the Heisenberg equations for all degrees of freedom to be handled classical as expanding the quantized degrees of freedom on their basis.

B7. The coupled set of equations for $\dot{\rho}_{\{m\},\{n\}}$ and $\dot{B}$ is sufficient to describe the dynamics of the system, hack everything into your PC, pronto!

[7] Note that, in the absence of other quantum numbers, we rather use to write $c(\mathbf{r}) = \psi(\mathbf{r})$.

Let us apply the procedure to the simplest case that the electronic excitation has been adiabatically eliminated and *all* remaining degrees of freedom can be treated classical. Then we do not require a Hamiltonian, nor the Schrödinger equation. We just take the expectation value of the Heisenberg equations (48.25) for all degrees of freedom which is easy to do, because there is no quantum state to be expanded: we just can replace the operators by c-numbers,

$$\boxed{\begin{aligned} \dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm - \imath U_0 e^{\mp 2\imath k z}\alpha_\mp + \eta_\pm \\ \dot{p} &= 2\imath\hbar k U_0(e^{-2\imath k z}\alpha_+^\dagger\alpha_- - e^{2\imath k z}\alpha_+\alpha_-^\dagger) \end{aligned}} \,. \tag{48.41}$$

These *totally classical* equations, called CARL equations, will be studied in the subsequent sections, while a thorough discussion of partially quantized equations of motion is postponed to Sec. 48.4.

48.1.5.1 CARL as a beam splitter

Neglecting spontaneous emission, $\gamma_0 = 0$, cavity pumping, $\eta = 0$, cavity decay, $\kappa = 0$, and cavity detuning, $\Delta_c = 0$, the CARL equations in the adiabatic approximation can be derived from the following Hamiltonian,

$$\hat{H} = \frac{\hat{p}^2}{2m} + \sum_\pm U_0\hat{a}_\pm^\dagger\hat{a}_\pm + U_0(e^{-2\imath k\hat{z}}\hat{a}_+^\dagger\hat{a}_- + e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger) \,, \tag{48.42}$$

and read,

$$\begin{aligned} \dot{\hat{a}}_\pm &= -\imath U_0\hat{a}_\pm - \imath U_0 e^{\mp 2\imath k\hat{z}}\hat{a}_\mp \\ \dot{\hat{p}} &= 2\imath\hbar k U_0(e^{-2\imath k\hat{z}}\hat{a}_+^\dagger\hat{a}_- - e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger) \,, \end{aligned} \tag{48.43}$$

or with the substitution $\hat{b}_\pm \equiv \hat{a}_\pm e^{\imath U_0 t}$,

$$\begin{aligned} \dot{\hat{b}}_\pm &= -\imath U_0 e^{\mp 2\imath k\hat{z}}\hat{b}_\mp \\ \ddot{\hat{b}}_\pm &= -U_0^2\hat{b}_\pm - 2k\dot{z}U_0 e^{\mp 2\imath k\hat{z}}\hat{b}_\mp \,, \end{aligned} \tag{48.44}$$

we see that, if the motion weren't a dynamic variable, $\dot{\hat{z}} = 0$, the field amplitudes would just perform harmonic oscillations.

On the other hand, with the substitution $\hat{c} \equiv \hat{a}_+ e^{\imath k\hat{z}} + \hat{a}_- e^{-\imath k\hat{z}}$ [8], the complete Hamiltonian rephrased as,

$$\boxed{\hat{H} = \frac{\hat{p}^2}{2m} + U_0\hat{c}^\dagger\hat{c}} \,. \tag{48.45}$$

Here, we see that, if the motion described by $(\hat{z}, \hat{p})$ weren't a dynamic variable, our system would simply be a harmonic oscillator vibrating with the frequency U_0.

[8] Provided we are allowed to commute the operators $\hat{z}$ and $\hat{a}_\pm$.

48.1.5.2 Classical limit of the equations of motion

For atoms much hotter than the recoil limit and macroscopic light intensities we may replace the quantum operators by complex numbers $z \equiv \hat{z}$, $\alpha_\pm \equiv \hat{a}_\pm$ and $\rho_{21} = \hat{\sigma}^-$. The classical equations of motion (48.41) for the coupled system of a single atom confined at the position $r = z$ of the dipolar potential of a ring cavity can be cast into the form,

$$\boxed{\begin{aligned} \begin{pmatrix} \dot{\alpha}_+ \\ \dot{\alpha}_- \end{pmatrix} &= \begin{pmatrix} -\kappa - \gamma_0 + \imath(\Delta_c - U_0) & -(\gamma_0 + \imath U_0)e^{-2\imath kz} \\ -(\gamma_0 + \imath U_0)e^{2\imath kz} & -\kappa - \gamma_0 + \imath(\Delta_c - U_0) \end{pmatrix} \begin{pmatrix} \alpha_+ \\ \alpha_- \end{pmatrix} + \begin{pmatrix} \eta_+ \\ \eta_- \end{pmatrix} \\ \dot{p} &= 2\hbar k\gamma_0(\alpha_+\alpha_+^* - \alpha_-\alpha_-^*) + 2\imath\hbar k U_0(\alpha_+^*\alpha_- e^{-2\imath kz} - \alpha_+\alpha_-^* e^{2\imath kz}) \end{aligned}} \,. \tag{48.46}$$

Recalling that $\alpha_\pm^*\alpha_\pm$ is the number of photons in the respective mode, we can interpret this equation as a rate equation: The number of photons in a mode α_+ changes by photon losses at a rate κ from resonator, or by gain due to backscattering from the counterpropagating mode, or by pumping with an external incident light field at rate η_+.

The equations (48.46) completely describe our coupled atom-cavity system. They are totally classical and work for both, atoms and macroscopic particles.

48.1.6 Cumulant expansion for CARL

The dynamics of quantum correlations such as $\hat{a}_+^\dagger\hat{a}_-$ or $\hat{a}_+\sigma^+$ can be derived from Heisenberg equations, as well. As an example, let us consider the adiabatically eliminated Hamiltonian (48.26) and ignore the quantized nature of the atomic motion, the relevant first-order field-field correlations are then $\hat{a}_+^2$, $\hat{a}_+^\dagger\hat{a}_+$, $\hat{a}_+^{\dagger 2}$, $\hat{a}_-^2$, $\hat{a}_-^\dagger\hat{a}_-$, $\hat{a}_-^{\dagger 2}$, $\hat{a}_+\hat{a}_-$, $\hat{a}_+\hat{a}_-^\dagger$, $\hat{a}_+^\dagger\hat{a}_-$, $\hat{a}_+^\dagger\hat{a}_-^\dagger$. From the Heisenberg equation we get, for instance,

$$\begin{aligned} \frac{d}{dt}\hat{a}_+^2 &= \imath[\hat{H}, \hat{a}_+^2] \\ &= -2\imath(U_0 - \Delta_c)\hat{a}_+^2 + 2U_0\left(e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger - e^{-2\imath k\hat{z}}\hat{a}_+\hat{a}_-\right) - 2\imath\eta_+\hat{a}_+ \,. \end{aligned} \tag{48.47}$$

This is the lowest order *cumulant expansion*. The expectation values form a system of 10 linear first order differential equations [149] from which we can calculate the steady-state of the system.

The correlation functions and spectra are obtained directly from the CARL equation for the cavity fields (48.25) using the Wiener-Khinchin theorem (40.81) and the quantum regression theorem (40.137). With the substitutions, $t \to 0$, $\hat{B} \to 1$, $\hat{A} \to d\hat{A}_k/d\tau$, and $\xi_i(\tau)\hat{A}_i(0) \to \zeta_i\hat{A}_i(\tau)$, the quantum regression theorem can be written in the form,

$$\boxed{\frac{d}{d\tau}\langle\hat{A}_k(\tau)\rangle = \sum_i \zeta_i\langle\hat{A}_i(\tau)\rangle \qquad \Longrightarrow \qquad \frac{d}{d\tau}\langle\hat{A}_k(\tau)\hat{C}(0)\rangle = \sum_i \zeta_i\langle\hat{A}_i(\tau)\hat{C}(0)\rangle} \,. \tag{48.48}$$

Applied, for example, to the correlation function (48.47), we obtain from the CARL equation (48.25), with $\gamma_0 = 0$ and $\Delta_c = 0$,

$$\frac{d}{d\tau}\langle \hat{a}_+(\tau)\hat{a}_+(0)\rangle = (-\kappa - \imath U_0)\langle \hat{a}_+(\tau)\hat{a}_+(0)\rangle - \imath U_0 e^{-2\imath k\hat{z}}\langle \hat{a}_-(0)\hat{a}_+(0)\rangle + \eta_+\langle \hat{a}_+(0)\rangle \ . \tag{48.49}$$

Repeating this calculation for the other first-order correlations functions we obtain a system of 10 linear first order differential equations, which can be solved via Laplace transform.

48.1.7 Exercises

48.1.7.1 Ex: Origin of quantum correlations

Derive the Hamiltonian (48.2) from the JCM Hamiltonian (40.21) transforming it into the co-rotating frame.

48.1.7.2 Ex: Linear pumping of a cavity mode

Study how the Hamiltonian $\hat{H}_{pmp} = \imath\eta^*\hat{a} - \imath\eta\hat{a}^\dagger$, describing linear pumping of a cavity mode, fills the cavity with photons in the absence of dissipation (see also (38.29)).

48.1.7.3 Ex: The adiabatically approximated Hamiltonian

a. Derive the adiabatically approximated Hamiltonian (48.26) from the total Hamiltonian (48.4).
b. Derive the CARL equations (48.25) directly from the adiabatically approximated Hamiltonian.
c. Show that, in the absence of pumping, the energy stored in the light fields is conserved separately from the mechanical energy of the atom.
d. Verify momentum conservation.

48.1.7.4 Ex: Hamiltonian after adiabatic elimination of internal states for a linear cavity including counter-rotating terms

Repeat the adiabatic elimination of Sec. 48.1.4 for a linear cavity including counter-rotating terms.

48.1.7.5 Ex: Periodicity of a lattice

Assume a symmetrically pumped ring cavity in equilibrium with an atom initially at rest. What photonic states are generated in the counterpropagating light modes, when the atom is kicked by an external force imparting a sudden recoil of $\hbar k_{kck}$.

48.1.7.6 Ex: Adiabatic elimination of the cavity modes

Derive the coherent part of the equations of motion (48.36) directly from the Hamiltonian (48.4) in the absence of pumping, $\eta_\pm = 0$, and in the limit of large cavity detunings, $|\Delta_c| \gg \kappa$.

48.2 CARL: The collective atomic recoil laser

The *collective atomic recoil laser* (*CARL*) was first predicted in 1994 [111] as an atomic analog of FEL. The idea consists of a monochromatic homogeneous beam of moving two-level atoms (all atoms have the same velocity), a strong counterpropagating pump laser beam, and a weak copropagating probe beam tuned to the blue side of the resonance. The lasers form a standing light wave that moves in the same direction as the atoms. Atoms that are faster than the velocity of the standing wave are rejected by the maxima of the dipolar potential created by the standing wave and feel a repulsive force. Atoms that are slower than the standing wave velocity are pushed by the dipole potential maxima and feel an accelerating force. These forces can be interpreted as backscattering of photons from the pump wave into the probe wave. This redistribution of energy amplifies the contrast of the stationary wave, which in turn amplifies the backscattering efficiency, etc. Therefore, the CARL converts kinetic energy into coherent radiation (or more precisely, into an increase of the energy difference between probe and pump) mediated by atomic bunching. It is a self-amplifying mechanism. The CARL signature is a transient exponential amplification for the incident probe, which defines the frequency of the 'CARL laser'. The first experimental realization of CARL used a ring cavity [542].

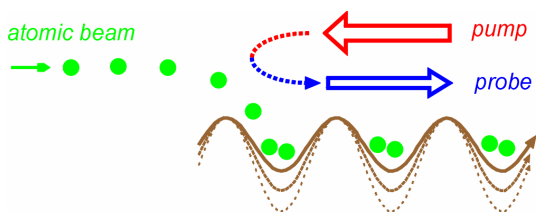

Figure 48.3: Collective atomic recoil laser.

48.2.1 Classical CARL equations for many mobile atoms

The preceding sections dealt with a single atom in a ring cavity. More interesting dynamics, however, emerge in the presence of several atoms, because their motion can be become correlated via their simultaneous interaction with the same two counter-propagating modes of the cavity, as illustrated in the following movie (watch movie). A talk on CARL can be assisted at (watch talk).

To describe experiments dealing with many atoms, we have to extend the equations of motion (48.26) to N atoms via $z \longrightarrow z_j$ and $p \longrightarrow p_j$, where $j = 1, N$,

$$\boxed{\begin{aligned} \dot{\alpha}_\pm &= (-\kappa - \imath N U_0)\alpha_\pm - \imath U_0 \sum_{j=1}^{N} e^{\mp 2\imath k z_j}\alpha_\mp + \eta_\pm \\ \dot{p}_j &= -2\imath\hbar k U_0(\alpha_+\alpha_-^* e^{2\imath k z_j} - \alpha_-\alpha_+^* e^{-2\imath k z_j}) \end{aligned}} \quad . \tag{48.50}$$

with the kinetic and potential energies [9],

$$E_{kin} = \sum_j \frac{p_j^2}{2m} \quad , \quad E_{pot} = \sum_j U_0 |\alpha_+ e^{\imath k z_j} + \alpha_- e^{-\imath k z_j}|^2 \ . \tag{48.51}$$

If the atomic density distribution is homogeneous, the phases of randomly scattered photons destructively interfere and the quantity,

$$b \equiv \tfrac{1}{N} \sum_j e^{-2\imath k z_j} \ , \tag{48.52}$$

called *bunching parameter*, vanishes. That is, the impact of the scatterers on the light modes cancels out, as we will see in Exc. 48.2.5.1 for the case of two atoms. If on the other hand, atoms accumulate in the antinodes of the standing wave, it increases the contrast of it can spread more efficiently collectively by Bragg scattering. The particularity of the CARL is that during the temporal evolution the bunching process can amplify itself leading to an exponential growth of the counterpropagating mode, accompanied by an increasingly pronounced self-bunching.

In general, the equations can not be solved analytically, especially when the pump varies over time. A first approach consists in iterating them numerically,

$$\begin{aligned} \alpha_\pm(t+dt) &= \alpha_\pm(t) + dt \ \left[-(\kappa + \imath N U_0 - \imath \Delta_c)\alpha_\pm - \imath N U_0 b \alpha_\mp + \eta_\pm(t)\right] \\ z_j(t+dt) &= z_j + dt \ \tfrac{1}{m} p_j \\ p_j(t+dt) &= p_j - dt \ 2\imath\hbar k U_0 (\alpha_+ \alpha_-^* e^{2\imath k z_j} - \alpha_- \alpha_+^* e^{-2\imath k z_j}) \ . \end{aligned} \tag{48.53}$$

In Exc. 48.2.5.2 we will extend the equations (48.50) to the presence of two atomic species, and in Exc. 48.2.5.3 we will use them to describe the response of the light fields to an inertially moving atom supposing that is does not feel the CARL force.

48.2.1.1 Locking of the pump laser

In practice the resonant frequency of a cavity fluctuates due to ambient noise. Hence, it is easier, experimentally, to lock the pump laser on a cavity mode, e.g. using the Pound-Drever-Hall method. This means,

$$\alpha_+ = \frac{\eta_+}{\kappa} \ . \tag{48.54}$$

In the presence of atoms, however, the resonant frequency can be shifted due to the refractive index of the atomic cloud [294]. Moreover, the shift depends on the atomic bunching and consequently varies during the dynamics of the CARL. The way the locking circuit works, is to continuously adjust the detuning between the laser and the cavity Δ_c (defined for the empty cavity) such as to maximize the amplitude of the field $|\alpha_+|$ and, hence, the transmission of the cavity filled with atoms. The dynamics of the detuning must be incorporated by an additional equation modeling the action of locking. Now that we know the effect, which an ideal lock should have, we can

[9] Note, that there is also a radial motion of the atom coupled to the axial movement. The coupling happens, because the axial motion influences the number of intracavity photons of the radiation field which, in turn, determines the depth of the dipole potential.

apply the boundary condition (48.54) and eliminate the pump mode α_+ from the dynamics of the system. That is, the following equations are usually sufficient to describe the CARL:

$$\boxed{\begin{aligned} \dot{\alpha}_- &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_- - \imath U_0 e^{-2\imath kz}\alpha_+ + \eta_- \\ m\ddot{z} &= 2\imath\hbar k U_0 \alpha_+(\alpha_- e^{-2\imath kz} - \alpha_-^* e^{2\imath kz}) \end{aligned}} \ . \tag{48.55}$$

The frequency offset of the cavity resonances caused by the atom, U_0, can exceed the width of the cavity κ. From equation (45.67) we know,

$$|\alpha_+(\infty)|^2 = \frac{\chi\chi^*}{(\chi^2 + U_0^2)(\chi^{*2} + U_0^2)}\eta_+^2 \ .$$

The maxima of $|\alpha_+(\infty)|^2$ as a function of Δ_c give the shifted resonances of the modes.

Example 358 (*Locking on transverse modes*): We already mentioned that as the CARL accelerates, the frequency of the light which is backscattered to the probe shifts to the red until it escapes from the resonant mode. What happens if we provide another resonant mode that can receive photons? We will show in the following calculation, that CARL simply picks up the closest mode to dump the photons. The starting point is generalized CARL equations to accommodate a second reverse mode labeled β_-,

$$\begin{aligned} \dot{\alpha}_+ &= -(\kappa - \imath\Delta_c)\alpha_+ - \imath U_0(u_+^* u_+ \alpha_+ + u_+^* u_- \alpha_- + u_+^* u_\beta \beta_-) + \eta_+ \\ \dot{\alpha}_- &= -(\kappa - \imath\Delta_c)\alpha_- - \imath U_0(u_-^* u_- \alpha_- + u_-^* u_+ \alpha_+ + u_-^* u_\beta \beta_-) \\ \dot{\beta}_- &= -(\kappa - \imath\Delta_\beta)\beta_- - \imath U_0(u_\beta^* u_\beta \beta_- + u_\beta^* u_+ \alpha_+ + u_\beta^* u_- \alpha_-) \\ m\ddot{x} &= -U_0 \nabla |\alpha_+ u_+ + \alpha_- u_- + \beta_- u_\beta|^2 \ , \end{aligned} \tag{48.56}$$

com $u_\pm = e^{\pm\imath kz}$ and $u_\beta = e^{-\imath k_\beta x}$. We obtain,

$$\begin{aligned} \dot{\alpha}_+ &= -(\kappa - \imath\Delta_c + \imath N U_0)\alpha_+ - \imath U_0 e^{-2\imath kz}\alpha_- - \imath U_1 e^{-\imath(k+k_\beta)x}\beta_- + \eta_+ \\ \dot{\alpha}_- &= -(\kappa - \imath\Delta_c + \imath N U_0)\alpha_- - \imath U_0 e^{2\imath kz}\alpha_+ - \imath U_1 e^{\imath(k-k_\beta)x}\beta_- \\ \dot{\beta}_- &= -(\kappa - \imath\Delta_\beta + \imath N U_1)\beta_- - \imath U_1 e^{\imath(k+k_\beta)x}\alpha_+ - \imath U_1 e^{-\imath(k-k_\beta)x}\beta_- \\ m\ddot{x} &= -U_0(2\imath k e^{2\imath kz}\alpha_-^*\alpha_+ - 2\imath k e^{-2\imath kz}\alpha_+^*\alpha_-) \\ &\quad - U_1(\imath(k+k_\beta)e^{\imath(k+k_\beta)x}\beta_-^*\alpha_+ - \imath(k+k_\beta)e^{-\imath(k+k_\beta)x}\alpha_+^*\beta_-) \\ &\quad - U_1(\imath(k-k_\beta)e^{\imath(k-k_\beta)x}\alpha_-^*\beta_- - \imath(k-k_\beta)e^{-\imath(k-k_\beta)x}\beta_-^*\alpha_-) \ . \end{aligned} \tag{48.57}$$

Note that $k - k_\beta \approx 0$ and $k + k_\beta \approx 2k$. The result of the simulation is displayed in Fig. 48.4.

48.2.1.2 Analytic approximations for one-sided pumping and perfect bunching

Here, we will assume for simplicity, that the atoms are perfectly bunched, $z_j = z$ and $p_j = p$, i.e. they have *zero temperature*. This means that we only need to consider a single equation of motion for the atoms. However, their coupling to the cavity modes is N times stronger, which means that we have to substitute $U_0 \longrightarrow U_N \equiv NU_0$ in the equation of motion for the cavity fields.

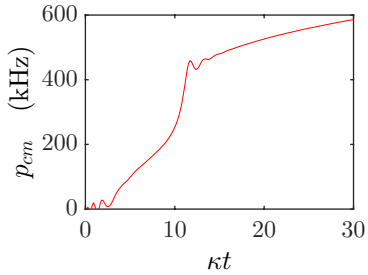

Figure 48.4: (code) The CARL locks to other modes of the cavity.

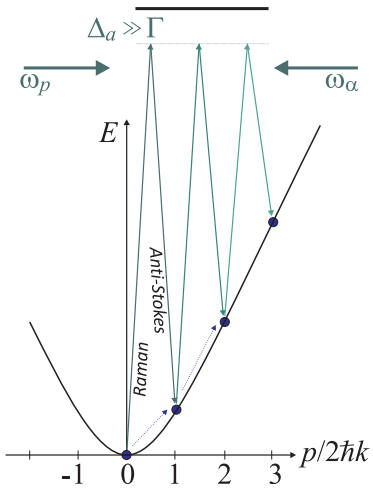

Figure 48.5: In the momentum picture the CARL acceleration process occurs as Raman-anti-Stokes processes along the free-particle dispersion relation.

When only one atom is in the cavity or when the atoms are perfectly bunched together, it is possible to derive analytical solutions. Particularly interesting is the following situation: We pump the cavity from one side. The pump is supposed to be dominant and locked to a resonance, such that we can neglect the feedback of the system on the pump, that is, we can assume, $\alpha_+ = \eta/\kappa$. Using the abbreviations $\chi \equiv \kappa + \imath U_0 - \imath\Delta_c$ and the photon recoil shift [336],

$$\omega_{\rm rec} \equiv \frac{\hbar k^2}{2m} \ , \tag{48.58}$$

the equations (48.26) then become,

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\chi\alpha_- - \imath U_N \alpha_+ e^{2\imath kz} \\ k\dot{v} &= 4\omega_{\rm rec}\imath U_0 \alpha_+ (\alpha_- e^{-2\imath kz} - \alpha_-^* e^{2\imath kz}) \end{aligned}} \ . \tag{48.59}$$

We consider the stationary case (48.26). Doing the ansatz,

$$\alpha_- \equiv \beta e^{2\imath kx} \qquad \text{where} \qquad \dot{\beta} = 0 \tag{48.60}$$

we assume that the atom and the standing wave have the same velocity, that is, they move in phase. We obtain as solution,

$$\beta = \frac{-\imath U_N \alpha_+}{\kappa + 2\imath k v} \quad , \quad k\dot{v} = 8\omega_{\rm rec} U_0^2 \alpha_+^2 \frac{2\kappa}{\kappa^2 + 4k^2 v^2} \ . \tag{48.61}$$

If $\kappa \ll 2kv$, then the differential equation is approximately solved by,

$$(kv)^3 = 3\varepsilon\kappa U_0^2 \alpha_+^2 t \ . \tag{48.62}$$

This means that the CARL frequency, that is, the frequency difference between the emitted probe wave and the incident light, increases temporarily. The frequency corresponds to the double Doppler shift. As the frequency of the probe light gradually shifts away from the cavity resonance, the probe light finally stops being amplified, and the amplitude of the probe field decreases: CARL is only a transient phenomenon. In fact, the behavior described by the equation (48.61) was observed in experiments [542].

Example 359 (*Universal scaling*): Our formula describing CARL,

$$\begin{aligned} \dot{\alpha}_- &= -\frac{\imath U_0 \eta_+}{\chi} \sum\nolimits_j e^{2\imath k z_j} - \chi \alpha_- \\ k\dot{v}_j &= -4\omega_{\rm rec} \imath U_0 \eta_+ \left(\frac{\alpha_-}{\chi^*} e^{-2\imath k z_j} - \frac{\alpha_-^*}{\chi} e^{2\imath k z_j} \right) - \gamma_{\rm frc} k v_j \ , \end{aligned} \tag{48.63}$$

where $\chi = \kappa + \imath N U_0 - \imath \Delta_c$, can be rewritten in terms of a universal 'scaling' if we define,

$$\begin{aligned} \tau &= 4\omega_{\rm rec}\rho t \quad \text{and} \quad \bar{\gamma} = \frac{\gamma_{\rm frc}}{4\omega_{\rm rec}\rho} \\ \theta_j &= 2kz_j \quad \text{and} \quad P_j = \frac{2kv_j}{4\omega_{\rm rec}\rho} \\ A &= \frac{\imath|\chi|}{\chi^*\sqrt{\rho N}}\alpha_- \quad \text{and} \quad \bar{\chi} = \frac{\chi}{4\omega_{\rm rec}\rho} \ . \end{aligned} \tag{48.64}$$

We obtain,

$$\begin{aligned} \dot{A} &= \frac{1}{N} \sum\nolimits_j e^{\imath\theta_j} - \bar{\chi} A \\ \dot{\theta} &= P_j \\ \dot{P}_j &= -2(A^* e^{-\imath\theta_j} + A e^{\imath\theta_j}) - \bar{\gamma} P_j \ . \end{aligned} \tag{48.65}$$

provided that the universal scaling parameter ρ is set to,

$$\rho \equiv \left(\frac{N U_0^2 \eta_+^2}{8\omega_{\rm rec}^2 |\chi|^2} \right)^{1/3} \ . \tag{48.66}$$

The meaning of the ρ parameter can be gathered by rewriting it in terms of the number of photons of the pump $|\alpha_+|^2 = \eta_+^2/\kappa^2$ and the depth of the dipolar potential $U_d = U_0|\alpha_+|^2$,

$$\rho^3 = \frac{N}{\alpha_+^2} \frac{U_d^2}{8\omega_{\rm rec}^2} \ . \tag{48.67}$$

The ρ parameter therefore indicates the number of atoms per photon and the ratio between the depth of the dipolar trap and the photonic recoil energy.

48.2.2 Observation of CARL in ring cavities

The first observation of CARL was achieved with a cloud of 100 μK cold rubidium atoms interacting with a high finesse ring cavity [542]. In a thermal cloud the atomic motion prevents bunching, i.e. $b = 0$ so that according to Eq. (48.50) the cavity fields do not couple to the atoms. Density fluctuations that could seed CARL dynamics are rapidly washed out by thermal motion.

This problem can be circumvented by applying a robust *pre-bunching*, which can be done by subjecting the atoms to a periodic potential, e.g. via a standing wave formed by two counterpropagating cavity modes. The atoms then arrange themselves into a periodic lattice, so that the bunching parameter is initially $b \simeq 1$. If one cavity is then extinguished, a CARL dynamics can take place, until thermal motion succeeds in washing out the periodic lattice. This dynamics is illustrated in the simulation exhibited in Fig. 48.6 for the case of strontium atoms. The finite temperature of the cloud is accounted for via an initial density and momentum distribution for the atoms given by,

$$p_{0,j} = \sqrt{mk_{\mathrm{B}}T}\ \zeta_j \qquad \text{and} \qquad z_{0,j} = \frac{\sqrt{2}}{k}\sqrt{\frac{k_{\mathrm{B}}T}{U_0}}\ \zeta_j\ , \tag{48.68}$$

where ζ_j is a normally distributed random variable.

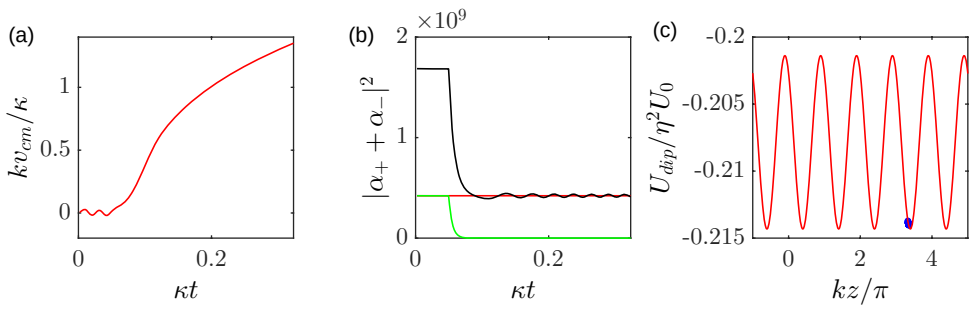

Figure 48.6: (code) Simulation for $N = 10^5$ strontium atoms at $T = 10\,\mu\mathrm{K}$ temperature interacting via their $\Gamma = (2\pi)$ kHz narrow intercombination line at $\lambda = 689\,\mathrm{nm}$ with a ring cavity (decay rate $\kappa = (2\pi)$ 1.7 MHz and waist $w_0 = 68.4\,\mu\mathrm{m}$). CARL dynamics is triggered by switching off one of two pump lasers whose intracavity power is $P = 1\,\mathrm{W}$. (a) Doppler shift of the CARL-accelerated atoms, (b) interference signal between the two cavity light modes, and (c) atomic distribution in the standing wave potential.

Example 360 (*Curiosities: Atomic transport around mirrors*): Displacement of the atomic cloud in a unidirectionally pumped ring-cavity. The left and right image in Fig. 48.7 are taken for different pumping directions α. The upper cloud shows atoms trapped in the main focus of the ring-cavity. The lower traces stem from atoms transported from the focus passed the mirrors T_1 and T_2 towards the incoupling mirror located at the place where the lower traces intersect. The lower trace are imaged twice, because the imaging beam is reflected from the incoupling mirror surface, before it is sent to a photodiode.

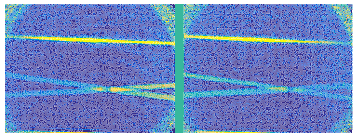

Figure 48.7: Displacement of the atomic cloud in a unidirectionally pumped ring-cavity. The left and right figures are taken for different pumping directions α. The upper cloud shows atoms trapped in the main focus of the ring-cavity. The lower traces stem from atoms transported from the focus passed the mirrors T_1 and T_2 towards the incoupling mirror located at the place where the lower traces intersect. The lower trace are imaged twice, because the imaging beam is reflected from the incoupling mirror surface, before it is sent to a photodiode.

48.2.2.1 CARL in the presence of friction forces

A feature of CARL, as it has been detected in Fig. 48.6 is, that it does not lead to a stationary state: the atoms are monotonically accelerated and the Doppler-shift of the backscattered probe light increases at the same pace. After a while, the frequency of the probe light runs out of the cavity resonance, so that the CARL dynamics starts to be suppressed. This led to a reduction of the oscillation amplitude of the interference signal observed in Fig. 48.6(b).

In order to maintain CARL strong we can think of limiting the acceleration by a friction force. How this works is illustrated in Fig. 48.8, where by subject the atoms to an optical molasses switched on at time $\kappa t = 0.3$. The friction can be incorporated into the CARl equations (48.50) via an additional force,

$$F_{\text{frc}} = -\beta_{\text{frc}} p \ . \tag{48.69}$$

We observe that the frequency shift of the backscattered light stabilizes at a lower value and that the oscillation amplitude of the interference signal is stronger than without molasses [943].

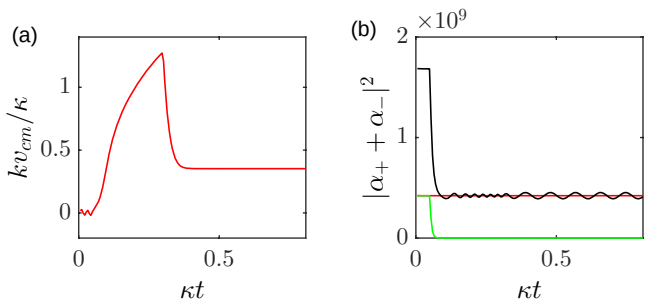

Figure 48.8: (code) Influence of an external friction force (switched on at $\kappa t = 0.3$) proportional to $\beta_{\text{frc}} = 3.8 \cdot 10^6\,\text{s}^{-1}$. Other parameters are the same as in Fig. 48.6.

Let us note that, while provide a nice intuition, the description of the impact of an optical molasses force is incomplete, because it disregards heating effects caused by random photon scattering processes. The temperature of the atomic cloud is given

by an equilibrium between friction and heating processes. The correct inclusion of optical molasses in the CARL dynamics will be studied in Sec. 48.6.1.

48.2.2.2 CARL in the presence of injected probe light

It is also interesting to study the impact of a weak injected probe light on the CARL dynamics. This light may have the same frequency as the pump light, $\eta_-/|\eta_-| = \eta_+/|\eta_+|$. This is for example the case, when light is backscattered from imperfection of the cavity mirror surfaces. Or may have a different frequency (provided the probe frequency is resonant to a cavity mode),

$$\eta_- = e^{\imath \Delta\nu t} \ . \tag{48.70}$$

The injected light fields η_+ and η_- create a standing light wave potential, in which the atoms move as being subject to an array of hurdles. The CARL force is too weak, the atoms will get stuck. We study this in Exc. 48.2.5.4. In Exc. 48.2.5.5 we study CARL dynamics for the case that the atoms are subject to an additional harmonic potential.

48.2.2.3 Impact of radiation pressure on CARL

CARL is a coherent force resulting from a coupling of only two counterpropagating modes of the cavity. As such, it can be derived from a potential. However, photons may also be scattered out of the cavity and get lost for the system. These processes give rise to an additional radiation pressure force, which has been given in Eq. (48.46),

$$F_{\rm rp} = 2\hbar k \gamma_0 (\alpha_+ \alpha_-^* - \alpha_- \alpha_+^*) \ . \tag{48.71}$$

But this force is weak when the laser is tuned far enough from the atomic resonance.

Fig. 48.9 shows a simulation of the impact of radiation pressure for the same system as in Fig. 48.6. For clarity the radiation pressure force has been exaggerated by a factor of 100.

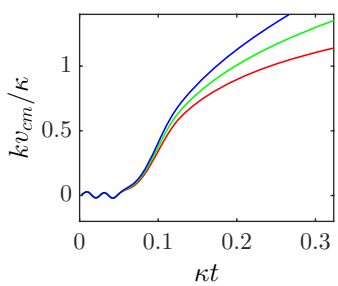

Figure 48.9: (code) Influence of radiation pressure on CARL.

48.2.3 Optical instability in ring cavities

We have until now concentrated on the regime of weak coupling, $NU_0 < 1$. If the pump laser is tuned closer to resonance, or if the number of atoms is increased, so that $NU_0 > 1$, we observe instabilities in the coupled atom-field dynamics, which critically depend on the pump intensities [683]. Imagine a sample of atoms trapped in an optical lattice formed by a symmetrically pumped ring cavity, $\eta_+ = \eta_-$. The system is stationary, the atoms are confined at the antinodes of the standing wave, the light fields are equal in strength, $\alpha_+ = \alpha_-$. At time $t = 0$ we suddenly reduce the pump rate η_- of the non-stabilized mode by only a few percent. The response of the system observed in experiment [683] is to completely break down the field α_-. The disappearance of the standing wave ejects most atoms and reduces NU_0, until the coupling gets so weak that the dynamics is essentially governed by the injected fields. The system recovers a stationary state, with much less atoms.

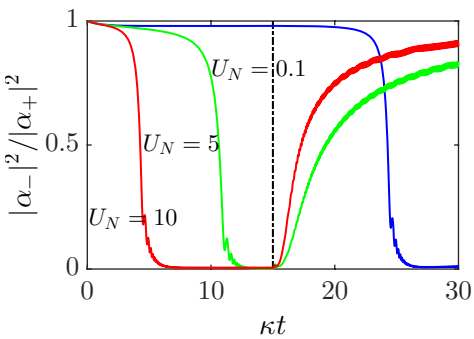

Figure 48.10: (code) Dynamics simulated with equations (48.46). At time $\kappa t = 0$ the pump rate η_- is reduced by 1%. After a certain time that depends on NU_0, the standing wave breaks down ejecting atoms from the mode volume. Here, we simulate this via an artificial linear trap loss process setting in at time $\kappa t = 15$. As a result of the diminishing NU_0 the standing wave recovers.

The physical explanation for the instability is reminiscent to the CARL behavior described in previous sections. Because atom-field coupling is strong, a small imbalance of the injected beam intensities is sufficient to displace the atoms to a location, where the light which they scatter into the reverse direction interferes destructively with the injected light. A simple argument explains, why the standing wave is attracted towards a position where it gets unstable. We treat the imbalance $\eta_+ > \eta_-$ as if it was due to a scatterer fixed in space inside the mode volume sitting on an edge of the standing wave (corresponding to a $\pi/4$ phase shift), such that it only scatters light from α_+ into α_-, but not the other way round. Whether the phase of the standing wave adjusts itself to that of pump field or such that the scatterer sits at the bottom of the potential well depends on the ratio of the coupling to the external field (given by κ) and to the scatterer (given by U_0). If U_0 is stronger, the field is pulled towards the scatterer dragging along the atoms which are free to move. The stationary situation is therefore a displacement of the standing wave and the atoms by $\lambda/4$, which is just the position where the cavity field α_- and the injected field

$\alpha_-^{(in)}$ are out of phase. The injected light is not transmitted through the cavity any more.

Note that the instability occurs in a plane wave situation, there is no need to consider the transversal motion. Furthermore, it is a single-atom effect, since we assume perfect bunching. We may therefore consider a single atom strongly coupled to the cavity and use the set of equations (48.46). In the *undepleted pump approximation* we assume $\dot{\alpha}_+ = 0$, and if the atom adiabatically follows the dynamics of the potential valley, $\ddot{x} = 0$, so that,

$$0 = -\chi\alpha_+ - \imath U_0\sqrt{\frac{\alpha_+\alpha_-^*}{\alpha_+^*\alpha_-}}\alpha_- + \eta_+ \ , \tag{48.72}$$

$$\dot{\alpha}_- = -\chi\alpha_- - \imath U_0\sqrt{\frac{\alpha_+^*\alpha_-}{\alpha_+\alpha_-^*}}\alpha_+ + \eta_- \ .$$

The first equation yields,

$$\alpha_+ = \frac{\eta_+}{\chi + \imath U_0\frac{|\alpha_-|}{|\alpha_+|}} \ , \tag{48.73}$$

$$|\alpha_+| \approx \frac{\eta_+}{\chi}\left(1 - \frac{U_0^2}{2\eta_+^2}|\alpha_-|^2\right) \ .$$

Plugging this result into the second equation and assuming the laser on resonance, $\Delta_c = NU_0$, so that we may replace χ by κ, we get,

$$\dot{\alpha}_- \approx -\kappa\alpha_- - \frac{\imath U_0\eta_+}{\kappa}\frac{\alpha_-}{|\alpha_-|} + \frac{\imath U_0^3}{2\kappa\eta_+}|\alpha_-|\alpha_- + \eta_- \ . \tag{48.74}$$

This equation describes *optical bistability*.

48.2.4 Phononic coupling of atoms mediated by a ring cavity

Phonons can be understood as vibrational excitations of quantum particles (atoms) in quantized traps. When atoms are interconnected in vibrational lattices, phonons can be transferred and shared between atoms [10]. Due to the particularity of the ring cavity of conserving the photonic momentum at each backscattering event, the photonic momentum can be understood as a phononic excitation, propagating in one dimension along the optical axis of the cavity.

We now consider a symmetrically pumped ring cavity [337]. The atoms are very cold and deep in the Lamb-Dicke regime. Using blue-detuned light the atoms will be trapped at the nodes of the standing wave, $kz_j = \pi/2 + kZ_j$, where Z_j are small displacements. Hence, we may expand,

$$e^{\mp 2\imath kz_j} \simeq -(1 \mp 2\imath kZ_j) \ . \tag{48.75}$$

With the abbreviation $\chi \equiv \kappa - \imath(\Delta_c - NU_0)$ and defining the center-of-mass of the small displacements, $Z_{cm} = \frac{1}{N}\sum_j Z_j$, the equation for the two field modes are,

$$\dot{\alpha}_\pm \simeq -\chi\alpha_\pm + \imath NU_0(\mp 2\imath kZ_{cm})\alpha_\mp + \eta \ . \tag{48.76}$$

[10] This is similar to the situation in micromasers, where several atoms can share a single photon.

Neglecting the impact of the atom on the amplitudes of the fields, we may derive the steady-state solution,

$$\alpha_\pm = \eta \frac{\chi + \imath N U_0 (1 \mp 2\imath k Z_{cm})}{\chi^2 + N^2 U_0^2} \ . \tag{48.77}$$

As shown in (48.28) the normalized field intensity can be written as,

$$\tfrac{1}{2\varepsilon_0 c E_1^2} I(z,t) = |\alpha_+|^2 + |\alpha_-|^2 + 2|\alpha_+||\alpha_-| \cos(2kz + 2\theta) \ , \tag{48.78}$$

provided the field amplitudes are expressed by,

$$\alpha_\pm = |\alpha_\pm| e^{\pm \imath \theta} \quad \text{such that} \quad \alpha_+ \alpha_-^* = |\alpha_+||\alpha_-| e^{2\imath\theta} \quad \text{and} \quad \tan 2\theta = \frac{\mathfrak{Im}\, \alpha_+ \alpha_-^*}{\mathfrak{Re}\, \alpha_+ \alpha_-^*} \ . \tag{48.79}$$

Now,

$$\begin{aligned} \tan 2\theta &= \frac{\mathfrak{Im}\,[\chi + \imath N U_0 (1 - 2\imath k Z_{cm})][\chi^* - \imath N U_0 (1 - 2\imath k Z_{cm})]}{\mathfrak{Re}\,[\chi + \imath N U_0 (1 - 2\imath k Z_{cm})][\chi^* - \imath N U_0 (1 - 2\imath k Z_{cm})]} \\ &= 4 N U_0 k Z_{cm} \frac{-\Delta_c + 2 N U_0}{-\kappa^2 - \Delta_c^2 + 4\Delta_c N U_0 - 4N^2 U_0^2 + 4N^2 U_0^2 (k Z_{cm})^2} \\ &\simeq \frac{4 N U_0 (\Delta_c - 2 N U_0)}{\kappa^2 + (\Delta_c - 2 N U_0)^2} k Z_{cm} \ . \end{aligned} \tag{48.80}$$

An individual atom in this optical potential feels the dipolar force,

$$\begin{aligned} m \ddot{z}_j &= [-\hbar U_0 \partial_z I]_{z=z_j} = 4\hbar k U_0 |\alpha_+||\alpha_-| \sin(2kz_j + 2\theta) \\ &= 4\hbar k U_0 \eta^2 \frac{|(\chi + i N U_0)^2 - 4N^2 U_0^2 (k Z_{cm})^2|}{|\chi^2 + N^2 U_0^2|^2} \sin\left(2kz_j + \frac{2 N U_0 (\Delta_c - 2 N U_0)}{\kappa^2 + (\Delta_c - 2 N U_0)^2} 2k Z_{cm}\right) \\ &\simeq \frac{4\hbar k U_0 \eta^2}{\kappa^2 + \Delta_c^2} \sin\left(2kz_j + \frac{2 N U_0 (\Delta_c - 2 N U_0)}{\kappa^2 + (\Delta_c - 2 N U_0)^2} 2k Z_{cm}\right) \equiv \frac{m}{2k} \omega_0^2 \sin(2kz_j - 2\mu_j k Z_{cm}) \ , \end{aligned} \tag{48.81}$$

where,

$$m\omega_0^2 \equiv \frac{8\hbar k^2 U_0 \eta^2}{\kappa^2 + 4U_0^2} \qquad \text{and} \qquad \mu_j \equiv \frac{2 N U_0 |2 N U_0 - \Delta_c|}{\kappa^2 + (2 N U_0 - \Delta_c)^2} \ . \tag{48.82}$$

Expanding this equation around the nodes we readily obtain,

$$\boxed{k\ddot{Z}_j + \omega_0^2 \mu_j \simeq \mu_j k Z_{cm} = \frac{\mu_j}{N} \sum_j k Z_j} \ , \tag{48.83}$$

which describes the force on a single atom. Note that the harmonic force, $\omega_0^2 k Z_j$, on the atom is continuously fed by the center-of-mass force, $\omega_0^2 \mu_j k Z_{cm}$. The above equation can be rewritten as,

$$\begin{pmatrix} k\ddot{Z}_1 \\ k\dot{Z}_1 \\ k\ddot{Z}_2 \\ k\dot{Z}_2 \\ . \end{pmatrix} = \begin{pmatrix} 0 & -\omega_0^2(1 - \frac{\mu_j}{N}) & 0 & -\omega_0^2 \frac{\mu_j}{N} & . \\ 1 & 0 & 0 & 0 & . \\ 0 & -\omega_0^2 \frac{\mu_j}{N} & 0 & -\omega_0^2(1 - \frac{\mu_j}{N}) & . \\ 0 & 0 & 1 & 0 & . \\ . & . & . & . & . \end{pmatrix} \begin{pmatrix} k\dot{Z}_1 \\ kZ_1 \\ k\dot{Z}_2 \\ kZ_2 \\ . \end{pmatrix} \ . \tag{48.84}$$

The eigenvalues of the matrix are $e = \imath\omega_0, \imath\omega_0\sqrt{1-\mu_j}$. Therefore, we expect, in addition to the secular frequency ω_0, a second oscillation frequency,

$$\omega_{cm} = \omega_0\sqrt{1-\mu_j} \ . \tag{48.85}$$

We find splitting in the strong coupling regime, $g > \Gamma$, but we consider the weak coupling regime, $g < \Gamma$, to implement the phononic coupling.

Example 361 (*Two-coupled atoms*): Here we rewrite the field equations for two atoms in center-of-mass coordinates,

$$Z = \frac{z_1 + z_2}{2} \qquad \text{and} \qquad z = z_2 - z_1 \ ,$$

finding,

$$\dot{\alpha}_\pm = (-\kappa + \imath\Delta_c - 2\imath U_0)\alpha_\pm - 2\imath U_0 \alpha_\mp e^{\mp 2\imath k Z} \cos kz + \eta \ .$$

48.2.4.1 Probing the phonon spectrum

To probe the phonon spectrum, we can measure (or simulate) the oscillation of a single atom $z_j(t)$ in the presence of several atoms. The Fourier spectrum of the oscillation should reveal the frequency components of the center-of-mass motion $Z(t)$ and the relative motion.

An experimental method for observing normal modes consists in parametrically exciting the atomic motion at a modulation frequency ω_ϕ and watch out for a resonant enhancement of the vibration amplitude near the secular frequency ω and the collective frequency ω_{cm} both defined in (48.82). In practice, the atomic vibration can be excited by an external force, for example, a Bragg spectroscopic setup as it is used for driving recoil-induced resonances (RIR),

$$\dot{p}_j = 2\imath\hbar k U_0(\alpha_+^*\alpha_- e^{-2\imath k z_j} - \alpha_+\alpha_-^* e^{2\imath k z_j}) + F_{rir}\sin\omega_\phi t \ . \tag{48.86}$$

Alternatively, we may shake the intracavity standing wave by modulating the phase of the pump field,

$$\eta_\pm(t) = \eta e^{\pm\imath\phi_0 \sin\omega_\phi t} \ . \tag{48.87}$$

Fig. 48.11 shows typical resonance curves obtained by simulating the CARL equations (48.50) together with the modulation term (48.87). Being shaken for a while, the atoms suffer parametric heating visible as a noticeable increase of their kinetic energy, as seen in Fig. 48.11(a). The atomic motion, in turn, acts back on the intracavity field fields leading to a modulated photon imbalance between both.

Note, that the phase modulation frequency should not exceed the cavity decay time, $\omega_\phi < \kappa$. Otherwise, even in the absence of atoms, we expect a low-pass behavior as discussed in Sec. 38.2.2, impeding that the applied phase modulation be transformed into an efficient shaking of the phase θ of the intracavity standing wave.

48.2.5 Exercises

48.2.5.1 Ex: Anticorrelated atoms

Study the CARL equations (48.50) for the case of two fixed atoms sitting at positions $kz_1 = kz_2 - \pi$.

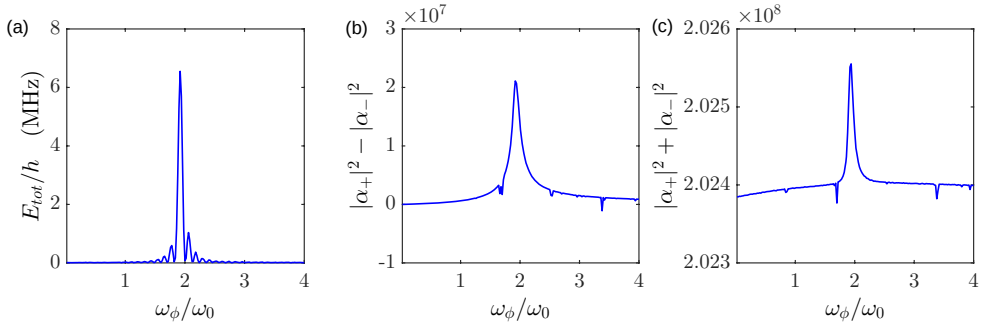

Figure 48.11: (code) Response of the cavity field to a phase modulation of the pump light. (a) Kinetic energy, (b) photon imbalance, and (c) total photon number. The simulation assumes $N = 10^6$ strontium atoms initially at $T = 1\,\mu\text{K}$ driven on the $\lambda = 689\,\text{nm}$ line and $\kappa/2\pi = 3.4\,\text{MHz}$, $\Delta_c = 2U_0$, $\eta = 10^4\kappa$, $NU_0/\kappa = -.02$, $\phi_0 = 0.01$. The calculated secular frequencies are $\omega_0 = 0.35\kappa$ and $\omega_0\sqrt{1-\mu_N} = 0.32\kappa$.

48.2.5.2 Ex: Coupled motion of Rb and Cs atoms in a ring-cavity

Find out by simulation of the classical CARL equation, whether the motion of a Rb atom and a Cs atom can be coupled to the same mode of a ring cavity.

48.2.5.3 Ex: Inertially moving atom in a ring-cavity

Illustrate by simulation of the classical CARL equation, how an inertially moving single atom pushes the wave formed by two counterpropagating modes of a ring cavity.

48.2.5.4 Ex: CARL in a harmonic potential

Extend the CARL dynamics by an additional harmonic potential for the atoms and study the steady state gain as a function of cavity detuning Δ_c.

48.2.5.5 Ex: Impact of potential barriers on CARL

Illustrate by simulation of the classical CARL equations how (a) mirror backscattering and (b) an external harmonic trapping potential influence the dynamics of an atom interacting with two counterpropagating modes of a ring cavity.

48.2.5.6 Ex: CARL without cavity

Discuss whether CARL can be observed without a ring-cavity.

48.2.5.7 Ex: Cavity cooling in a ring cavity

Study cavity cooling in a ring cavity as a function of (a) friction and (b) detuning.

48.2.5.8 Ex: Motion of atoms in a ring-cavity including internal states

Motion of atoms in a ring-cavity, including internal states.

48.3 Phenomena related to CARL

The *collective atomic recoil laser* (CARL) unifies the principles of the FEL and LWI. Assume two-level atoms in their ground state moving against the pump beam $\mathbf{k}_2$. An (at first) weak probe beam k_1 which is blue detuned with respect to $\mathbf{k}_2$ builds a together with $\mathbf{k}_2$ a standing wave fraction moving in direction $\mathbf{v}$. This fraction gives rise to a moving dipole potential $V(\mathbf{r})$ and a light force on the atoms. If the moving standing wave is slower than the atoms (and the light frequency detuning from the atomic resonance is suitable), the atoms fall into the potential valleys by rescattering photons from the pump into the probe wave. This way they amplify the probe (they push the ponderomotive wave like the FEL), deepen the light potential valleys, are therefore further focused, etc.. We get a self-amplifying avalanche and feedback. In this process, the kinetic energy of the atoms is transformed into laser light. Or to resume: Collective recoil with self-bundeling produced by cooperative Compton-scattering generates coherent laser light [111].

The following notes first discuss the basic equations of motion in the limit of very far detuning, where the internal dynamics can be adiabatically eliminated. Then we turn our attention to some characteristic features of CARL.

48.3.1 Recoil-induced resonances

The *recoil-induced resonances* (RIR) can be explained in two complementary pictures [204]. In the Raman picture, an atomic transition stimulates Raman transitions between momentum states of the free atom without influencing the atomic excitation (the atom remains in a dark state) $\rho_{\text{atom}} \otimes |\mathbf{p}\rangle\langle\mathbf{p} + 2\hbar\mathbf{k}|$. Absorption $\Delta > 0$ or amplification $\Delta > 0$ of the probe field $\mathbf{k}_s$ by the pump field $\mathbf{k}_p$ is a result of the population imbalance. However, it is not an excitation imbalance (compare LWI) $\rho_{\text{atom}} \otimes |\mathbf{p} + 2\hbar\mathbf{k}\rangle\langle\mathbf{p} + 2\hbar\mathbf{k}| - \rho_{\text{atom}} \otimes |\mathbf{p}\rangle\langle\mathbf{p}|$. In the Rayleigh picture the RIRs are an effect of coherent backward *Bragg scattering* of the probe wave at the phase-lag between the induced light-shift grating and the atomic density grating resulting from the periodic optical potential.

48.3.1.1 RIR-spectroscopy

Two laser beams 1 and 2 having each two different frequencies $\omega - \Delta\omega/2$ and $\omega + \Delta\omega/2$ are irradiated from two different directions enclosing a small angle θ into the atomic trap,

$$\begin{aligned}\mathcal{E}(\mathbf{r}, t) &= \mathcal{E}_1 + \mathcal{E}_2 \\ &= \mathcal{E}^{(0)} \left[\cos\left(\mathbf{k}_1 \cdot \mathbf{r} - (\omega - \tfrac{1}{2}\Delta\omega)t\right) + \cos(\mathbf{k}_2 \cdot \mathbf{r} - \left(\omega + \tfrac{1}{2}\Delta\omega)t\right)\right] \\ &\approx 2\mathcal{E}^{(0)} \cos\left(\mathbf{K} \cdot \mathbf{r} - \omega t\right) \cos\left(\tfrac{1}{2}\mathbf{q} \cdot \mathbf{r} - \tfrac{1}{2}\Delta\omega t\right) \ ,\end{aligned} \tag{48.88}$$

where $\mathbf{q} \equiv \mathbf{k}_2 - \mathbf{k}_1$ and $\mathbf{k} \equiv \frac{1}{2}(\mathbf{k}_2 + \mathbf{k}_1)$. The cycle-averaged intensities are $I_i(t) = 2\varepsilon_0 c|\mathcal{E}_i|^2 = 4\varepsilon_0 c\mathcal{E}^{(0)} \cos\left(\frac{1}{2}\mathbf{q} \cdot \mathbf{r} - \frac{1}{2}\Delta\omega t\right)$. Atoms coherently interacting with the light

fields (which are tuned far from any atomic resonance) can redistribute the photons between the optical modes in a *nearly-degenerate* four-wave mixing process (4WM) thus modifying the amplitudes $\mathcal{E}_i^{(0)}$ so that a signal occurs.

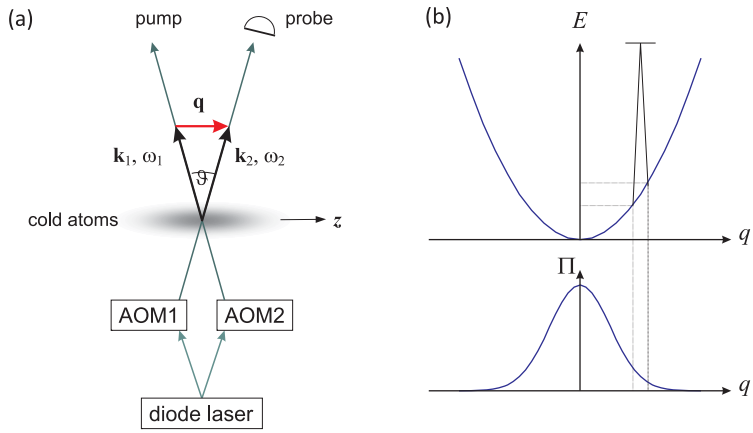

Figure 48.12: Principle scheme for RIR spectroscopy.

From symmetry considerations, it is easy to see that a homogeneous density distribution (along $\mathbf{q}$) of the motionless atoms does not give rise to a signal, neither. So let us assume that the atoms be bunched inside an optical grating according to some periodic distribution $n(z) = n_0 \sin^2 k_\lambda z$, but disregard their kinetics. The signals then generalize to,

$$\begin{aligned}\mathcal{E}_1(z,t) &= \mathcal{E}_1 + \beta n(z)\chi^{(3)}(\mathcal{E}_1+\mathcal{E}_2)\mathcal{E}_1\mathcal{E}_2\mathcal{E}_1 + \beta n(z)\chi^{(3)}(\mathcal{E}_1+\mathcal{E}_2)\mathcal{E}_1\mathcal{E}_2\mathcal{E}_1 \\ &= \mathcal{E}_1 + \beta n(z)\chi^{(3)}\left(2\mathcal{E}^{(0)}\cos\left(\tfrac{1}{2}qz - \tfrac{1}{2}\Delta\omega t\right)\right)\mathcal{E}_1\mathcal{E}_2\mathcal{E}_1\end{aligned} \tag{48.89}$$

and analogous for $\mathcal{E}_2(z,t)$. Or following Lambert-Beer [537],

$$\begin{aligned}I_1(x,z,t) &= |\mathcal{E}_1|^2 \exp\left(2\imath\frac{\pi}{\lambda}\int \chi^{(3)}\left(2E^{(0)}\cos\left(\tfrac{1}{2}qz - \tfrac{1}{2}\Delta\omega t\right)\right)dy\right) \\ &= |\mathcal{E}_1|^2 \exp\left(2\imath\frac{\pi}{\lambda}\int n(x,y,z)...dy\right) \\ &= |\mathcal{E}_1|^2 \exp\left(2\imath\frac{\pi}{\lambda}n_0\sin^2 k_\lambda z\int ...dy\right) \\ I_1(t) &= \int I_1(x,z,t)dxdz\ .\end{aligned} \tag{48.90}$$

Regarding the momentum transfer, the 4WM process can be interpreted as Bragg scattering af the atoms at one of the two counterpropagating standing waves. We develop the theory if Bragg scattering in Sec. 52.2.

48.3.1.2 Temperature measurements via RIR

Temperature measurement are usually carried out by the time-of-flight method followed by absorption imaging. Alternatively, one can perform spectroscopy of RIR

resonances. In the latter case, we detect intensity variations in a probe laser beam, i.e. the polarisation of the sample under the influence of *all* irradiated laser beams. We have seen that $\alpha \propto \mathfrak{Im}\,\chi \propto \mathfrak{Im}\,\mathcal{P} \propto \mathfrak{Im}\,\rho_{12}$. It is thus sufficient to calculate the atomic coherences, if necessary including the motional states of the atoms. Calculated by [397]

$$W(t) = \frac{\pi}{2}\frac{\Omega_1\Omega_2}{\Delta}\sqrt{\frac{mv}{k_\mathrm{B}T}}\left[\frac{\partial}{\partial v}e^{-mv^2/2k_\mathrm{B}T}\right]_{v=\Delta\omega(t)/q} . \tag{48.91}$$

48.3.1.3 RIR-spectroscopy on trapped atoms

In the case of free particles, the Raman beams interact for every detuning with a different velocity class of atoms. The atoms are almost not disturbed. In the case of trapped atoms, a coherence can be excited, and since the atoms periodically change their velocity, be read out or reexcited at a later time. The same atom can thus interact with the Raman beams at different times/detunings. If the trap is a standing wave, the situation is complicated by the fact that there are two overlapping gratings: The standing wave and the Raman grating. However, if the trap is much deeper than the Raman grating the atoms can be considered as localized.

The signature of atomic oscillation is a modulation in the RIR signal with the periodicity of the secular frequency [536, 760].

Let us consider a standing-wave dipole-trap with $\omega_z = 2\pi \times 700\,\mathrm{kHz}$, $\omega_r = 2\pi \times 1\,\mathrm{kHz}$ and $U_{dip} = h \times 30\,\mathrm{MHz} \;= 4000 \times 2\varepsilon = 45\omega_z = 2100\omega_z$. The $100\,\mu\mathrm{K}$ cold atoms are therefore deep inside at the bottom of trap. This implies that the atomic energy levels are sharp and equally distant, and that the transitions are degenerate upon coupling by Raman-beams. If we apply a scan of $\pm 2\pi \times 300\,\mathrm{kHz}$, we will not excite the longitudinal motion. But the radial motion can be excited. As seen earlier the absorption signal is $\alpha \propto \mathfrak{Im}\,\rho_{12}$. What happens to the coherence, if the radiation is swept across a resonance depends on the scanning speed. If the scan is slow, we expect $\alpha \propto \mathfrak{Im}\,\rho_{12}(\infty)$. We should be able to resolve the resonances [397, 399, 398] as peaks at $\pm\omega_r, \pm 2\omega_r, ...$ In contrast, if the scan is fast, as long as Δ_c is far from resonance, the population of the excited level ρ_{22} is just too small and nothing happens. When Δ_c passes through 0, the coherence ρ_{12} is excited, and can now be driven by the laser even when Δ_c is tuned far away. The coherence precesses faster and faster.

Let us compare to the situation of a laser swept across an electric dipole resonance. In analogy to the cavity response in reflection to a laser scanned across an eigenfrequency, we might expect a ringing coming from interference of the radiating electric dipole (which has been induced while the laser was close to resonance) with the original laser frequency. The radiated electric field is proportional to the excited state population. If we allow for a change of the input field, for example $\Delta_c(t)$, the Bloch-equations must be numerically integrated,

$$\rho(t + dt) = \rho(t) + dt\; M\rho(t) \; . \tag{48.92}$$

It is already clear that we should expect a ringing with exactly the time-dependent frequency $\Delta_c(t)$. Fig. 48.13 shows

This simple mathematical model only assumes a resonance with a given width and a frequency-scanned oscillator. The physical nature of the resonance and the level splitting are not specified and the formalism should be applicable to a variety of

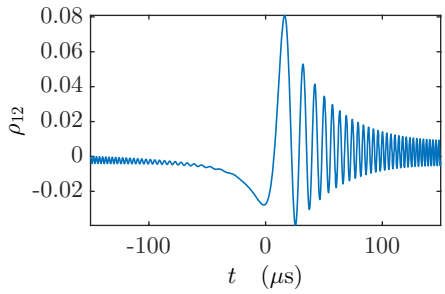

Figure 48.13: (code) Time-evolution of the atomic coherence as the driving laser frequency is swept across resonance. The parameters are $\Gamma = 2\pi \times 8\,\text{kHz}$, $\Omega = 0.2\Gamma$, $\Delta = -50\Gamma..50\Gamma$ and $t = -150..150\,\mu\text{s}$.

situations. A ringing is, in fact, observed for RIR scans, if the scanning speed is too fast, in particular for atoms trapped in optical lattices. Ringing can also be generated in classical harmonic oscillators and laser-driven two-level systems as we will see in Exc. 52.5.4.1.

48.3.1.4 RIR versus CARL

The dynamics is characterized by backaction of the atomic motion onto the cavity field. In this respect there is a connection to RIR resonances in the limit investigated by [537]. While normal RIR is the action of the atomic motion on light fields, they demonstrate that in the same time the Raman-lattice influences the atomic motion. The coherence is limited by the time the photon spends in the sample (similar to the limitation of superradiant Rayleigh scattering, without photonic recycling by a ring-cavity). Real backaction in the sense of coherent interdependence of the photonic and the kinetic degrees of freedom requires recycling of the photons.

48.3.2 FEL: the free electron laser

Normal lasers work by an inversion in the internal degrees of freedom, that is, bound electrons are excited to energetically higher orbitals, from where they can decay by emitting monochromatic light of well-defined frequency. Because, the *free electron laser* (*FEL*) works with beams of *free* electrons, they are tunable over wide frequency ranges. They have much higher efficiencies above 65%.

The principle is the following: Relativistic electrons are guided through an *undulator*, which is a device producing a magnetic field with periodically alternating polarization. Here, the electrons are subjected to a Lorentz force, $\mathbf{F} = -e\mathbf{v} \times \mathbf{B}$, forcing the electrons to oscillate with the periodicity of the undulator field. This corresponds to a dipole moment interacting with the incident light field. The transverse velocity of the electrons within the magnetic field of an incident light produces a Lorentz force in the axial direction called *ponderomotive force*. This force accelerates the electrons when they are a bit slower than the ponderomotive wave. Otherwise the electrons are decelerated. In the second case, the energy of the electrons is transmitted to the light field, which leads to a *bunching* of the atoms. Because it is a parametric

process, there is a continuous energy flow between the field and the motion of the e^- (analogous to parametric Raman cooling). Thus, the FEL converts the kinetic energy of the electron beam into laser radiation. The inversion in a FEL can be interpreted as a relative displacement of the probability distributions for absorption and emission of photons in momentum space,

$$\begin{aligned} W_{abs}(\Delta) &= \mathrm{sinc}^2 \tfrac{1}{2}(\Delta + \varepsilon/2) \\ W_{abs}(\Delta) &= \mathrm{sinc}^2 \tfrac{1}{2}(\Delta - \varepsilon/2) \ , \end{aligned} \tag{48.93}$$

where $\varepsilon = \hbar k^2/2m_e$. The gain is a convolution of the difference of the above distribution with the momentum distribution of the electrons [830].

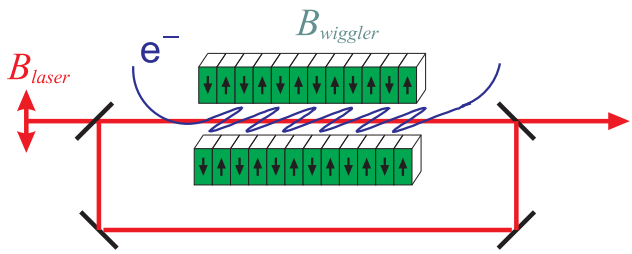

Figure 48.14: Free electron laser.

There various kinds of FELs. In stimulated Compton FELs, described by the shown Feyman graphs, the electrons are scattered by virtual (momentum transfer without energy transfer) photons of the wiggler. In Bremsstrahlungs FEL, the electrons are scattered at a static field. Virtual photons of the static field are scattered at the electrons, who then emit Bremsstrahlung an change their propagation direction. In Raman FELs very dense electron beams produce charge density oscillations, which provides an additional effect. Free Electron Lasers already have a wide range of application ranging from biology and medicine to lithography and material science.

48.3.3 CARL in an ion storage ring

Bonifacio *et al.* [112] suggested to study collective atomic recoil lasing (CARL) with relativistic atoms. They found that using very fast atoms it should, in principle, be possible to get large CARL frequency shifts and much higher power enhancement factors than observed in free-electron lasers (FEL). Relativistic atomic velocities can be achieved in heavy ion accelerators such as the GSI heavy ion accelerator in Darmstadt and TSR ion storage ring in Heidelberg. Therefore the question arises, if CARL could be an alternative way to produce very energetic and intense UV radiation in concurrence to the FEL. In fact, CARL-based systems may prove more powerful and versatile as their electronic counterparts: Cooling techniques based on electron beams or on hybrid optical-radiofrequency friction forces are able to cool the ionic beams down to mK temperatures.

The CARL which has been predicted ten years ago by Bonifacio *et al.* [111], has recently been observed with cold atoms stored in a high-finesse ring cavity [542, 943]. This proof of principle, now may motivate a deeper study of the figure of merit of a

relativistic CARL. This short note, however, shows that a relativistic CARL is still, in my opinion, far from being realizable.

48.3.4 Matter wave superradiance

There is a close relationship between CARL and the phenomenon of *matter wave superradiance* (or *superradiant Rayleigh scattering*) [110, 805], which will be discussed in the following sections.

In 1999 the group of W. Ketterle at the MIT made a surprising observation, when it illuminated an elongated Bose-Einstein condensate with a short linearly polarized laser pulse traversing the condensate perpendicularly to the long axis [464]. Instead of producing radiation with a dipole pattern, as we might expect for a polarized atomic cloud undergoing Rayleigh scattering, they observed emission of directional light bursts along the symmetry axis of the condensate. They also observed that some of the atoms were accelerated at angles of 45°. And these atoms could emit other generations of atoms at angles of 45°.

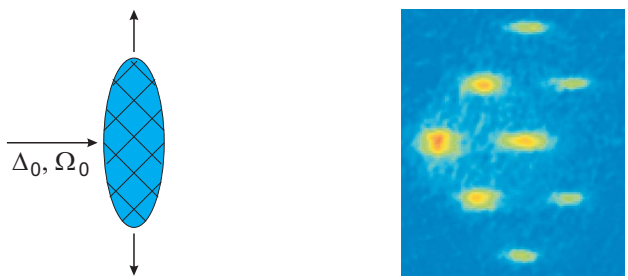

Figure 48.15: (code) Flight-of-time measurement of the atomic momentum distribution after matter wave superradiance.

The phenomenon was explained as follows. Let us imagine a first photon scattered by an atom into the direction of the long axis of the condensate. This atom will be accelerated by the photonic recoil in a direction of 135° with respect to the direction of the photon, and it will interfere with the rest of the condensate thus generating a standing matter wave of oriented in such a way, that the following photons are scattered into the same direction as the first one via Bragg scattering. This reinforces the contrast of the matter wave, etc.. We obtain an exponential gain of photons in the mode defined by the first scattered photon, as well as of the mode receiving the scattered matter wave. As the path of the gain is longer along the long axis of the condensate, this mode is favored. That is, the condensate can be considered as a cavity embracing the solid angle $\Omega_{\rm sol}$.

The Rayleigh scattering rate for a single atom is,

$$R_1 = \sin^2\theta\sigma(\Delta_a)\frac{I}{\hbar\omega}\frac{3\Omega_{\rm sol}}{8\pi}\ , \tag{48.94}$$

where $\theta$is the angle between the polarization of the incident laser (intensity I) and the direction into which the light is scattered. The cross-section is $\sigma(\Delta_a) = \sigma_0\frac{\Gamma^2}{4\Delta^2+2\Omega^2+\Gamma^2}$, where $\sigma_0 = 3\frac{\lambda^2}{2\pi}$. Now, for the set of atoms, the superradiant scattering rate is not

only amplified by the number of condensed atoms, N, but also by the number of atoms, N_r, already being in the mode receiving scattered atoms,

$$R_{sr} = R_1 N \frac{N_r + 1}{2} \ . \tag{48.95}$$

This is the *superradiance matter wave*.

48.3.5 Exercises

48.3.5.1 Ex: Good and bad cavity regime

What are the characteristics distinguishing the good from the bad cavity limit.

48.3.5.2 Ex: Ringing in resonant systems

In this exercise we study ringing in (a) an excited classical harmonic oscillator and (b) in a laser-driven two-level system.

48.4 Quantization of the atomic motion in cavities

At the beginning of this chapter we set up the complete Hamiltonian of the coupled atom-cavity system. Then tracing over dissipative degrees of freedom, we derived the master equation or derived the Heisenberg equations for the operators appearing in the remaining Hamiltonian quantum mechanically. But then for CARL we restricted to a classical treatment of the motion, as well as of the cavity modes.

Resuming the discussion started in Sec. 48.1.5 we will, in the remaining sections of this chapter, analyze effects due to the *quantization* of degrees of freedom represented by operators. The present section will (i) on a quantum description of the motion (with and without adiabatic elimination of the internal atomic dynamics and (ii) on issues arising from the presence of many atoms.

48.4.1 Quantum description of the motion

Concretely, let us analyze again the situation of a single atom interacting with a ring cavity. We assume validity of the adiabatic elimination of the internal atomic excitation and want to treat the light fields as classical. In contrast, the atomic motion is considered as quantum:

$$|\psi\rangle = |z\rangle_{\text{motion}} \otimes \cancelto{\text{classical}}{|\alpha_+\rangle \otimes |\alpha_-\rangle} \otimes \cancelto{\text{adiab.elim.}}{|i\rangle_{\text{electron}}} \to |z\rangle \ . \tag{48.96}$$

Since the motion, being the only quantum degree of freedom, is not subject to dissipation, we may use the Schrödinger equation in addition to Heisenberg equations for the light fields. Then, following the procedure outlined in Sec. 48.1.5, with z being the only quantum number, we find that the system is completely described by the dynamics of the expansion coefficients,

$$\begin{aligned} \imath\hbar \frac{d}{dt} \langle z|\psi(t)\rangle &= \langle z|\hat{H}|\psi(t)\rangle \\ \dot{\alpha}_\pm &= \langle z| \tfrac{\imath}{\hbar}[\hat{H}, \hat{a}_\pm] - \kappa \hat{a}_\pm |z\rangle \ . \end{aligned} \tag{48.97}$$

Plugging in the Hamiltonian (48.26), we obtain the Schrödinger equation for the particle's motional wavefunction [11],

$$\imath\hbar\frac{d}{dt}\langle z|\psi(t)\rangle = \frac{p^2}{2m}\langle z|\psi(t)\rangle + U_0\langle z|\hat{a}_+^\dagger\hat{a}_- e^{-2\imath k\hat{z}} + \hat{a}_+\hat{a}_-^\dagger e^{2\imath k\hat{z}}|\psi(t)\rangle \ , \tag{48.98}$$

and the Heisenberg equations for the light fields,

$$\begin{aligned}\dot{\alpha}_\pm &= \langle z|(-\kappa+\imath\Delta_c-\imath U_0)\hat{a}_\pm + \imath U_0 e^{\mp 2\imath k\hat{z}}\hat{a}_\mp + \eta_\pm|z\rangle \\ &= (-\kappa+\imath\Delta_c-\imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\langle z|\int dz|\psi(t)\rangle\langle\psi(t)|e^{\mp 2\imath k\hat{z}}|z\rangle + \eta_\pm \\ &= (-\kappa+\imath\Delta_c-\imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\int dz|\psi(z,t)|^2 e^{\mp 2\imath kz} + \eta_\pm \ .\end{aligned} \tag{48.99}$$

In summary,

$$\boxed{\begin{aligned}\dot{\psi}(z) &= \frac{\imath\hbar}{2m}\frac{d^2}{dz^2}\psi(z) - \imath U_0\left(\alpha_+^\dagger\alpha_- e^{-2\imath kz} + \alpha_+\alpha_-^\dagger e^{2\imath kz}\right)\psi(z) \\ \dot{\alpha}_\pm &= (-\kappa+\imath\Delta_c-\imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\int dz|\psi(z)|^2 e^{\mp 2\imath kz} + \eta_\pm\end{aligned}} \ . \tag{48.100}$$

These are the new CARL equations that should be used in cases when the particle is *slower than the recoil velocity*, in which its motion must be described as a propagating matter wave. Note, that under this form, the equations can easily be generalized to apply to macroscopic wavefunctions such as a Bose-Einstein condensate.

The expectation value of the particle's position is then calculated via,

$$\begin{aligned}z(t) &= \langle\psi(0)|\hat{z}(t)|\psi(0)\rangle = \langle\psi(0)e^{-\imath\hat{H}t}|\hat{z}|e^{\imath\hat{H}t}\psi(0)\rangle \\ &= \langle\psi(t)|\hat{z}|\psi(t)\rangle = \int\langle\psi(t)|z\rangle\langle z|\hat{z}|z'\rangle\langle z'|\psi(t)\rangle dz dz' = \int z|\psi(t,z)|^2 dz \ .\end{aligned} \tag{48.101}$$

We can verify that the expectation value of the particle's position satisfies the classical equation of motion,

$$\begin{aligned}m\ddot{z} &= \langle\psi(t)|m\ddot{\hat{z}}|\psi(t)\rangle = 2\imath\hbar kU_0\left(\hat{a}_+^\dagger\hat{a}_-\langle\psi(t)|e^{-2\imath k\hat{z}}|\psi(t)\rangle - \hat{a}_+\hat{a}_-^\dagger\langle\psi(t)|e^{2\imath k\hat{z}}|\psi(t)\rangle\right) \\ &= 2\imath\hbar kU_0\left(\hat{a}_+^\dagger\hat{a}_- e^{-2\imath k\langle\psi(t)|\hat{z}|\psi(t)\rangle} - \hat{a}_+\hat{a}_-^\dagger e^{2\imath k\langle\psi(t)|\hat{z}|\psi(t)\rangle}\right) \\ &= 2\imath\hbar kU_0\left(\hat{a}_+^\dagger\hat{a}_- e^{-2\imath kz} - \hat{a}_+\hat{a}_-^\dagger e^{2\imath kz}\right) \ .\end{aligned} \tag{48.102}$$

48.4.1.1 About the origin of quantized motion

The quantization of the light field into photons is, as discussed in Chp. 40, an intrinsic property of light. In contrast, the quantization of atomic motion is less obvious, because the atoms are not confined in a trapping potential. The reason for it lies in

[11] Terms of the Hamiltonian (48.26) which do not depend on z or p have been ignored, as they can be removed form the Schrödinger equation by a simple unitary transformation. Note that this can be done even though these terms depend on the field amplitudes $\alpha_\pm$.

the monochromaticity of the driving laser fields and the one-dimensional geometry of the system, which allow us to write the recoil operator (23.293) or (24.143) as,

$$\boxed{e^{2\imath k\hat{z}} = \int |p + 2\hbar k\rangle\langle p| dp} \ . \tag{48.103}$$

Inserting it into the interaction part of the CARL Hamiltonian,

$$\hat{H}_{int} = U_0(e^{-2\imath k\hat{z}}\hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger) \ , \tag{48.104}$$

the Schrödinger equation for the expanded wavefunction

$$|\psi\rangle = \int c(p)|p\rangle dp \tag{48.105}$$

yields,

$$\begin{aligned} \imath\hbar\frac{d}{dt}\langle p|\psi\rangle &= U_0\hat{a}_+^\dagger\hat{a}_-\langle p|e^{-2\imath k\hat{z}}|\psi\rangle + U_0\hat{a}_+\hat{a}_-^\dagger\langle p|e^{2\imath k\hat{z}}|\psi\rangle \\ = \imath\hbar\frac{d}{dt}c(p) &= U_0[\hat{a}_+^\dagger\hat{a}_- c(p+2\hbar k) + \hat{a}_+\hat{a}_-^\dagger c(p-2\hbar k)] \ . \end{aligned} \tag{48.106}$$

That is, if the initial momentum distribution is narrow, $\Delta p \ll 2\hbar k$, and if CARL-induced recoil due to backscattering of photons between counterpropagating modes is the only force acting on the atoms, the momentum of the atoms can only adopt discrete values in units of $2\hbar k$, *as if the atomic velocity were quantized.* That is, the quantization of the field is, in some way, imprinted on the distribution of the atomic moment, so that we may as well use a discrete notation,

$$|\psi\rangle = \sum_\nu c_\nu|\nu\rangle \ , \tag{48.107}$$

such that [12],

$$\imath\hbar\frac{d}{dt}c_\nu = U_0\hat{a}_+^\dagger\hat{a}_- c_{\nu+1} + U_0\hat{a}_+\hat{a}_-^\dagger c_{\nu-1} \ . \tag{48.108}$$

Example 362 (*Analogy to the Bose-Hubbard Hamiltonian*): Interestingly the CARL Hamiltonian with quantized motion (48.104) has, in momentum space, a similar shape as the 1D Bose-Hubbard Hamiltonian in position space,

$$\begin{aligned} \hat{H} &= \sum_\nu \hbar\omega_{\rm rec}\nu^2 + U_0\sum_\nu\Big(|\nu-1\rangle\langle\nu|\hat{a}_+^\dagger\hat{a}_- + |\nu-1\rangle\langle\nu|\hat{a}_+\hat{a}_-^\dagger\Big) \\ &= \hbar\omega_{\rm rec}\sum_\nu\nu^2 + U_0\hat{a}_+^\dagger\hat{a}_-\sum_\nu\hat{A}_{\nu-1}^\dagger\hat{A}_\nu + U_0\hat{a}_+\hat{a}_-^\dagger\sum_\nu\hat{A}_{\nu+1}^\dagger\hat{A}_\nu \ . \end{aligned}$$

[12] Note that, instead of expanding the state $|\psi\rangle$, we could expand the motional wavefunction into plane waves,

$$\langle z|\tilde{\psi}\rangle = \tilde{\psi}(z) = \tfrac{1}{\sqrt{2\pi}}\sum_n c_n(t)e^{2\imath nkz} \qquad \text{normalized as} \qquad \int dz|\tilde{\psi}(z)|^2 = 1 = \sum_n |c_n(t)|^2 \ .$$

Insertion of this expansion into the quantized CARL equations (48.100) yields the same results.

Now, it is important to understand that the statement that *photonic recoil is quantized does not mean that the dipolar optical force can only be transmitted in units of* $2\hbar k$, as if the force needed to accumulate a certain amount of energy before it makes a sudden transition to a different momentum state. Rather, the probability to find an initially resting atom subject to a force in the momentum state $2\hbar k$ gradually increases with time. The atom gradually evolves into a coherent superposition of states $|0\rangle + |2\hbar k\rangle + |4\hbar k\rangle + ..$, and only when we *measure* the momentum distribution will it have to decide in which state it ended up. The expectation value of the center-of-mass momentum linearly, as long as the force is constant. A slide show on the quantized CARL can be viewed at (watch talk).

48.4.2 Discretization of the momentum states

We will now assume that, for the physical reasons described above, the motional state of the atom can only exist with momenta corresponding to multiples of twice the photonic recoil.

48.4.2.1 Schrödinger equation approach

We basically repeat the treatment of Sec. 48.4.1, but now expanding the motion on a discrete basis of momenta labeled by an integer number ν,

$$|\psi\rangle = |\nu\rangle_{\text{motion}} \otimes \cancelto{\text{classical}}{|\alpha_+\rangle \otimes |\alpha_-\rangle} \otimes \cancelto{\text{adiab.elim.}}{|i\rangle_{\text{electron}}} \to |\nu\rangle \ . \tag{48.109}$$

Applying the recipe detailed at the beginning of Sec. 48.4, we write down the same Schrödinger equation as in (48.98) [13], but now projecting on $\langle\nu|$ rather than on $\langle z|$ and inserting the expansion (48.107) and,

$$e^{2\imath k\hat{z}} = \sum_\nu |\nu+1\rangle\langle\nu| \qquad \text{and} \qquad \hat{p} = \sum_\nu \nu 2\hbar k|\nu\rangle\langle\nu| \ . \tag{48.110}$$

We get,

$$\langle\nu|\imath\hbar\frac{d}{dt}\sum_{\nu''} c_{\nu''}|\nu''\rangle = \langle\nu|\sum_{\nu'}\frac{(\nu' 2\hbar k)^2}{2m}|\nu'\rangle\langle\nu'| \tag{48.111}$$
$$+ U_0\left(\sum_{\nu'}|\nu'-1\rangle\langle\nu'|\hat{a}_+^\dagger\hat{a}_- + \sum_{\nu'}|\nu'+1\rangle\langle\nu'|\hat{a}_+\hat{a}_-^\dagger\right) \ .$$

And from the Heisenberg equation (48.15) for light modes,

$$\langle\psi|\dot{\hat{a}}_\pm|\psi\rangle = \langle\psi|(-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_\pm - \imath U_0 e^{\mp\imath 2k\hat{z}}\hat{a}_\mp + \eta_\pm|\psi\rangle \ , \tag{48.112}$$

we get,

$$\sum_{\nu',\nu''}\langle\nu'|c_\nu^*\dot{\hat{a}}_\pm c_{\nu''}|\nu''\rangle = \sum_{\nu,\nu',\nu''}\langle\nu'|c_{\nu'}^*\left[(-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_\pm - \imath U_0|\nu\mp 1\rangle\langle\nu|\hat{a}_\mp + \eta_\pm\right]c_{\nu''}|\nu''\rangle \ . \tag{48.113}$$

[13] Here again, as done in Sec. 48.4.1, we ignore terms of the Hamiltonian (48.26) which do not depend on z or p.

Finally,

$$\boxed{\begin{aligned} \dot{c}_\nu &= -4\imath\omega_{\rm rec}\nu^2 c_\nu - \imath U_0\left(\alpha_+^*\alpha_- c_{\nu+1} + \alpha_+\alpha_-^* c_{\nu-1}\right) \\ \dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm - \imath U_0\alpha_\mp \sum_\nu c_{\nu\mp1}^* c_\nu + \eta_\pm \end{aligned}} \,. \tag{48.114}$$

In Exc. 48.4.7.1 and 48.4.7.2 we study the equations (48.114) in the presence of a constant external force.

48.4.2.2 Master equation approach

As in the situation under study the motion is the only quantum degree of freedom and not subject to dissipation, a master equation approach is useless, and we will show it here only for completeness.

In 48.4.7.3 we show a derivation obtained by directly inserting the adiabatically simplified Hamiltonian (48.26) into the Liouville equation (48.8). The result is,

$$\boxed{\begin{aligned} \dot{\rho}_{\mu,\nu} &= \imath(\nu-\mu)\left[(\nu+\mu)\omega_{\rm rec} - \Delta_c\right]\rho_{\mu,\nu} \\ &\quad + \imath U_0\left[\alpha_+^*\alpha_-(\rho_{\mu,\nu-1} - \rho_{\mu+1,\nu}) + \alpha_-^*\alpha_+(\rho_{\mu,\nu+1} - \rho_{\mu-1,\nu})\right] \\ \dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm - \imath U_0\alpha_\mp \sum_\nu \rho_{\nu,\nu\mp1} + \eta_\pm \end{aligned}} \,. \tag{48.115}$$

48.4.3 Quantization of atomic motion without adiabatic elimination

So far we have discussed the quantization of the atomic motion in the CARL equations, which were obtained by adiabatic elimination of the electronically excited state. In the following, we will quantize the motion directly in the equations of motion (48.15) for the observables and in the Liouville equation for the density operator. We quantize the atomic motion along the optical z-axis simply by assuming that, in this direction, the momentum only exists in multiples of $\hbar k$, and organize up the Hilbert space like this,

$$|\psi\rangle = |\nu\rangle_{\rm motion} \otimes |i\rangle_{\rm electron} \otimes \cancelto{\text{classical}}{|n\rangle_+ \otimes |m\rangle_-} \to |\nu, i\rangle \,, \tag{48.116}$$

that is, skipping the quantum number counting the photons, we will treat the light fields classically, $\hat{a}_\pm = \alpha_\pm$,

$$\begin{aligned} \hat{p} &= \sum_\nu \nu\hbar k|\nu\hbar k\rangle\langle\nu\hbar k| \otimes \mathbb{I} \\ e^{-\imath k\hat{z}} &= \sum_\nu |\nu\hbar k - \hbar k\rangle\langle\nu\hbar k| \otimes \mathbb{I} \\ \hat{\sigma}^+ &= \mathbb{I} \otimes |2\rangle\langle 1| \\ \hat{\rho} &= |\psi\rangle\langle\psi| = \sum_{\mu,\nu,i,j} c_{\mu,i}^* c_{\nu,j} |\mu\rangle\langle\nu| \otimes |i\rangle\langle j| \end{aligned} \,, \tag{48.117}$$

where in the last equation we defined $c_{\nu,j} = \langle p, j|\psi(t)\rangle = \langle \nu\hbar k, j|\psi(t)\rangle = \langle \nu, j|\psi(t)\rangle$, such that,

$$\rho_{\mu,\nu;i,j} \equiv \langle \mu, i|\hat{\rho}|\nu, j\rangle = c^*_{\mu,i} c_{\nu,j} \ . \tag{48.118}$$

Adopting the short notation $|\nu\rangle \equiv |\nu\hbar k\rangle$ we can write the state of the system,

$$\begin{aligned}
|\psi(t)\rangle &= \sum_\nu c_{\nu,1}|\nu\hbar k, 1\rangle + c_{\nu,2}|\nu\hbar k, 2\rangle \qquad (48.119)\\
\langle\psi(t)|\hat{p}|\psi(t)\rangle &= \hbar k \sum_\nu \nu(|c_{\nu,1}|^2 + |c_{\nu,2}|^2)\\
\langle\psi(t)|e^{\pm\imath k\hat{z}}|\psi(t)\rangle &= \sum_\nu (c^*_{\nu\pm1,1}c_{\nu,1} + c^*_{\nu\pm1,2}c_{\nu,2})\\
\langle\psi(t)|\hat{a}|\psi(t)\rangle &= \alpha \sum_\nu (|c_{\nu,1}|^2 + |c_{\nu,2}|^2) = \alpha\\
\langle\psi(t)|\hat{\sigma}^-|\psi(t)\rangle &= \sum_\nu c^*_{\nu,1}c_{\nu,2}\\
\langle\psi(t)|\hat{\sigma}_z|\psi(t)\rangle &= \sum_\nu (|c_{\nu,2}|^2 - |c_{\nu,1}|^2) \ .
\end{aligned}$$

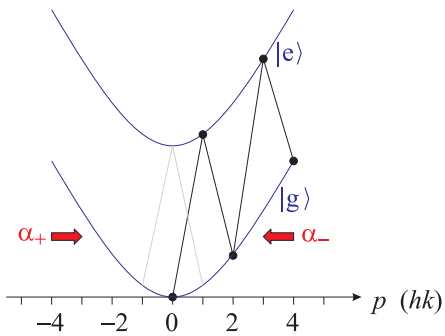

Figure 48.16: Illustration of the quantized motion.

To describe the dynamics of the system we could use the Schrödinger equation, but the Hamiltonian (48.4) does not contain spontaneous emission nor cavity decay. So, let us employ the equations of motion (48.15), which were derived from a master equation. The equation of motion for the field yields,

$$\begin{aligned}
\dot{\alpha}_\pm &= \langle\psi(t)|\dot{\hat{a}}_\pm|\psi(t)\rangle = \langle\psi(t)|(-\kappa + \imath\Delta_c)\hat{a}_\pm - \imath g\hat{\sigma}^- e^{\mp\imath k\hat{z}} + \eta_\pm|\psi(t)\rangle \qquad (48.120)\\
&= (-\kappa + \imath\Delta_c)\alpha_\pm + \eta_\pm - \imath g \sum_\nu c^*_{\nu\mp1,1}c_{\nu,2}\\
&= (-\kappa + \imath\Delta_c)\alpha_\pm + \eta_\pm - \imath g \sum_\nu \rho_{\nu\mp1,\nu;1,2} \ .
\end{aligned}$$

For the atomic motion we get,

$$\dot{x} = \langle\psi(t)|\dot{\hat{x}}|\psi(t)\rangle = \frac{1}{m}\langle\psi(t)|\hat{p}|\psi(t)\rangle = \frac{\nu\hbar k}{m} \ , \tag{48.121}$$

and

$$\begin{aligned}
\dot{p} &= \langle\psi(t)|\dot{\hat{p}}|\psi(t)\rangle \qquad (48.122)\\
&= \langle\psi(t)|\imath g\hbar k\hat{\sigma}^-\left(\hat{a}_+^\dagger e^{-\imath k\hat{z}} - \hat{a}_-^\dagger e^{\imath k\hat{z}}\right) - \imath g\hbar k\hat{\sigma}^+\left(\hat{a}_+ e^{\imath k\hat{z}} - \hat{a}_- e^{-\imath k\hat{z}}\right)|\psi(t)\rangle\\
&= \sum_\nu \imath g\hbar k\left(\alpha_+^* c_{\nu-1,1}^* c_{\nu,2} - \alpha_-^* c_{\nu+1,1}^* c_{\nu,2} - \alpha_+ c_{\nu+1,1} c_{\nu,2}^* + \alpha_- c_{\nu-1,1} c_{\nu,2}^*\right)\\
&= \sum_\nu \imath g\hbar k(\alpha_+^*\rho_{\nu-1,\nu;1,2} - \alpha_-^*\rho_{\nu+1,\nu;1,2} - \alpha_+\rho_{\nu,\nu+1;2,1} - \alpha_-\rho_{\nu,\nu-1;2,1})\ .
\end{aligned}$$

48.4.3.1 Maxwell-Bloch equations without adiabatic elimination

Analogously to the treatment in Sec. 39.3.2, we will now derive the master equation without adiabatic elimination of the excited state (in this case called *Maxwell-Bloch equations* from the Liouville equation [first line of Eq. (48.8)] using the Hamiltonian (48.4). The coherent part is,

$$\begin{aligned}
\dot{\rho}_{\mu,\nu;i,j} &\equiv \langle\mu,i|\dot{\hat{\rho}}|\nu,j\rangle = -\imath\langle\mu,i|[\hat{H},\hat{\rho}]|\nu,j\rangle \qquad (48.123)\\
&= -\imath\sum_{p,u}\langle\mu,i|\hat{H}|p,u\rangle\rho_{p,\nu;u,j} + \imath\sum_{p,u}\rho_{\mu,q;i,v}\langle p,u|\hat{H}|\nu,j\rangle\\
&= -\imath\left[\frac{(\mu\hbar k)^2}{2m} - \Delta_a\delta_{i2} - \Delta_c(|\alpha_+|^2 + |\alpha_-|^2) - \imath\eta_+(\alpha_+ - \alpha_+^*) - \imath\eta_-(\alpha_- - \alpha_-^*)\right]\rho_{\mu,\nu;i,j}\\
&\quad - \imath g\left[\alpha_+^*\delta_{i1}\rho_{\mu+1,\nu;2,j} + \alpha_+\delta_{i2}\rho_{\mu-1,\nu;1,j} + \alpha_-^*\delta_{i1}\rho_{\mu-1,\nu;2,j} + \alpha_-\delta_{i2}\rho_{\mu+1,\nu;1,j}\right]\\
&\quad + \imath\left[\frac{(\nu\hbar k)^2}{2m} - \Delta_a\delta_{j2} - \Delta_c\left(|\alpha_+|^2 + |\alpha_-|^2\right) - \imath\eta_+(\alpha_+ - \alpha_+^*) - \imath\eta_-(\alpha_- - \alpha_-^*)\right]\rho_{\mu,\nu;i,j}\\
&\quad + \imath g\left[\alpha_+^*\delta_{j2}\rho_{\mu,\nu-1;i,1} + \alpha_+\delta_{j1}\rho_{\mu,\nu+1;i,2} + \alpha_-^*\delta_{j2}\rho_{\mu,\nu+1;i,1} + \alpha_-\delta_{j1}\rho_{\mu,\nu-1;i,2}\right]\\
&= \left[\imath\frac{(\nu^2-\mu^2)(\hbar k)^2}{2m} + \imath\Delta_a(\delta_{i2} - \delta_{j2})\right]\rho_{\mu,\nu;i,j}\\
&\quad + \imath g\left[\alpha_+^*\left(\delta_{j2}\rho_{\mu,\nu-1;i,1} - \delta_{i1}\rho_{\mu+1,\nu;2,j}\right) + \alpha_+\left(\delta_{j1}\rho_{\mu,\nu+1;i,2} - \delta_{i2}\rho_{\mu-1,\nu;1,j}\right)\right.\\
&\qquad \left. + \left(\alpha_-^*\delta_{j2}\rho_{\mu,\nu+1;i,1} - \delta_{i1}\rho_{\mu-1,\nu;2,j}\right) + \alpha_-\left(\delta_{j1}\rho_{\mu,\nu-1;i,2} - \delta_{i2}\rho_{\mu+1,\nu;1,j}\right)\right]\ .
\end{aligned}$$

The incoherent part comprises the spontaneous decay [second line of Eq. (48.8)],

$$\begin{aligned}
\langle\mu,i|\mathcal{L}_{atom-vac}\hat{\rho}|\nu,j\rangle &= -\gamma\langle\mu,i|\left[\hat{\sigma}^+\hat{\sigma}^-\hat{\rho} - 2\hat{\sigma}^-\hat{\rho}\hat{\sigma}^+ + \hat{\rho}\hat{\sigma}^+\hat{\sigma}^-\right]|\nu,j\rangle \qquad (48.124)\\
&= -\gamma\sum_{p,u}\langle\mu,i|\hat{\sigma}^+\hat{\sigma}^-|p,u\rangle\rho_{p,\nu;u,j} + 2\gamma\sum_{p,u,q,v}\langle\mu,i|\hat{\sigma}^-|p,u\rangle\rho_{p,q;u,v}\langle q,v|\hat{\sigma}^+|\nu,j\rangle.\\
&\quad - \gamma\sum_{p,u}\rho_{\mu,p;i,u}\langle p,u|\hat{\sigma}^+\hat{\sigma}^-|\nu,j\rangle\\
&= -\gamma\left[\delta_{i2}\rho_{\mu,\nu;i,j} - 2\delta_{i1}\delta_{j1}\rho_{\mu,\nu;2,2} + \delta_{j2}\rho_{\mu,\nu;i,j}\right]
\end{aligned}$$

and the cavity decay [third line of Eq. (48.8)],

$$\langle\mu,i|\mathcal{L}_{cavity-vac,\pm}\hat{\rho}|\nu,j\rangle = -\kappa\langle\mu,i|\hat{a}_\pm^\dagger\hat{a}_\pm\hat{\rho} - 2\hat{a}_\pm\hat{\rho}\hat{a}_\pm^\dagger + \hat{\rho}\hat{a}_\pm^\dagger\hat{a}_\pm|\nu,j\rangle = 0\ . \qquad (48.125)$$

Finally, using the definition of the recoil shift $\omega_{\rm rec} = \hbar k^2/2m$ we get,

$$\boxed{\begin{aligned}
\dot\rho_{\mu,\nu;1,1} &= \imath(\nu^2-\mu^2)\omega_{\rm rec}\rho_{\mu,\nu;1,1} + 2\gamma\rho_{\mu,\nu;2,2} \\
&+ \imath\hbar g\left[-\alpha_+^*\rho_{\mu+1,\nu;2,1} + \alpha_+\rho_{\mu,\nu+1;1,2} - \alpha_-^*\rho_{\mu-1,\nu;2,1} + \alpha_-\rho_{\mu,\nu-1;2,1}\right] \\
\dot\rho_{\mu,\nu;1,2} &= \left[\imath(\nu^2-\mu^2)\omega_{\rm rec} - \imath\hbar\Delta_a\right]\rho_{\mu,\nu;1,2} - \gamma\rho_{\mu,\nu;1,2} \\
&+ \imath\hbar g\left[\alpha_+^*\rho_{\mu,\nu-1;1,1} - \alpha_+^*\rho_{\mu+1,\nu;2,2} + \alpha_-^*\rho_{\mu,\nu+1;1,1} - \alpha_-^*\rho_{\mu-1,\nu;2,2}\right] \\
\dot\rho_{\mu,\nu;2,1} &= \left[\imath(\nu^2-\mu^2)\omega_{\rm rec} + \imath\hbar\Delta_a\right]\rho_{\mu,\nu;2,1} - \gamma\rho_{\mu,\nu;2,1} \\
&- \imath\hbar g\left[\alpha_+\rho_{\mu-1,\nu;1,1} - \alpha_+\rho_{\mu,\nu+1;2,2} + \alpha_-\rho_{\mu+1,\nu;1,1} - \alpha_-\rho_{\mu,\nu-1;2,2}\right] \\
\dot\rho_{\mu,\nu;2,2} &= \imath(\nu^2-\mu^2)\omega_{\rm rec}\rho_{\mu,\nu;2,2} - 2\gamma\rho_{\mu,\nu;2,2} \\
&+ \imath\hbar g\left[\alpha_+^*\rho_{\mu,\nu-1;2,1} - \alpha_+\rho_{\mu-1,\nu;1,2} + \alpha_-^*\rho_{\mu,\nu+1;2,1} - \alpha_-\rho_{\mu+1,\nu;1,2}\right] \\
\dot\alpha_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm + \eta_\pm - \imath g\sum_\nu \rho_{\nu\mp1,\nu;1,2}
\end{aligned}} \quad . \tag{48.126}$$

We note $\hat\rho_{\mu,\nu;2,1} = \hat\rho^*_{\nu,\mu;1,2}$.

The equations (48.126) form a set a equations to describe the quantized CARL without adiabatic elimination. And as shown in the derivation of the CARL equations (48.25), they contain radiation pressure. In Exc. 48.4.7.4 we study the quantized CARL Maxwell-Bloch equations without adiabatic elimination of the excited state for a three-level system.

48.4.4 Quantized motion with many particles

The Hamiltonian (48.98) holds for a single atom. If clouds of thermal atoms are considered, we may switch to a classical description of the motion, as done in (48.46). In the case of very cold (below the recoil limit) but still independent atoms, we may assume that they all are coherently distributed over the same momentum states. We may then apply a unique momentum state expansion for all atoms, as shown in the subsequent section.

If on the other hand quantum statistics play a role, then we need to replace the wavefunction in the Schrödinger equation (48.98) by field operators, as done in Sec. 52.5. In the following sections, we will restrict to single atoms that can be in a coherent superposition of momentum states or many atoms in a matter wave that can be treated as a c-number, e.g. a Bose-condensate without fluctuations.

48.4.4.1 Modal expansion of the motion of many independent atoms in the adiabatic approximation for one-sided pumping

Our starting point is the quantum version of the CARL equations (48.25), where we neglect spontaneous emission, $\gamma_0 = 0$. Setting $\alpha_+ = \eta_+/\kappa$ and $\eta_- = 0$ we get,

$$\boxed{\begin{aligned}
\dot{\hat a}_- &= (-\kappa + \imath\Delta_c - \imath U_0)\hat a_- - \imath U_0\tfrac{\eta_+}{\kappa}e^{-2\imath k\hat z_j} \\
m\ddot{\hat z}_j &= 2\imath\hbar k U_0(\hat a_+^\dagger\hat a_- e^{-2\imath k\hat z_j} - \hat a_+\hat a_-^\dagger e^{2\imath k\hat z_j})
\end{aligned}} \quad , \tag{48.127}$$

where the index j runs over all atoms. For this case, the total momentum is a constant of motion for N atoms is,

$$[\hat{H}, 2\hbar k \hat{a}_-^\dagger \hat{a}_- + \sum_{j=1}^{N} \hat{p}_j] = 0 \ . \tag{48.128}$$

where the Hamiltonian is obtained from (48.26) by eliminating the mode α_+ and summing over all atoms,

$$\hat{H} = \sum_j \left[\frac{\hat{p}_j^2}{2m} + \frac{\eta_+}{\kappa} U_0 \left(e^{-2\imath k \hat{z}_j} \hat{a}_- + e^{2\imath k \hat{z}_j} \hat{a}_-^\dagger \right) \right] + (U_0 - \Delta_c) \hat{a}_-^\dagger \hat{a}_- \ . \tag{48.129}$$

To treat the motion as being quantized we define a base $|\nu\rangle_j$,

$$\hat{p}_j |\nu\rangle_j = 2\hbar k \nu |\nu\rangle_j \qquad \text{and} \qquad |\psi(z_j)\rangle = \sum_\nu c_{j,\nu} |\nu\rangle_j \ , \tag{48.130}$$

and calculate the expected value of the equations (48.127) regarding the atomic motion,

$$\begin{aligned} \frac{d\hat{a}_-}{dt} &= (-\kappa - \imath \Delta_c) \hat{a}_- - \imath U_0 \tfrac{\eta_+}{\kappa} \sum_j \langle \psi(z_j) | e^{-2\imath k \hat{z}_j} | \psi(z_j) \rangle \\ &= (-\kappa + \imath \Delta_c - \imath U_0) \hat{a}_- - \imath U_0 \tfrac{\eta_+}{\kappa} \sum_{j,\mu,\nu} c_{j,\mu}^* c_{j,\nu_j} \langle \mu | e^{-2\imath k z_j} | \nu \rangle_j \\ &= (-\kappa + \imath \Delta_c - \imath U_0) \hat{a}_- - \imath U_0 \tfrac{\eta_+}{\kappa} \sum_{j,\nu} c_{j,\nu}^* c_{j,\nu+1} \ . \end{aligned} \tag{48.131}$$

We do not use the second equation (48.127), but instead we use the Schrödinger equation $\imath\hbar \frac{d|\psi(z_j\rangle}{dt} = \hat{H}|\psi(z_j)\rangle$, which yields,

$$\begin{aligned} \imath\hbar \sum_\nu \frac{dc_{j,\nu}}{dt} |\nu\rangle_j = \sum_\nu \frac{1}{2m} p_j^2 c_{j,\nu} |\nu\rangle_j + \hbar \Delta_c \hat{a}_-^\dagger \hat{a}_- \sum_\nu c_j(\nu) |\nu\rangle_j \\ + \hbar U_0 \eta \sum_\nu (\hat{a}_-^\dagger e^{-2\imath k z_j} + \hat{a}_- e^{2\imath k z_j}) c_{j,\nu} |\nu\rangle_j \ . \end{aligned} \tag{48.132}$$

Projecting on ${}_j\langle\mu|$, we obtain [186],

$$\boxed{\begin{aligned} \dot{c}_{j,\mu} &= -4\imath\omega_{\text{rec}} \mu^2 c_{j,\mu} - \imath \Delta_c \hat{a}_-^\dagger \hat{a}_- c_{j,\mu} - \imath U_0 \eta [\hat{a}_-^\dagger c_{j,\mu+1} + a_- c_{j,\mu-1}] \\ \dot{\hat{a}}_- &= -(\kappa + \imath \Delta_c) \hat{a} + N U_0 \eta \sum_\nu c_{j,\nu}^* c_{j,\nu+1} \end{aligned}} \ , \tag{48.133}$$

where we took the expectation value of Eq. (48.131). The equations (48.133) can be used for numerical simulations [781].

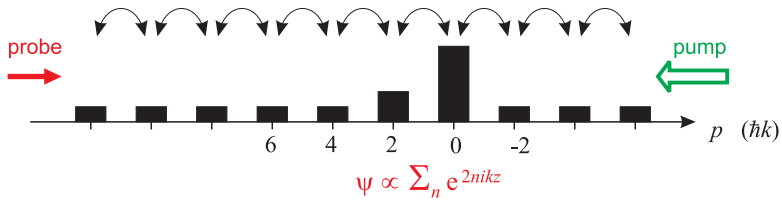

Figure 48.17: Probe light and 'bunching' when the temperature is raised.

48.4.4.2 Equations for the density matrix

The equations (48.133) allow to calculate the derivatives of the density matrix given by,

$$\varrho_{\mu,\nu} \equiv e^{-\imath(\mu-\nu)\Delta_c t}\frac{1}{N}\sum_j c_j^*(\mu)c_j(\nu) \ , \tag{48.134}$$

yielding,

$$\begin{aligned}\frac{d\varrho_{\mu,\nu}}{dt} &= e^{-\imath(\mu-\nu)\Delta_a t}N^{-1}\sum_j\left(\dot{c}_{j,\mu}^* c_{j,\nu} + c_{j,\mu}^*\dot{c}_{j,\nu} - \Delta_c c_{j,\mu}^* c_{j,\nu}\imath(\mu-\nu)\right) \\ &= e^{-\imath(\mu-\nu)\Delta_a t}N^{-1}\sum_j[\imath\omega_r(\mu^2-\nu^2) - \Delta_c\imath(\mu-\nu)]c_{j,\mu}^* c_{j,\nu} + \\ &\quad + \imath U_0\eta\left[ac_{j,\mu+1}^* c_{j,\nu} - ac_{j,\mu}^* c_{j,\nu-1} + \hat{a}^\dagger c_{j,\mu-1}^* c_{j,\nu} - \hat{a}^\dagger c_{j,\mu}^* c_{j,\nu+1}\right] \ .\end{aligned} \tag{48.135}$$

Introducing $\tilde{a} \equiv ae^{\imath\Delta_c t}$ we finally obtain,

$$\boxed{\begin{aligned}\frac{d\varrho_{\mu,\nu}}{dt} &= \imath(\mu-\nu)[\omega_r(\mu+\nu) - \Delta_c]\varrho_{\mu,\nu} \\ &+ \imath U_0\eta\left[\tilde{a}(\varrho_{\mu+1,\nu} - \varrho_{\mu,\nu-1}) + \tilde{a}^\dagger(\varrho_{\mu-1,\nu} - \varrho_{\mu,\nu+1})\right] \\ \frac{d\tilde{a}}{dt} &= -\kappa\tilde{a} - \imath NU_0\eta\sum_\nu \varrho_{\nu,\nu+1}\end{aligned}} \ . \tag{48.136}$$

These are the CARL equations for the density matrix. In 48.4.7.3 we show an alternative derivation obtained by directly inserting the adiabatically simplified Hamiltonian (48.26) into the Liouville equation (48.8).

We note, that $\sum_\nu \varrho_{\nu,\nu+1}$ is the 'bunching' and that $\varrho_{\mu,\nu}^* = \varrho_{\nu,\mu}$. The average moment is given by $\langle p\rangle = \sum_\nu \nu\varrho_{\nu,\nu}$. In the Figs. 48.18 and 48.19 we show simulations in the semi-classical regimes $\rho \gg 1$ in the 'bad-cavity' limit, $\kappa > 1$, and the 'good-cavity' limit $\kappa \ll 1$.

Here are some movies illustrating the quantum CARL dynamics, simulated using the momentum state expansion (watch movie) and (watch movie). The following dynamics were calculated via direct integration of the Schrödinger equation without momentum state expansion: Bloch oscillations (watch movie), CARL dynamics (watch movie), and joint Bloch and CARL dynamics (watch movie). See also (watch talk).

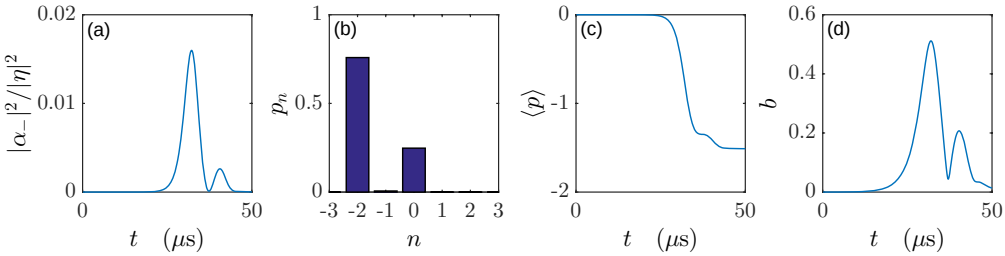

Figure 48.18: (code) Simulation of the CARL equation (48.133) in the superradiant, semi-classical, 'bad-cavity' regime for $\kappa_c = 4$, $\rho = 4$, $\Delta_c = 0$.

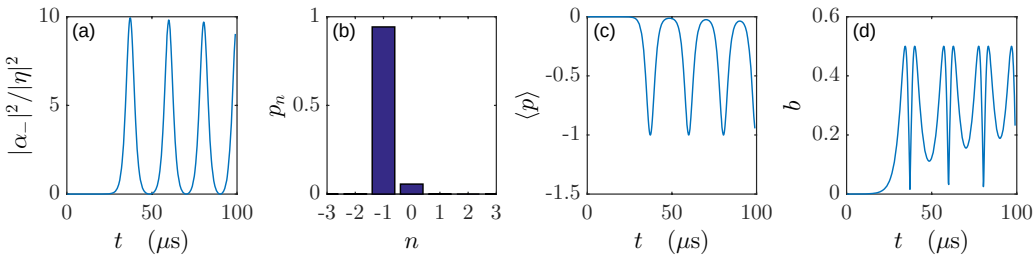

Figure 48.19: (code) Simulation of the CARL equation (48.133) in the superradiant, semi-classical, 'good-cavity' regime for $\kappa_c = 0.02$, $\rho = 4$, $\Delta_c = 0$.

48.4.5 Approximation for a bimodal momentum distribution

We observe that in the quantum regime the momentum distribution of the matter wave is bimodal, that is, only two momentum states are simultaneously populated. This justifies a simplification of the equations (48.136), assuming that at a given time, atoms must either be in a specific state $|\mu\rangle_j$ or in a superposition of this state is an adjacent state $|\mu - 1\rangle_j$. Hence,

$$\begin{aligned}
\frac{d\varrho_{\mu,\mu}}{dt} &= -\imath U_0 \eta(\tilde{a}\varrho_{\mu,\mu-1} - \tilde{a}^\dagger \varrho_{\mu-1,\mu}) = -\frac{d\varrho_{\mu-1,\mu-1}}{dt} \\
\frac{d\varrho_{\mu-1,\mu}}{dt} &= -\imath[(2\mu-1)\omega_r - \Delta_c]\varrho_{\mu-1,\mu} + \imath U_0 \eta \tilde{a}(\varrho_{\mu,\mu} - \varrho_{\mu-1,\mu-1}) \\
\frac{d\tilde{a}}{dt} &= -\imath N U_\mu \eta \varrho_{\mu-1,\mu} - \kappa_c \tilde{a} \ .
\end{aligned} \tag{48.137}$$

Introducing the coherence $S_\mu = \varrho_{\mu-1,\mu}$ and the inversion $W_\mu = \varrho_{\mu,\mu} - \varrho_{\mu-1,\mu-1}$ and postulating the normalization $1 = \varrho_{\mu,\mu} + \varrho_{\mu-1,\mu-1}$,

$$\begin{aligned}
\frac{dW_\mu}{dt} &= -2\imath U_0 \eta(\tilde{a} S_\mu^* - \tilde{a}^\dagger S_\mu) \\
\frac{dS_\mu}{dt} &= -\imath[(2\mu-1)\omega_r - \Delta_c] S_\mu + \imath U_0 \eta \tilde{n} a W_\mu \\
\frac{d\tilde{a}}{dt} &= -\imath N U_0 \eta S_\mu - \kappa_c \tilde{a} \ .
\end{aligned} \tag{48.138}$$

48.4.5.1 Linearization and stability analysis

We assume that the atoms are initially 'bunched' in a specific state $|\mu\rangle_j$. Only adjacent momentum states are coupled,

$$\begin{aligned}\frac{d\varrho_{\mu+1,\mu}}{dt} &= \imath[\omega_r(2\mu+1)-\Delta_c]\varrho_{\mu+1,\mu} + \imath U_0\eta\tilde{a}^\dagger(\varrho_{\mu,\mu}-\varrho_{\mu+1,\mu+1}) \\ \frac{d\varrho_{\mu-1,\mu}}{dt} &= -\imath[\omega_r(2\mu-1)-\Delta_c]\varrho_{\mu-1,\mu} + \imath U_0\eta\tilde{a}(\varrho_{\mu,\mu}-\varrho_{\mu-1,\mu-1}) \\ \frac{d\tilde{a}}{dt} &= -\imath N U_0\eta(\varrho_{\mu,\mu+1}+\varrho_{\mu-1,\mu}) - \kappa_c\tilde{a}\ .\end{aligned} \tag{48.139}$$

Conjugate the upper equation and build the sum and difference, $B_\mu \equiv \varrho_{\mu,\mu+1}+\varrho_{\mu-1,\mu}$ and $D_\mu \equiv \varrho_{\mu,\mu+1}-\varrho_{\mu-1,\mu}$,

$$\begin{aligned}\frac{dB_\mu}{dt} &= \imath(\Delta_c-2\mu\omega_r)B_\mu - \imath\omega_\mu D_\mu + \imath U_0\eta\tilde{a}(\varrho_{\mu+1,\mu+1}-\varrho_{\mu-1,\mu-1}) \\ \frac{dD_\mu}{dt} &= \imath(\Delta_c-2\mu\omega_r)D_\mu - \imath\omega_r B_\mu - 2\imath U_0\eta\tilde{a} + \imath U_0\eta\tilde{a}(\varrho_{\mu+1,\mu+1}-2\varrho_{\mu,\mu}+\varrho_{\mu-1,\mu-1}) \\ \frac{d\tilde{a}}{dt} &= -\imath N U_0\eta B_\mu - \kappa_c\tilde{a}\ .\end{aligned} \tag{48.140}$$

Use $\varrho_{\mu,\mu} \simeq 1$ and abbreviate $\delta_\mu \equiv 2r\omega_\mu - \Delta_c$,

$$\begin{aligned}\frac{dB_\mu}{dt} &= -\imath\delta_\mu B_\mu - \imath\omega_r D_\mu \\ \frac{dD_\mu}{dt} &= -\imath\omega_r B_\mu - \imath\delta_r D_\mu - 2\imath U_0\eta\tilde{a} \\ \frac{d\tilde{a}}{dt} &= -\imath N U_0\eta B_\mu - \kappa_c\tilde{a}\ .\end{aligned} \tag{48.141}$$

Seeking solution proportional to $x \equiv \bar{x}e^{\imath(\lambda-\delta_\mu)t}$,

$$\begin{aligned}\imath\lambda\bar{B}_\mu &= -\imath\omega_\mu\bar{D}_\mu \\ \imath\lambda\bar{D}_\mu &= -\imath\omega_\mu\bar{B}_\mu - 2\imath U_\mu\eta\bar{a} \\ \imath(\lambda-\delta_\mu)\bar{a} &= -\imath N U_0\eta\bar{B}_\mu - \kappa_c\bar{a}\ .\end{aligned} \tag{48.142}$$

Abbreviating $\Lambda_m \equiv \delta_m + \imath\kappa_c$, the characteristic equation is,

$$\det\begin{pmatrix}\lambda & \omega_r & 0 \\ \omega_r & \lambda & 2U_0\eta \\ NU_0\eta & 0 & \lambda-\Lambda_\mu\end{pmatrix} = \lambda^3 - \Lambda_\mu\lambda^2 - \omega_r^2\lambda + \omega_r^2\Lambda_\mu + 2NU_0^2\eta^2\omega_r = 0\ . \tag{48.143}$$

The gain is given by the imaginary part of λ. We have exponential amplification if $\mathrm{Im}\,\lambda < 0$. Hence, we search for solution with the lowest imaginary value.

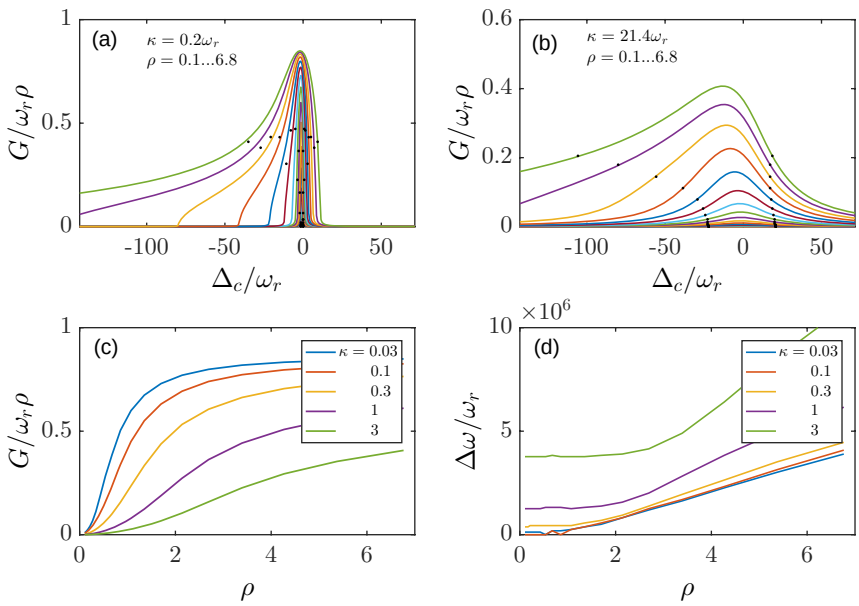

Figure 48.20: (code) Gain dependence on ρ and κ.

48.4.5.2 Universal scaling

To simplify the formulae simplify, we rescale them. We start from Eq. (48.136) and use the substitution for universal scaling,

$$\begin{aligned} \theta_j &\equiv 2kz_j \quad \text{and} \quad \bar{p}_j \equiv 2kv_j/\rho\omega_r \\ \tau &\equiv \rho\omega_r t \quad \text{and} \quad \kappa \equiv \kappa_c/\omega_r\rho \\ \bar{\lambda} &\equiv \lambda/\omega_r\rho \quad \text{and} \quad \bar{\delta}_\mu \equiv \delta_\mu/\omega_r\rho = 2\mu/\rho + \Delta_c/\omega_r\rho \\ \bar{A} &\equiv (2/N\rho)^{1/2}\bar{a} \quad \text{and} \quad \eta U_\mu \equiv \sqrt{\rho^3\omega_r^2/2N} \ . \end{aligned} \tag{48.144}$$

This reproduces the Bonifacio notation,

$$\begin{aligned} \bar{\lambda}\bar{B}_\mu + \rho^{-1}\bar{D}_\mu &= 0 \\ \bar{\lambda}\bar{D}_\mu + \rho^{-1}\bar{B}_\mu + \rho\bar{A} &= 0 \\ (\bar{\lambda} - \bar{\delta}_\mu - \imath\kappa)\bar{A} + \bar{B}_\mu &= 0 \ . \end{aligned} \tag{48.145}$$

Skipping the bars, the characteristic equation reads,

$$\det \begin{pmatrix} \lambda & \rho^{-1} & 0 \\ \rho^{-1} & \lambda & \rho \\ 1 & 0 & \lambda - \delta_\mu - \imath\kappa \end{pmatrix} = (\lambda - \delta_\mu - \imath\kappa)(\lambda^2 - \rho^{-2}) + 1 = 0 \ . \tag{48.146}$$

Let us first discuss the semiclassical limit, $\rho \gg 1$. In the good-cavity regime, $\kappa \simeq 0$, we may neglect the recoil shift, $2m\omega_r \to 0$, so that $\Lambda = \Delta_c$. The gain is largest

when $\Delta_c \to 0$. The characteristic equation reduces to $\lambda^3 = -1$, yielding the solutions $\lambda = 1, \frac{1}{2}(1 \pm \imath\sqrt{3})$. Hence, the gain $G = -\mathfrak{Im}\,\lambda$, is

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\sqrt{3} \\ \Delta\omega_G &\simeq \omega_r\rho \gg \kappa_c, \omega_r \ . \end{aligned} \tag{48.147}$$

The gain bandwidth $\Delta\omega_G$ being much larger than the recoil frequency, the Bragg condition for scattering between different momentum states is approximately fulfilled for a large number of initial momenta. I.e. although the momentum transfer is quantized, $\Delta_c = n\omega_r$, the atoms can be accelerated to high velocities. From Eq. (48.140)(a) we see $|\bar{D}_\mu/\bar{B}_\mu| = \rho|\bar{\lambda}| \gg 1$, i.e. $\varrho_{\mu,\mu+1} \simeq \varrho_{\mu-1,\mu}$.

In the superradiant regime, $\kappa > 1$, of the semiclassical limit the characteristic equation reduces to $\lambda^2 = -\imath/\kappa$, i.e. $\lambda = \pm(1-\imath)/\sqrt{2\kappa}$.[14] Hence, the gain is,

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\sqrt{2/\kappa} \\ \Delta\omega_G &\simeq \kappa_c = \omega_r\rho\kappa \gg \omega_r \ . \end{aligned} \tag{48.148}$$

In fact, the relative gain bandwidth is on the order of $\Delta\omega_G/\omega_r \simeq \rho \propto \left(nNU_0^2\right)^{1/3}$. Since recoil can be neglected we can have absorption or emission. The gain results from the difference bewteen the average rates of both.

Now we turn to the quantum limit, $\rho < 1$. In the good-cavity regime, $\kappa \simeq 0$, $\lambda = \rho^{-1} + \frac{1}{2}(\delta_m - \rho^{-1}) - \frac{1}{2}\sqrt{(\delta_m - \rho^{-1})^2 - 2\rho}$. Hence, the gain is,

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\mathfrak{Im}\sqrt{(\delta_m - \rho^{-1})^2 - 2\rho} \simeq \tfrac{1}{2}\omega_r\rho\sqrt{2\rho} \\ \Delta\omega_G &= \omega_r\rho^{3/2} < \omega_r \ . \end{aligned} \tag{48.149}$$

In fact, the relative gain bandwidth is on the order of $\Delta\omega_G/\omega_r \simeq \rho^{3/2} \propto \sqrt{nNU_0^2}$. Here recoil plays a role so that we have emission without absorption. Gain results exclusively from emission. From Eq. ((48.140)a) we see $|\bar{D}_m/\bar{B}_m| = \rho|\bar{\lambda}| \simeq 1$, i.e. $\varrho_{m,m+1} \ll \varrho_{m-1,m}$.

In the superradiant regime, $\kappa > 1$, of the quantum limit, $\lambda = \rho^{-1} + \frac{\rho}{2}[(\delta_m - \rho^{-1}) + \imath\kappa]^{-1}$. Hence,

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\frac{\rho\kappa}{(\delta_m - \rho^{-1})^2 + \kappa^2} \simeq \tfrac{1}{2}\frac{\omega_r\rho^2}{\kappa} \\ \Delta\omega_G &= \kappa_c > \omega_r\rho \ . \end{aligned} \tag{48.150}$$

The various regimes may be summarized in the following phase diagram. We will see later, that each region produces qualitatively different solutions of the full (non-linearized) equations.

[14] The assertion $\mathfrak{Re}\,\lambda \ll \kappa$ used to simplify the characteristic equation is compatible with the solution.

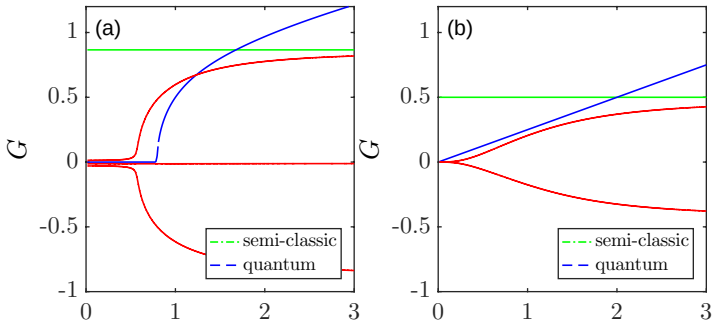

Figure 48.21: (code) Analytical approximations of the characteristic equation for the various regimes in the good-cavity limit $\kappa = 0.03$ (a) and the superradiant limit $\kappa = 2$ (b).

48.4.6 Simulation of random quantum trajectories

Spontaneous emission can induce a random walk of the atoms, which be accounted for by a proper master equation. We write the master equation for the density operator of a dissipative system, as shown in (46.94) [155, 1012],

$$\boxed{\dot{\hat{\rho}} = \imath[\hat{\rho}, \hat{H}] - \tfrac{1}{2}\sum_{\mu}\{\hat{\rho}, \hat{L}_\mu^\dagger \hat{L}_\mu\} + \sum_{\mu} \hat{L}_\mu \hat{\rho} \hat{L}_\mu^\dagger} \ . \tag{48.151}$$

The first term describes the coherent part, the second part dissipation, and the third quantum jumps. The dissipative operators $\hat{L}_\mu$ appearing in the Lindblad terms model the impact of the environment. An alternative to solving the master equation consists in simulating single trajectories of the system with a Schrödinger equation, accounting for dissipation by a non-Hermitian effective Hamiltonian and for quantum fluctuations by a stochastic noise term.

As an example, let us consider the Hamiltonian for an atom interacting with a standing wave potential,

$$\hat{H} = \frac{\hat{p}^2}{2m} + U \cos k\hat{x} \ , \tag{48.152}$$

where $\hat{p} = \hbar q \hat{\nu} = -\imath\hbar d/dx$. We define a momentum basis $|\phi(\tau_0)\rangle = \sum_\nu c_\nu |\nu\rangle$ with $\sum_\nu |c_\nu|^2 = 1$. In this basis, the momentum and the position operator can be expanded as usual,

$$\hat{p} = \hbar q \sum_{\nu=-\infty}^{\infty} \nu |\nu\rangle\langle\nu| \quad \text{and} \quad \cos k\hat{x} = \tfrac{1}{2} \sum_{\nu=-\infty}^{\infty} (|\nu+1\rangle\langle\nu| + |\nu-1\rangle\langle\nu|) \ , \tag{48.153}$$

where $\hbar q$ is the momentum transferred upon a kick. The expectation value for the momentum and the position are then,

$$\langle\hat{p}\rangle = \sum_\nu \hbar q \nu |c_\nu|^2 \qquad \text{and} \qquad \langle\cos k\hat{x}\rangle = \tfrac{1}{2}\sum_\nu (c_\nu^* c_{\nu-1} + c_\nu^* c_{\nu+1}) \ . \tag{48.154}$$

The Lindblad operators describe deceleration of the rotor. With $\mu = \pm$, we get,

$$\hat{L}_\pm = g \sum_{\nu=0}^{\infty} \sqrt{\nu+1} |\pm\nu\rangle\langle\pm\nu \pm 1| \ , \tag{48.155}$$

such that,

$$\hat{L}_\pm^\dagger \hat{L}_\pm = g^2 \sum_{\nu=0}^{\infty} \nu |\pm\nu\rangle\langle\pm\nu| \quad \text{and} \quad \hat{L}_+^\dagger \hat{L}_+ + \hat{L}_-^\dagger \hat{L}_- = g^2 \sum_{\nu=-\infty}^{\infty} |\nu|\, |\nu\rangle\langle\nu| \ . \tag{48.156}$$

Now, as we have seen in Sec. 39.4.3, we may treat the first part of the Lindblad terms in (48.151) as the dissipative part of an an *effective Hamiltonian*,

$$\boxed{\hat{H}_{eff} = \hat{H} - \tfrac{\imath}{2} \sum_\mu \hat{L}_\mu^\dagger \hat{L}_\pm} \ . \tag{48.157}$$

That is, we can attempt a *quantum Monte Carlo wavefunction simulation* of an effective Schrödinger equation.

We define the quantity $dp_\pm \equiv \langle\phi(\tau_0)|\hat{L}_\pm^\dagger \hat{L}_\pm|\phi(\tau_0)\rangle d\tau$,

$$\frac{dp_+}{d\tau} = g^2 \sum_\nu |c_\nu|^2 \quad \text{and} \quad \frac{dp_-}{d\tau} = g^2 \sum_\nu |c_{-\nu}|^2 \ . \tag{48.158}$$

To perform simulations, we start with $|\phi(\tau_0)\rangle$. After a time $d\tau$, we generate a uniform random number ζ. After infinitesimal time, we compare the random number to the accumulated probability. If $\zeta > dp_\mu$, we say that a quantum jump occurred. The new wavefunction is,

$$|\phi(\tau_0)\rangle \to \frac{\hat{L}_\pm|\phi(\tau_0)\rangle}{\|\hat{L}_\pm|\phi(\tau_0)\rangle\|} = \frac{\sum_{\nu\geq 0}\sqrt{\nu+1}c_{\pm\nu\pm1}|\nu\rangle}{\sqrt{\sum_{\nu\geq 0}\nu|c_{\pm\nu}|^2}} \ . \tag{48.159}$$

If in contrast, $\zeta < 1 - \sum_\mu dp_\mu$, then the system continues to evolve slowly. However, dissipation losses have to be compensated by renormalization,

$$|\phi(\tau_0)\rangle \to \frac{(1 - \frac{\imath}{\hbar}\hat{H}_{eff}dt)|\phi(\tau_0)\rangle}{\sqrt{1 - \sum_k dp_k}} \ , \tag{48.160}$$

where the evolution is

$$\begin{aligned}
(|\phi(dt)\rangle &= 1 - \imath\hat{H}_{eff}dt/\hbar)|\phi(\tau_0)\rangle \qquad (48.161)\\
&= \left(1 - \tfrac{\imath}{\hbar}dt\frac{\hat{p}^2}{2m} - \tfrac{\imath}{\hbar}dtU\cos k\hat{x} - \tfrac{1}{2\hbar}dt\sum_\pm \hat{L}_\pm^\dagger \hat{L}_\pm\right)\sum_\nu c_\nu|\nu\rangle\\
&= \sum_\nu c_\nu|\nu\rangle - \tfrac{\imath}{\hbar}dt\tfrac{1}{2}\sum_\nu c_\nu\hbar^2\nu^2|\nu\rangle - \tfrac{\imath}{\hbar}dt\tfrac{1}{2}\sum_\nu c_\nu U(|\nu+1\rangle + |\nu-1\rangle)\\
&\quad - \frac{g^2}{2\hbar}dt\sum_{\nu\geq 0}\nu(c_\nu|\nu\rangle + c_{-\nu}|-\nu\rangle)\\
&= |\phi(\tau_0)\rangle - \frac{\imath}{2\hbar}dt\sum_\nu c_\nu\left[\nu(\hbar^2\nu - \imath g^2)|\nu\rangle + U|\nu+1\rangle + U|\nu-1\rangle\right] \ .
\end{aligned}$$

With this we can now follow the evolution of observables, such as $\langle\phi(t)|\nu\rangle\langle\nu|\phi(t)\rangle$, $\langle\phi(t)|\hat{p}|\phi(t)\rangle$, and $\langle\phi(t)|\cos k\hat{x}|\phi(t)\rangle$, in time.

48.4.7 Exercises

48.4.7.1 Ex: Quantized CARL equations in the presence of a constant external force

a. Generalize the quantized CARL equations (48.100), respectively, (48.114) for the presence of a constant external force.
b. Now, we consider a unidirectionally pumped ring cavity, with the pump laser locked to a cavity mode, in the presence of an external periodic potential. Show that this system is equivalent to CARL in a ring cavity pumped from both sides.

48.4.7.2 Ex: Competition between CARL and Bloch oscillations

Reproduce the simulations of [807].

48.4.7.3 Ex: Alternative derivation of the Maxwell-Bloch with adiabatic elimination

Derive the directly from the Liouville equation (48.8) using the Hamiltonian (48.26) in adiabatic elimination.

48.4.7.4 Ex: Maxwell-Bloch equations without adiabatic elimination

Derive the Maxwell-Bloch equations for a three-level system coupled to a ring cavity without adiabatic elimination, but with quantized motion.

48.4.7.5 Ex: Linearized quantum CARL

Analyze the quantum CARL according to [740].

48.5 Quantized light interacting with atoms moving in cavities

Cavity QED has been studied extensively in the context of the Jaynes-Cummings model in Sec. 40.2 and of cooperative scattering in Sec. 45.1, however, without addressing the issue of atomic motion which, via photonic recoil, inevitably influences the dynamics. We also started a discussion on the role of photonic recoil in Sec. 43.3, which will be continued in the following sections in the context of ring cavities,

$$\begin{aligned} \dot{c}_{n_+,n_-,i} &= \frac{d}{dt}\langle \mathbf{r}, \alpha_+, \alpha_-, i|\psi(t)\rangle = \langle \mathbf{r}, \alpha_+, \alpha_-, i|\frac{-\imath}{\hbar}\hat{H}|\psi(t)\rangle \\ \dot{\alpha}_\pm &= \langle\psi(t)|\dot{\hat{a}}_\pm|\psi(t)\rangle = \langle\psi(t)|\tfrac{\imath}{\hbar}[\hat{H},\hat{a}_\pm] - \kappa\hat{a}_\pm|\psi(t)\rangle \ . \end{aligned} \tag{48.162}$$

Concretely, we will be using the Hamiltonian (48.26), obtained after adiabatic elimination of the excited state.

48.5.1 QED in ring cavities

Macroscopic high-finesse ring cavities interacting with a cloud of cold atoms allowed to enter the regime of strong collective coupling. However, new interesting aspects arise from the regime of strong coupling on the level of individual atoms.

Todays research projects on cold atoms in cavities are essential divided into two classes, each class realizing an opposite regime: Cavity quantum electrodynamics (CQED) experiments as they are done by the groups of Rempe [545] and Kimble use microcavities having mode volumes so small that few photons give rise to macroscopic field strength. In such cavities the atom-field coupling is made to exceed all other decay rates. The other regime is that of cavity-cooling mainly investigated by Vuletic at the MIT and, in the case of ring cavities, of the collective atomic recoil laser (CARL) realized in the Tübingen research group. In this second regime the cavities are so large that the light fields can be considered as classical.

An interesting question is, whether the two regimes can be married to realize a system, where collective effects and entanglement between optical and atomic modes can be observed. The central idea is not to increase the coupling strength by reducing the mode volume, but to reduce the decay rates, in particular the natural linewidth of the atomic transition by choosing an atomic species that can be laser-cooled on a narrow intercombination line.

Example 363 (*CQED by reducing the ring cavity mode volume*): Technically a ring cavity design with $(w, L, F) = (30\,\mu\text{m}, 4\,\text{cm}, 200000)$ is feasible. This is enough to get below the critical atom number, but this is not sufficient to get into the CQED regime. Reducing Γ seems unavoidable.
The isotope ^{88}Sr posses a narrow transition which can be used for optical cooling. The following table compares the various systems, i.e. a CQED example taken from Rempe, the macroscopic ring cavity with rubidium used in our Tübingen CARL experiments and a cavity tuned close to the strontium intercombination line.

experiment	Rempe, Rb	Tübingen, Rb	São Carlos, Sr
Γ	$(2\pi)6$ MHz	$(2\pi)6$ MHz	$(2\pi)7.6$ kHz
F	440000	80000	200000
κ	$(2\pi)0.7$ MHz	$(2\pi)22$ kHz	$(2\pi)19$ kHz
w	29 µm	100 µm	30 µm
L	500 µm	8.5 cm	4 cm
g	$(2\pi)4$ MHz	$(2\pi)88$ kHz	$(2\pi)13$ kHz
N_{crit}	0.5	34	1.6
n_{sat}	1.1	2312	0.16

With $N = 10^4$ the cooperativity parameter N/N_{crit} is in all cases well above 1.

48.5.2 Description of quantized light fields in cavities

In order to calculate the evolution of photon distributions in the counter-propagating modes $\hat{a}_\pm$ of a ring cavity, we develop CARL in a Fock basis. For simplicity, we first consider the *motion of a single atom as classical* and fixed (i.e. not as a degree of freedom), and we apply the adiabatic approximation. I.e. we have only two quantized

degrees of freedom, which we organize like,

$$|\psi\rangle = \cancelto{\text{classical}}{|\nu\rangle_{\text{motion}}} \otimes \cancelto{\text{adiab.elim.}}{|i\rangle_{\text{electron}}} \otimes |n\rangle_+ \otimes |n\rangle_- \to |n_+, n_-\rangle \ , \tag{48.163}$$

Expanding the fields into Fock states,

$$\boxed{|\psi\rangle = \sum_{n_+,n_-} c_{n_+,n_-} |n_+, n_-\rangle} \ , \tag{48.164}$$

the field operators and the density matrix read,

$$\begin{aligned}
\hat{a}_+ &= \sum_{n_+} \sqrt{n_+} |n_+ - 1\rangle\langle n_+| \otimes \mathbb{I} = \sum_{n_+,n_-} \sqrt{n_+} |n_+ - 1, n_-\rangle\langle n_+, n_-| \\
\hat{a}_- &= \mathbb{I} \otimes \sum_{n_-} \sqrt{n_-} |n_- - 1\rangle\langle n_-| = \sum_{n_+,n_-} \sqrt{n_+} |n_+ - 1, n_-\rangle\langle n_+, n_-| \\
\hat{\rho} &= |\psi\rangle\langle\psi| = \sum_{m_+,m_-,n_+,n_-} c^*_{m_+,m_-} c_{n_+,n_-} |m_+, m_-\rangle\langle n_+, n_-| \ .
\end{aligned} \tag{48.165}$$

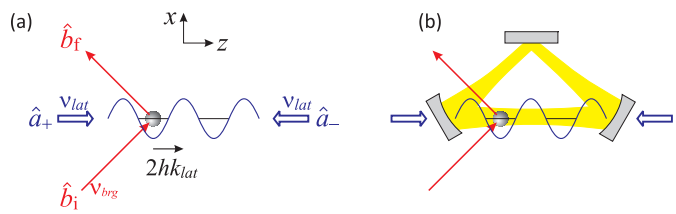

Figure 48.22: (a) Bragg scattering at a 1D optical lattice. (b) Same as in (a), but now the optical lattice is generated by the mode of an optical ring cavity.

Note that the master equation using the Lindbladt operator traces over the reservoir. Hence, the master equation only treats the cavity modes, but does not allow predictions on the quantum behavior of outcoupled fields. In order to describe e.g. quantum correlations in output field, one needs an input-output theory [190, 340].

In the case of classical motion quantum light fields,

$$\boxed{\begin{aligned}
\dot{c}_{n_+,n_-} &= \imath(\Delta_c - U_0)(n_+ + n_-)\ c_{n_+,n_-} \\
&- \imath U_0 \left(e^{-2\imath kz} \sqrt{n_+(n_- + 1)}\ c_{n_+-1,n_-+1} - e^{2\imath kz} \sqrt{(n_+ + 1)n_-}\ c_{n_++1,n_--1} \right) \\
&- \eta_+ \left(\sqrt{n_+ + 1}\ c_{n_++1,n_-} - \sqrt{n_+}\ c_{n_+-1,n_-} \right) \\
&- \eta_- \left(\sqrt{n_- + 1}\ c_{n_+,n_-+1} - \sqrt{n_-}\ c_{n_+,n_--1} \right) \\
\dot{z} &= 2\imath\hbar k U_0 \sum_{n_+,n_-} \Big(e^{-2\imath kz} \sqrt{(n_+ + 1)n_-}\ c^*_{n_++1,n_--1} c_{n_+,n_-} \\
&\qquad - e^{2\imath kz} \sqrt{n_+(n_- + 1)}\ c^*_{n_+-1,n_-+1} c_{n_+,n_-} \Big)
\end{aligned}} \ . \tag{48.166}$$

48.5.3 Photon backscattering for fixed atomic position

To tackle the problem of quantized light field we first assume an atom fixed in space, that is, we completely *disregard the motional degree of freedom* by setting $\hat{p} = 0$ and restricting to the Hamiltonian,

$$\hat{H} = \sum_{\pm} \omega_{\pm} \hat{a}_{\pm}^{\dagger} \hat{a}_{\pm} - \imath\eta_{\pm}(\hat{a}_{\pm} - \hat{a}_{\pm}^{\dagger}) + U_0(\hat{a}_{+}^{\dagger}\hat{a}_{-}e^{-2\imath k\hat{z}} + \hat{a}_{-}^{\dagger}\hat{a}_{+}e^{2\imath k\hat{z}}) \ . \tag{48.167}$$

In Exc. 48.5.7.1 we show how to cast the Hamiltonian into a matrix form using an appropriate basis already used in the discussion of the beam splitter in the photon representation in Sec. 37.5.1.

In Exc. 48.5.7.2(a) we derive the equations of motion for the components c_{n_+,n_-} of the state vector from the Schrödinger equation cavity decay. In Exc. 48.5.7.3(a) we derive the equations of motion for the components $\rho_{m_+,n_+;m_-n_-} = \langle m_+, m_-|\hat{\rho}|n_+, n_-\rangle$ of the density operator. Simulations performed based on these equations of motion are shown in Fig. 48.23).

The simulations reveal a number of interesting facts:

- The field amplitudes $|\alpha_{\pm}|^2$ execute oscillations due to CARL coupling, but with preserved Poissonian shape of the photon number distributions.
- When simulations are done with initial Fock states, they eventually relax to a Glauber state.
- The mean photon numbers and the atomic coordinates evolve in a continuous way.

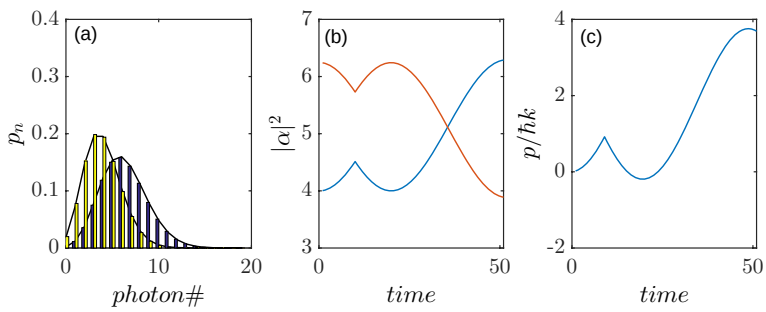

Figure 48.23: (code) Time-evolution of CARL with one classical atom and two quantized field modes. (a) Photon number distributions of two modes after some evolution time t. (b) Time-evolution of the mean photon number; at time $t = 10$, the atom is suddenly displaced. (c) Time-evolution of the (classical) atomic trajectory.

These observations are not surprising, once we understood the backscattering as a linear coupling between the modes being mediated by a beam splitter Hamiltonian of type (37.136) [15],

$$\hat{H}_{int} = U_0(\hat{a}_{+}^{\dagger}\hat{a}_{-}e^{-2\imath kz} + \hat{a}_{+}\hat{a}_{-}^{\dagger}e^{2\imath kz}) \ , \tag{48.168}$$

[15] Which itself represents a generalized displacement operator,

$$\hat{H}_{int} \simeq U_0(\alpha_{+}^{*}e^{-2\imath kz}\hat{a}_{-} + \alpha_{+}e^{2\imath kz}\hat{a}_{-}^{\dagger}) \equiv \imath\hbar\beta^{*}\hat{a}_{-} - \imath\hbar\beta\hat{a}_{-}^{\dagger} \ ,$$

for which we found the relationship (37.137),

$$\boxed{e^{-\imath \hat{H}_{int} t} \hat{a}_{\pm} e^{\imath \hat{H}_{int} t} = \hat{a}_{\pm} \cos U_0 t \pm \hat{a}_{\mp} e^{\mp 2\imath k z} \sin U_0 t} \ . \tag{48.169}$$

This means, that we expect (for a fixed location z of the atom) an oscillatory behavior of the field amplitudes $|\alpha_{\pm}|^2$ and also of the phase (encoded in $\alpha_+^* \alpha_-$), but no modification of the coherent photon statistics. On the contrary, as shown in Sec. 37.5.1, a beam splitter tends to transform sub-Poissonian states into Poissonian ones. In fact, *CARL is nothing else than a movable beam splitter.*

Non-linearity may come into play, if photonic recoil is included, i.e. if the *atomic motion itself becomes a degree of freedom.* This is the next step of our problem, that needs to be solved.

48.5.4 Quantized light fields and quantized recoil

The simulations of the preceding section show that the CARL Hamiltonian (48.168), despite the appearance of photon creation and annihilation operator, does not request recoil to be quantized: If an arbitrary momentum kick of the atom can be absorbed by the light fields, then an arbitrary dipole force can be transmitted to the atomic momentum! The momentum conservation law (48.17) does not imply quantization of photonic recoil. The question is now, how to conceal this fact with the observation of discrete momentum sidemodes [857]. We have seen earlier, that the quantization of the motion is transferred from the quantized photon fields via the operator (48.103) to the atom: An initially resting atom can only adopt motional states with momenta equal to a multiple of $2\hbar k$.

We will now take the quantization of the atomic momentum for granted and study quantized light modes coupled by *recoiling atoms*, we extend our Hilbert space like,

$$|\psi\rangle = |\nu\rangle_{\text{motion}} \otimes \cancel{|i\rangle_{\text{electron}}} \xrightarrow{\text{adiab.elim.}} \otimes |n\rangle_+ \otimes |n\rangle_- \to |\nu, n_+, n_-\rangle \ , \tag{48.170}$$

Expanding the motion and fields [16],

$$\boxed{|\psi\rangle = \sum_{\nu, n_+, n_-} c_{\nu, n_+, n_-} |\nu, n_+, n_-\rangle} \ , \tag{48.171}$$

the momentum kick operator reads,

$$e^{-2\imath k \hat{z}} \otimes \mathbb{I} \otimes \mathbb{I} = \sum_{\nu} |\nu\hbar k - 2\hbar k, n_+, n_-\rangle\langle \nu\hbar k, n_+, n_-| \ . \tag{48.172}$$

since defining $\beta \equiv \frac{\imath U_0}{\hbar} \alpha_+ e^{2\imath k z}$, we find,

$$B(\beta t) = e^{-\imath \hat{H}_{int} t/\hbar} = e^{\beta^* t \hat{a}_- - \beta t \hat{a}_-^\dagger} \ .$$

[16] Note the fact, which is important for computation, that the dimension of the Hilbert space increases a lot, that is like dim $\nu \cdot$ dim $n_+ \cdot$ dim n_-, where $\nu, n_\pm$ are the numbers of states considered.

The equations of motions derived in Exc. 48.5.7.2 from the Schrödinger equation are now generalized to,

$$\boxed{\begin{aligned}\dot{c}_{\nu,n_+,n_-} &= \imath(\Delta_c - U_0)(n_+ + n_-)c_{\nu,n_+,n_-} \\ &- \imath U_0\left(\sqrt{n_+(n_- + 1)}c_{\nu-1,n_+-1,n_-+1} - \sqrt{(n_+ + 1)n_-}c_{\nu+1,n_++1,m_--1}\right) \\ &- \eta_+\left(\sqrt{n_+ + 1}c_{\nu,n_++1,n_-} + \sqrt{n_+}c_{\nu,n_+-1,n_-}\right) \\ &- \eta_-\left(\sqrt{n_- + 1}c_{\nu,n_+,n_-+1} + \sqrt{n_-}c_{\nu,n_+,n_--1}\right)\end{aligned}} \; . \tag{48.173}$$

Note that the general shape of fully quantized Schrödinger equations looks like,

$$\dot{c}_{\nu',n'_+,n'_-} = \begin{pmatrix} \ddots & & \vdots & \\ \cdots & & \mathcal{B}_{\{\nu',n'_+,n'_-\};\{\nu,n_+,n_-\}} & \cdots \\ & & \vdots & \ddots \end{pmatrix} c_{\nu,n_+,n_-} \tag{48.174}$$

and for fully quantized master equations,

$$\begin{aligned}&\dot{\rho}_{\{\mu',m'_+,m'_-\};\{\nu',n'_+,n'_-\}} \\ &= \begin{pmatrix} \ddots & & \vdots & \\ \cdots & & \mathcal{L}_{\{\mu',m'_+,m'_-;\nu',n'_+,n'_-\};\{\mu,m_+,m_-;\nu,n_+,n_-\}} & \cdots \\ & & \vdots & \ddots \end{pmatrix} \rho_{\{\mu,m_+,m_-\};\{\nu,n_+,n_-\}} \; .\end{aligned} \tag{48.175}$$

However, the mere inclusion of a third degree of freedom coupled to the other two degrees in the same linear fashion will modify the behavior of the system, which will continue to oscillate as it did before, now just involving the atomic motion in this dynamics. This behavior can only change, when we additionally consider the force equation,

$$\dot{\hat{p}} = 2\hbar k U_0(\hat{a}_+^\dagger \hat{a}_- e^{-2\imath kz} - \hat{a}_+ \hat{a}_-^\dagger e^{2\imath kz}) \; , \tag{48.176}$$

which will lead to feedback. Inserting the expansion (48.171),

$$\dot{c}_{\nu,n_+,n_-} = 2\hbar k U_0\left(c_{\nu,n_+,n_-}\sqrt{n_+(n_- + 1)} - c_{\nu,n_+,n_-}\sqrt{n_+(n_- + 1)}\right) \; . \tag{48.177}$$

Note that, in contrast to CARL equations, the fully quantized equations (48.173) *are linear*. That is, it is the 'classization' [17] of the degrees of freedom which introduces the non-linearities, which are typical for CARL, e.g. the feedback introduced by classical light fields. The process of 'classization' corresponds to *tracing* over degrees of freedom, which we want to treat classically and thus remove from the Hamiltonian.

48.5.4.1 Calculation of observables

Once the time evolution of the coefficients $c_{\nu,n_+,n_-}(t)$ has been determined by solving the differential equation (48.173) we can calculate the observables in the following

[17] As opposed to the term quantization.

way. The probability distribution for photon numbers in the mode α_+ is given by,

$$\begin{aligned} P_{n_+}(t) &= \langle\psi(t)|\mathbb{I}\otimes|n_+\rangle\langle n_+|\otimes\mathbb{I}|\psi(t)\rangle \\ &= \sum_{\nu,n_-}\langle\nu,n_+,n_-|\nu,n_+,n_-\rangle = \sum_{\nu,n_-}|c_{\nu,n_+,n_-}(t)|^2 \ , \end{aligned} \tag{48.178}$$

the mean photon number by,

$$\langle\hat{n}_+(t)\rangle = |\alpha_+(t)|^2 = \sum_{n_+} n_+ P_{n_+}(t) = \sum_{\nu,n_+,n_-} n_+|c_{\nu,n_+,n_-}(t)|^2 \ , \tag{48.179}$$

and similarly for α_-. The probability distribution for momentum states is given by,

$$P_\nu(t) = \sum_{n_+,n_-}|c_{\nu,n_+,n_-}(t)|^2 \ , \tag{48.180}$$

the mean momentum by,

$$\langle\hat{p}(t)\rangle = \sum_{\nu,n_+,n_-}\nu\hbar k|c_{\nu,n_+,n_-}(t)|^2 \ , \tag{48.181}$$

the mechanical kinetic energy by,

$$\begin{aligned} E_{kin}(t) = \frac{\langle\hat{p}^2\rangle}{2m} &= \sum_{\nu,n_+,n_-}\frac{(\nu\hbar k)^2}{2m}|c_{\nu,n_+,n_-}(t)|^2 \\ &= \sum_{\nu,n_+,n_-}\nu^2\hbar\omega_{\rm rec}|c_{\nu,n_+,n_-}(t)|^2 \ , \end{aligned} \tag{48.182}$$

and the potential energy by,

$$\begin{aligned} E_{pot}(t) &= \hbar U_0\langle e^{-2\imath k\hat{z}}\hat{a}_+^\dagger\hat{a}_- + e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger\rangle \\ &= \hbar U_0\sum_{\nu,n_+,n_-}\Big(c^*_{\nu+1,n_++1,n_--1}c_{\nu,n_+,n_-}\sqrt{(n_++1)n_-} \\ &\qquad + c^*_{\nu-1,n_+-1,n_-+1}c_{\nu,n_+,n_-}\sqrt{n_+(n_-+1)}\Big) \ . \end{aligned} \tag{48.183}$$

With this we can check conservation of the total photon number,

$$\langle\hat{n}_+(t)\rangle + \langle\hat{n}_-(t)\rangle = const \ , \tag{48.184}$$

of the mechanical energy,

$$E_{kin}(t) + E_{pot}(t) = const \ , \tag{48.185}$$

and of total linear momentum,

$$\hbar k[\langle\hat{n}_+(t)\rangle - \langle\hat{n}_-(t)\rangle] - \langle\hat{p}(t)\rangle = const \ . \tag{48.186}$$

48.5.4.2 Master equation for CQED with atomic recoil in the adiabatic approximation

Using the Hamiltonian (48.26) or (48.98), the expansion of the recoil operator (48.103), the expansion of the photon field operators (48.165), and the matrix representation of the density operator (37.20), that is,

$$\hat{\rho} = \sum_{\mu,\nu;m_+,n_+;m_-,n_-} |\mu, m_+, m_-\rangle \rho_{\mu,\nu;m_+,n_+;m_-,n_-} \langle \nu, n_+, n_-| \ , \tag{48.187}$$

the master equation (48.8) becomes,

$$\boxed{\langle \mu, m_+, m_-|\dot{\hat{\rho}}|\nu, n_+, n_-\rangle = -\imath\langle \mu, m_+, m_-|[\hat{H}, \hat{\rho}]|\nu, n_+, n_-\rangle + \mathcal{L}_{cavity-vac,\pm}\hat{\rho}} \ , \tag{48.188}$$

with the coherent contributions,

$$\begin{aligned}
&\langle \mu, m_+, m_-|[\tfrac{\hat{p}^2}{2m}, \hat{\rho}]|\nu, n_+, n_-\rangle = \omega_{\rm rec}(\mu^2 - \nu^2)\rho_{\mu,\nu;m_+,n_+;m_-,n_-} \qquad (48.189)\\
&\langle \mu, m_+, m_-|[(U_0 - \Delta_c)\hat{a}_\pm^\dagger \hat{a}_\pm, \hat{\rho}]|\nu, n_+, n_-\rangle = (U_0 - \Delta_c)n_\pm \rho_{\mu,\nu;m_+,n_+;m_-,n_-}\\
&\langle \mu, m_+, m_-|[-\imath\eta_+(\hat{a}_+ - \hat{a}_+^\dagger), \hat{\rho}]|\nu, n_+, n_-\rangle\\
&\quad = -\imath\eta_+ \Big(\sqrt{m_+}\rho_{\mu,\nu;m_+-1,n_+;m_-,n_-} - \sqrt{m_+ + 1}\rho_{\mu,\nu;m_++1,n_+;m_-,n_-}\\
&\qquad\qquad + \sqrt{n_+}\rho_{\mu,\nu;m_+,n_+-1;m_-,n_-} - \sqrt{n_+ + 1}\rho_{\mu,\nu;m_+,n_++1;m_-,n_-}\Big)\\
&\langle \mu, m_+, m_-|[-\imath\eta_-(\hat{a}_- - \hat{a}_-^\dagger), \hat{\rho}]|\nu, n_+, n_-\rangle\\
&\quad = -\imath\eta_- \Big(\sqrt{m_-}\rho_{\mu,\nu;m_+,n_+;m_--',n_-} - \sqrt{m_- + 1}\rho_{\mu,\nu;m_+,n_+;m_-+1,n_-}\\
&\qquad\qquad + \sqrt{n_-}\rho_{\mu,\nu;m_+,n_+;m_-,n_--1} - \sqrt{n_- + 1}\rho_{\mu,\nu;m_+,n_+;m_-,n_-+1}\Big)\\
&\langle \mu, m_+, m_-|[U_0 e^{-2\imath k\hat{z}}\hat{a}_+^\dagger \hat{a}_-, \hat{\rho}]|\nu, n_+, n_-\rangle\\
&\quad = U_0 \Big(\sqrt{m_+(m_- + 1)}\rho_{\mu+1,\nu;m_+-1,n_+;m_-+1,n_-} + \sqrt{(m_+ + 1)m_-}\rho_{\mu-1,\nu;m_++1,n_+;m_--1,n_-}\Big)\\
&\langle \mu, m_+, m_-|[U_0 e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger, \hat{\rho}]|\nu, n_+, n_-\rangle\\
&\quad = U_0 \Big(\sqrt{(n_+ + 1)n_-}\rho_{\mu,\nu-1;m_+,n_++1m_-,n_--1} + \sqrt{n_+(n_- + 1)}\rho_{\mu,\nu+1;m_+,n_+-1;m_-,n_-+1}\Big) \ ,
\end{aligned}$$

and the incoherent contributions,

$$\begin{aligned}
&\langle \mu, m_+, m_-| - \kappa[\hat{a}_+^\dagger \hat{a}_+\hat{\rho} - 2\hat{a}_+\hat{\rho}\hat{a}_+^\dagger + \hat{\rho}\hat{a}_+^\dagger \hat{a}_+]|\nu, n_+, n_-\rangle \qquad (48.190)\\
&\qquad = -\kappa\Big(m_+\rho_{\mu,\nu;m_+,n_+;m_-,n_-} + n_+\rho_{\mu,\nu;m_+,n_+;m_-,n_-}\\
&\qquad\qquad -2\sqrt{(m_+ + 1)(n_+ + 1)}\rho_{\mu,\nu;m_++1,n_++1;m_-,n_-}\Big)\\
&\langle \mu, m_+, m_-| - \kappa[\hat{a}_-^\dagger \hat{a}_-\hat{\rho} - 2\hat{a}_-\hat{\rho}\hat{a}_-^\dagger + \hat{\rho}\hat{a}_-^\dagger \hat{a}_-]|\nu, n_+, n_-\rangle\\
&\qquad = -\kappa\Big(m_-\rho_{\mu,\nu;m_+,n_+;m_-,n_-} + n_-\rho_{\mu,\nu;m_+,n_+;m_-,n_-}\\
&\qquad\qquad -2\sqrt{(m_- + 1)(n_- + 1)}\rho_{\mu,\nu;m_+,n_+;m_-+1,n_-+1}\Big) \ .
\end{aligned}$$

48.5.5 Kicking and forcing an atom in a ring cavity

The question we want to elucidate here is, how a coupled atom-ring cavity system reacts to a kick transferring an arbitrary amount of momentum to the atom. We studied

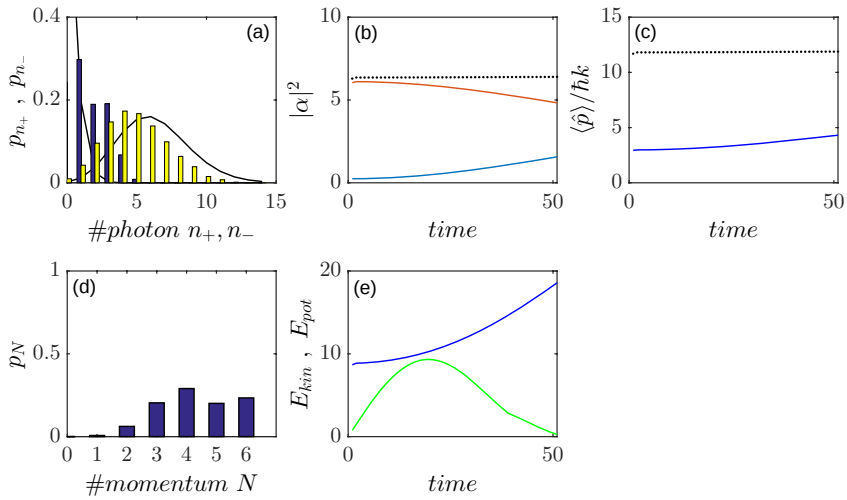

Figure 48.24: (code) Time-evolution of CARL with one classical atom and two quantized field modes. (a) Photon number distributions of two modes after some evolution time t. (b) Time-evolution of the mean photon number; at time $t = 10$, the atom is suddenly displaced. (c) Time-evolution of the (classical) atomic trajectory.

a similar question when studying the kicking of a harmonic oscillator in Sec. 24.6.2, however, the situation is quite different now because, in contrast to the harmonic oscillator, the motion of an atom subject to CARL dynamics is not localized and, hence, *not quantized*. That is, an arbitrarily kicked atom is not bound to join one of those momentum states it would populate when kicked by photonic recoil. Hence, a momentum state expansion like (48.107) is not appropriate, so that we have to go a step back and consider the Hamiltonian (48.26) again. See also (watch talk).

48.5.5.1 Kicking

Let us first describe the kick as an incoherent disruptive one time event transforming operators, the Hamiltonian and the system's state like,

$$\hat{A} \longrightarrow e^{-\imath q\hat{z}}\hat{A}e^{\imath q\hat{z}} \quad , \quad |\psi\rangle \longrightarrow e^{\imath q\hat{z}}|\psi\rangle \tag{48.191}$$

and in particular,

$$\hat{H} \longrightarrow e^{-\imath q\hat{z}}\hat{H}e^{\imath q\hat{z}} = \hat{H}(\hat{z}, \hat{p} - \hbar q) \quad , \quad \langle p|\psi\rangle \longrightarrow \langle p|e^{\imath q\hat{z}}|\psi\rangle = \langle p - \hbar q|\psi\rangle \ . \tag{48.192}$$

The Schrödinger equation tells us the system's evolution after the kick,

$$\imath\hbar\frac{d}{dt}\langle p|\psi\rangle = \frac{p^2}{2m}\langle p|\psi\rangle + U_0\left(\langle p|e^{-2\imath k\hat{z}}|\psi\rangle\hat{a}_+^\dagger\hat{a}_- + \langle p|e^{2\imath k\hat{z}}|\psi\rangle\hat{a}_+\hat{a}_-^\dagger\right) \ . \tag{48.193}$$

We remind that this equations contains CARL feedback via the simultaneous presence of $\hat{z}$ and $\hat{p}$. If we want to disregard the CARL force (assuming, for example, that the motion is totally imposed by an external force, as done in Sec. 45.1.8 in order to focus on the behavior of the light fields), we must not project the Schrödinger equation on $\langle p|$ but treat the motional degree of freedom as classical.

48.5.5.2 Forcing

Let us now describe the kick as a force $F(t) = mg\theta(t)$ being switched on at a given time, but being constant afterward,

$$\hat{H} = \frac{\hat{p}^2}{2m} + U_0 \left(e^{-2\imath k\hat{z}} \hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}} \hat{a}_+ \hat{a}_-^\dagger \right) + mg\hat{z} \ . \tag{48.194}$$

We note that with (23.267) the Hamiltonian transformed into the accelerated frame reads,

$$\begin{aligned} \hat{H} &\longrightarrow e^{-\imath mg\hat{z}t/\hbar} \hat{H} e^{\imath mg\hat{z}t/\hbar} + \imath\hbar \left(\frac{d}{dt} e^{\imath mg\hat{z}t/\hbar} \right)^\dagger e^{\imath mg\hat{z}t/\hbar} = \hat{H}(\hat{z}, \hat{p} - mgt) - mg\hat{z} \\ &= \frac{(\hat{p} - mgt)^2}{2m} + U_0 \left(e^{-2\imath k\hat{z}} \hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}} \hat{a}_+ \hat{a}_-^\dagger \right) \ . \end{aligned} \tag{48.195}$$

The Schrödinger equation for the transformed wavefunction $|\psi\rangle = |\tilde{\psi}\rangle e^{\imath mg\hat{z}t/\hbar}$, which tells us the system's evolution during the force,

$$\imath\hbar \frac{d}{dt} \langle p|\tilde{\psi}\rangle = \frac{(p - mgt)^2}{2m} \langle p|\tilde{\psi}\rangle + U_0 \left(\langle p|e^{-2\imath k\hat{z}}|\tilde{\psi}\rangle \hat{a}_+^\dagger \hat{a}_- + \langle p|e^{2\imath k\hat{z}}|\tilde{\psi}\rangle \hat{a}_+ \hat{a}_-^\dagger \right) \ , \tag{48.196}$$

has a similar shape to Eq. (48.193).

48.5.5.3 Vibrating

Another option might be to additionally confine the atom in a harmonic potential [996],

$$\begin{aligned} \hat{H} &= \frac{\hat{p}^2}{2m} + U_0 \left(e^{-2\imath k\hat{z}} \hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}} \hat{a}_+ \hat{a}_-^\dagger \right) + \frac{m}{2} \omega^2 \hat{z}^2 \\ &= \hbar\omega(\hat{A}^\dagger \hat{A} + \tfrac{1}{2}) + U_0 \left[D^\dagger(\alpha) \hat{a}_+^\dagger \hat{a}_- + D(\alpha) \hat{a}_+ \hat{a}_-^\dagger \right] \ , \end{aligned} \tag{48.197}$$

where $D(\alpha) \equiv e^{\alpha \hat{A}^\dagger - \alpha^* \hat{A}}$ with $\alpha \equiv \frac{2\imath k a_{ho}}{\sqrt{2}}$.

48.5.5.4 Quantized equations of motion

In both cases, 'kicking' and 'forcing', we may discretize momentum space, although in the latter case we need to transform back into the lab frame after having solved the Schrödinger equation (48.173).

48.5.6 Quantum correlations

Superradiant or CARL scattering exist due to a correlation of subsequent scattering events. In the quantum regime, the emergence of quantum correlations, such as entanglement and squeezing is to be expected as a consequence of CARL dynamics [665, 738, 757, 747, 748, 934, 187, 188, 189]. The advantage of doing CARL with BECs is the possibility to exploit the instability in the good-cavity regime to parametrically

amplify optical and matter waves, manipulate matter wave coherence properties and generate entanglement.

For the description of the dynamics of the fields, i.e. the momentum sidemodes and the cavity modes, a first-quantized treatment of the atomic motion [740] would be sufficient. All information can be extracted from a numerical simulation of the quantum CARL equations. However, here we are also interested in quantum correlations. Hence, in a first-quantized treatment of the atomic motion, the coefficients $\hat{c}_n$ must be treated as field operators. Alternatively, we derive the basic equations rigorously from a second-quantized treatment.

48.5.6.1 Generation of squeezing and entanglement via CARL

An experiment by [761] produces squeezing in transmission of a cavity resonantly interacting with single atoms. The effect was induced by vacuum Rabi-splitting. In our case we have a ring cavity, we operate far from equilibrium, we have classical Stark splitting. Hence, we may expect squeezing and entanglement from the CARL dynamics.

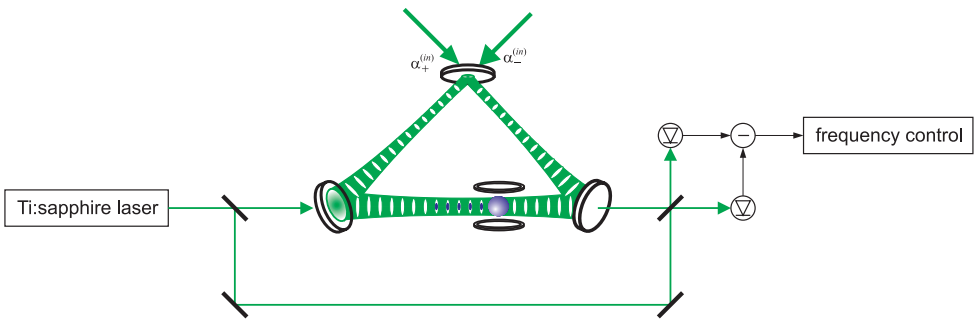

Figure 48.25: Production and detection of squeezing.

Differences between entanglement and correlation (correlations involve time or space coordinates $g(\tau)$, particles correlate across space and time, coherence).

Bragg scattering of light at an atomic grating (or simply the splitting of light at a beam splitter) is an irreversible process (see Sec. 37.5). CARL can be interpreted in terms of Bragg scattering of light at an atomic grating, which is generated itself by the Bragg scattering. Hence, the scattering of early photons influences the scattering of late photons, i.e. the scattering processes get correlated, the dynamics gets a history. The correlation between subsequent scattering processes is what preserves the coherence in CARL and superradiant Rayleigh scattering.

It is now interesting to ask how this classical correlations will behave in the quantum regime, i.e. upon 1. quantization of the motion of individual atoms and upon 2. quantization of atomic particle field. Following [665, 664, 667, 666, 738, 739, 747, 748], non-classical correlations such as entanglement of matter wave modes, and entanglement between matter-wave and optical modes is expected.

48.5.6.2 Quantum non demolition measurements with CARL

According to [748], a ring cavity could lend itself to quantum non demolition measurements. They consider our ring cavity being pumped from both sides through an incoupling mirror. A so-called pump mode is injected with a p-polarized light field, and a probe mode with a s-polarized light field. The light of the probe mode leaking through a mirror gives information about the atoms (e.g. via the refraction index). The counterpropagating pump light gives access to higher-order moments of the atom distribution.

The problem is that the effect is based on photon exchange between the modes, and those are orthogonally polarized. Even more problematic is that, in practice, the modes have different frequencies. Other work on this subject has been done by [49, 288, 634, 635, 166].

48.5.7 Exercises

48.5.7.1 Ex: Analogy between CARL and two-atom Dicke states

a. Write the Hamiltonian (48.167) in matrix form using the basis,

$$\psi_k = \{|0,0\rangle, |0,1\rangle, |1,0\rangle, |0,2\rangle, |1,1\rangle, |2,0\rangle, ...\} \ .$$

b. Now restrict to the finite number of states $\psi_k = \{|0,0\rangle, |0,1\rangle, |1,0\rangle, |1,1\rangle\}$ and discuss the analogy between CARL and two-atom Dicke states.

48.5.7.2 Ex: Cavity QED with Schrödinger equation

Assume a symmetrically pumped ring cavity in equilibrium with an atom at a fixed position.
a. Derive the equations of motion for the components for the probability amplitudes in a Fock state basis.
b. Express the possible initial states $|\alpha_+, \alpha_-\rangle$, $|\alpha_+, n_-\rangle$, and $|n_+, n_-\rangle$ in the Fock state basis. How to calculate the photon distribution p_{n_+}, the amplitudes of field modes $\alpha_\pm$, and the atom's position and momentum at later times of the evolution?

48.5.7.3 Ex: Cavity QED with density matrix

Assume a symmetrically pumped ring cavity in equilibrium with an atom at a fixed position.
a. Derive the equations of motion for the components of the density operator.
b. Write down the density operator describing two decoupled Glauber states? How to retrieve the Fock state populations from the density operator?
c. Now, assume that the atom can move. What will be the evolution of the motional state?

48.5.7.4 Ex: Photon number and momentum conservation

a. Calculate the evolution under CARL interaction, $e^{-\imath \hat{H}_{carl} t} \hat{n}_\pm e^{\imath \hat{H}_{carl} t}$, of the photon numbers in each mode and show that the total photon number is conserved.

b. Assuming conservation of total momentum calculate the evolution of the atomic momentum.

48.5.7.5 Ex: Self-synchronization of Bloch oscillations

Study the Bloch-CARL dynamics for the case of a sinusoidally modulated CARL pump light intensity. Choose as the modulation frequency the expected Bloch oscillation frequency and a variable phase delay.

48.6 Atomic self-organization in light fields

The CARL phenomenon introduced in the previous chapter raises a variety of questions, such as: How does it compare to an ordinary laser? Is there a phase transition? Of what kind would be this transition (in the Ehrenfest or Landau classification scheme)? What are the coherence properties (measured by correlation functions)? How do these properties depend on the random motion (temperature) of the atoms? These issues will be addressed in this chapter and in the later chapter within the models of *Langevin*, *Fokker*-Planck, *Vlasov*Vlasov, and *Kuramoto*.

48.6.1 The Langevin model

48.6.1.1 CARL with damping

We saw in the previous chapter that CARL is a transient phenomenon, the atoms and the phase of the light wave being continuously accelerated. However, it is possible to force stationary behavior by providing additional friction for the atoms. Such friction can be carried out by an *optical molasses* (see Sec. 49.2.1) characterized by a friction coefficient $\gamma_{\rm frc}$. The friction force can be added to the CARL equations of motion (48.69),

$$\begin{aligned} \dot{\alpha}_- &= -\kappa\alpha_- - \imath U_0\alpha_+ \sum_m e^{2\imath k z_m} \\ k\dot{v}_n &= 4i\omega_{\rm rec} U_0 \alpha_+ (\alpha_- e^{-2\imath k z_n} - \alpha_-^* e^{2\imath k z_n}) - \gamma_{\rm frc} k v_n \ . \end{aligned} \tag{48.198}$$

Now, the balance of forces happens at a well-defined atomic velocity, which incidentally corresponds to a well-defined CARL frequency. Assuming perfect 'bunching' $e^{2\imath k z_m} = e^{2\imath k z}$, and balanced forces, $\dot{v}_m = 0$ e $\alpha_- = \beta e^{2\imath k z}$ with $\dot{\beta} = 0$, we obtain for $\kappa \ll 2kv$,

$$\begin{aligned} \alpha_- &= \tfrac{-\imath N U_0 \alpha_+}{\kappa + 2\imath k v} e^{2\imath k z} \\ (kv)^3 &= \frac{2\omega_{\rm rec}\kappa N U_0^2 \alpha_+^2}{\gamma_{\rm frc}} \ . \end{aligned} \tag{48.199}$$

This result will be derived in Exc. 48.6.7.1.

Optical molasses obviously are subject to a cooling limit coming from the random scattering of photons. As a consequence, atoms follow a *random walk* in the momentum space, which leads to the diffusion and heating of atoms and impedes the

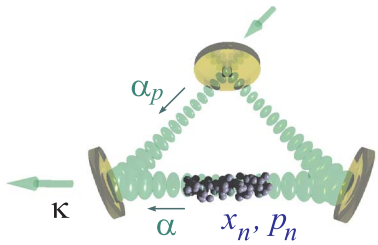

Figure 48.26: Scheme of the ring cavity.

bunching of atoms. It also turns out that a minimal grouping is required to initialize CARL. Therefore, there is a threshold behavior as a function of the equilibrium temperature of the molasses,

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\kappa\alpha_- - \imath U_0 \alpha_+ \textstyle\sum_m e^{2\imath k z_m} \\ k\dot{v}_n &= 4\imath\omega_{\rm rec} U_0 \alpha_+ (\alpha_- e^{-2\imath k z_n} - \alpha_-^* e^{2\imath k z_n}) - \gamma_{\rm frc} k v_n + \xi_n(t) \end{aligned}} \quad . \tag{48.200}$$

The equation corresponds to a *Langevin equation*, where the stochastic term $\xi_n(t)$ describes white noise. We can simulate this equation by a Runge-Kutta method, where the atoms are continually exposed to random momentum changes. For N atoms we need to solve $2N+2$ Langevin equations to describe the dynamics of all degrees of freedom. The Langevin equations are associated to so-called *Fokker-Planck equations* [943, 783, 478, 942]. These describe the temporal evolution of the atomic density along the optical x-axis. With these equations we replace the $2N$ trajectories of individual particles by a one-dimensional field $P(x,t)$. The *Vlasov equation* represents a different approach: Here we assume that the equilibrium between cooling and heating is achieved by a continuous thermalization process described by a single rate γ_{th} [18].

48.6.1.2 Characterization of an optical molasses

Optical molasses is discussed in Sec. 49.2.1. In Exc. 49.2.5.1 we will show how, through a linearization of the radiative pressure force, we arrive at the following approximation,

$$\mathbf{F} = -\gamma_{\rm frc}\mathbf{v} \qquad \text{with} \qquad \gamma_{\rm frc} \simeq -\sqrt{3}\hbar k^2 s(1+s)^{-3/2} \ , \tag{48.201}$$

where $s = I/I_s$ is the saturation parameter. This formula estimates the maximum friction force, when the lasers are tuned close to an atomic resonance [19].

A more fundamental problem is the interdependence of the molasses friction and the CARL. In fact, because the dipole potential influences the detuning of the molasses

[18] Through a linearization of the CARL equations, the cavity dissipation itself is found to exert a friction force to the atoms [418, 337]. This implies the existence of diffusion and a finite equilibrium temperature even at if the atoms are initially at $T = 0$.

[19] We note that atomic species exhibiting a hyperfine structure in the ground state are subject to cooling phenomena called 'polarization gradient cooling', which can cause much higher friction coefficients.
We also note that, when the molasses is applied to atoms confined to a potential, the atomic levels can be displaced (e.g., by light-shift or the Zeeman effect). This causes an inhomogeneous effective detuning of the laser beams generating the molasses.

beams by light-shifting the D_2 line, the γ_{th} coefficient depends on Δ_a and η_+ (the reverse field $|\alpha_-|$ may be neglected). The threshold equations must then be solved in a self consistent way. It might however be possible to determine γ_{th} only slightly above threshold, where the modification is small, $\gamma_{th} \approx \gamma_{th}^{(thresh)}$.

48.6.1.3 Fluctuation-dissipation theorem

Trajectories of ensembles of particles subject to friction and stochastic forces can be described by *Langevin equations*. The friction and the diffusion forces are related by the *fluctuation-dissipation theorem*. This theorem states that, for a thermal sample of atoms whose coordinates θ_n follow,

$$\ddot{\theta}_n = -\gamma_{\rm frc}\dot{\theta}_n + \xi_n(t) \ , \tag{48.202}$$

the Langevin force $\xi(t)$ fluctuates stochastically with,

$$\langle \xi_n(t) \rangle = 0 \qquad \text{and} \qquad \langle \xi_n(t)\xi_m(t+\tau) \rangle = 2\gamma_{\rm frc}^2 D_T \delta_{mn}\delta(\tau) \ . \tag{48.203}$$

Here, the *diffusion coefficient*,

$$D_T = \frac{\sigma^2}{\gamma_{\rm frc}} \tag{48.204}$$

is related to the width of the Maxwell-Boltzmann velocity distribution,

$$\sigma = 2k\sqrt{\frac{k_{\rm B}T}{m}} \ . \tag{48.205}$$

48.6.1.4 Langevin simulations

The Langevin equations of CARL can be simulated, including the random term of the Langevin force, using the *Runge-Kutta method* [453]. The procedure consists in propagating a general first order differential equation,

$$\boxed{\dot{x} = f(x) + g(t)} \ , \tag{48.206}$$

subject to a deterministic force f and a stochastic noise g satisfying,

$$\langle g(t) \rangle = 0 \qquad \text{and} \qquad \langle g(t)g(t') \rangle = 2D\delta(t-t') \tag{48.207}$$

as follows,

$$\boxed{\begin{array}{rrcl} & x(dt) & = & x_0 + \frac{1}{2}dt[f(x_0) + f(\tilde{x})] + \zeta(2Ddt)^{1/2} \\ \text{with} & \tilde{x} & \equiv & x_0 + f(x_0)dt + \zeta(2Ddt)^{1/2} \end{array}} \ , \tag{48.208}$$

where ζ is a random variable distributed according to a normal (Gaussian) distribution normalized as [20],

$$\langle \zeta \rangle = 0 \qquad \text{and} \qquad \langle \zeta^2 \rangle = 1 \ . \tag{48.209}$$

[20] The MATLAB random number generator satisfies this requirement: $\langle \zeta_n \rangle \triangleq sum(randn(1,N))/N = 0$ and $\langle \zeta_n^2 \rangle \triangleq sum(randn(1,N).\wedge 2)/N = 1$.

48.6.1.5 Langevin simulation in the adiabatic approximation

Now, we apply this method to the CARL subject to an optical molasses. Making the adiabatic approximation $\ddot{\theta}_n = 0$, the starting point is,

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\kappa\alpha_- - \imath U_0 \alpha_+ \sum_m e^{\imath\theta_m} && \equiv B(\alpha_-, \theta_n) \\ \dot{\theta}_n &= \frac{8i\omega_{\rm rec} U_0 \alpha_+}{\gamma_{\rm frc}} (\alpha_- e^{-\imath\theta_n} - \alpha_-^* e^{\imath\theta_n}) + \frac{\xi_n(t)}{\gamma_{\rm frc}} && \equiv F(\alpha_-, \theta_n) + \tfrac{\xi_n(t)}{\gamma_{\rm frc}} \end{aligned}} \,. \tag{48.210}$$

In order to apply the Runge-Kutta method (48.208), we identify the variables and functions,

$$x(t) \equiv \begin{pmatrix} \alpha_-(t) \\ \theta_n(t) \end{pmatrix} \quad , \quad f(x) \equiv \begin{pmatrix} B(\alpha_-, \theta_n) \\ F(\alpha_-, \theta_n) \end{pmatrix} \quad , \quad g(t) \equiv \begin{pmatrix} 0 \\ \xi_n(t)/\gamma_{\rm frc} \end{pmatrix} \,, \tag{48.211}$$

such that,

$$\tilde{x} = \begin{pmatrix} \tilde{\alpha}_- \\ \tilde{\theta}_n \end{pmatrix} = \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \end{pmatrix} + dt \begin{pmatrix} B(\alpha_-(0), \theta_n(0)) \\ F(\alpha_-(0), \theta_n(0)) \end{pmatrix} + \begin{pmatrix} 0 \\ \zeta_n \sqrt{2D_T dt} \end{pmatrix} \tag{48.212}$$

and

$$\begin{aligned} x(dt) &= \begin{pmatrix} \alpha_-(dt) \\ \theta_n(dt) \end{pmatrix} \\ &= \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \end{pmatrix} + \frac{dt}{2} \left[\begin{pmatrix} B(\alpha_-(0), \theta_n(0)) \\ F(\alpha_-(0), \theta_n(0)) \end{pmatrix} + \begin{pmatrix} B(\tilde{\alpha}_-, \tilde{\theta}_n) \\ F(\tilde{\alpha}_-, \tilde{\theta}_n) \end{pmatrix} \right] + \begin{pmatrix} 0 \\ \zeta_n \sqrt{2D_T dt} \end{pmatrix} \,. \end{aligned} \tag{48.213}$$

The Langevin equation can be used to simulate the temporal evolution of CARL. Fig. 48.27 shows a simulation of the frequency and amplitude of the CARL based on prescription (48.208).

48.6.1.6 Langevin simulation of the full dynamics

Without adiabatic approximation, the starting point is,

$$\boxed{\begin{aligned} \dot{\alpha}_- &= \kappa\alpha_- - \imath U_0 \alpha_+ \sum_m e^{\imath\theta_m} && \equiv B(\alpha_-, \theta_n) \\ \dot{\theta}_n &= V_n \\ \dot{V}_n &= 8i\omega_{\rm rec} U_0 \alpha_+ (\alpha_- e^{-\imath\theta_n} - \alpha_-^* e^{\imath\theta_n}) - \gamma_{\rm frc} V_n + \xi_n(t) && \equiv F(\alpha_-, \theta_n, V_n) + \xi_n(t) \end{aligned}} \,. \tag{48.214}$$

In order to apply the Runge-Kutta method (48.208), we identify the variables and functions,

$$x(t) \equiv \begin{pmatrix} \alpha_-(t) \\ \theta_n(t) \\ V_n(t) \end{pmatrix} \quad , \quad f(x) \equiv \begin{pmatrix} B(\alpha_-, \theta_n) \\ V_n \\ F(\alpha_-, \theta_n, V_n) \end{pmatrix} \quad , \quad g(t) \equiv \begin{pmatrix} 0 \\ 0 \\ \xi_n(t) \end{pmatrix} \,, \tag{48.215}$$

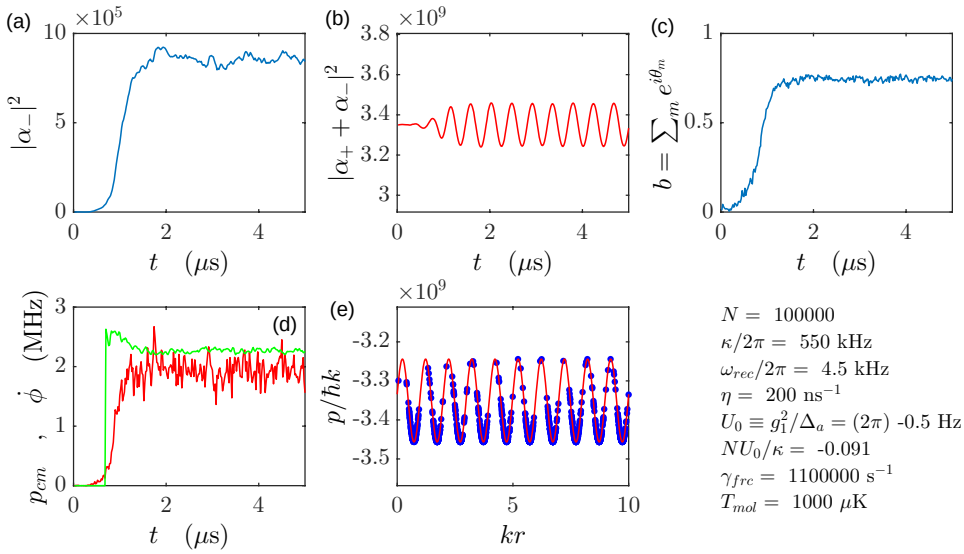

Figure 48.27: (code) Time evolution with phase transition of the viscous CARL in the adiabatic approximation. Shown are (a) the number of photons in the probe mode, (b) the beat signal, (c) the bunching, (d) the phase of the standing wave and the position of the center-of-mass of the cloud, and (e) the dipole potential calculated from (48.21) with the atomic distribution.

such that,

$$\tilde{x} = \begin{pmatrix} \tilde{\alpha}_- \\ \tilde{\theta}_n \\ \tilde{V}_n \end{pmatrix} \equiv \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \\ V_n(0) \end{pmatrix} + dt \begin{pmatrix} B\left(\alpha_-(0), \theta_n(0)\right) \\ V_n(0) \\ F\left(\alpha_-(0), \theta_n(0), V_n(0)\right) \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \zeta_n \sqrt{2\gamma_{\rm frc}^2 D_T dt} \end{pmatrix} \tag{48.216}$$

and

$$x(dt) = \begin{pmatrix} \alpha_-(dt) \\ \theta_n(dt) \\ V_n(dt) \end{pmatrix} = \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \\ V_n(0) \end{pmatrix} + \frac{dt}{2} \left[\begin{pmatrix} B\left(\alpha_-(0), \theta_n(0)\right) \\ V_n(0) \\ F\left(\alpha_-(0), \theta_n(0), V_n(0)\right) \end{pmatrix} + \begin{pmatrix} B(\tilde{\alpha}_-, \tilde{\theta}_n) \\ \tilde{V}_n \\ F(\tilde{\alpha}_-, \tilde{\theta}_n, \tilde{V}_n) \end{pmatrix} \right] + \begin{pmatrix} 0 \\ 0 \\ \zeta_n \sqrt{2\gamma_{\rm frc}^2 D_T dt} \end{pmatrix} . \tag{48.217}$$

48.6.2 The Fokker-Planck and the Vlasov model

The *Fokker-Planck equation* for a density distribution $Q(\mathbf{r}, t)$,

$$\frac{dQ}{dt} + Q\nabla \cdot \mathbf{v} = D\nabla^2 Q \ , \tag{48.218}$$

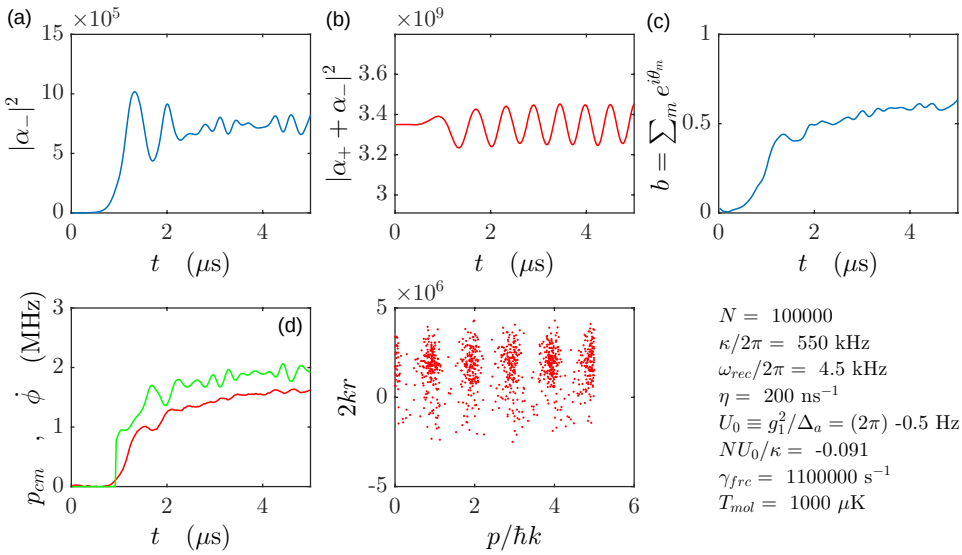

Figure 48.28: (code) Time evolution of the complete dynamics of the viscous CARL with phase transition. Same parameters as in Fig. 48.27. Shown are (a) the number of photons in the probe mode, (b) the beat signal, (c) the bunching, (d) the phase of the standing wave and the position of the center-of-mass of the cloud, and (e) the dipole potential calculated from (48.21) with the atomic distribution.

represents a generalization of the *continuity equation*, since with $\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla$, we obtain,

$$\frac{\partial Q}{\partial t} = -\nabla \cdot (\mathbf{v} Q) + D \nabla^2 Q \ . \tag{48.219}$$

If ρ is a local density, it the continuity equation reads,

$$\frac{d\rho}{dt} + \rho \nabla \cdot \mathbf{v} = 0 \ . \tag{48.220}$$

Knowing,

$$\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \ , \tag{48.221}$$

we obtain,

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \mathbf{v}) \ . \tag{48.222}$$

The Fokker-Planck equation is just a generalization to include a diffusion process,

$$\frac{d\rho}{dt} + \rho \nabla \mathbf{v} = D_x \frac{\partial^2 \rho}{\partial x^2} \ , \tag{48.223}$$

or

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \mathbf{v}) + D_x \frac{\partial^2 \rho}{\partial x^2} \ . \tag{48.224}$$

48.6.2.1 Thermalization in the Fokker-Planck equation

We now apply the Fokker-Planck equation to the density distribution (48.210) of an atomic cloud subjected to the CARL force [943, 783]. As CARL is a one-dimensional process, we can use $\nabla \to \partial\theta$ and replace the velocity field $\mathbf{v} \to \dot{\theta}$:

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\kappa\alpha_- - \imath N U_0 \alpha_+ b \\ \frac{\partial Q}{\partial t} &= \frac{8\imath\omega_{\rm rec} U_0 \alpha_+}{\gamma_{\rm frc}} \frac{\partial}{\partial\theta}\left[(\alpha_- e^{-\imath\theta} - \alpha_-^* e^{\imath\theta})Q\right] + D_\theta \frac{\partial^2 Q}{\partial\theta^2} \end{aligned}} \ . \tag{48.225}$$

The position diffusion coefficient can be estimated by,

$$D_\theta = \frac{\langle k^2 v^2\rangle}{\gamma_{\rm frc}} \ . \tag{48.226}$$

The normalization and the 'bunching' $|b|$ are given by,

$$1 = \int_0^{2\pi} Q(\theta,t)d\theta \quad , \quad b \equiv \int_0^{2\pi} Q(\theta,t)e^{-\imath\theta}d\theta \ . \tag{48.227}$$

To simulate the equations (48.225) we expand the distribution function in spatial harmonics [783],

$$Q(\theta,t) \equiv \sum_\nu Q_\nu(t) e^{\imath\nu\theta} \ . \tag{48.228}$$

In this expansion the normalization and the bunching become,

$$Q_0 = 1/2\pi \quad , \quad |b| = 2\pi|Q_1| \ , \tag{48.229}$$

and the equations (48.225) immediately yield,

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -2\pi\imath N U_0 \alpha_+ Q_1 - \kappa\alpha_- \\ \frac{dQ_\nu}{dt} &= \frac{8\omega_{\rm rec} U_0 \alpha_+}{\gamma_{\rm frc}} \nu \left(\alpha_- Q_{\nu+1} + \alpha_-^* Q_{\nu-1}\right) - \nu^2 D_\theta Q_\nu \end{aligned}} \ . \tag{48.230}$$

We will derive the results (48.229) and (48.230) in Exc. 48.6.7.3. Also,

$$kv = \frac{d}{dt}\arctan\frac{\mathfrak{Im}\,\alpha_-}{\mathfrak{Re}\,\alpha_-} \ , \tag{48.231}$$

and,

$$\begin{aligned} \langle\dot{\theta}\rangle &\equiv \int_0^{2\pi} \dot{Q}(\theta,t)d\theta = \sum_\nu \dot{Q}_\nu(t)\int_0^{2\pi} e^{\imath\nu\theta}d\theta \\ &= \sum_\nu \frac{8\omega_{\rm rec} U_0\alpha_+}{\gamma_{\rm frc}}\nu\left(\alpha_- Q_{\nu+1}\alpha_-^* Q_{\nu-1}\right)\delta_{\nu 0} = \frac{16\omega_{\rm rec} U_0\alpha_+}{\gamma_{\rm frc}}\mathfrak{Re}\left(\alpha_- Q_1^*\right) \ . \end{aligned} \tag{48.232}$$

These equations can be easily simulated.

Matlab simulations of the Fokker-Planck equation, shown in Fig. 48.29, reproduce quantitatively the curves previously obtained by simulations of the Langevin equations.

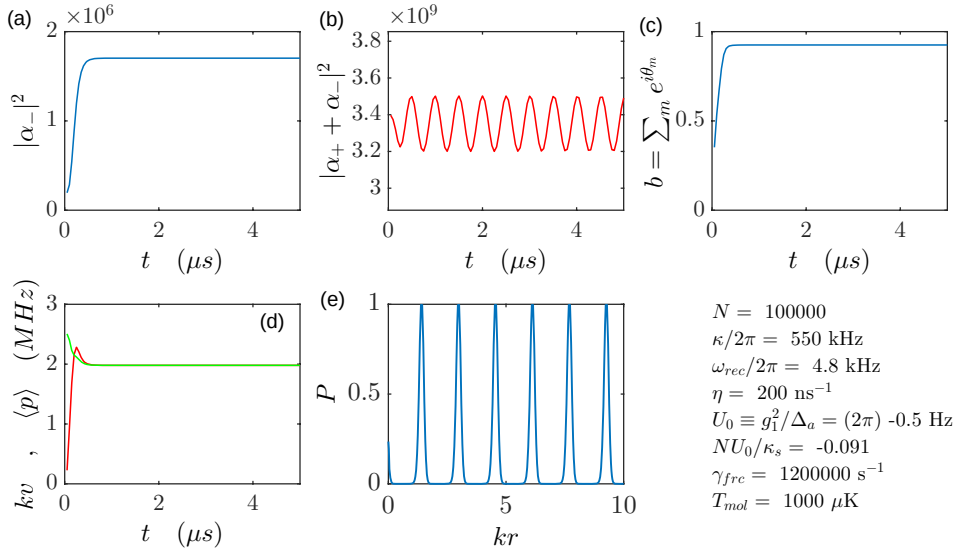

Figure 48.29: (code) Temporal evolution of the complete dynamics with phase transition of the viscous CARL. The same parameters as in Fig. 48.27. Shown are (a) the number of photons in the probe mode, (b) the beat signal, (c) the bunching, (d) the phase of the standing wave and the position of the center-of-mass of the cloud, and (e) the atomic density distribution.

48.6.2.2 Bistability and instability of the viscous CARL

The threshold can be found by simulating the Fokker-Planck equation while varying a control parameter (pumping power, temperature, number of atoms) sufficiently slowly, that the system always remains in a steady state. Fig. 48.30 shows the behavior of the CARL, while the pump power is linearly reduced and then linearly increased at different velocities. We observe a bistability that slightly depends on the speed of the ramp. The behavior of the mass-center velocity kv_{cm} and the phase of the standing wave, $\dot{\phi}$, are different [782] [21].

48.6.3 Thermalization in the Vlasov equation

The basic equations describing our ring-cavity filled with atoms are [542],

$$\boxed{\begin{aligned} \dot{\alpha}_- &= \kappa\alpha_- - \imath U_0 \alpha_+ \sum_m e^{\imath\theta_m} \\ \dot{\theta}_n &= V_n \\ \dot{V}_n &= 8\imath\omega_{\rm rec} U_0 \alpha_+ (\alpha_- e^{-\imath\theta_n} - \alpha_-^* e^{\imath\theta_n}) - \gamma_{\rm frc}(V_n - V_n^{(0)}) \end{aligned}} \quad , \tag{48.233}$$

[21] We can expect a second phase transition when the pump power exceeds a critical value, because for $NU_0 > \kappa$, the CARL becomes unstable again: It will unlock from the self-determined frequency and start to oscillate strongly. However, this effect is not described by the equations used for the simulation, which suppose an adiabatic elimination of the inertia.

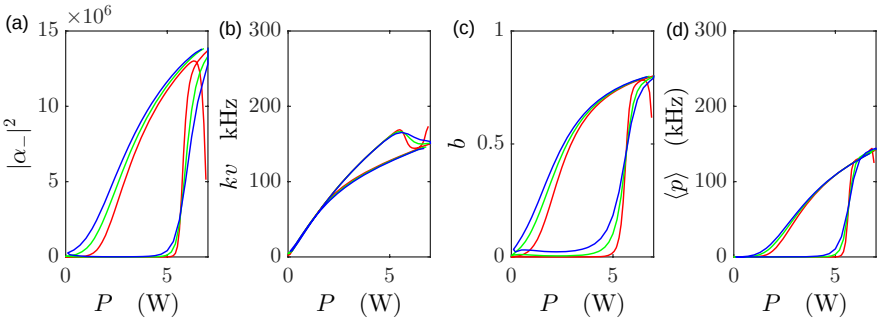

Figure 48.30: (code) Bistability of CARL near the threshold when the power is ramped at different paces.

if we assume the pump mode to be stationary $\alpha_+ = \eta_+/\kappa^{-1}$ and define the atomic bunching parameter by $b = \frac{1}{N}\sum_j e^{2ikx_j}$. A non-zero steady-state temperature is reached, if we allow the steady-state velocities of the atoms $v_j^{(0)}$ to be *different* for all atoms and distributed according to a Maxwell-Gaussian velocity distribution. The assumption of a common steady-state velocity for all atoms obviously results in perfect bunching and cooling to $T = 0$.

Let us introduce a local phase space density of the atomic cloud $Q(x, p, t)$ as a two-dimensional field in phase space. The time-evolution of this quantity is given by the so-called *Vlasov equation* (or collisionless Boltzmann equation),

$$0 = \partial_t Q + v\partial_x Q + F\partial_p Q + \gamma_{th}(Q - Q_0) \ , \tag{48.234}$$

where v and F are the center-of-mass velocity and force taken from equation (48.233) without the friction term. According to this equation the atomic cloud tends to a stationary distribution Q_0 as time goes on. Following Bonifacio *et al.* [113] and Javaloyes [479, 480, 481], we replace the friction term by an additional (Vlasov) equation:

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\imath N U_0 \alpha_+ b - \kappa\alpha_- \\ \dot{\theta} &= \omega_{\rm rec} V \\ \dot{V} &= \imath U_0 \alpha_+ (\alpha_- e^{-\imath\theta} - \alpha_-^* e^{\imath\theta}) \\ 0 &= \partial_t Q + \dot{\theta}\partial_\theta Q + \dot{\varrho}\partial_\varrho Q + \gamma_{\rm frc}(Q - Q_0) \end{aligned}} \ . \tag{48.235}$$

The bunching parameter can now be rewritten in terms of

$$b = \int_0^{2\pi} d\theta \int_{-\infty}^{\infty} d\varrho \ Q(\theta, \varrho, t) \ e^{2\imath\theta} \ . \tag{48.236}$$

The equilibrium distribution is chosen to be a homogeneous cloud with a Maxwell-Boltzmann velocity distribution,

$$Q_0 = \frac{1}{2\pi}\sqrt{\frac{\sigma}{\pi}} e^{-\sigma\varrho^2} \ , \tag{48.237}$$

where $\sigma \equiv \hbar\omega_{\rm rec}/k_{\rm B}T$ with $\omega_{\rm rec} \equiv \hbar k^2/2m$ such that $\int_0^{2\pi} d\theta \int_{-\infty}^{\infty} Q_0 d\varrho = 1$. We now perform a linear stability analysis. We expand Q around the steady state, $Q(\theta,\varrho,t) = Q_0(\varrho) + Q_1(\theta,\varrho,t)$ and retain to first order,

$$0 = \partial_t Q_1 + \dot\theta\partial_\theta Q_1 + \dot\varrho\partial_\varrho Q_0 + \gamma_{th} Q_1 \ . \tag{48.238}$$

Now we look for a time-dependent particular solution by inserting the ansatz,

$$\begin{aligned} \alpha_-(t) &= \beta_- e^{\imath\lambda t} \qquad \text{with} \qquad \dot\beta_- = 0 \\ Q_1(\theta,\varrho,t) &= H_1(\varrho) e^{-2\imath\theta} e^{\imath\lambda t} + c.c. \ , \end{aligned} \tag{48.239}$$

where $i\lambda \equiv \lambda_g + i\lambda_\omega$ into the field equation (48.235)a, the first order expansion of the Vlasov equation (48.238) (only retaining co-rotating terms) and into the expression for bunching (48.236). This ansatz accounts for the fact that, in steady state, we expect a fixed CARL frequency ν and a spatially modulated density distribution of the atoms. The set of equations becomes,

$$\begin{aligned} qi\lambda\beta_- &= -\kappa\beta_- - \imath N U_0 \tilde\eta_+ b e^{-\imath\lambda t} \\ 0 &= \imath\lambda H_1(\varrho) - 4\imath\omega_{\rm rec}\varrho H_1(\varrho) + \imath U_0\tilde\eta_+\beta_-\partial_\varrho Q_0 + \gamma_{th} H_1(\varrho) \\ b &= \int_0^{2\pi} d\theta \int_{-\infty}^{\infty} d\varrho \ H_1(\varrho) e^{\imath\lambda t} \ . \end{aligned} \tag{48.240}$$

With the definition,

$$\begin{aligned} \Gamma(\sigma,\gamma_{th},\imath\lambda) &\equiv \int_{-\infty}^{\infty} \frac{d\varrho \ \partial_\varrho Q_0}{\imath\lambda - 4\imath\omega_{\rm rec}\varrho + \gamma_{th}} \\ &= -\int_{-\infty}^{\infty} \frac{d\varrho \ 4\imath\omega_{\rm rec} Q_0}{(\imath\lambda - 4\imath\omega_{\rm rec}\varrho + \gamma_{th})^2} \ , \end{aligned} \tag{48.241}$$

the solution of the above set of equations is,

$$\begin{aligned} H_1(\varrho) &= \frac{-\imath U_0\tilde\eta_+\beta_-\partial_\varrho Q_0}{\imath\xi - 4\imath\omega_{\rm rec}\varrho + \gamma_{th}} \\ b &= -e^{\imath\xi t}\imath U_0\tilde\eta_+\beta_- 2\pi\Gamma(\sigma,\gamma_{th},\imath\lambda) \\ 0 &= \left[\kappa + \imath\lambda + N U_0^2\tilde\eta_+^2 \ 2\pi\Gamma(\sigma,\gamma_{th},\imath\lambda)\right] \ \beta_- \ . \end{aligned} \tag{48.242}$$

48.6.3.1 Calculation of the threshold

The bifurcation where the reverse field crosses the threshold to lasing occurs at $\lambda_g = 0$. We divide the field equation in real and imaginary parts,

$$\begin{aligned} \kappa + N U_0^2\tilde\eta_+^2 \ 2\pi\mathfrak{Re}\,\Gamma(\sigma,\gamma,\imath\lambda_\omega) &= 0 \\ \nu + N U_0^2\tilde\eta_+^2 \ 2\pi\mathfrak{Im}\,\Gamma(\sigma,\gamma,\imath\lambda_\omega) &= 0 \ . \end{aligned} \tag{48.243}$$

Now the condition $\lambda_\omega\mathfrak{Re}\,\Gamma(\sigma,\gamma_{th},\imath\lambda_\omega) = \kappa\mathfrak{Im}\,\Gamma(\sigma,\gamma_{th},\imath\lambda_\omega)$ leads to,

$$\int_{-\infty}^{\infty} \frac{d\varrho \ \varrho e^{-\sigma\varrho^2}(\kappa\lambda_\omega - 2\kappa\varepsilon\varrho + \lambda_\omega\gamma_{th})}{(\lambda_\omega - 2\varepsilon\varrho)^2 + \gamma_{th}^2} = 0 \ . \tag{48.244}$$

The values λ_ω where this integral is zero are inserted into one of the equations (48.243). Finally,

$$\tilde{\eta}_+^2 = \frac{-1}{N\tilde{U}_0^2\ 2\pi\Re\mathfrak{e}\,\kappa\Gamma(\sigma,\gamma_{th},\imath\lambda_\omega)}\ , \tag{48.245}$$

is the expression for the pump power threshold as a function of temperature σ, friction γ_{th}, cavity damping κ and coupling constant U_0. The intracavity CARL power is,

$$P_+ = \hbar\omega\delta\ \tilde{\eta}_+^2\ . \tag{48.246}$$

λ_ω is the associated CARL frequency, i.e. the frequency difference between probe and pump.

The final equations show that the threshold power drops as NU_0^2 increases. To see the dependencies of the threshold power on T and γ_{th}, we have to evaluation of the integral (48.244). Fig. 48.31 shows a numerical evaluation of Eqs. (48.244),(48.245) and (48.246) for finite T and γ_{th}.

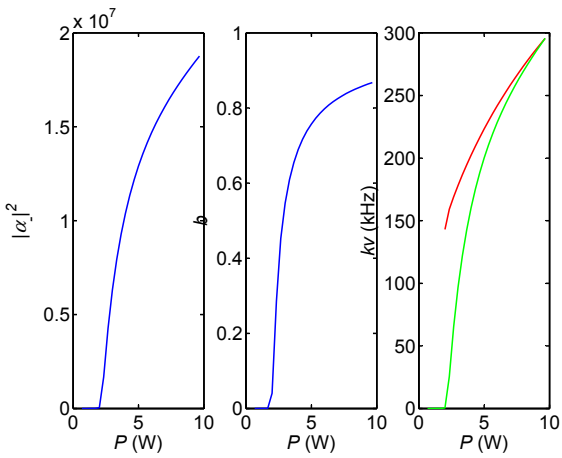

Figure 48.31: (code) Intracavity threshold power as a function of temperature and friction coefficient. The coupling strength is set to $\tilde{U}_0 = -10^{-7}$, the atom number is $N = 10^6$.

Apparently, the threshold pump power drops with vanishing friction and with low temperatures. For typical experimental situations, $T \approx 100\ \mu$K and $\gamma_{th} \approx 10\kappa$, we expect threshold powers on the order of about $P_+ = 1$ W, corresponding to $P_+^{(out)} = 4\ \mu$W leaking out of the cavity.

48.6.4 The Kuramoto model

Ripples on a dusty street driven by cars, rapids in a river arising spontaneously or behind an obstacle, wind blowing over a water surface spontaneously creating waves. Imagine a photon wind blowing over an atomic sea. Just like for water waves friction hinders boundless acceleration. The analogies are wind-molasses-friction, water-atoms, wind-acceleration-field, gravitation-dipole-force. The phenomenon is closely related to the *dissipative structure*. See also (watch talk) and (watch talk).

Our system has the advantage over macroscopic systems, that the hypothesis of uniform coupling is exactly satisfied, because the coupling medium, i.e. the light fields are delocalized within the cavity mode. In contrast, rapids develop exclusively behind the perturbation. There are no delay times effects and no spatial constraints due to a finite size of the individual oscillators.

The viscous CARL system is representative for of the vast class of *Kuramoto systems* [895]. This can be seen most appropriately by rewriting the CARL equations in terms of phase and amplitude of individual atoms. Another approach is via the Fokker-Planck equation, for which there already exists a Kuramoto equivalence.

Why is it interesting to investigate yet another coupled oscillator system? Our CARL is fully classical, although we deal with microscopic particle, such as atoms and photons. However, our system bears the possibility of being transferred to quantum situations, and thus to study the coupling of large ensembles of quantum oscillators. Furthermore, the coupling mechanism is well understood and controlable by experiment. Because the coupling goes through the standing wave fraction, it depends on the atom number and the coupling strength independently. Furthermore, the tunable friction force (temperature) corresponds to a variable width of the distribution of the oscillator frequencies, which we can manipulate in-situ and on-line.

Another realization of the Kuramoto model would be atoms in a ring cavity standing wave. Cold trapped atoms have the same oscillation frequencies. And thus do not need to synchronize. For hot atoms, however, the oscillation period depends on their kinetic energy.

The equation for the phases of the atoms is similar to the Kuramoto model [481],

$$\boxed{\dot{\theta}_n = \frac{K}{N}\sum_m \sin(\theta_n - \theta_m) - \xi_n(t)} \ . \tag{48.247}$$

The CARL equations which describes the dynamics of an ensemble of mean-field coupled oscillators, belong to the class of Kuramoto systems [480]. The main differences are: a Dirac-like distribution of eigenfrequencies and a mean-field self-consistently provided by a dynamical equation. Hence, in contrast to the original Kuramoto model, where the collective oscillation frequency is just the mean of the individual frequencies, the CARL frequency is self-determined and depends also on control parameters. This phenomenon is known from other systems like rhythmic applause, which only takes place by a reduction of the individual frequencies of clapping hands, towards a resonance. For this to happen the mean-field must self-adjust while the individual oscillators synchronize, e.g. the noise produce by the audience must adjust to the average desire of the audience to produce a satisfying level of noise.

In [969] is stated: 'The essence of the problem is the competition between the intrinsic disorder (i.e. noise and diffusion) and the dynamical coupling strength. In the Kuramoto model, the disorder enters via the distribution of natural frequencies, while the effective coupling strength is set by the parameter combination $K\cos\alpha_j$.'

48.6.4.1 Phase formalism of CARL

The starting point is the CARL equations (48.50). We make ansatz,

$$\alpha_+ \equiv \alpha_1 \quad , \quad \alpha_- \equiv \alpha_2\, e^{\imath\phi} \quad , \quad \eta_+ \equiv \eta_1 \quad , \quad \eta_- \equiv \eta_2\, e^{\imath\Delta} \ , \tag{48.248}$$

where the quantities with numeric suffixes are real, such that,

$$|\alpha_+ + \alpha_-|^2 = \alpha_1^2 + \alpha_2^2 + 2\alpha_1\alpha_2 \ \cos\phi \ . \tag{48.249}$$

By this ansatz we assume that a pumping laser is locked to the mode α_+ of the ring cavity, such that the phases of the fields α_+ and η_+ are equal and, without loss of generality, zero. On the other hand, the phase ϕ of the probe mode is a dynamic variable. Inserting the ansatz into the equations (48.50) we obtain,

$$\begin{aligned}
\dot{\alpha}_1 &= -(\kappa + \imath N U_0 - \imath\Delta_c)\alpha_1 - \imath U_0 \sum_n e^{-\imath\theta_n + \imath\phi}\alpha_2 + \eta_1 \ , \\
\dot{\alpha}_2 + \imath\dot{\phi}\alpha_2 &= -(\kappa + \imath N U_0 - \imath\Delta_c)\alpha_2 - \imath U_0 \sum_n e^{\imath\theta_n - \imath\phi}\alpha_1 + \eta_2 e^{\imath\Delta - \imath\phi} \ , \\
\ddot{\theta}_n &= 16\omega_{\rm rec} U_0 \alpha_1\alpha_2 \sin(\theta_n - \phi) \ .
\end{aligned} \tag{48.250}$$

The first two equations, which describe the dynamics of the fields, can be separated into real and imaginary parts,

$$\begin{aligned}
\dot{\alpha}_1 &= -\kappa\alpha_1 - U_0 \sum_n \sin(\theta_n - \phi)\alpha_2 + \eta_1 \\
\dot{\alpha}_2 &= -\kappa\alpha_2 + U_0 \sum_n \sin(\theta_n - \phi)\alpha_1 + \eta_2 \cos(\phi - \Delta) \ , \\
\Delta_c &= N U_0 \left(1 + N^{-1} \sum_n \cos(\theta_n - \phi)\frac{\alpha_2}{\alpha_1}\right) \ , \\
\dot{\phi} &= \Delta_c - N U_0 \left(1 + N^{-1} \sum_n \cos(\theta_n - \phi)\frac{\alpha_1}{\alpha_2}\right) - \frac{\eta_2}{\alpha_2}\sin(\phi - \Delta) \ .
\end{aligned} \tag{48.251}$$

Eliminating Δ_c, we can substitute the third and fourth equations for,

$$\dot{\phi} = U_0 \left(\frac{\alpha_2}{\alpha_1} - \frac{\alpha_1}{\alpha_2}\right) \sum_n \cos(\theta_n - \phi) - \frac{\eta_2}{\alpha_2}\sin(\phi - \Delta) \ . \tag{48.252}$$

Defining the 'bunching' parameter,

$$b \equiv |b| e^{\imath\psi} \equiv N^{-1} \sum_n e^{\imath\theta_n} \ , \tag{48.253}$$

we finally obtain, in the presence of friction and dissipation,

$$\boxed{\begin{aligned}
\dot{\alpha}_1 &= -\kappa\alpha_1 - N U_0 \alpha_2 |b| \sin(\psi - \phi) + \eta_1 \\
\dot{\alpha}_2 &= -\kappa\alpha_2 + N U_0 \alpha_1 |b| \sin(\psi - \phi) + \eta_2 \cos(\phi - \Delta) \\
\dot{\phi} &= N U_0 \left(\tfrac{\alpha_2}{\alpha_1} - \tfrac{\alpha_1}{\alpha_2}\right) |b| \cos(\psi - \phi) - \tfrac{\eta_2}{\alpha_2}\sin(\phi - \Delta) \\
\ddot{\theta}_n &= 16\omega_{\rm rec} U_0 \alpha_1\alpha_2 \sin(\theta_n - \phi) - \gamma_{\rm frc}\dot{\theta}_n + \xi_n
\end{aligned}} \ . \tag{48.254}$$

A particularly interesting case is that of unidirectional pumping, $\eta_2 = 0$. Assuming that the pump mode be not affected,$\dot{\alpha}_1 = 0$, and that the probe mode be weak,

$\alpha_1 \gg \alpha_2$, and making the adiabatic approximation, $\ddot{\theta}_n = 0$, of the atomic motion, we obtain,

$$\boxed{\begin{aligned} \dot{\alpha}_2 &= -\kappa\alpha_2 + NU_0\alpha_1|b|\sin(\psi-\phi) \\ \dot{\phi} &\simeq -\frac{NU_0\alpha_1}{\alpha_2}|b|\cos(\psi-\phi) \\ \dot{\theta}_n &= \frac{\xi_n}{\gamma_{\text{frc}}} + \frac{16\omega_{\text{rec}}U_0\alpha_1\alpha_2}{\gamma_{\text{frc}}}\sin(\theta_n-\phi) \end{aligned}} \ . \tag{48.255}$$

We note that the equation for the phases of the atoms is similar to the Kuramoto equation (48.247).

48.6.4.2 Relationship between CARL and Kuramoto

The viscous CARL described by the formulas (48.255) corresponds to the Kuramoto model [895]. Defining $\theta_n \equiv 2kx_n$ as the position of the nth atom, we assume the pump laser to be in resonance and write $\alpha_+ \equiv \eta_+/\kappa$ [542]. The diffusion in the momentum space is a process that limits the temperature in optical molasses.

We start from the Langevin equations (48.210). In addition, we assume that the standing wave propagates at a constant velocity, which is to say that for a strong viscous damping, the system quickly finds a steady state. This condition is formulated by $d_t|\alpha_-| = 0$ and $\dot{\alpha}_- = i\omega_{ca}\alpha_-$ with constant velocity ω_{ca}, which may be different from the velocity of the center of mass kv. We note that this assumption can introduce a considerable error, when used to describe temporal phase transitions, since, as shown by simulations of the complete dynamics (48.214), the mode α_- exhibits a transient behavior, as well. We obtain from the first Eq. (48.210),

$$\alpha_- = -\frac{\imath U_0\alpha_+}{\imath\omega_{ca}+\kappa}\sum_m e^{\imath\theta_m} \ . \tag{48.256}$$

Substituting Eq. (48.256) into the second equation (48.210),

$$\begin{aligned} \dot{\theta}_n &= \frac{\xi_n}{\gamma_{fr}} + \frac{8\omega_{\text{rec}}NU_0^2\alpha_+^2}{\gamma_{fr}}\frac{1}{N}\sum_m\left(\frac{e^{\imath\theta_m-\imath\theta_n}}{\imath\omega_{ca}+\kappa} + \frac{e^{-\imath\theta_m+\imath\theta_n}}{-\imath\omega_{ca}+\kappa}\right) \\ &= \frac{\xi_n}{\gamma_{fr}} + \frac{16\omega_{\text{rec}}NU_0^2\alpha_+^2}{\gamma_{fr}(\omega_{ca}^2+\kappa^2)}\frac{1}{N}\sum_m\left[\kappa\cos(\theta_m-\theta_n)+\omega_{ca}\sin(\theta_m-\theta_n)\right] \ . \end{aligned} \tag{48.257}$$

Defining the *order parameter*,

$$b \equiv |b|e^{\imath\psi} \equiv \frac{1}{N}\sum_m e^{\imath\theta_m} \ , \tag{48.258}$$

which also implies,

$$|b|\sin(\psi-\theta_n) = \frac{1}{N}\sum_m \sin(\theta_m-\theta_n) \ , \tag{48.259}$$

we can write Eq. (48.259) as,

$$\dot{\theta}_n = \frac{\xi_n}{\gamma_{fr}} + \frac{8\varepsilon NU_0^2\alpha_+^2\kappa}{\gamma_{fr}(\omega_{ca}^2+\kappa^2)}|b|\left[\cos(\psi-\theta_n)+\frac{\omega_{ca}}{\kappa}\sin(\psi-\theta_n)\right] \ . \tag{48.260}$$

In the 'good cavity' limit, $\kappa \ll \omega$, using $(2kv)^3 = 8\varepsilon N U_0^2 \alpha_+^2 \kappa/\gamma_{fr}$ and additionally assuming small amplitude oscillations, $\psi \approx \theta_n$, that is, good 'bunching',

$$\dot{\theta}_n \approx \frac{\xi_n}{\gamma_{fr}} + \frac{(2kv)^3}{\omega_{ca}^2}|b| + \frac{(2kv)^3}{\kappa\omega_{ca}}|b|\sin(\psi - \theta_n) \ . \tag{48.261}$$

This shows that in the limit of perfect 'bunching' $\omega_{ca} = 2kv$ must be satisfied. If really $\kappa \ll \omega$ is valid, we can despise the cosine. Introducing the Kuramoto coupling constant,

$$K \equiv \frac{16\omega_{\rm rec} N U_0^2 \alpha_+^2 \omega_{ca}}{\gamma_{fr}(\omega_{ca}^2 + \kappa^2)} \approx \frac{1}{\kappa}\left(\frac{16\omega_{\rm rec} N U_0^2 \alpha_+^2 \kappa}{\gamma_{fr}}\right)^{2/3} = (4\omega_{\rm rec}\rho)^2 \left(\frac{4}{\kappa\gamma_{fr}^2}\right)^{1/3} , \tag{48.262}$$

using $2\varepsilon\rho = (4\varepsilon N U_0^2 \alpha_+^2)^{1/3}$, Eq. (48.260) is precisely the one used by the *Kuramoto model* of N coupled harmonic oscillators synchronizing over time,

$$\boxed{\dot{\theta}_n \approx \frac{\xi_n}{\gamma_{fr}} + \frac{\kappa K}{\omega_{ca}}|b| + K|b|\sin(\psi - \theta_n)} \ . \tag{48.263}$$

Oscillators with $\omega_n \leq K|b|$ are locked. For a reasonable 'bunching' this is satisfied in the 'good cavity' limit.

48.6.4.3 Kuramoto model with inertial effects

It is possible to incorporate inertial effects into the Kuramoto model [2]: allowing for $\ddot{\theta}_n \neq 0$, but still assuming $d_t|\alpha_-| = 0$ and $\dot{\alpha}_- = i\omega\alpha_-$, the equation (48.257) becomes,

$$\begin{aligned}\ddot{\theta}_n &= -\gamma_{fr}\dot{\theta}_n + \xi_n + \frac{16\omega_{\rm rec} N U_0^2 \alpha_+^2}{\omega^2 + \kappa^2}\frac{1}{N}\sum_m \left[\kappa\cos(\theta_m - \theta_n) + \omega\sin(\theta_m - \theta_n)\right] \\ &= -\gamma_{fr}\dot{\theta}_n + \xi_n + \frac{\kappa}{\omega}K|b|\cos(\psi - \theta_n) + K|b|\sin(\psi - \theta_n) \ .\end{aligned} \tag{48.264}$$

48.6.4.4 Fokker-Planck equation

Let us write the *Kuramoto equation* including stochastic noise,

$$\dot{\theta}_n = \omega + K|b|\sin(\psi - \theta_n) + \xi_n(t) \ , \tag{48.265}$$

define the order parameter,

$$b = |b|e^{\imath\psi} \ , \tag{48.266}$$

and the Langevin-force $\langle\xi_n(t)\rangle = 0$ and $\langle\xi_n(t)\xi_m(\tau)\rangle = 2D\delta_{ij}\delta(t-\tau)$.

The Fokker-Planck equation associated to Eq. (48.265) reads,

$$\frac{\partial\rho}{\partial t} = -\frac{\partial\rho\ \left[\omega + K|b|\sin(\psi - \theta)\right]}{\partial\theta} + D\frac{\partial^2\rho}{\partial\theta^2} \ , \tag{48.267}$$

where $D = \sigma^2/\gamma_{fr}$. Inserting $\rho(\theta, t) \equiv \sum_\nu \rho_\nu(t)e^{\imath\nu\theta}$,

$$\frac{\partial\rho_\nu}{\partial t} = -(\nu^2 D + \imath\nu\omega)\rho_\nu + \tfrac{1}{2}\nu K\left(b^*\rho_{\nu-1} - b\rho_{\nu+1}\right) \ , \tag{48.268}$$

especially,

$$\int_0^{2\pi} \rho(\theta,t)d\theta = 1 \qquad \Longrightarrow \qquad \rho_0 = \tfrac{1}{2\pi} \ , \tag{48.269}$$

and we defined the bunching as $|b|$, where,

$$b \equiv \int_0^{2\pi} \rho(\theta,t)e^{-i\theta}d\theta \qquad \Longrightarrow \qquad b \equiv 2\pi\rho_1 \ . \tag{48.270}$$

48.6.4.5 Laser-type equation for CARL

Defining the displacement of the nth atomic oscillator as,

$$E_n \equiv e^{\imath\theta_n} \ , \tag{48.271}$$

we can rewrite the second equation (48.210) as,

$$\dot{E}_n = \frac{\imath\xi_n}{\gamma_{fr}}E_n - \frac{8\omega_{\rm rec}U_0\alpha_+}{\gamma_{fr}}(\alpha_- - \alpha_-^* E_n^2) \ . \tag{48.272}$$

Substituting α_- by the integral of the first equation (48.210),

$$\dot{E}_n = \frac{\imath\xi_n}{\gamma_{fr}}E_n + \frac{8\omega_{\rm rec}\imath NU_0^2\alpha_+^2}{\gamma_{fr}}\left(\int be^{-\kappa(t-t')}dt' + E_n^2\int b^* e^{-\kappa(t-t')}dt'\right) \ . \tag{48.273}$$

In the limit $e^{-\kappa(t-t')} = \kappa^{-1}\delta(t-t')$ we obtain an equation similar to that of an ordinary laser,

$$\begin{aligned}\dot{E}_n &= \frac{\imath\xi_n}{\gamma_{fr}}E_n + \frac{8\omega_{\rm rec}\imath NU_0^2\alpha_+^2}{\gamma_{fr}\kappa}(b + b^* E_n^2) \\ &= \frac{\imath\xi_n}{\gamma_{fr}}E_n + \frac{8\omega_{\rm rec}\imath NU_0^2\alpha_+^2}{\gamma_{fr}\kappa}\left(\sum_m E_m + \sum_m E_m^* E_n^2\right) \ .\end{aligned} \tag{48.274}$$

48.6.5 Thermodynamics of the CARL process

There is an analogy between the laser threshold and a second-order phase transition [835], p. 341 *ff*: '... The usual treatment of laser behavior is a self-consistent field theory. In the laser analysis each atom develops a radiating dipole in an electromagnetic field due to (i.e. emitted by) all the other atoms. The radiation field produced by an ensemble of radiating atoms is then calculated in a self-consistent fashion. (...This) suggests the identification of the laser electric field as the variable corresponding to the (...) order parameter and the atomic population inversion as that corresponding to the temperature.'

Note that numerical simulations revealed that in certain regimes the CARL corresponds to a first-order phase transition: At high temperatures the probe to pump power diagram shows bistability [479] and [782].

The correspondence between CARL and a common laser is illustrated by the table below. A number of questions arise from the analogy:

The CARL being a laser without inversion, what is the equilibrium parameter? Is it the temperature of the atomic cloud? How to calculate the density of states?

	ferromagnet	laser
control parameter	external magnetic field H	pump intensity $\mathcal{S}$
equilibrium parameter	temperature T	population inversion σ
order parameter	magnetization $\langle M\rangle = \begin{cases} 0 & T > T_c \\ c\sqrt{\frac{T_c - T}{T}} & T < T_c \end{cases}$	electric field $\langle E\rangle = \begin{cases} 0 & \sigma > \sigma_c \\ c\sqrt{\frac{\sigma_c - \sigma}{\sigma}} & \sigma < \sigma_c \end{cases}$
probability density	$P(M) \propto e^{-F(M)/k_{\mathrm{B}}T}$	P-representation $P(x,y) \propto e^{-G(x,y)/K\sigma}$
thermodyn. free energy	$F = F(T,H)$	$G(x,y)$
heat capacity	$C(T) = \frac{\partial E(T)}{\partial T}$	?

	CARL atoms	CARL light
control parameter	pump intensity η	pump intensity η
equilibrium parameter	temperature T	?
order parameter	bunching $b = \begin{cases} 0 & T > T_c \\ ? & T < T_c \end{cases}$	electric field $\langle\alpha\rangle = \begin{cases} 0 \\ ? \end{cases}$
probability density	?	?
thermody. free energy	?	?
heat capacity	?	?

48.6.6 CARL as a laser

Why is CARL a laser? What is the basic difference between CARL and an AOM or a moving Bragg mirror? CARL is essentially based on exponential self-amplification. This self-amplification is in fact observed in our switch-off experiment [542]. But a laser is normally understood as a steady-state system. For CARL to find to a steady-state we have to insert friction forces.

Gordon rewrites the CARL as a common laser: He generalizes the linear stability analysis (previous Sec.) and retains the lowest-order nonlinearity. The Fokker-Planck equations read:

$$\begin{aligned} \frac{dB_n}{d\tau} &= \imath n(aB_{n-1} + a^* B_{n+1}) - n^2 D B_n \\ \frac{da}{d\tau} &= B_1 - \kappa a \ , \end{aligned} \tag{48.275}$$

with $B_0 = 1$ and $B_{-n} = B_n^*$. Linearization means $B_{n>1} = 0$,

$$\begin{aligned} \frac{dB_1}{d\tau} &= \imath a - D B_1 \\ \frac{da}{d\tau} &= B_1 - \kappa a \end{aligned} \tag{48.276}$$

or,

$$\frac{d^2a}{d\tau^2} + (\kappa + D)\frac{da}{d\tau} + (\kappa D - \imath)a = 0 \tag{48.277}$$
$$\frac{d^2B_1}{d\tau^2} + (\kappa + D)\frac{dB_1}{d\tau} + (\kappa D - \imath)B_1 = 0$$

The determinant is,

$$\det\begin{pmatrix} -D-\lambda & \imath \\ 1 & -\kappa-\lambda \end{pmatrix} = (D+\lambda)(\kappa+\lambda) - \imath = 0 \tag{48.278}$$

Including the lowest-order nonlinear term means $B_{n>2} = 0$,

$$\frac{dB_2}{d\tau} = 2\imath a B_1 - 4DB_2 \tag{48.279}$$
$$\frac{dB_1}{d\tau} = \imath a + \imath a^* B_2 - DB_1$$
$$\frac{da}{d\tau} = B_1 - \kappa a$$

Assuming $dB_2/d\tau = 0$,

$$\frac{dB_1}{d\tau} = \imath a - \left(\frac{|a|^2}{2D} + D\right)B_1 \tag{48.280}$$
$$\frac{da}{d\tau} = B_1 - \kappa a$$

or,

$$\frac{d^2B_1}{d\tau^2} + (\kappa + D)\frac{dB_1}{d\tau} + (\kappa D - \imath)B_1 = -\frac{1}{2D}\left(\frac{d}{d\tau} + \kappa\right)|a|^2 B_1 \tag{48.281}$$
$$= -(K_1|a|^2 - K_2|a|^4)B_1$$
$$\frac{d^2a}{d\tau^2} + (\kappa + D)\frac{da}{d\tau} + (\kappa D - i)a = -\frac{|a|^2}{2D}\left(\frac{d}{d\tau} + \kappa\right)a$$

substitute $a(\tau) = A(\tau)e^{\lambda\tau}$ and Eq. (xx),

$$e^{\lambda\tau}\left(\frac{d^2}{d\tau^2} + 2\lambda\frac{d}{d\tau} + \lambda^2\right)A + e^{\lambda\tau}\left((\kappa + D)\frac{d}{d\tau} + (\kappa + D)\lambda\right)A - (\lambda^2 + D\lambda + \kappa\lambda)e^{\lambda\tau}A \tag{48.282}$$
$$= -\frac{|e^{\lambda\tau}A|^2}{2D}\left(e^{\lambda\tau}\frac{dA}{d\tau} + \lambda e^{\lambda\tau}A + \kappa e^{\lambda\tau}A\right)$$

neglect $d^2A/d\tau^2$and $|A|^2 dA/d\tau$,

$$e^{\lambda\tau}2\lambda\frac{dA}{d\tau} + e^{\lambda\tau}(\kappa + D)\frac{dA}{d\tau} = -\frac{|e^{\lambda\tau}A|^2}{2D}\left(\lambda e^{\lambda\tau}A + \kappa e^{\lambda\tau}A\right) \tag{48.283}$$

substitute back $a(\tau) = A(\tau)e^{\lambda\tau}$,

$$\begin{aligned}\frac{da}{d\tau} &= \lambda a - \frac{\lambda+\kappa}{2D(2\lambda+\kappa+D)}|a|^2 a \\ &= \lambda a - C|a|^2 a\end{aligned} \tag{48.284}$$

or,

$$\frac{d|a|^2}{d\tau} = 2|a|^2 \mathfrak{Re}\,\lambda - 2|a|^4 \mathfrak{Re}\,C \tag{48.285}$$

in steady-state,

$$0 = \lambda a - C|a|^2 a\ . \tag{48.286}$$

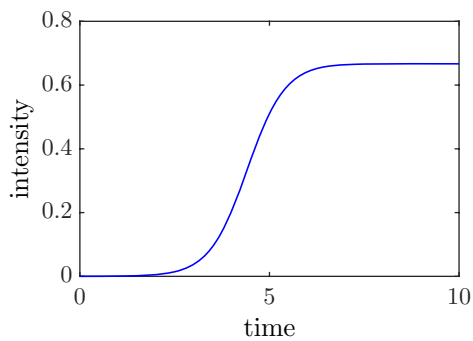

Figure 48.32: (code) Laser crossing the threshold.

According to A. Politi a general laser theory exists, there is no point in repeating this for CARL. The analogy is there and evident.

48.6.6.1 CARL as a ferromagnet

A similar treatment with $a(\tau) = A(\tau)e^{\lambda\tau}$ and $B_1(\tau) = \beta(\tau)e^{\lambda\tau}$ and $d^2\beta/d\tau^2 = 0$ and $|A|^2 d\beta/d\tau = 0$ and $\beta d|A|^2/d\tau = 0$ results in,

$$\begin{aligned}\frac{dB_1}{d\tau} &= \lambda B_1 - \frac{2\lambda+\lambda^*+\kappa}{2D(2\lambda+\kappa+D)}|a|^2 B_1 \\ &= \lambda B_1 - \tilde{C}|a|^2 B_1\ ,\end{aligned} \tag{48.287}$$

i.e. the instability comes from the field and it drives the bunching.

48.6.6.2 Out-of-equilibrium thermodynamics

Strictly speaking the above analogy is flawed. In particular the analogy between CARL bunching and ferromagnetic ordering is not good. While the ferromagnetic ordering occurs as a thermodynamic phase transition, the CARL bunching is driven by a dissipative force, which triggers spatio-temporal instabilities. Therefore viscous

CARL occurs far from thermodynamic equilibrium. This may point towards an interpretation of CARL bunching as a *dissipative structure* along the lines traced by Prigogine, who showed that *non-equilibrium may be a source of order*.

On the other hand, the laser itself is a system operating far from thermal equilibrium, since it requires a pump to emit steady-state radiation. Perhaps a comparison with *estruturas de Bénard* is better than with ferromagnets. Bénard structures occur as spontaneous breaking of translational symmetry, just like CARL. One could say that the periodicity of CARL is predefined by the pump laser wavelength, and thus not surprising. However, the size of the periodic structures is always fixed by boundary conditions in a more or less complicated way. For example, the size of the Bénard structures is fixed by the viscosity, the provided amount of heat, etc., the wavelength of surface waves can be calculated from first principles, i.e. the Navier-Stokes equations and the continuity equation for given boundary conditions. The symmetry breaking resides in the exact *place*, where the Bénard structure develops. It is the *phase*, which is broken, just like for CARL.

The Kuramoto model and the Weiss model of ferromagnetism are both mean field theories [844]. Despite the fundamental difference that ferromagnetism is a thermodynamic feature and Kuramoto a nonequilibrium phenomenon, they are far-reaching analogies. The role of temperature in ferromagnetism is played by external noise in Kuramoto. CARL is clearly a dissipative structure: *It survives only as long as energy is fed to the system.*

48.6.6.3 Finite and infinite temperature reservoirs

The phase transition is ruled by a competition of dissipation and diffusion. If the reservoir has zero temperature $\gamma_{\text{frc}} \neq 0$ but $D = \sigma^2/\gamma_{\text{frc}} = 0$, i.e. we have dissipation without diffusion. In this case, we do not expect a threshold behavior. The Lindtbladt operator for coupling to a finite-temperature reservoir is something like $\mathcal{L} \approx \kappa(\bar{n}+1)\{...emission...\} + \kappa\bar{n}\{...absorption...\} + \eta\{...phase\ noise...\}$, where $\bar{n}$ is the mean photon number at thermal equilibrium with a given temperature $T \propto \bar{n}/(\bar{n}+1)$. The interpretation in terms of dissipation without diffusion is correct according to A. Buchleitner. There are three kinds of noises: 0 temperature noise for $\bar{n} \to 0$, ∞ temperature noise for $\bar{n} \approx \bar{n}+1$ and phase noise. Thus for $T = 0$ the energy flux goes only from the system to the reservoir. At $T > 0$ entropy may go from the reservoir to the system. The system reaches its cooling limit when the temperatures of the system and the reservoir are balanced.

But how to explain Doppler cooling or cavity-cooling? The electromagnetic vacuum is an effective $T = 0$ reservoir, but the cooling is nevertheless limited by the spontaneous decay width or the cavity linewidth, resp.. Why does coupling to a zero-temperature reservoir not cool down to zero? Apparently, the coupling is afflicted by vacuum noise. This permits coupling of degrees of freedom having different temperatures without reaching a temperature equilibrium. Examples are the limit of cavity-cooling to the cavity decay width or simply Doppler-cooling by spontaneous emission.

Interprete damping as scattering into continuum!

48.6.7 Exercises

48.6.7.1 Ex: Viscous CARL

Assuming a perfect 'bunching', $e^{2\imath kz_m} = e^{2\imath kz}$, e $\alpha_- \equiv \beta e^{2\imath kz}$ with $\dot{\beta} = 0$ and $\ddot{z} = 0$ derive the equations (48.199).

48.6.7.2 Ex: Langevin simulations

Langevin simulations

48.6.7.3 Ex: Fokker-Planck equations

Derive the equations (48.229) and (48.230) from (48.227) and (48.225) applying the expansion (48.228).

48.6.7.4 Ex: Kuramoto simulations

Implement the Kuramoto model with pendulum clocks.

48.7 Coherent properties of CARL

In Sec. 48.6.1 we have demonstrated collective interaction of atoms with light fields and how the application of friction via optical molasses can lead to stationary CARL radiation at a self-determined frequency [541]. We have demonstrated that the molasses also lead to diffusion resulting in a threshold behavior and in atomic self-organization at finite temperatures [783, 943]. An interesting question is whether the temperature not only determines the collective behavior, but also the deviation from it. The temperature being related to the amount of random walk on top of the center-of-mass motion, we may wonder whether the viscous CARL radiation bears a signature of the atomic temperature not only in the self-determined CARL frequency, but also in the laser emission bandwidth. It is conceivable that the autocorrelation functions and the emission spectrum of the CARL are influenced by the fact that the atoms experience a random walk in momentum space due to the diffusion in the optical molasses.

In this section, we will attempt an analytical approach, present numerical simulations and discuss how to access to the informations experimentally. The Fokker-Planck approach described in Refs. [783, 943] is particularly well adapted to calculating collective variables. In contrast the simulation of the Langevin equation conveniently gives access to the noise properties.

48.7.1 Analytical derivation of the coherence

Our starting point are the Langevin equations (48.210) [783, 943] in the adiabatic limit, $\ddot{\theta}_n = 0$. The Langevin noise force is uncorrelated,

$$\langle \xi_n^*(t)\xi_m(t+\tau)\rangle \equiv \lim_{T\to\infty} \frac{1}{T}\int_0^T \xi_n^*(t)\xi_m(t+\tau)d\tau = 2D_{\dot{\theta}}\delta_{mn}\delta(\tau) \ , \tag{48.288}$$

where the momentum diffusion coefficient $D_{\dot\theta} = \gamma_{fr}\sigma^2$ is proportional to the atoms' equilibrium temperature, which is related to the Maxwell-Gaussian velocity spread by $\sigma \equiv 2k\sqrt{k_{\rm B}T/m}$. In contrast, the trajectories of the atoms are not, because all atoms are motionally coupled by the fields, so that the noise imparted to one atom is sensed by all others. Therefore the relationship (48.289) certainly does not hold for the atomic positions,

$$\langle\theta_n^*(t)\theta_m(t+\tau)\rangle \nsim \delta_{mn}\delta(\tau) \ . \tag{48.289}$$

48.7.1.1 Single atom

So, let us first concentrate on a single atom coupled to the cavity fields. If its velocity only fluctuates a little around a mean value ω_{ca}, we may write $\theta(t) \equiv \omega_{ca}t+\varphi(t)$. The randomized position has a Gaussian statistics leading to a Brownian motion described by a Wiener-Levy stochastic process: $\langle\varphi(t)\rangle = 0$ and $\langle\varphi(t)\varphi(t+\tau)\rangle = D_\theta(2t+\tau-|\tau|)$ ([835], p. 344),

$$R_{\dot\theta}(\tau) = \langle[\omega_{ca}+\dot\varphi(t)][\omega_{ca}+\dot\varphi(t+\tau)]\rangle = \langle\dot\varphi(t)\dot\varphi(t+\tau)\rangle = 2D_\theta\delta(\tau) \ , \tag{48.290}$$

where $D_\theta = \sigma^2/\gamma_{fr}$ is the position diffusion coefficient. Note that deterministic parts are removed from the function in order to satisfy $\langle\dot\varphi(t)\rangle = 0$. In that case the *spectral density of fluctuations of the atomic phase* is constant,

$$S_{\dot\theta}(f) = \int_{-\infty}^{\infty} R_{\dot\theta}(\tau)e^{-2\pi\imath f\tau}d\tau = 2D_\theta \ . \tag{48.291}$$

Note that $S_{\dot\theta}(f) = f^2S_\theta(f)$. The *variance of the fluctuations* for white noise is or,

$$\sigma^2_{\dot\theta}(\tau) = \langle\dot\varphi(t)^2\rangle = \frac{D_\theta}{\tau} \ . \tag{48.292}$$

Under the assumption $\dot\alpha_- = \imath\omega_{ca}\alpha_-$ and introducing the abbreviation $\alpha_0 \equiv -\imath U_0\alpha_+/(\kappa+\imath\omega_{ca})$, the first equation (48.210) takes the form $\alpha_- = \alpha_0 e^{\imath\theta}$ such that the *autocorrelation function of the field amplitude* reads,

$$\begin{aligned} R_\alpha(\tau) &\equiv \langle\alpha_-^*(t)\alpha_-(t+\tau)\rangle \\ &= |\alpha_0|^2\langle e^{\imath[\theta(t+\tau)-\theta(t)]}\rangle \\ &= |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\langle e^{\imath[\varphi(t+\tau)-\varphi(t)]}\rangle = |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\langle e^{\imath\tau\dot\varphi(t)}\rangle \ . \end{aligned} \tag{48.293}$$

In the case of a Gaussian distribution for the noise amplitude with $\dot\varphi(t) = \dot\varphi(-t)$, we have $\langle\dot\varphi^{2k-1}\rangle/(2k-1)! = 0$ and $\langle\dot\varphi^{2k}\rangle/(2k)! = \langle\frac{1}{2}\dot\varphi^2\rangle^k/k!$ [222, ?, 293],

$$\begin{aligned} \langle e^{\imath\tau\dot\varphi(t)}\rangle &= \sum_k \frac{\imath^k\langle\tau^k\dot\varphi(t)^k\rangle}{k!} = \sum_k \frac{\imath^{2k}\langle\tau^{2k}\dot\varphi(t)^{2k}\rangle}{(2k)!} \\ &= \sum_k \frac{\langle-\frac{1}{2}\tau^2\dot\varphi(t)^2\rangle^k}{k!} = e^{-\frac{1}{2}\tau^2\langle\dot\varphi(t)^2\rangle} \ . \end{aligned} \tag{48.294}$$

Apparently, noise mainly affects the field's phase and not its amplitude. Note that the *first-order coherence* is just the normalized autocorrelation $g^{(1)}(\tau) \equiv R_\alpha(\tau)/R_\alpha(0)$,

$$\begin{aligned} g^{(1)}(\tau) &= e^{\imath\omega_{ca}\tau}e^{-\omega_{ca}^2\tau^2\sigma_{\dot\theta}^2/2} \\ &= e^{\imath\omega_{ca}\tau}e^{-D_\theta|\tau|/2} \ . \end{aligned} \tag{48.295}$$

The *power spectral density* is a Lorentzian,

$$S_\alpha(\omega) = |\alpha_0|^2 \int_{-\infty}^{\infty} R_\alpha(\tau) e^{-\imath\omega\tau} d\tau \tag{48.296}$$
$$= \frac{|\alpha_0|^2 D_\theta^2}{(\omega-\omega_{ca})^2 + D_\theta^2} \ .$$

The CARL *emission bandwidth* is thus $\frac{1}{2}D_\theta$. The above results show that the CARL laser bandwidth increases linearly with temperature and reduces with the friction force. In our experiment we have $\gamma_{fr} = 5\kappa$ and $\sigma = 10\kappa$, so that $D_\theta = \sigma^2/\gamma_{fr} = 20\kappa$. The CARL bandwidth is extremely large as compared to the CARL frequency $\omega_{ca} = 5\kappa$. The reason is that we only considered a single atom. The impact of several atoms will partially compensate and reduce the linewidth.

48.7.1.2 Many atoms, hand-waving

In order to account for the combined effect of many atoms, we reconsider the Eq. (48.210). If $\dot{\alpha}_- = \imath\omega_{ca}\alpha_-$, we may write it like,

$$\alpha_- = \alpha_0 \sum_m e^{\imath\theta_m} \ , \tag{48.297}$$
$$\dot{\theta_n} = \frac{4\varepsilon\imath U_0 \alpha_+ \alpha_0}{\gamma_{fr}} \sum_m \left(e^{\imath\theta_m - \imath\theta_n} + e^{-\imath\theta_m + \imath\theta_n}\right) + \frac{\xi_n}{\gamma_{fr}} \ .$$

The light mode α_- appears to be a superposition of coherent waves having the same frequencies, $\alpha_m(t) = \alpha_0 e^{i\omega_{ca}t + i\varphi_m(t)}$, but interrupted by random phase jumps. We may thus try an analogous argumentation as for pressure broadening,

$$\langle \alpha_-^*(t)\alpha_-(t+\tau)\rangle = |\alpha_0|^2 \int \sum_n e^{-\imath\omega_{ca}t - \imath\varphi_n(t)} \sum_m e^{\imath\omega_{ca}t + \imath\omega_{ca}\tau + \imath\varphi_n(t+\tau)} dt$$
$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum_{n,m} \int e^{\imath\varphi_m(t+\tau) - \imath\varphi_n(t)} dt = N\langle \alpha_n^*(t)\alpha_m(t+\tau)\rangle \delta_{nm} \ .$$

Cross-terms vanish, the autocorrelation function is just the sum of the single-atom components. However, while we may view the noise impact of the atoms as coming from a single atom, the rate of the phase jumps is much higher, than for a single atom. For one atom the probability density for encountering a coherent interval of length τ is given by $p_1(\tau)d\tau = \frac{1}{2}D_\theta e^{-D_\theta|\tau|/2}d\tau$ [590]. Thus,

$$\langle \alpha_1^*(t)\alpha_1(t+\tau)\rangle = |\alpha_0|^2 e^{\imath\omega_{ca}\tau} e^{-D_\theta|\tau|/2} = |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \int_\tau^\infty p_1(\tau')d\tau' \ . \tag{48.298}$$

For N atoms we expect a probability density for encountering a coherent intervall of length τ,

$$p_N(\tau)d\tau = p_1(\tau/N)d\tau = \frac{D_\theta}{2\sqrt{N}} e^{-D_\theta|\tau|/2\sqrt{N}} d\tau \ , \tag{48.299}$$

such that $\int_0^\infty p_N(\tau')d\tau' = 1$. However this remains to prove. Thus,

$$g_N^{(1)}(\tau) = e^{\imath\omega_{ca}\tau} \int_\tau^\infty p_N(\tau')d\tau' = e^{\imath\omega_{ca}\tau - D_\theta|\tau|/2\sqrt{N}} \ . \tag{48.300}$$

The second-order correlation function is,

$$g_N^{(2)}(\tau) = 1 + |g_N^{(1)}(\tau)|^2 \ . \tag{48.301}$$

The laser bandwidth is accordingly reduced by,

$$D_N = \frac{D_\theta}{\sqrt{N}} \ . \tag{48.302}$$

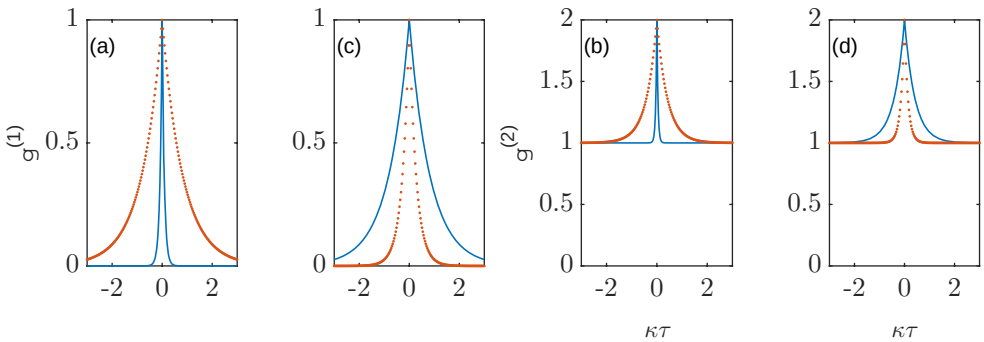

Figure 48.33: (code) First and second-order correlation functions. The solid and dotted lines in (a) and (b) are calculated for $N = 1$ and $N = 100$, resp.. The solid and dotted lines in (c) and (d) are calculated for $T = 100\,\mu\text{K}$ and $T = 300\,\mu\text{K}$, resp..

Fig. 48.33 shows the dependencies of the correlation functions on N and T. For $N = 10^6$ atoms the CARL bandwidth becomes $\beta_N = 0.01\kappa$, which is already well below any mechanical noise. The linewidth reduction with increasing atom numbers is quantitatively supported by numerical simulations (see below).

48.7.1.3 Many atoms, formal

In order to account for the combined effect of many atoms, we reconsider the Eq. (48.210). If $\dot{\alpha}_- = \imath\omega_{ca}\alpha_-$, we get,

$$\alpha_- = -\frac{\imath U_0 \alpha_+}{\kappa + \imath\omega_{ca}} \sum_m e^{\imath\theta_m} \ , \tag{48.303}$$

$$\dot{\theta_n} = \frac{4\varepsilon U_0^2 \alpha_+^2}{\gamma_{fr}\left(\kappa + \imath\omega_{ca}\right)} \sum\nolimits_m \left(e^{\imath\theta_m - \imath\theta_n} + e^{-\imath\theta_m + \imath\theta_n}\right) + \frac{\xi_n}{\gamma_{fr}} \ .$$

The autocorrelation is then,

$$R_\alpha(\tau) \equiv \langle \alpha_-^*(t)\alpha_-(t+\tau)\rangle = \frac{U_0^2\alpha_+^2}{\kappa^2 + \omega_{ca}^2} \sum_{n,m} \langle e^{\imath\theta_n(t+\tau) - \imath\theta_m(t)}\rangle \tag{48.304}$$

$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m} \langle e^{\imath\varphi_n(t+\tau) - \imath\varphi_m(t)}\rangle = |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m,k} \frac{\imath^k}{k!} \langle [\varphi_n(t+\tau) - \varphi_m(t)]^k\rangle$$

$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m,k} \frac{\imath^k}{k!} \sum\nolimits_{j=0}^{k} (-1)^j \binom{k}{j} \langle \varphi_n(t+\tau)^j \varphi_m(t)^{k-j}\rangle \ .$$

The main role of cavity-induced interparticle correlations is to self-consistently establish a constant center-of-mass motion ω_{ca}. We may, to first order, neglect the possibility that the coupling correlates the noise, since the noise is imprinted from the outside, i.e. the molasses. Therefore, $\langle\varphi_n(t+\tau)\varphi_m(t)\rangle \propto \delta_{nm}$,

$$\begin{aligned}\langle\varphi_n(t+\tau)^j\varphi_m(t)^{k-j}\rangle &= \sum\nolimits_{\text{all pairs}}\langle\varphi_n(t+\tau)^2\rangle^{j/2}\langle\varphi_m(t)^2\rangle^{k/2-j/2} \\ &= \frac{j!}{2^{j/2}(j/2)!}\frac{(k-j)!}{2^{(k-j)/2}(k/2-j/2)!}\langle\varphi_n(t+\tau)^2\rangle^{j/2}\langle\varphi_m(t)^2\rangle^{k/2-j/2}\end{aligned} \tag{48.305}$$

so that,

$$R_\alpha(\tau) = |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\sum_{n,m,k}\frac{\imath^k}{k!}\sum_{j=0}^{k}\binom{k}{j}\frac{j!}{2^{j/2}(j/2)!}\frac{(k-j)!}{2^{(k-j)/2}(k/2-j/2)!}\langle\varphi_n(t+\tau)^2\rangle^{j/2}\langle\varphi_m(t)^2\rangle^{k/2-j/2}\ , \tag{48.306}$$

where j and k are even,

$$\begin{aligned}R_\alpha(\tau) &= |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\sum\nolimits_{n,m,k}\frac{\imath^k}{2^{k/2}(k/2)!}\sum_{j=0}^{k}\binom{k/2}{j/2}\langle\varphi_n(t+\tau)^2\rangle^{j/2}\langle\varphi_m(t)^2\rangle^{k/2-j/2} \\ &= |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\sum_{n,m,k}\frac{1}{(k/2)!}\left(-\frac{1}{2}\langle\varphi_n(t+\tau)^2\rangle - \frac{1}{2}\langle\varphi_m(t)^2\rangle\right)^{k/2} \\ &= |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\sum_n e^{-\frac{1}{2}\langle\varphi_n(t+\tau)^2\rangle}\sum\nolimits_m e^{-\frac{1}{2}\langle\varphi_m(t)^2\rangle} = |\alpha_0|^2 N^2 e^{\imath\omega_{ca}\tau}e^{-\frac{1}{2}\langle\varphi_n(t+\tau)^2\rangle}e^{-\frac{1}{2}\langle\varphi_n(t)^2\rangle}\ .\end{aligned} \tag{48.307}$$

48.7.1.4 Memory effects

Relax adiabaticity, $\dot\alpha_- \neq \imath\omega_{ca}\alpha_-$, substitute $\beta = e^{\kappa t}\alpha_-$,

$$\begin{aligned}\dot\theta &= \frac{4\varepsilon\imath U_0\alpha_+}{\gamma_{fr}}\left(\beta e^{-\imath\theta-\kappa t} - \beta^* e^{\imath\theta-\kappa t}\right) + \frac{\xi}{\gamma_{fr}}\ , \\ \beta &= -\imath U_0\alpha_+\int^t e^{\imath\theta+\kappa t'}dt'\ .\end{aligned} \tag{48.308}$$

so that,

$$\begin{aligned}R_\alpha(\tau) &\equiv \langle\alpha_-^*(t)\alpha_-(t+\tau)\rangle = \langle e^{-\kappa t}\beta^*(t)e^{-\kappa t-\kappa\tau}\beta(t+\tau)\rangle \\ &= e^{-\kappa\tau}\langle e^{-2\kappa t}\beta^*(t)\beta(t+\tau)\rangle \\ &= U_0^2\alpha_+^2 e^{-\kappa\tau}\int\int^t\int^{t+\tau} e^{\imath\theta(t'')-\imath\theta(t')+\kappa t'+\kappa t''-2\kappa t}dt''dt'dt \\ &= U_0^2\alpha_+^2 e^{-\kappa\tau}\int\int^t\int^{t+\tau} e^{\imath\omega_{ca}t''-\imath\omega_{ca}t'+\imath\varphi(t'')-\imath\varphi(t')+\kappa t'+\kappa t''-2\kappa t}dt''dt'dt\ .\end{aligned} \tag{48.309}$$

Using the representation of half the δ-distribution $\int^t e^{(\imath\omega_{ca}+\kappa)t'}dt' = \delta_{1/2} = \lim_{\kappa\to 0}\frac{1}{\kappa+\imath\omega_{ca}}$.

48.7.1.5 Schawlow-Townes limit for CARL

The ultimate limit for the spectral purity of a perfectly stable laser oscillator is the *Schawlow-Townes limit* [816]. The origin of this limitation is the discrete nature of the light field. Similarly to quantum projection noise, which is caused by the discretisation of atomic energy levels, the optical *shot-noise* registered in photodetectors arises from the discrete repartition of electromagnetic energy in photons. With a laser power P, a cavity bandwidth κ and an interrogation time τ, the Allan variance [**?**] and the linewidth of a Schawlow-Townes limited laser are given by,

$$\sigma_{\mathrm{ST}}(\tau) = \frac{1}{\omega/\kappa}\frac{1}{\sqrt{(P/\hbar\omega)\tau}} \ , \tag{48.310}$$
$$\beta = \kappa^2\frac{\hbar\omega}{P} \ .$$

In the case of CARL, using $P = \delta\hbar\omega|\alpha_-|^2$ the variance is $\sigma^2_{\mathrm{ST}}(\tau) = \kappa/\tau\omega\delta|\alpha_-|^2 \approx 10^{-20}$ s$/\tau$. The shot-noise which limits the CARL is not the one of the CARL light itself, but the random momentum kicks imparted by molasses-cooled atoms. The CARL linewidth is $\beta = \kappa^2/\delta|\alpha_-|^2 = 10^{-14}\kappa$.

The time-lap between two scattering events for a single atom be distributed according to $p_1(\tau)d\tau = \gamma e^{-\gamma\tau}d\tau$. What is the waiting time distribution for two atoms [819]? Schenzle related the waiting time distribution to the autocorrelation function $g^{(2)}(\tau)$.

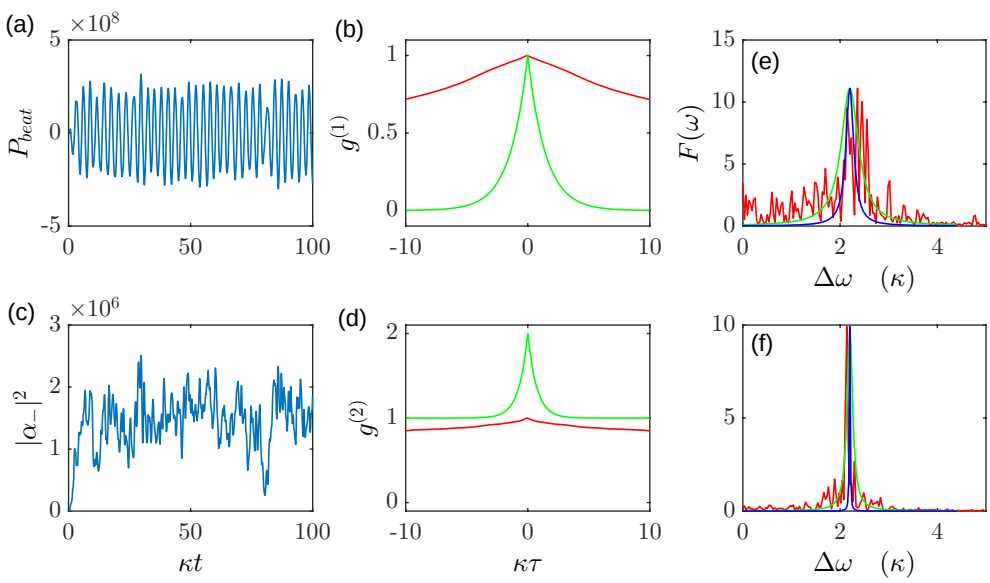

Figure 48.34: Simulated time-dependence of the (a) beat and the (b) intensity signals. Calculated (c) first and second-order correlation functions. The temperature was set to $T = 100\,\mu$K and the atom number to $N = 40$. (e-f) Spectra of the CARL laser for (e) 4 and (f) 40 atoms. The total coupling constant NU_0 has been held constant, only the number of atoms whose trajectories are simulated is varied.

Fig. 48.34(e-f) shows spectra of the CARL frequency obtained by Fourier-transforming the autocorrelation function of a Langevin-simulated trajectory of the CARL frequency. The width results from thermal fluctuations in the atomic motion induced by momentum diffusion in the molasses. It is clearly visible that the width is reduced when the atom number is increased, thus confirming Eq. (48.302).

48.7.2 Measuring the coherence properties

We may also attempt to verify the predictions in experiment. Our signals are the beams transmitted through the cavity mirrors.

48.7.2.1 Homodyne signal

Ideally in order to get the full information on the the first-order coherence, we should record both the in-phase and the quadrature component of the field $\alpha_- = \mathfrak{Re}\,\alpha_- + i\mathfrak{Im}\,\alpha_-$ by homodyning it with the local oscillator α_+. Thus we need to use both ports of the beamsplitter: For the in-phase component we get,

$$\begin{aligned} P^{(\mathrm{ph})}_{\mathrm{hody}} &\propto b^\dagger b - c^\dagger c \\ &= |\alpha_+\sqrt{\eta} + \alpha_-\sqrt{1-\eta}|^2 - |\alpha_+\sqrt{1-\eta} - \alpha_-\sqrt{\eta}|^2 \\ &= (1-2\eta)(|\alpha_-|^2 - |\alpha_+|^2) + 4\sqrt{\eta-\eta^2}\alpha_+\mathfrak{Re}\,\alpha_- \ . \end{aligned} \tag{48.311}$$

For a 50% beamsplitter the offsets disappear, $P^{(\mathrm{ph})}_{\mathrm{hody}} \propto= 2\alpha_+\mathfrak{Re}\,\alpha_-$, which means that the homodyne signal is insensitive to intensity noise in the individual ports. Similarly we obtain for the quadrature component,

$$\begin{aligned} P^{(qu)}_{\mathrm{hody}} &\propto |\alpha_+\sqrt{\eta} + \imath\alpha_-\sqrt{1-\eta}|^2 - |\alpha_+\sqrt{1-\eta} - \imath\alpha_-\sqrt{\eta}|^2 \\ &= -2\alpha_+\mathfrak{Im}\,\alpha_- . \end{aligned} \tag{48.312}$$

By mounting a piezo on one of the mirrors in the homodyne loop, we can influence which quadrature component to map. Is there a way how to get $\mathfrak{Im}\,\alpha_-$ and $\mathfrak{Re}\,\alpha_-$ simultaneously?

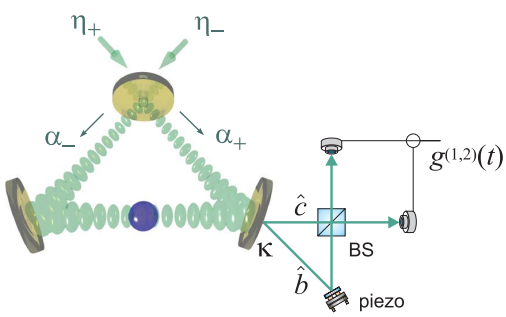

Figure 48.35: Homodyning the counterpropagating beams.

Knowing α_- we can calculate the *first order coherence*,

$$g^{(1)}(\tau) \equiv \frac{\langle\alpha^*(t)\alpha(t+\tau)\rangle}{\langle\alpha^*(t)\alpha(t)\rangle} = \frac{\int\alpha^*(t)\alpha(t+\tau)dt}{\int\alpha(t)^2dt} \ , \tag{48.313}$$

the *second-order coherence*,

$$g^{(2)}(\tau) \equiv \frac{\langle \alpha^*(t)\alpha^*(t+\tau)\alpha(t+\tau)\alpha(t)\rangle}{\langle \alpha^*(t)\alpha(t)\rangle^2} = \frac{\int P_-(t)P_-(t+\tau)dt}{\int P_-(t)dt} \ , \tag{48.314}$$

and the *emission spectrum* (power spectral density),

$$F(\omega) = \frac{1}{\pi}\mathfrak{Re}\int g^{(1)}(\tau)e^{\imath\omega\tau}d\tau \ . \tag{48.315}$$

All these quantities can be evaluated from numerical simulations of the Langevin equations.

Example 364 (*Real Signals*): What is recorded in experiment is the probe field power P_{probe} and only one quadrature component of the beat between the probe and the pump. The probe signal is simply,

$$P_- \propto |\alpha_-|^2 \ . \tag{48.316}$$

So it may be used directly for the $g^{(2)}(\tau)$ intensity correlation function (48.314) analogous to the *Hanbury-Brown-Twiss* experiment.
In contrast, the beat signal is obtained in a *Young* type experiment,

$$P_{beat} \propto |\alpha_+ \pm \alpha_-|^2 = |\alpha_+|^2 + |\alpha_-|^2 \pm 2\alpha_+\mathfrak{Re}\,\alpha_- \ , \tag{48.317}$$

because we may assume α_+ real. Obviously, the beat signal oscillates between the limits $\pm 2\alpha_+|\alpha_-|$. Using only one port of the beamsplitter, we miss information on the other quadrature phase. The question arises now, how to calculate the spectrum if only the real part of the field $\mathfrak{Re}\,\alpha$ is known. The interesting quantity is $|g^{(1)}(\tau)|$, because it contains the information on the photon statistics. This function is smooth (it does not oscillate) and should in our case describe an exponential decay (48.295). Fortunately, from numerical calculation it seems that $|g^{(1)}(\tau)|$ is just the convolution of $\langle\mathfrak{Re}\,\alpha(t)\mathfrak{Re}\,\alpha(t+\tau)\rangle/\langle\mathfrak{Re}\,^2\alpha(t)\rangle$, so that we may recover the informations. For the spectrum, which is calculated from the complex quantity $g^{(1)}(\tau)$ the question is more delicate. It comes down to asking if,

$$F(\omega) \propto \mathfrak{Re}\int \langle\mathfrak{Re}\,\alpha(t)\mathfrak{Re}\,\alpha(t+\tau)\rangle\ e^{\imath\omega\tau}d\tau \tag{48.318}$$

gives the correct spectrum (48.315).

48.7.2.2 Impact of finite time window

Technical noise may overrule the thermal noise just like in ordinary lasers. This situation may change if atom numbers are low, so that we have bad statistics, or if the collective force is strong enough to correlate the noise.

The spectral width may also be limited by the finite time window $t \in [-\frac{1}{2}t_0, \frac{1}{2}t_0]$, which is taken for computing the spectrum. Even a perfect harmonic oscillation $\alpha_-(t) = \alpha_- e^{\imath\omega_{ca}t}$ will then have a finite bandwidth,

$$\begin{aligned}\mathcal{F}_{a_-}(\omega) &= \mathcal{F}[\alpha_- e^{\imath\omega_{ca}t}] \star \mathcal{F}[\chi_{[-t_0/2,t_0/2]}(t)] \\ &= \alpha_-\delta(\omega-\omega_{ca}) \star \sqrt{\frac{2}{\pi}}\frac{\sin\frac{1}{2}\omega t_0}{\omega} = \alpha_-\sqrt{\frac{2}{\pi}}\frac{\sin\frac{1}{2}(\omega-\omega_{ca})t_0}{(\omega-\omega_{ca})} \ .\end{aligned} \tag{48.319}$$

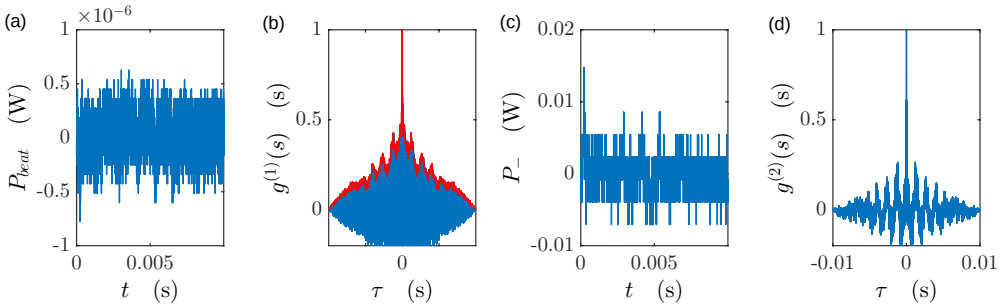

Figure 48.36: (code) Measured trajectories (a) and (b) and correlation functions (c) and (d) of the CARL laser. The coupling constant was $NU_0 = -0.1$.

The spectrum $S_{\alpha_-}(\omega) = |\mathcal{F}_{a_-}(\omega)|^2$ has a bandwidth of $\beta = 5.6/t_0$. For example an oscillation observed for a period 100 times longer than the cavity decay time, $t_0 = 100/\kappa$, the bandwidth will be $\beta = 0.056\kappa$. Simulations are based on the Langevin equation.

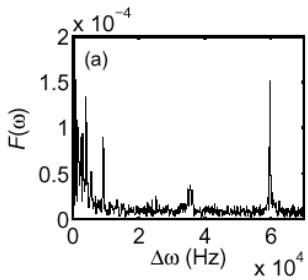

Figure 48.37: Spectrum of the CARL calculated from the first-order correlation function in Fig. 48.36(c). The coupling constant was $NU_0 = -0.1\kappa$.

48.7.3 Exercises

48.7.3.1 Ex: Autocorrelation functions

48.7.3.2 Ex: Signal-to-noise ratio of Bloch oscillations

You want to evaluate the stability of a noisy periodic signal. How many noisy oscillations do you have to observe in order to evaluate the oscillation period with a given S/N ratio [993].

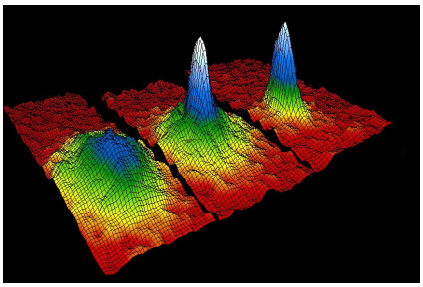
Part X

Degenerate Interacting Bose and Fermi Gases

Preface to the part *AtomOptics*



The field of *atom optics* deals with the motion of atoms and its control by technical tools. At high velocities with no external forces, the atoms follow straight paths, similar to light beams in *classical optics*. At low speeds, they propagate as waves, similarly to wave optics in Maxwell's theory of *electrodynamics*. The term *atom optics* emphasizes the analogy and the duality in the behavior of microscopic particles.

The *duality principle* is one of the fundamental ideas of quantum mechanics. The appearance of an object as a wave or as a particle depends on the situation in which it is observed. While the wave nature of light was well established in classical physics since a long time, Louis de Broglie was the first in 1924 to apply the duality principle also to massive particles and to predict that particles, under certain conditions, behave like waves whose wavelengths increase as their velocity decreases. Each particle (or sample of particles) is delocalized along a distance corresponding to the 'de Broglie wavelength'. This feature of the matter was soon discovered experimentally in electron beams and is still used today in commercial devices, for example in electron microscopes.

The laser was discovered in 1956. In a laser, light particles are forced to oscillate synchronously, that is, coherently. By analogy, we can raise the question whether a similar phenomenon can occur with massive particles, and whether it is possible to construct an *atom laser*. Such a device would emit coherent matter waves just as the laser emits coherent light. When a gas is cooled to very low temperatures, the Broglie waves of the atoms become very long and, if the gas is sufficiently dense, eventually overlap. If the gas consists of a single species of bosonic particles with all atoms being in the same quantum state, their Broglie waves interfere constructively thus and form a huge wave of coherent matter. This matter wave is described by a single wavefunction exhibiting long range order and having a single phase. If this wavefunction is formed inside a trap, all atoms accumulate in its ground state. Thus, we obtain a pure quantum state of many bodies in the kinetic degree of freedom [22]. The transition of a gas from individual atoms to a degenerate mesoscopic many-body quantum state occurs as a phase transition named *Bose-Einstein condensation* (BEC) as a homage to Bose and Einstein who predicted the effect already in 1924 [117, 289].

In chapter 49 we review experimental techniques which are essential for the preparation and study of ultracold atomic clouds of atoms. In Chp. 50 we study properties

[22] In particular, for very cold atoms whose internal excitation occurs on a very different energy scale, the corresponding degree freedom is frozen and does not influence the kinetics.

of quantum-degenerate gases. In Chp. 51 we concentrate on superfluid features of Bose-condensates. In Chp. 52 we focus on the interaction of Bose-condensates with radiation fields.

Chapter 49

Manipulation of atomic gases

The course begins in this chapter with a presentation of the most important experimental techniques for cooling, trapping, manipulating and detecting atomic gases. The knowledge of these techniques will allow for a better understanding of how it is possible to generate and analyze all the effects mentioned above. Chp. 30 sets the foundations for the theoretical description of many-body fields with particular attention to issues arising from quantum statistics. Chp. 50 introduces the phenomenon of Bose-Einstein condensation, and the subsequent chapters focus on the thermodynamic, superfluid, coherent and dielectric properties of condensates.

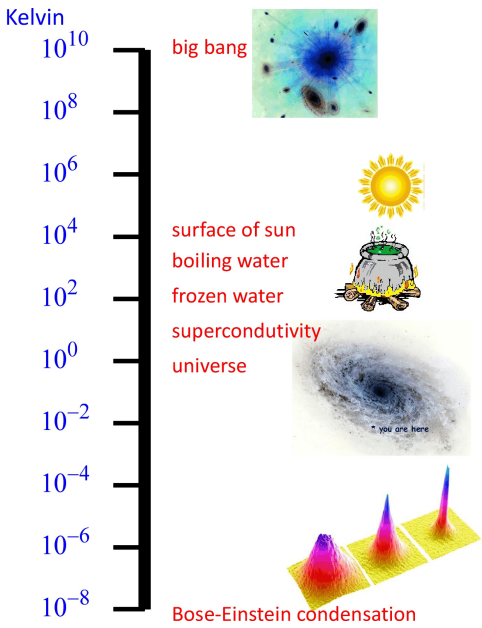


Figure 49.1: Temperature scale.

The incomparable success of atomic optics has been rewarded with 20 nobel prices in the last 25 years (Dehmelt, Paul, Ramsey, Cohen-Tannoudji, Chu, Phillips, Cornell, Wieman, Ketterle, Hänsch, Glauber, Hall, Wineland, Haroche, Ahskin) plus several indirectly related noble prices (De Gennes, Leggett, Thouless, Haldane, Kosterlitz). For review articles on BEC see [716, 216, 197, 359, 795, 873], [510] or check in internet

sites *http://amo.phy.gasou.edu/bec.html* and *http://jila.edu/bec.html*.

In this chapter we review the basic techniques of *Atomic Optics*, emphasizing the cooling, trapping and measurement of cold atomic gases. See also (watch talk) and (watch talk).

49.1 The atomic motion

49.1.1 The atom as a matter wave

We have already emphasized that atomic optics deals with the motion of atoms in a gas, that is, we are interested only in the external degrees of freedom of the atoms. To describe the motion of a free massive particle in one dimension, we write the Hamiltonian,

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} \ . \tag{49.1}$$

Therefore, the general solution of the stationary Schrödinger equation,

$$\hat{H}\psi(x) = E\psi(x) \ , \tag{49.2}$$

is,

$$\psi(x) = Ae^{\imath kx} + Be^{-\imath kx} \qquad \text{with} \qquad k = \sqrt{\frac{2mE}{\hbar^2}} \ . \tag{49.3}$$

Note, that the wavefunctions $e^{\imath kx}$ are not quadratically integrable. On the other hand, they do not represent real physical systems. In practice, we need to consider wavepackets or specify a finite volume for the particle.

Note also that the eigenvalue spectrum of is continuous. To warrant the interpretation of the wavefunction as a probability density we will require quadratic integrability, $\int |\psi|^2 d^3r = 1$. This means that the wavefunction can not be infinite in a finite volume, but it can be infinite in an infinitely small volume.

The description of the atomic motion by a wave equation emphasizes the fact that microscopic particles have wave properties with each atom corresponding to a velocity-dependent *de Broglie wave*,

$$\boxed{\lambda_{\rm dB} = \frac{h}{p}} \ , \tag{49.4}$$

which describes the coherence length of the atom.

49.1.1.1 Characteristic velocities

The behavior of an atom described by the Schrödinger equation depends very much on its kinetic energy. At high velocities (or short de Broglie waves), it will behave like a classical particle with a well-defined trajectory. At low velocities (or long de Broglie waves), it will propagate like a wave and exhibit phenomena such as diffraction and interference. Therefore, it is important to highlight some characteristic velocity regimes.

Most optical cooling techniques are based on the removal of kinetic energy upon light scattering on electronic transitions. It is, therefore, interesting to compare the kinetic energy (or temperature) of an ensemble of atoms with the width Γ of the transition. The *Doppler limit* is given by (see Exc. 49.1.3.1),

$$k_{\mathrm{B}}T_{\mathrm{D}} = \frac{\hbar}{2}\Gamma \ . \tag{49.5}$$

We can also compare the kinetic energy with the energy transferred to an atom by the absorption of a single photon. The *photonic recoil* energy is given by,

$$k_{\mathrm{B}}T_{\mathrm{rec}} = \frac{\hbar^2 k^2}{2m} \ . \tag{49.6}$$

Atomic clouds with temperatures around $T \simeq T_{\mathrm{D}} = 10..1000\,\mu\mathrm{K}$ are called *cold*. Clouds with temperatures around and below $T \lesssim T_{\mathrm{rec}} = 0.1..10\,\mu\mathrm{K}$ are called *ultra-cold*.

In most atomic optical experiments we do not work with individual atoms (or ions), but with relatively dilute ensembles of atoms, called *clouds*. In general, clouds can not be described by a single wavefunction. Either we describe every atom by a separate and independent wavefunction (which only works when the atoms do not interact), or we describe the cloud by probability distributions (such as the 'density matrix'). Let us now consider a thermal cloud. The *Maxwell-Boltzmann distribution* of velocities is,

$$g(\mathbf{v}) = \sqrt{\frac{m}{2\pi k_{\mathrm{B}}T}}^{\,3} e^{-m\mathbf{v}^2/2k_{\mathrm{B}}T} \ . \tag{49.7}$$

This distribution is normalized, $\int g(\mathbf{v})d^3\mathbf{v} = \int_0^\infty 4\pi v^2 g(v)dv = 1$. Average velocity is now

$$\bar{v} = \int v g(v) dv = \sqrt{\frac{k_{\mathrm{B}}T}{m}} \ . \tag{49.8}$$

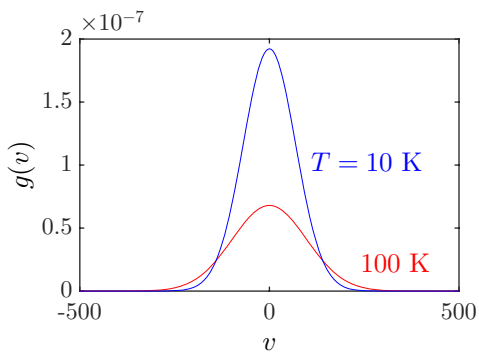

Figure 49.2: (code) Maxwell-Boltzmann distribution.

Maxwell-Boltzmann's law was experimentally proven by Otto Stern in 1920, using a primitive atomic beam and a simple time-of-flight technique based on a rotating drum for selecting atomic velocities. With the advent of laser spectroscopy, the MB

law and its limitations can be tested with highly improved accuracy. This law describes well the behavior of weakly interacting hot atoms. Deviations from this law are insignificant until, at low temperatures, quantum effects come into play. For this to happen the temperature must be so low that the atomic Broglie wavelengths become comparable to the average distance between particles. For a gas in thermal equilibrium the characteristic wavelength, called *thermal de Broglie wavelength*, is,

$$\boxed{\lambda_{\rm therm} \equiv \frac{h}{m\bar{v}} = \sqrt{\frac{2\pi\hbar^2}{mk_{\rm B}T}}} \ . \tag{49.9}$$

It represents an average over the de Broglie wavelengths of all atoms of the sample. When a dense gas is sufficiently dense, so that this quantity exceeds the average distance between atoms,

$$\rho \equiv n\lambda_{\rm therm}^3 > 1 \ , \tag{49.10}$$

where n is the atomic density, we enter a new regime, where the *Maxwell-Boltzmann law* ceases to be valid. Since $\lambda_{\rm therm} \propto T^{-1/2}$, this regime corresponds to low temperatures. The quantity ρ is called *phase space density*. A phase space density approaching 1 means an increased probability of finding *more than one atom per elementary phase space cell*. We then enter the regime of quantum degeneracy, where the Boltzmann statistics must be replaced by the Bose-Einstein statistics, in the case of bosons, or the Fermi-Dirac statistics, in the case of fermions. For a deeper discussion of quantum statistics of ideal gases we refer to Secs. 29.3 and 29.4. From the condition $n\lambda_{\rm therm}^3 \simeq 1$, we obtain

$$k_{\rm B}T_{\rm c} = \frac{1}{m}\left(\frac{2\pi\hbar}{\lambda_{\rm therm}}\right)^2 = \frac{(2\pi\hbar)^2 n^{2/3}}{m} \ . \tag{49.11}$$

For example, an atomic gas with density $n \sim 10^{16}\,{\rm cm}^{-3}$ and temperature 900 K is certainly in the classical regime, since $n^{-1/3} \sim 10^6\,{\rm cm} \ \gg \lambda_{\rm dB} = 10^{-9}\,{\rm cm}$. To observe quantum effects, we need relatively dense and cold clouds of atoms. In most gases, lowering the temperature or increasing the density promotes the system to liquidity before the quantum regime is reached. Well-known exceptions are spin-polarized hydrogen (H↑), which does not become liquid and helium, which exhibits quantum degeneracy effects in the liquid phase, although these effects are quite complex due to strong interparticle forces.

We have already seen that all particles in the quantum world are either *bosons* with integer spin or *fermions* with semi-integer spin. Fermions do not share a quantum state, because they must follow the *Pauli's exclusion principle*. They obey a quantum statistical distribution called *Fermi-Dirac distribution* (FD). In contrast, bosons enjoy to share a quantum state and even encourage other bosons to join them in a process called *bosonic stimulation*. Bosons obey a quantum statistical distribution called *Bose-Einstein distribution* (BE). The basic difference between the MB-statistics on one hand and the BE- or FD-quantum statistics on the other is that the former applies to identical particles which, however, are distinguishable from each other, while the second describes identical indistinguishable particles. For the BE/FD statistics one can derive [520] the occupancy number (29.90) for a non-degenerate quantum state

having the energy ε when the system is kept at temperature T,

$$\boxed{w_{T,\mu} = \frac{1}{e^{\beta(\varepsilon-\mu)} \mp 1}} \,, \tag{49.12}$$

where we used the abbreviation $\beta \equiv 1/k_{\mathrm{B}}T$. The upper sign refers to the BE statistics, the lower sign to the FD statistics. The chemical potential μ is an important system parameter, which helps to normalize the distribution (49.12) to the total number of particles,

$$N = \sum_{\varepsilon} w_{T,\mu}(\varepsilon) \ . \tag{49.13}$$

Similarly, the total energy of the system is given by,

$$E = \sum_{\varepsilon} \varepsilon w_{T,\mu}(\varepsilon) \ . \tag{49.14}$$

A very remarkable effect occurs in a bosonic gas at a certain characteristic *critical temperature* T_{c}: below this temperature a substantial fraction of the total number of particles occupies the lowest energy state, while all other states are occupied by a negligible number of particles. Above the transition temperature the macroscopic observables of the gas, such as pressure, heat capacity, etc., receive contributions of all states with a certain statistical weight, but without favoring the state of lower energy. Below the transition temperature, the observables are altered by a macroscopic occupation of the ground state, which results in dramatic changes of the thermodynamic properties. The phase transition is named after Shandrasekar Bose [117] and Albert Einstein [289] *Bose-Einstein condensation* (BEC).

49.1.2 Bose-Einstein condensation

The first hint, that Bose-Einstein condensation was more than just a theoretical fantasy came from London [587], who linked the newly discovered phenomenon of superfluidity in ^{4}He to BEC. However, the interpretation of the λ-point in terms of BEC was not obvious, because strong interactions between particles concealed the role of quantum statistics, and the thermodynamic potentials exhibited divergences at the critical temperature instead of discontinuities, as expected for an ideal gas BEC. These uncertainties triggered an intense search for other systems. In 1954, Schafroth pointed out that electron pairs can be seen as composite bosons and may form Bose-Einstein condensates at low temperatures [815]. In 1957, Bardeen, Cooper and Schrieffer developed the microscopic theory of superconductivity [61], after other researchers, including Blutt, Schaffrot, Fröhlich and Bogolubov, had suggested a relationship of this phenomenon to Bose condensation of electron pairs (nowadays called Cooper pairs).

Motivated by the need to test the concept of condensation of composite particles in weakly interacting systems, in 1962 *Blatt et al.* proposed the investigation of the BEC in gases of *excitons* [95]. Excitons are bound electron-hole pairs that can form a weakly interacting gas in certain non-metallic crystals. They are interesting because their small mass allows BEC at high temperatures and gas density can be controlled over a wide range, by only modifying the intensity of the optical excitation. Being

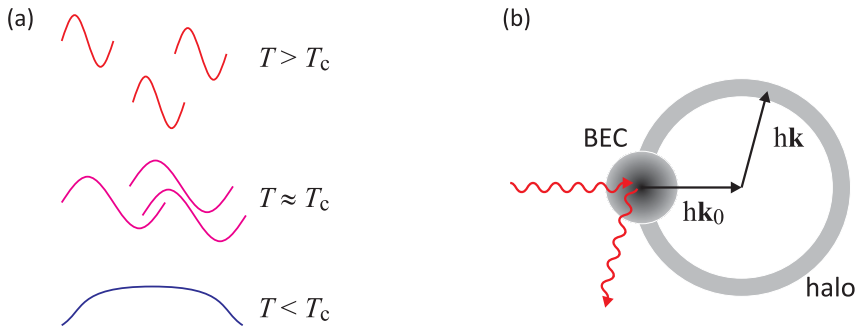

Figure 49.3: (a) Illustration of atomic Broglie waves at different temperatures with respect to the critical temperature. (b) Illustration of the recoil temperature: An atom recoiled by the momentum imparted by absorption of a single photon is ejected from the BEC.

quasi-particles, excitons can be created and annihilated, that is their number is not conserved. Excitons were discovered in 1968, and the first evidence for Bose-Einstein of biexciton molecules in a CuCl crystal dates back to 1979 [164].

The laser as coherence phenomenon between photons shares many analogies with condensates. However, photons are quasi-particles as well, and again their number is not conserved [1]. Hence, there is no phase transition: When an optical cavity containing photonic modes is cooled, the photons prefer to disappear in the walls of the cavity instead of condensing.

Hecht [420] suggested in 1959, followed by Stwalley and Nosanow [896] in 1976, that an atomic hydrogen gas with polarized spins would be an appropriate candidate for BEC. The advantage of this system is that interactions between atoms are weak and only give rise to a negligible quantum depletion below 1%. In 1978 Greytak and Kleppner started at the MIT intensive efforts to generate BECs in dilute hydrogen gases. In the 1990s, important advances in the cooling of atoms using laser light allowed to reach very low temperatures, and the invention of the magneto-optical trap (MOT) for neutral atoms permitted their spatial confinement and the compression of their density. These successes boosted efforts to try to create BEC in alkaline gases, which have electronic level schemes that lend themselves to optical cooling. Later, it was discovered that the phase space density in MOTs is limited by radiation trapping effects. As a solution to this problem, scientists had to learn how to trap atoms without the use of light in conservative traps, e.g. by their magnetic dipole moment, and to replace optical cooling with *evaporative cooling*. This was the crucial step that finally permitted to reach BEC in alkaline gases in 1995. Later, the hydrogen experiment, which initially stimulated the alkaline experiments, now taking advantage of their success, has been taken to BEC as well [326].

Why did it take so long to reach Bose-Einstein condensation, seven decades after its prediction by Bose and Einstein? How can we *see* when we have a condensate? What are the characteristics of a BEC accessible to observation and how to measure them? These are the answers that we will answer in the following sections. Solve Exc. 49.1.3.2.

[1] The chemical potential of photons is $\mu = 0$.

49.1.3 Exercises

49.1.3.1 Ex: Fundamental temperature limits

Calculate the Doppler limit, the recoil limit, and the threshold to quantum degeneracy for an atomic cloud of density $n = 10^{14}\,\mathrm{cm}^{-3}$ for the sodium $D2$ transition ($\lambda = 590\,\mathrm{nm}$, $\Gamma/2\pi = 10\,\mathrm{MHz}$) and the rubidium $D2$ transition ($\lambda = 780\,\mathrm{nm}$, $\Gamma/2\pi = 6\,\mathrm{MHz}$).

49.1.3.2 Ex: Boson or fermion?

Whether an atom is a fermion or boson solely depends on its total spin. Half-integer spin particles are fermions, integer spin particles are bosons. For example, Rb atoms have in the ground state $J = 1/2, I = 7/2$ and F integer, and therefore are bosons. Ca^+ ions have $J = 1/2$ and no hyperfine structure, and thus are fermions. ^{6}Li has the half-integer F and is a boson.
Decide on the bosonic or fermionic nature of the following atoms/molecules:
^{85}Rb with $I = 3/2$ in the state $^2S_{1/2}$
^{88}Sr with $I = 0$ in the state $^1S_0$
^{88}Sr with $I = 0$ in the state $^3P_2$
^{87}Sr with $I = 9/2$ in the state $^1S_0$
$^{172}Yb^+$ with $I = 0$ in the state $^2S_{1/2}$
$^{171}Yb^+$ with $I = 1/2$ in the state $^2S_{1/2}$

49.2 Optical cooling

As discussed in Sec. 43.2, the force exerted by a light field on an atom can be of two types: a dissipative force arising called *radiation pressure*, which is often used for optical cooling purposes, and a conservative *dipolar force* which often serves for the engineering of optical trapping potentials. Both applications of optical forces will be detailed in the following sections.

49.2.1 Optical molasses

In the *Doppler cooling* model, we treat the phenomenology of optical forces quantitatively by considering the amplitude, phase and frequency of a classical field interacting with the dipole of an atomic transition in a two-level atom. From Eq. (43.25) and previous definitions of Ω and Ω_{sat}, and with the intensity $I \propto \mathcal{E}^2$, we can write the *saturation parameter*,

$$s = \frac{I}{I_{\mathrm{sat}}} = \frac{\Omega^2}{\Omega_{\mathrm{sat}}^2} = \frac{\Omega^2}{\Gamma^2/2} \ , \tag{49.15}$$

and

$$\mathbf{F}_{\mathrm{rp}} = \frac{\hbar \mathbf{k} \Gamma}{2} \frac{s}{(2\Delta/\Gamma)^2 + 1 + s} \ . \tag{49.16}$$

Now, if we consider an atom propagating in $\mp z$ direction with the velocity v_z counterpropagating to a light wave detuned by Δ from the resonance, the total detuning will be

$$\Delta \longrightarrow \Delta \mp k v_z \ . \tag{49.17}$$

where the term kv_z is the Doppler shift. The force $F_\pm$ acting on the atom will be in the direction opposite to the motion,

$$\mathbf{F}_\pm = \pm\frac{\hbar\mathbf{k}\Gamma}{2}\frac{s}{(2(\Delta \mp kv_z)/\Gamma)^2 + 1 + s} \ . \tag{49.18}$$

Supposing now, that we have two light fields propagating in directions $\pm z$, the total force will be $\mathbf{F} = \mathbf{F}_+ + \mathbf{F}_-$. If kv_z is small compared to Γ and Δ, we find through a Taylor expansion,

$$F_z \simeq 4\hbar ks\frac{kv_z(2\Delta/\Gamma)}{[1 + s + (2\Delta/\Gamma)^2]^2} \ . \tag{49.19}$$

This expression shows that, if the detuning Δ is negative (that is, on the red side of the resonance), then the cooling force will oppose the motion and be proportional to the atomic velocity. Fig. 49.4 shows this decelerating dissipative force as a function of v_z at a detuning $\Delta = -\Gamma$ with $I = I_{\rm sat}/2$. The one-dimensional motion of the atom is thus behaving like being subject to a friction force which is proportional to the atomic velocity,

$$F_z \simeq \alpha_{\rm d} v_z \qquad \text{with} \qquad \alpha_{\rm d} = s\frac{-4k^2(2\Delta/\Gamma)}{1 + s + (2\Delta/\Gamma)^2} \ . \tag{49.20}$$

The proportionality factor, is just the *friction coefficient*.

However, the atom will not cool down indefinitely. At some point, the Doppler cooling rate will be balanced by the heating rate coming from the momentum fluctuations of the atom absorbing and remitting photons. The *Doppler cooling limit* is given by,

$$k_{\rm B}T = \hbar\frac{\Gamma}{2} \ , \tag{49.21}$$

as we will see in Exc. 49.2.5.1. This limit is generally, for alkaline atoms, on the order of dozens of micro-Kelvin. In the early years of cooling and trapping, the Doppler limit was thought to be a real physical barrier. But in 1988, several groups have shown that, in fact, atoms could be cooled well below the Doppler limit. The effect arises in atoms, whose ground state exhibits a hyperfine structure. We will show simplified one-dimensional models for sub-Doppler cooling in the next section. Resolve the Exc. 49.2.5.2.

49.2.2 Sub-Doppler cooling

It turns out that atoms with a hyperfine structure in the ground state can be cooled below the Doppler limit (49.5). To explain this unexpected observation, models involving a slow motion of the atoms in polarization gradients of a standing light wave have been invoked. The phenomenon is now known as *polarization gradient cooling*.

Two principal mechanisms for cooling atoms to temperatures below the Doppler limit are based on spatial polarization gradients. These two mechanisms, however, invoke very different physical processes and are distinct by the spatial dependence of the light polarization. A key point is that these sub-Doppler mechanisms only work on atoms with multiple ground state levels. Two parameters, the friction coefficient and the capture velocity, determine the importance of these cooling processes. In this

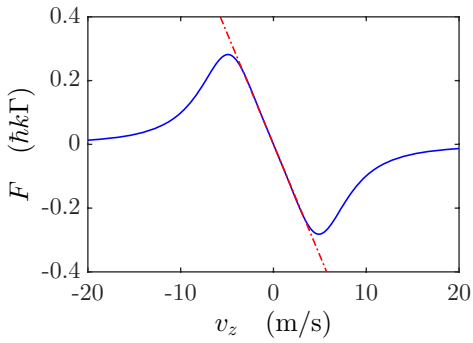

Figure 49.4: (code) Doppler force due to one-dimensional radiative pressure as a function of atomic velocity along the z-axis for red detuning $\Delta = -\Gamma$ at a light intensity of $I = 2I_{\rm sat}$. The solid line shows the exact expression for the restoring force [Eq (49.18)]. The broken line shows the approximate linear expression of the velocity dependence according to Eq. (49.19).

section we compare the expressions for these quantities in the sub-Doppler regime to those found by the conventional one-dimensional Doppler cooling model for optical molasses.

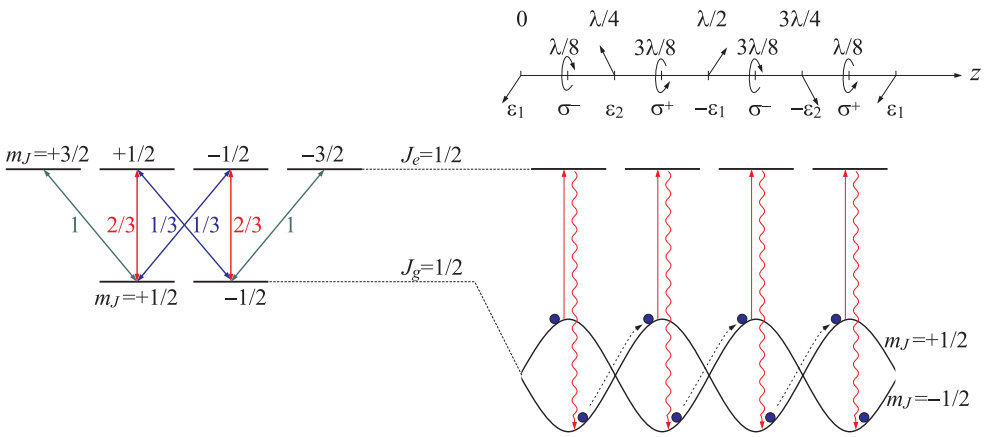

Figure 49.5: The upper line shows, how the polarization changes as a function of position (in units of a wavelength) for the 'lin-perp-lin' standing wave configuration. The figure below shows a simplified picture of the Sisyphus cooling mechanism for an atom with two levels, $J_g \leftrightarrow J_e$.

49.2.2.1 Lin ⊥ lin molasses

In the first case, two counterpropagating light waves with orthogonal linear polarizations form a standing wave. This configuration is familiarly called lin-perp-lin. Fig. 49.5 illustrates the change of polarization every period of $\lambda/8$ from linear to circular to linear again, but rotated by 90°, and so on [220]. Along the same distance, the light-atom coupling produces a periodic energy shift (light-shift) of the ground

state Zeeman levels. To illustrate the cooling mechanism, we assume the simplest case, a transition $J_g = \frac{1}{2} \longrightarrow J_e = \frac{3}{2}$. As shown in Fig. 49.5 an atom moving through the region $z \simeq \lambda/8$, where the polarization is σ_-, will see its population pumped to $J_g = -\frac{1}{2}$. In addition, the Clebsch-Gordan coefficients that control the dipolar coupling of the $J_e = \frac{3}{2}$ require that the $J_g = -\frac{1}{2}$ couples to σ_- with a force three times larger than the $J_g = +\frac{1}{2}$ does. The difference of the coupling forces leads to the light-shift between the two fundamental states shown in Fig. 49.5. As the atom continues to move toward $+z$, the relative coupling forces are reversed near $3\lambda/8$, where the polarization is essentially σ_+. Thus, the relative energy levels of the two hyperfine fundamental states oscillate 'out of phase' when the atom moves through the standing wave.

The fundamental idea is that the optical pumping rate, which always redistributes population to the lower hyperfine level, delays the light-shift of the atom moving through the field. The result is a 'Sisyphus effect', where the atom spends most of its time in sub-levels climbing a potential hill and thus converting kinetic energy into potential energy. This accumulated potential energy is subsequently dissipated by spontaneous emission to the electromagnetic modes of the vacuum. Simultaneously, the spontaneous emission transfers the population back to the lower one of two ground state levels. The lower diagram of Fig. 49.5 illustrates the phase delay of optical pumping. For this cooling mechanism to work, the optical pumping time, which is controlled by the intensity of the light, must be sufficiently slow to give the atom enough time to climb a noticeable part of the light-shift potential. This time essentially depends on the speed of the atom. As the atom is moving slowly, having previously been cooled by the Doppler mechanism, the light field must be weak in order to decrease the optical pumping rate. Interestingly, this physical picture combines the conservative dipole optical force, whose spatial integral gives rise to the mounts and valleys of the potential on which the atom moves, and the irreversible dissipation of energy by spontaneous emission, which is necessary for any type of cooling.

We can obtain simple expressions for the friction coefficient and the capture velocity after some definitions. As in the Doppler cooling model we define the friction coefficient $\alpha_{\rm lpl}$ as the proportionality constant between the force F and the atomic velocity v,

$$F = -\alpha_{\rm lpl} v \ . \tag{49.22}$$

We assume that the light field is tuned to the red of the transition J_g - J_e,

$$\Delta = \omega - \omega_0 \ , \tag{49.23}$$

and we denote the light-shifts of the levels $J_g = \pm\frac{1}{2}$ as $\Delta_\pm$, respectively. At the position $z = \lambda/8$, we find $\Delta_- = 3\Delta_+$ and at $z = 3\lambda/8$, $\Delta_+ = 3\Delta_-$. As the applied field is tuned to red, all $\Delta_\pm$ have negative values. Now, for the cooling mechanism to be efficient, the optical pumping time $\tau_{\rm p}$ should be similar to the time needed for an atom with velocity v to move from the bottom to the top of the potential, $\frac{\lambda/4}{v}$,

$$\tau_{\rm p} = \frac{\lambda/4}{v} \tag{49.24}$$

or

$$\Gamma' \simeq kv \ , \tag{49.25}$$

where $\Gamma' = 1/\tau_{\rm p}$ and $\lambda/4 \simeq 1/k$. Now, the energy W dissipated during a cycle of escalation and spontaneous emission is essentially the average energy difference between the light-shifted ground states, $\Delta_{\rm ls} \equiv \Delta_+ + \Delta_-$, that is $W \simeq -\hbar\Delta_{\rm ls}$. Therefore, the rate for energy dissipation is,

$$\frac{dW}{dt} = \Gamma'\hbar\Delta_{\rm ls} \ . \tag{49.26}$$

At the same time, every temporal energy change of a system can always be expressed as $\frac{dW}{dt} = \mathbf{F}\cdot\mathbf{v}$. Therefore, in this one-dimensional model, considering Eq. (49.23), we can write,

$$\frac{dW}{dt} = -\alpha_{\rm lpl}v^2 = -\Gamma'\hbar\Delta_{\rm ls} \ , \tag{49.27}$$

such that with (49.25),

$$\alpha_{\rm lpl} = -\frac{\Gamma'\hbar\Delta_{\rm ls}}{v^2} \simeq -kv\frac{\hbar\Delta_{\rm ls}}{v^2} \simeq -\frac{\hbar k^2\Delta_{\rm ls}}{\Gamma'} \ . \tag{49.28}$$

Note that since $\Delta < 0$, $\alpha_{\rm lpl}$ is a positive quantity. Also note, that for large detunings, $(\Delta \gg \Gamma)$ Eq. (43.24) gives,

$$\frac{U}{\hbar} = \frac{\Delta_{\rm ls}}{4} = \frac{\Omega^2}{4\Delta} \ . \tag{49.29}$$

It is also true that for light-shifts, which are large compared to the natural width of ground state ($\Delta_{\rm ls} \gg \Gamma'$), and for large red detunings ($\Delta \gtrsim 4\Gamma$),

$$\frac{\Gamma}{\Gamma'} \simeq \frac{\Delta^2}{4\Omega^2} \ . \tag{49.30}$$

Therefore, the sub-Doppler friction coefficient can also be written,

$$\alpha_{\rm lpl} = -\frac{\hbar k^2\Delta}{4\Gamma} \tag{49.31}$$

Eq. (49.31) makes two remarkable predictions: Firstly, in the 'lin-perp-lin' configuration the sub-Doppler friction coefficient can be a large number in comparison to $\alpha_{\rm d}$. Note that from Eq. (49.20), with $I \lesssim I_{\rm sat}$ and $\Delta \gg \Gamma$,

$$\alpha_{\rm d} \simeq \hbar k^2\left(\frac{\Gamma}{\Delta}\right)^3 \ , \tag{49.32}$$

and

$$\frac{\alpha_{\rm lpl}}{\alpha_{\rm d}} \simeq \left(\frac{\Delta}{\Gamma}\right)^4 \ . \tag{49.33}$$

Secondly, $\alpha_{\rm lpl}$ is independent of the intensity of the applied field. This last result is different from the friction coefficient, which is proportional to the field intensity up to until saturation (see Eq. (49.20)). However, although $\alpha_{\rm lpl}$ seems impressive, the range of atomic velocities where it can operate is constrained by the condition,

$$\Gamma' \simeq kv \ . \tag{49.34}$$

The ratio of the capture velocities for sub-Doppler versus Doppler cooling is therefore only,

$$\frac{v_{\rm lpl}}{v_{\rm d}} \simeq \frac{4\Delta_{\rm ls}}{\Delta} \ . \tag{49.35}$$

Fig. 49.6 graphically illustrates the comparison between the Doppler and the 'lin-perp-lin' sub-Doppler cooling mechanisms. The dramatic difference of the capture ranges is evident. Note also that the slopes of the curves give the friction coefficients and that, within the capture range, the slope is much steeper for the sub-Doppler mechanism.

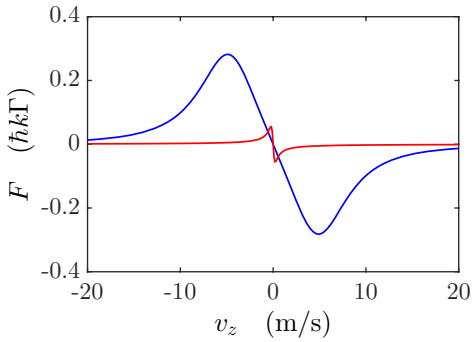

Figure 49.6: (code) Comparison of slopes, amplitudes, and capture ranges for Doppler and Sisyphus cooling.

49.2.2.2 σ^+-σ^- molasses

The second mechanism operates with two counterpropagating light beams, which are circularly polarized in opposite directions. When the two counterpropagating beams have the same amplitude, the resulting polarization is always linear and orthogonal to the propagation axis, but the tip of the polarization vector traces a helix with a periodicity of λ [see Fig. 49.7(b)]. The physics of this sub-Doppler mechanism *does not involve hill-climbing nor spontaneous emission*, but an imbalance of the photon scattering rates by the two counterpropagating light waves as the atom moves along the z-axis. This imbalance leads to a velocity-dependent force counteracting the atomic displacement. The essential factor leading to the different scattering rates is the creation of a population orientation along the z-axis between the sub-levels of the atomic ground state. The more populated sub-levels scatter more photons. Now, considering the energy level diagram (see Fig. 49.5) and the symmetry of the Clebsch-Gordan coefficients, it is evident that transitions $J_g = \frac{1}{2} \leftrightarrow J_e = \frac{3}{2}$ coupled by linearly polarized light can not produce an orientation of the population in the ground state. In fact, the simplest system exhibiting this effect is $J_g = 1 \leftrightarrow J_e = 2$. A measure for this orientation is the magnitude of the matrix element $\langle J_z \rangle$ between the sublevels $J_{g_z} = \pm 1$. For an atom at rest at the position $z = 0$ interacting with the light polarized along the y-direction, the light-shifts Δ_0 and $\Delta_\pm$ of the three sub-levels of the ground state would be,

$$\Delta_{+1} = \Delta_{-1} = \tfrac{3}{4}\Delta_0 \ , \tag{49.36}$$

and the stationary populations would be 4/17, 4/17 e 9/17, respectively. Obviously, linearly polarized light does not produce a stationary orientation, $\langle J_z \rangle_s = 0$. But when the atom begins to move along the z-axis with velocity v, it sees a linear polarization precessing about the axis of propagation at an angle $\varphi = kz = -kvt$. This precession gives rise to a new term in the Hamiltonian, $V = kvJ_z$. Furthermore, when we transform to a rotating coordinate system, the eigenfunctions of the Hamiltonian of the atom moving in this new 'inertial' system become linear combinations of the basis functions of the resting atom. The expectation value of the stationary orientation operator J_z, is now zero in the inertial system [220],

$$\langle J_z \rangle = \frac{40}{17} \frac{\hbar k v}{\Delta_0} = \hbar(\Pi_+ - \Pi_-) \ . \tag{49.37}$$

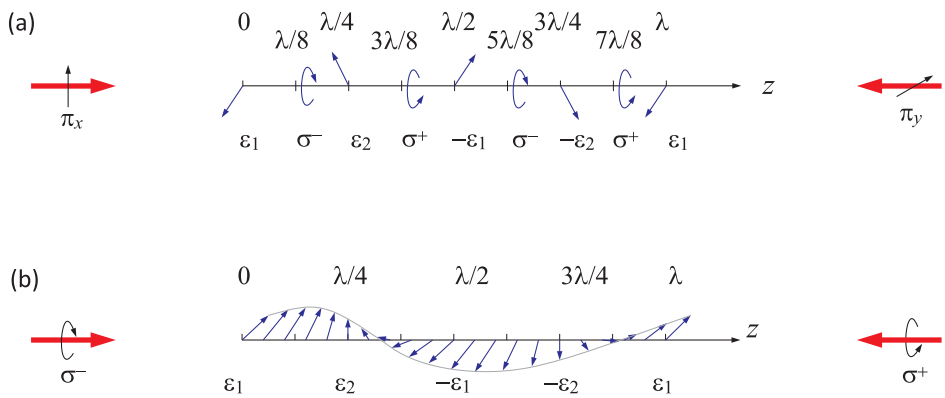

Figure 49.7: Polarization as a function of position (in units of a wavelength) for the σ^+-σ^- standing wave configuration.

Note that, as the expectation value of the orientation is nonzero only when the atom moves. In Eq. (49.37) we denote the populations of the sub-levels $|\pm>$ as $\Pi_\pm$, and we interpret nonzero matrix elements as a direct measure of the population difference between the ground state levels $|\pm>$. Note that, since Δ_0 is negative (red tuning), the Eq. (49.37) tells us, that the population Π_- is larger than Π_+. Now, when an atom traveling in $+z$ direction is exposed to two light waves with polarizations $\sigma_\mp$ propagating in the $\mp z$ directions, the preponderance of population in the state $|-\rangle$ will result in a higher scattering rate from the wave propagating in $-z$ direction. Therefore, the atom will be subject to a total force opposite to its movement and proportional to its velocity. The differential scattering rate is,

$$\frac{40}{17} \frac{kv}{\Delta_0} \Gamma' \ . \tag{49.38}$$

With a quantized momentum of $\hbar k$ transferred at each scattering event, the total force is,

$$F = \frac{40}{17} \frac{\hbar k^2 v \Gamma'}{\Delta_0} \ . \tag{49.39}$$

The friction coefficient $\alpha_{\rm cp}$ is,

$$\alpha_{\rm cp} = -\frac{40}{17}\hbar k^2 \frac{\Gamma'}{\Delta_0} \ , \tag{49.40}$$

which is a positive quantity, since Δ_0 is negative for red detuning. Comparing α_{cp} with $\alpha_{\rm lpl}$ we see, that α_{cp} must be much smaller, because we always assumed that the light shifts Δ are much larger than the linewidths Γ'. However, the heating rate due to fluctuations of the recoil is also much lower. Thus, the minimum temperatures that can be reached with the two sub-Doppler mechanisms are comparable.

Although the Doppler cooling mechanism also depends on an imbalance of scattering from counterpropagating light waves, in this case the imbalance comes from the fact that the Doppler shift experienced by the moving atoms leads to different probabilities for photon scattering. For the sub-Doppler mechanism the scattering probabilities from the two light waves are the same, but the ground state populations are not. The state with the largest population suffers the highest scattering rate.

49.2.3 Raman cooling

49.2.3.1 Optical cooling of confined particles

It is also possible to cool ions confined in a trap [975]. The direction of their motion and their velocity change periodically with the secular frequencies ζ_r und ζ_z. For optical cooling it is sufficient to irradiate a single red-detuned running-wave light field: In a real ion trap the cylindrical symmetry cannot be realized with absolute precision so that we get different secular frequencies $\zeta_x \neq \zeta_y \neq \zeta_z$ and a coupling of the degrees of freedom for all directions of space. The cooling of the ionic motion in a single direction results in a cooling of the motion in the other directions.

In the rest system of an ion oscillating in a harmonic trap the Doppler-shift of the laser frequency changes periodically: $\mathbf{v}(t) = \mathbf{v}_0 \cos \zeta_{r,z} t$. The ion absorbs therefore in its rest system the light on a withb of sidebands whose distance and strength depend on the oscillation frequency and amplitude. The absorption profile of a transition in such a harmonically vibrating ion follows as a convolution of the Lorentz profile $\mathcal{L}_\Gamma$, describing the naturally broadened resonance, with a function $\mathcal{S}$, describing the splitting of the absorption profile into sidebands [469]:

$$\mathcal{A}(\Delta) = (\mathcal{L}_\Gamma \star \mathcal{S})(\Delta) \quad , \quad \mathcal{S}(\Delta) = \sum_n \mathcal{J}_n(\mathbf{k}\cdot\mathbf{v}_0/\zeta_{r,z})^2 \delta(\Delta - n\zeta_{r,z}) \ . \tag{49.41}$$

$\mathcal{J}_n$ denotes the Bessel function of nth order. In essence, the system is governed by three time-constants: The natural decay width of the cooling transition Γ is a measure for the inneratomic time scale, since it determines the average duration of absorption-emissions cycles. The secular frequencies $\zeta_{r,z}$ determine the time scales for changes in the external degrees of freedom, i.e. for changes of the ion's location and velocity. The Doppler-shift kv_0 of the resonance frequency in the return point of the ion motion finally, is a measure for the kinetic energy of the ion.

The relative importance of these three characteristic frequencies reveal the state of the ion in the trap. The modulation index $\mathbf{k}\mathbf{v}_0/\zeta_{r,z}$ decides on the height and the number of sidebands in the excitation spectrum. The better the ion has been cooled,

the smaller the modulation index and the smaller the height and number of sidebands. The kinetic energy of the ion is,

$$E_{\text{kin}} = \frac{1}{2}mv_0^2 = \frac{1}{2}m\zeta_{r,z}^2 x_0^2 \ . \tag{49.42}$$

The modulation index $\mathbf{k}\mathbf{v}_0/\zeta_{r,z} = kx_0 = 2\pi x_0/\lambda$ is also called *Lamb-Dicke parameter*. By cooling the Lamb-Dicke parameter is so much reduced and the ion is so well localized that its motional sidebands are smaller than the wavelength of the exciting light. It then is in the so-called Lamb-Dicke regime $x_0 \ll \lambda$ [**?**] and has so small motional sidebands that they do not contribute to the line shape and do not influence the line width. Therefore the linear Doppler effect vanishes.

The quantity $\zeta_{r,z}/\Gamma$ defines the *resolution* of the sidebands. If the resolution is poor, we talk about weak confinement, else about strong confinement. Therefore the same ion can be weakly confined with respect to an allowed transition and strongly confined with respect to a forbidden transition. The cooling processes in the two cases of strong and weak trapping must be described differently. At weak confinement the oscillation frequency $\zeta_{r,z}$ is so slow that many absorption-emission cycles with the time constant Γ^{-1} can occur during one oscillation period. Cooling process and cooling limit are approximately the same as for free particles and are described by Doppler cooling.

49.2.3.2 Raman sideband cooling

In the case of strong confinement for the description of the cooling process we must consider the quantization of the motional energy in the harmonic potential. The two levels coupled by the narrow transition split into vibrational sublevels $|n_{r,z}\rangle$, which are populated in thermal equilibrium according to the Bose-Einstein distribution and have the kinetic energies E_{kin},

$$n_{r,z} = \frac{1}{e^{\hbar\zeta_{r,z}/k_{\text{B}}T} - 1} \qquad \text{and} \qquad E_{\text{kin}} = \hbar\zeta_{r,z}(n_{r,z} + \tfrac{1}{2}) \ . \tag{49.43}$$

To perform the so-called optical cooling *sideband cooling* [975] the laser is tuned to the first lower sideband. The laser light is then scattered in a Raman-Anti-Stokes process at the excited electronic state with a vibrational quantumnumber lower by 1 $|e, n_{r,z} - 1\rangle$. The subsequent spontaneous decay occurs most probably to the same vibrational substate of the ground state $|g, n_{r,z} - 1\rangle$. The net effect of such a scattering process therefore is a transition to the next lower vibrational quantum number. The zero point energy of the ion in the trapping potential cannot be underscored by cooling, $E_{\text{kin}} > \frac{1}{2}\hbar\zeta_{r,z}$ (for the Yb^+ ion it is $E_{\text{kin}} > 2\,\text{neV}$). However, the uncertainty of the kinetic energy, and the temperature T given by (49.43) have no lower limit [257].

At every absorption process, free particles carry away the momentum of the photons $\hbar k$. The recoil of a free Yb^+ ion corresponds to the frequency shift $\varepsilon/2\pi = 5.3\,\text{kHz}$. On a narrow transition, it yields a resonance at the frequency ε. For trapped ions, this is not the case, because the momentum is absorbed by the whole trap (see analogy to the *Mößbauer effect*).

49.2.3.3 Stimulated Raman sideband cooling

We may use two lasers detuned far from resonance to couple two vibrational states. However, additional dissipation by optical pumping is still required.

Numerous schemes have been tested to cool neutral atoms in optical lattices. For the schemes to work, the ion should be already in the Lamb-Dicke regime. Otherwise, transitions with transfer of higher vibrational quantum numbers $n_{r,z}$ are possible during spontaneous emission. The Lamb-Dicke limit is set by $kr < 1$, or,

$$\langle n \rangle = \frac{m\omega_{\rm trp}}{2\hbar k^2} \ . \tag{49.44}$$

This means that higher trap frequencies ease the required temperature at which sideband cooling can start to work.

49.2.4 Adiabatic cooling of an optical lattice

Adiabatic cooling by [505] in 1D. Defining the lattice constant Q_0, the Boltzmann factor $f_{\rm B} \equiv e^{-\hbar\omega/k_{\rm B}T}$, the initial thermal population $\pi_n = (1-f_{\rm B})f_{\rm B}^n$, the recoil energy $E_{\rm rec} \equiv \frac{\hbar^2 k^2}{2m}$,

$$\frac{k_{\rm B}T}{2} = \sum_n \frac{\pi_n}{\hbar Q_0} \int_{(n+1)^{th}\text{Bloch band}} \frac{p^2}{2m} dp = 2\sum_n \frac{\pi_n}{\hbar Q_0} \int_{n\hbar Q_0/2}^{(n+1)\hbar Q_0/2} \frac{p^2}{2m} dp \tag{49.45}$$

$$= 2E_{\rm rec}\left(\frac{Q_0}{k}\right)^2 \sum_{n=0}^{\infty} \pi_n \frac{3n^2+3n+1}{24} = E_{\rm rec}\left(\frac{Q_0}{k}\right)^2 \frac{1+4f_{\rm B}+f_{\rm B}^2}{12(1-f_{\rm B})^2} \ . \tag{49.46}$$

Furthermore,

$$f_{\rm B} = \frac{\bar{n}}{1+\bar{n}} \qquad \Longleftrightarrow \qquad \bar{n} = \frac{f_{\rm B}}{1-f_{\rm B}} \ .$$

49.2.5 Exercises

49.2.5.1 Ex: Optical molasses

Optical molasses are created (in one dimension) by two beams counterpropaganting lasers tuned to red of an atomic transition. Each of the laser beams exerts on the atoms the radiative pressure force $F_\pm = \hbar k \frac{\Gamma}{2} \frac{s}{[2(\Delta \pm kv)/\Gamma]^2+1+s}$. Δ is the detuning of the laser, ν is the velocity of an atom.
a. Show that for small velocities ($|kv| \ll \Gamma$ and $\Delta \leq \Gamma$) the optical molasses can be understood as a friction force and calculate the friction coefficient.
b. Heating processes caused by spontaneous emission limit the minimum temperature that can be reached in optical molasses. Calculate the laser tuning, where the temperature reaches its minimum value and specify the cooling limit.
Help: Suppose a one-dimensional molasses and assume, that the spontaneous emission only happens along this dimension. The heating rate follows from the scattering rate R through $\left(\frac{dE}{dt}\right)_{\rm heat} = \frac{d}{dt}\frac{\langle p^2\rangle}{2m} = \frac{\hbar^2 k^2}{2m} 2R$, the cooling rate follows from $\left(\frac{dE}{dt}\right)_{\rm cool} = Fv$.

49.2.5.2 Ex: Atomic fountain

In atomic fountains atoms are accelerated upward by a 'moving optical molasses'. After the molasses has been switched off, they perform a ballistic flight in the Earth gravitational field. The moving molasses is generated by two pairs of counterpropagating laser beams intersecting at right angle and oriented both at an angle of 45° with respect to gravity. The upgoing beams are tuned to the blue, and the counterpropagating downgoing beams have the same detuning to the red side of the atomic resonance ($\lambda = 780\,\mathrm{nm}$). Supposing that the resonator is close to the position of the molasses and has with negligible length, what should be the detuning in order to achieve 1 s time period between the two passages of the atoms through the microwave resonator?

49.3 Optical and magneto-optical traps

49.3.1 The magneto-optical trap

An apparently fatal obstacle to the confinement of particles by optical forces is Earnshaw's optical theorem. This theorem states that, if a force is proportional to the light intensity, its divergence must be zero because the divergence of the Poynting vector expressing the directional flux of intensity is zero inside a volume without sources nor sinks of radiation. The absence of divergence precludes the possibility of a restoring force to the interior at all places of a closed surface [33]. However, Earnshaw's optical theorem can be bypassed by a clever trick. The internal degrees of freedom of the atom (i.e., its electronic energy levels) can change the proportionality between the force and the Poynting vector in a position-dependent manner, such that the optical Earnshaw's theorem does not apply. Spatial confinement is then possible using the radiative pressure force generated by counterpropagating light beams. The most common trap configuration is based on a radial magnetic field gradient produced by a quadrupolar field and three pairs of counterpropagating circularly polarized laser beams tuned to the red of an atomic transition and intersecting at right angles at the point where the field is zero. This *magneto-optical trap* (*MOT*) uses the position-dependent Zeeman shift of the electronic levels as the atom moves in the radially increasing magnetic field. The use of circularly polarized light which is red-detuned by about Γ results in a spatially varying transition probability, whose effect is to produce a restoring force that pulls the atom back to the origin. To understand better how the trapping scheme works, we consider a two-level atom with a transition $J = 0 \to J = 1$ moving along the z-direction. We apply a magnetic field $\mathcal{B}(z)$ growing linearly with the distance from the origin. The Zeeman shifts of the electronic levels depend on the position,

$$\Delta_{\mathcal{B}} = \frac{\mu_{\mathrm{B}} g_F m_F}{\hbar} \frac{d\mathcal{B}}{dz} z \equiv \partial_z \omega_{\mathrm{Zeem}} \ , \tag{49.47}$$

see Fig. 49.8. We also apply counterpropagating laser beams along the directions $\pm z$ with circular polarizations of opposite signs and tuned to the red of the atomic transition. It is clear from Fig. 49.8 that an atom moving in $\pm z$ direction will scatter $\sigma_{\mp}$ type photons at a faster rate than $\sigma_{\pm}$ type photons, because the Zeeman effect

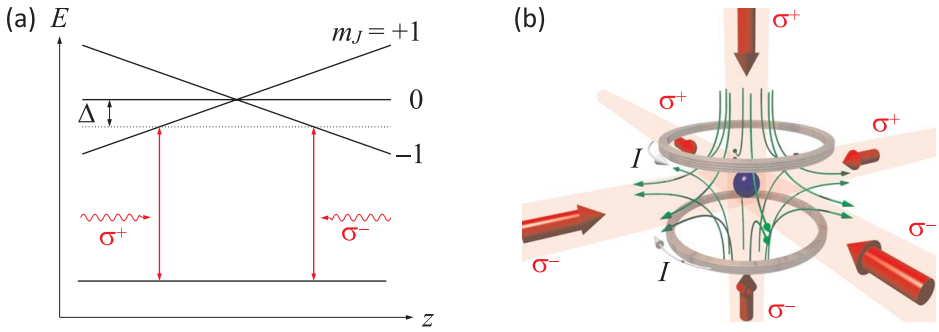

Figure 49.8: Left: Diagram of the energy level shift in an MOT, when an atom moves out of the center of the trap. A restoring force is observed around the indicated resonance positions. Right: Scheme of a typical MOT set up showing the six laser beams and the current-carrying coils in anti-Helmholtz configuration producing the quadrupolar magnetic field.

will pull the $\Delta m_J = \mp 1$ transition closer to the laser frequency. The expression for the radiation pressure force extends Eq. (49.18) to include the Doppler effect kv_z and the Zeeman effect,

$$F_{\pm z} = -\frac{\hbar k}{2}\Gamma \frac{2\Omega^2}{4(\Delta \pm kv_z \pm z\partial_z\omega_{\text{Zeem}})^2 + 2\Omega^2 + \Gamma^2} \ . \tag{49.48}$$

The atom will, therefore, feel a restoring force which pushes it back to the origin. If the laser beams are red-detuned by an amount $\Delta = -\Gamma$, the Doppler shift of the atomic motion introduces velocity-depending term to the restoring force, such that for small displacements and velocities the total restoring force can be expressed by the sum of a term which is linear in the velocity and a term which is linear in the displacement,

$$F_{\text{MOT}} = F_{1z} + F_{2z} = -\alpha\dot{z} - \kappa z \ , \tag{49.49}$$

as we will study in Exc. 49.3.3.1. From Eq. (49.49) we can derive the equation of motion of a damped harmonic oscillator with mass m,

$$\ddot{z} + \frac{2\alpha}{m}\dot{z} + \frac{\kappa}{m}z = 0 \ . \tag{49.50}$$

The damping constant α and the spring constant κ can be written compactly in terms of atomic parameters and the field as,

$$\kappa = \frac{16\hbar k\Gamma\Omega^2\Delta\partial_z\omega_{\text{Zeem}}}{4\Delta^2 + 2\cdot 6\Omega^2 + \Gamma^2} \ . \tag{49.51}$$

and

$$\alpha = \kappa\frac{k}{\partial_z\omega_{\text{Zeem}}} \ . \tag{49.52}$$

Typical conditions for MOT are $\Omega = \Gamma/2$, $\Delta = -\Gamma$. For typical MOTs,

$$\alpha \simeq 2\cdot 10^{-22}\,\text{Ns/m} \qquad \text{and} \qquad \kappa \simeq 3.7\cdot 10^{-19}\,\text{N/m} \ . \tag{49.53}$$

We can also estimate the curvature of the MOT,

$$\omega = \sqrt{\frac{\kappa}{m}} \simeq (2\pi)\ 200\,\mathrm{Hz}\ . \tag{49.54}$$

Solve Exc. 49.3.3.2.

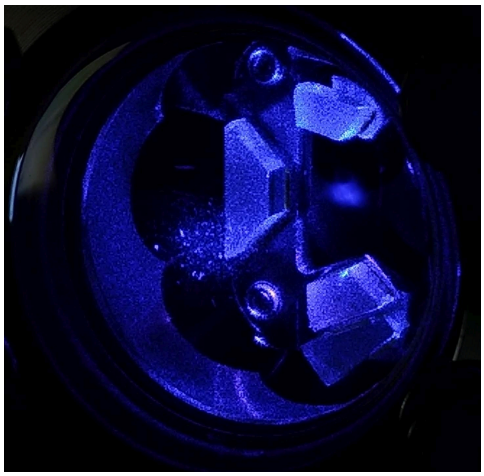

Figure 49.9: Picture of a strontium MOT operated at 461 nm. The atomic cloud, which consists of about 10^6 atoms at 5 mK temperature is visible as a diffuse spot located inside a three-mirror ring cavity.

MOTs are realized with current-carrying coils in anti-Helmholtz configuration which generates a quadrupolar geometry potential. Near the center, the magnetic field and its absolute value are well approximated by,

$$\vec{\mathcal{B}} = q \begin{pmatrix} x \\ y \\ -2z \end{pmatrix} \qquad \text{and} \qquad |\vec{\mathcal{B}}| = q\mathcal{B}\sqrt{r^2 + 4z^2}\ , \tag{49.55}$$

with $r^2 = x^2 + y^2$ and the gradient $q \equiv \partial_r B$ is a constant, which depends only on the geometry of the coils and the current in them. Thus, the extension of the above results to three dimensions is simple if we consider the fact that the gradient of the quadrupolar field in the z-direction is twice the gradient in the radial directions x and y, such that $\kappa_z = 2\kappa_x = 2\kappa_y$.The damping term, which proportional to the velocity, implies that the kinetic energy E is dissipated from the atom (or a cloud of atoms) as,

$$E/E_0 = e^{-2\alpha t/m}\ , \tag{49.56}$$

where m is the atomic mass and E_0 the kinetic energy at the beginning of the cooling process. Therefore, the dissipative force term cools the atomic cloud and, at the same time, combines with the position-dependent term to confine it. The time constant for the damping,

$$\tau = \frac{m}{2\alpha} \tag{49.57}$$

is typically dozens of microseconds. It is important to keep in mind that a MOT is anisotropic, since the restoring force is proportional to the anisotropic field gradients. Because of its dissipative non-conservative nature, it is is more accurate to characterize a MOT by the maximum capture rate, rather than by a 'potential depth'.

In early experiments MOTs were loaded from a decelerated atomic beam. Later it was shown, that the low-velocity tail of the Maxwell-Boltzmann distribution provides a sufficient amount of atoms that can be captured by a MOT, so that it can be loaded directly from an atomic vapor at room temperature. Now many groups in the world use these assemblies for applications ranging from precision spectroscopy to the optical control of reactive collisions; the MOT has become the working horse of atom optics.

49.3.1.1 Density in a MOT

A typical MOT captures up to a billion atoms in a volume of a few $1\,\mathrm{mm}^3$ resulting in densities of $\sim 10^{10}\,\mathrm{cm}^{-3}$. Although a MOT works as a versatile and robust 'reaction cell' for many applications, the frequencies of the light beams must be tuned close to atomic transitions, which bears the disadvantage that a considerable fraction of atoms remains in excited states. This fact is at the origin of two processes limiting the density of a MOT: (1) losses of trapped atoms by collisions and (2) repulsive forces between the atoms caused by reabsorption of photons scattered within the cloud. Collisional losses arise from two sources: (i) hot atoms of the residual gas inside the chamber can elastically collide with cold atoms and kick them out of the MOT, and (ii) cold atoms in excited states can undergo inelastic binary collisions. 'Photon-induced repulsion' or *radiation trapping* arises when a trapped atom spontaneously emits a photon, which is then reabsorbed by other atoms. If the optical density of the cloud is high, it can take a long time for the photon to find its way out [2]. Since any photon exchange between two atoms will increase their relative momentum by $2\hbar k$, this leads to a repulsive force, which is proportional to the absorption cross section for the incident light beam. When this repulsive force balances the confining force exerted by the MOT, any increase in the number of trapped atoms augments its size, but its density.

49.3.1.2 Dark SPOT

In order to overcome the 'radiation trapping' effect, the atoms can be optically pumped into a 'dark' hyperfine level of the ground state that does not interact with the MOT light. In a conventional MOT one usually employs an auxiliary light beam called 'repumper', copropagating with the MOT beams, but tuned to another transition between hyperfine levels of the ground and excited states. The repumper recycles the population leaking out of the (not perfectly) cyclic MOT transition. As an example, Fig. 49.10 shows the MOT and repumper transitions for sodium.

In contrast to this conventional MOT, the scheme known as the *dark spontaneous force optical trap* (dark SPOT), passes the repumping beam through a glass plate the center of which is obstructed by a small circular disk. The shadow of this disk is projected into the center of the trap in such a way that the atoms in the center are

[2] E.g. a photon at the center of the sun will take thousands of years to get out.

not repumped back into the cyclic transition, but spend most of their time ($\sim 99\%$) in 'dark' hyperfine levels. While the cooling and confinement force continue to operate on the periphery of MOT, its center does not feel any radiation pressure. Dark SPOTs are able to increase the density of a trapped cloud by almost *two orders* of magnitude.

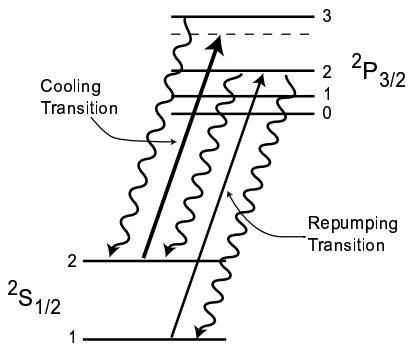

Figure 49.10: Hyperfine structure in sodium atoms showing the usual cooling, pumping, and repumping transitions.

49.3.2 Optical dipole traps

When temporal variations are to be applied to a confinement potential, magnetic fields are not the best choice, because they are slow and of limited spatial resolution. On the other side, laser beams can be varied quickly and in localized well. The dipole force exerted by a far-detuned laser beam can be derived from the gradient of the Rabi frequency $\mathbf{F} = -\nabla(\mathbf{d} \cdot \vec{\mathcal{E}})$. Hence, it can be derived from an optical potential, which can be used for trapping. The force may be attractive (toward the intensity maximum) or repulsive.

Compared to MOTs, optical traps (*far off-resonance optical trap*, FORT) are tuned far away from resonances, where the population in excited states is insignificant and spontaneous forces are absent. Note from Eq. (43.22), that spontaneous forces fall off with the square of the detuning while the potential derived from the dipolar force only decreases linearly with the detuning. The off-resonant optical density is negligible, so that radiation trapping is not an issue. The most simple FORT consists of a single focussed, linearly polarized gaussian laser beam tuned far to the red of an atomic resonance. For large detunings and strong field gradients the Eqs. (43.24) and Eqs. (43.25) become [388],

$$\boxed{U(\mathbf{r}) \simeq \frac{\hbar\Omega(\mathbf{r})^2}{4\Delta} = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}I(\mathbf{r}) \quad \text{and} \quad \hbar\gamma_{\text{sct}}(\mathbf{r}) \simeq \sigma_a(\Delta)\frac{I(\mathbf{r})}{\omega} = \frac{3\pi c^2}{2\omega_0^3}\left(\frac{\Gamma}{\Delta}\right)^2 I(\mathbf{r})}\,, \tag{49.58}$$

using the Rabi frequency $\hbar\Omega = d_{12}\mathcal{E}$, the dipole moment $d_{12} = \sqrt{3\pi\varepsilon_0\hbar\Gamma/k^3}$, and the intensity $I = \frac{\varepsilon_0}{2}c|\mathcal{E}|^2$. This shows that the potential becomes directly proportional to the light intensity and inversely proportional to the detuning. Therefore, at large

detuning but very high intensity, the depth of the FORT can be maintained, although the atoms do not absorb photons. Important advantages of FORTs as compared to MOTs are: (1) high densities ($\sim 10^{12}\,\mathrm{cm}^{-3}$) and (2) a well-defined polarization axis along which the atoms can be aligned or oriented (polarization of the spins).

Since lasers beams can easily be manipulated in position, intensity, and frequency, they can realize a large wide variety of possible geometries. For example, with a focused laser beam, one may influence the local density of a condensate and stir it around by moving the position of the laser beam. Strongly focused laser beams are often used for transporting or manipulating microscopic objects in arrangements called *optical tweezers*. And with standing light waves, it is possible to form periodic optical lattices in one, two or three dimensions (see Sec. 51.4.2).

49.3.2.1 Spin relaxation

When the atomic ground state has a hyperfine structure, another relaxation mechanism can be observed: Near-resonance Raman scattering can induce transitions between hyperfine states causing a population redistribution of between Zeeman substates called *spin relaxation*. In magnetic traps, this can lead to losses, because not all Zeeman substates are trapped.

The rate of an arbitrary scattering process starting from an initial state $|F, m\rangle$ through several possible excited states $|F'_j, m'_j\rangle$ to a final state $|F''m''\rangle$ is, according to the formula of Kramers-Heisenberg [648],

$$\gamma_{Fm\to F'm'} \propto \left| \sum_j \frac{\alpha^{(F'_j m'_j)}_{Fm\to F'm'}}{\Delta_{F'_j m'_j}} \right|^2 . \tag{49.59}$$

Far from resonance the scattering decreases as Δ^2 for Rayleigh scattering, $Fm = F'm'$. Raman scattering, $Fm \neq F'm'$, is further suppressed by destructive interference of the different scattering paths.

In the case of rubidium, we calculate,

$$\gamma_{\mathrm{spin}} = \frac{3c^2\omega^4}{8\pi}\frac{70}{81}\Gamma^2 \left| \left(\frac{1}{\omega_{D1}}\right)^3 \frac{1}{\Delta_{D1}} - \left(\frac{1}{\omega_{D2}}\right)^3 \frac{1}{\Delta_{D2}} \right|^2 \frac{I_0}{\hbar\omega} . \tag{49.60}$$

49.3.2.2 Potential of a Gaussian beam

The *far-off resonance optical trap* (FORT) is an example of an optical trap based on dipole forces [388]. The intensity distribution of a gaussian beam with a diameter of w_0 at its waist is [3],

$$I(\mathbf{r}) = \frac{2P}{\pi w_0^2} e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} , \tag{49.61}$$

where P is the total power of the beam and $z_R \equiv \pi w_0^2/\lambda$ the *Rayleigh length* at a given wavelength λ. The dipolar potential is given by (49.58). Using the potential depth,

$$\boxed{U_0 \equiv \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}\frac{2P}{\pi w_0^2}} , \tag{49.62}$$

[3] See script on *Electrodynamics* (2023).

which is $U_0 < 0$ for red-detuned light, we can approach the potential near its center, that is, near the optical axis, $r \ll \frac{1}{2}w_0$, and within the range of the Rayleigh length, $z \ll \pi w_0^2/\lambda$, by a harmonic potential [4],

$$U(\mathbf{r}) \simeq U_0 e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} \simeq U_0 \left(1 - \frac{2x^2+2y^2}{w_0^2} - \frac{z^2}{z_R^2}\right) \tag{49.63}$$
$$\equiv U_0 + \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 \equiv k_\mathrm{B}T \left(\frac{U_0}{k_\mathrm{B}T} + \frac{r^2}{2\bar{r}^2} + \frac{z^2}{2\bar{z}^2}\right) .$$

This leads to the equivalences,

$$\boxed{\begin{array}{rclcrcl} \omega_r & = & \frac{2}{w_0}\sqrt{\frac{U_0}{m}} & , & \omega_z & = & \frac{1}{z_R}\sqrt{\frac{2U_0}{m}} \\ \bar{r} & = & \frac{w_0}{2}\sqrt{\frac{k_\mathrm{B}T}{U_0}} & , & \bar{z} & = & z_R\sqrt{\frac{k_\mathrm{B}T}{2U_0}} \end{array}} . \tag{49.64}$$

Solve Excs. 49.3.3.3 and 49.3.3.4.

Example 365 (*Dipole trap for rubidium*): The formulas (49.58) hold for a two-level system. In case of the $D1$- and $D2$-lines of rubidium, we must consider all contributions weighted by the respective detunings,

$$U_0 \equiv \sigma_0 \frac{\hbar\Gamma}{4}\left(\frac{1}{\Delta_{D1}} + \frac{g_{D2}/g_{D1}}{\Delta_{D2}}\right)\frac{I_0}{\hbar\omega} \simeq \frac{3\hbar\pi c^2}{2\omega^2}\frac{\Gamma}{\Delta}\frac{I_0}{\hbar\omega} ,$$

where $g_{D2}/g_{D1} = 2$.
Similarly, the spontaneous emission rate is,

$$\gamma_\mathrm{sct} \simeq \frac{\pi c^2\Gamma^2}{2\omega^2}\left(\frac{1}{\Delta_{D1}^2} + \frac{g_{D2}/g_{D1}}{\Delta_{D2}^2}\right)\frac{I_0}{\hbar\omega} .$$

The spontaneous emission rate decays faster with detuning than the potential depth. Thus, heating can be avoided by working at large detunings and providing higher laser intensities. Defining the recoil temperature by,

$$T_\mathrm{rec} = \frac{\hbar^2 k^2}{k_\mathrm{B} m} ,$$

the *heating rate* is [388],

$$\dot{T} = \frac{1}{3}T_\mathrm{rec}\gamma_\mathrm{sct} = \frac{\hbar^2 k^2}{3mk_\mathrm{B}}\gamma_\mathrm{sct} .$$

[4] The diameter of a Gaussian beam can be characterized in several ways,

$$\bar{r}_{1/\sqrt{e}\text{-radius}} = \frac{\bar{r}_{1/e^2\text{-radius}}}{\sqrt{2}} = \sqrt{2}\,\bar{r}_{1/e^2\text{-radius}} = \frac{\bar{r}_{1/2\text{-radius}}}{2\ln 2} ,$$

and $\bar{r}_\text{-rms} \equiv \bar{r}_{1/\sqrt{e}\text{-diam}}$ and $\bar{r}_\text{-hwhm} \equiv \bar{r}_{1/2\text{-diam}}$ and $\bar{r}_\text{-diam} = 2\bar{r}_\text{-radius}$.

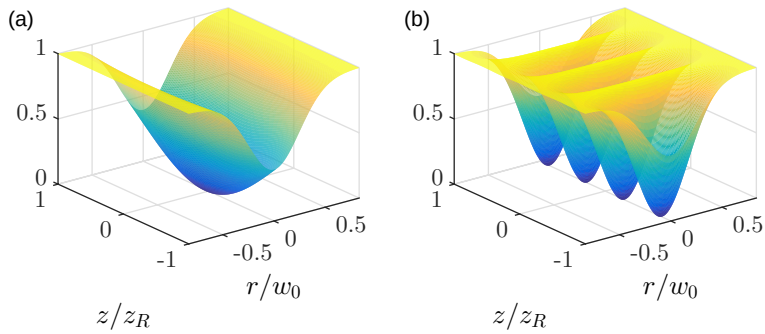

Figure 49.11: (code) (left) Dipole potential created by a Gaussian beam. (right) Dipole potential created by a stationary light wave.

49.3.2.3 Trapping in standing light waves

If both counterpropagating modes are pumped at different powers, $P_\pm$, the intensity distribution is,

$$I(\mathbf{r}) = \frac{2}{\pi w_0^2} e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} \left| \sqrt{P_+} e^{\imath kz} + \sqrt{P_-} e^{-\imath kz} \right|^2 . \tag{49.65}$$

Defining the contrast of the standing wave as,

$$C_{sw} \equiv \frac{4\sqrt{P_+P_-}}{(\sqrt{P_+}+\sqrt{P_-})^2} , \tag{49.66}$$

we can express the potential depth by,

$$\boxed{U_0 = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}\frac{2(\sqrt{P_+}+\sqrt{P_-})^2}{\pi w_0^2} = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}\frac{8(\sqrt{P_+P_-})^2}{\pi w_0^2 C_{sw}}} . \tag{49.67}$$

Therefore, within the Rayleigh length, the potential is,

$$\begin{aligned} U(\mathbf{r}) &\simeq U_0 e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} \frac{P_+ + P_- + 2\sqrt{P_+P_-}\cos kz}{P_+ + P_- + 2\sqrt{P_+P_-}} \\ &\simeq C_{sw} U_0 e^{-2\rho^2/w_0^2} \frac{P_+ + P_- + 2\sqrt{P_+P_-}\cos kz}{4\sqrt{P_+P_-}} . \end{aligned} \tag{49.68}$$

Neglecting terms containing higher powers of the coordinates than squared, we can also write,

$$U(\mathbf{r}) \simeq U_0 \left(1 - \frac{2x^2}{w_0^2} - \frac{2y^2}{w_0^2} - \frac{\sqrt{P_+P_-}}{(\sqrt{P_+}+\sqrt{P_-})^2} k^2 z^2 + ... \right) . \tag{49.69}$$

This leads to the identities,

$$\boxed{\begin{array}{lllllllll} \omega_r & = & \frac{2}{w_0}\sqrt{\frac{U_0}{m}} & , & \omega_z & = & \frac{1}{z_R}\sqrt{\frac{2U_0}{m}} & , & \omega_{lat} = k\sqrt{\frac{C_{sw}U_0}{2m}} \\ \bar{r} & = & \frac{w_0}{2}\sqrt{\frac{k_\mathrm{B}T}{U_0}} & , & \bar{z} & = & \frac{\sqrt{2}}{k}\sqrt{\frac{k_\mathrm{B}T}{U_0}} & & \end{array}} . \tag{49.70}$$

Solve the Excs. 49.3.3.5, 49.3.3.6, and 49.3.3.7.

49.3.3 Exercises

49.3.3.1 Ex: Linearization of the MOT

Derive the friction coefficient and the spring constant for a MOT.

49.3.3.2 Ex: Design of a Zeeman slower

In this exercise we will design a 'decreasing field *Zeeman slower*' for strontium (see also Exc. 39.5.6.3).
a. Calculate the mean velocity of atoms in a strontium gas heated to 500° C. What is the Doppler shift for an atom moving at this velocity at the cooling transition at $\lambda = 461\,\text{nm}$ (linewidth 30.5 MHz)?
b. Assuming you want to decelerate a fraction of 20% of the atoms flying in a

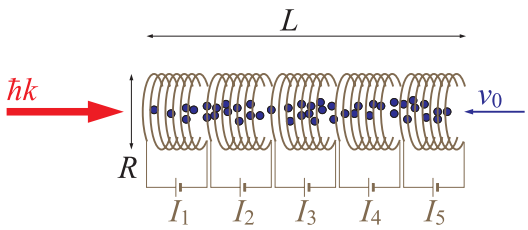

Figure 49.12: Design of a Zeeman slower.

particular direction, to what frequency should a counterpropagating laser (intensity $I = 20\,\text{mW/cm}^2$) be tuned in order to slow down the atoms?
c. Suppose the strontium atoms were always in resonance with the counterpropagating laser light while being decelerated. What would be the evolution of their Doppler shift along their trajectory (supposed to be on a straight line antiparallel to the laser beam).
d. In order to maintain the laser always in resonance we need to compensate for the diminishing Doppler shift along the atomic trajectory. This can be done exploiting the Zeeman shift induced by a magnetic field. We will now design a magnetic field generating an appropriate Zeeman shift. For simplicity, let us assume 5 identical radial solenoids distributed over $L = 30\,\text{cm}$ as sketched in Fig. 49.12, the only adjustable parameters being the currents in all solenoids, which need to be optimized such as to compensate the Doppler shift along the atom's trajectory.
e. Simulate the 1D trajectory of an atom cooled by the Zeeman slower.

49.3.3.3 Ex: Dipole trap near an intercombination line

a. Strontium has a strong transition ($\Gamma_{461} = (2\pi)\ 30.5\,\text{kHz}$) at 461 nm and a weak intercombination resonance ($\Gamma_{689} = (2\pi)\ 7.6\,\text{kHz}$) at 689 nm. A Gaussian laser beam with the power $P = 10\,\text{mW}$ focused to a waist of $w_0 = 100\,\mu\text{m}$ is tuned $\Delta_{689} = -(2\pi)\ 10\,\text{GHz}$ below the intercombination transition. Calculate the potential depth and the vibration frequencies for atoms trapped by this laser beam considering both resonances. What is the scattering rate on the two transitions.

b. Supposes that the trapped atomic cloud consists of $N = 10^8$ atoms at the temperature $T = 10\,\mu\text{K}$. Calculate the atomic density n_0 in the center of the cloud.

49.3.3.4 Ex: Dipole trap with a focused beam

a. Calculate the vibration frequencies of ^{87}Rb atoms confined in an optical trap consisting of a focused laser beam with the power $P = 10\,\text{W}$ and the beam diameter $w_0 = 100\,\mu\text{m}$. The laser beam is tuned 5 nm to the red side of the rubidium $D1$ resonance located at $\lambda = 795\,\text{nm}$.
b. Assume that the trapped atomic cloud consists of $N = 10^8$ atoms at the temperature $T = 100\,\mu\text{K}$. Calculate the atomic density n_0 in the center of the cloud.
c. The cross section for elastic collisions is $\sigma = 10^{-12}\,\text{cm}^2$. How many times do atoms meet on average?

49.3.3.5 Ex: Optical lattice

A laser beam with wavelength $\lambda_{\text{dip}} = 1064\,\text{nm}$, power $P = 2\,\text{W}$, and diameter $w_0 = 50\,\mu\text{m}$ is subdivided into three retroreflected beams intersecting at right angles. With this configuration we form a cubic optical lattice for strontium atoms, whose relevant transition lies at $\lambda_{Sr} = 461\,\text{nm}$ and has a decay width of $\Gamma_{Sr} = (2\pi)\,32\,\text{MHz}$. Calculate the potential depth and the secular frequencies.

49.3.3.6 Ex: Minimum optical lattice depth

Estimate the minimum required intensity of two counterpropagating laser beams tuned 7 GHz to the red of the strontium intercombination transition at 689 nm necessary to sustain an optical lattice exhibiting a single vibrational level.

49.3.3.7 Ex: Ring shaped optical potential

An interesting system is the $1D$ array of annular optical potentials realized in a standing wave formed by red-detuned Gaussian beam and a counterpropagating blue-detuned doonat-mode. In general, the tight longitudinal confinement freezes out the axial motion by *quantum confinement*. It can be readily shown [982] that in the far-off resonance case and if the potential is approximate by a harmonic potential around its minimum the eigenenergy spectrum is given by,

$$E_{pq} = U_0 + \hbar\omega(q + \tfrac{1}{2}) + \frac{\hbar^2 p^2}{2mR_0^2} \ .$$

It thus reproduces the ro-vibrational spectrum of a $2D$ artificial molecule and gives rise to two normal motions. In its ground state, we have the atom optical analog of a $2D$ rigid rotator. Gravity plays formally the same role as static electric fields for molecules. Such systems might be interesting for investigating the selection rules for transitions between ro-vibrational states involving conservation of total angular momentum of light and atoms and yield insight into the concept of orbital angular momentum of light fields.

49.3.3.8 Ex: Time-averaged trap

For sufficiently fast periodic displacements of a far-detuned laser beam it is possible to engineer effective more complicated trapping potential. What are the conditions for modulation speed? Simulate the effective trapping potential generated by a vibrating laser beam.

49.4 Magnetic traps

Purely magnetic traps are widely used in atom optics, where they served, e.g., for the first realizations of Bose-Einstein condensation (BEC). The most important feature that distinguishes magnetic traps is, that they do not need light to confine atoms. Hence, they are free of heating effects caused by photonic absorption, which turned out to be necessary condition for reaching BEC. Magnetic traps rely on the interaction of atomic spins with magnetic fields and gradients designed to contain the atoms. Depending on the sign of U and $\mathbf{F}$, atoms in states whose energy increases or decreases with the magnetic field are called 'low-field seekers' or 'high-field seekers', respectively. One might think, that it should be possible to trap atoms in any of these states, generating either a magnetic field minimum or a maximum. Unfortunately, only low-field seekers can be trapped in static magnetic fields, because in free space magnetic fields can not form maxima. Even though low-field seekers are not in the energetically lowest hyperfine levels, they can still be trapped because the rate of spontaneous emission through the magnetic dipole is $\sim 10^{-10}\,\mathrm{s}^{-1}$, and hence completely negligible. However, spin changing collisions can induce losses and limit the maximum densities. Solve Exc. 49.4.5.1.

The most basic static magnetic trap for neutral atoms is generated by a pair of current-carrying coils in anti-Helmholtz configuration (similar to the geometry used for a MOT), producing an axially symmetric qudrupolar magnetic field. Since this field configuration always has a central point, where the magnetic field disappears, non-adiabatic Majorana transitions can occur when the atom passes through the zero point. The transitions transfers population from a low-field seeking state to a high-field seeker, which consecutively is expelled from the trap. This problem can be overcome by using a different magnetic field geometries. One example is the so-called *magnetic bottle* also called the *Ioffe-Pritchard trap*, where the minimum field amplitude has a finite value different from zero. Other methods to eliminate the zero-field point are time-varying potentials, such as the time-orbiting potential (TOP) trap, or the application of an 'optical plug', which consist in an intense dipolar optical laser beam, tuned to the blue of an atomic transition, focused into the center of a quadrupole trap where the magnetic field is zero, and repelling the atoms from this area.

49.4.1 Quadrupolar traps and Majorana spin-flips

The most basic static magnetic trap for neutral atoms is generated by a pair of current-carrying coils in anti-Helmholtz configuration producing an axially symmetric quadrupolar magnetic field, as shown in Fig. 49.13.

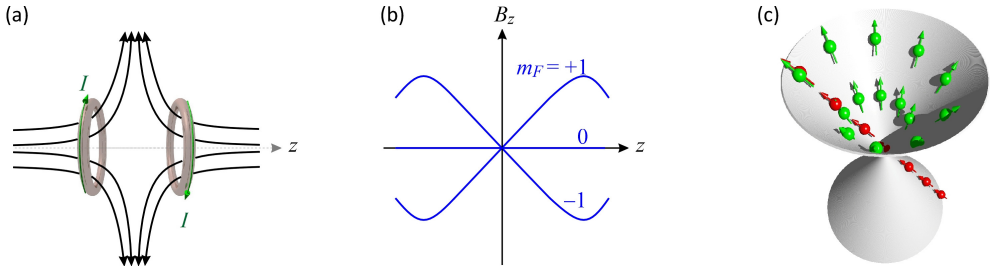

Figure 49.13: (a) Quadrupolar magnetic trap generated by a pair of current-carrying wires in anti-Helmholtz configuration. (b) Ground state energy levels of ^{23}Na, $^2S_{1/2}$, $F = 1$ as a function of axial distance from the trap center. (c) Illustration of Majorana spin-flips: The red atom passes through the hole, while the green one moves adiabatically avoiding the hole.

Close to the trap center an expansion of the magnetic field generated by anti-Helmholtz coils yields,

$$\vec{\mathcal{B}} = \begin{pmatrix} x \\ y \\ -2z \end{pmatrix} \partial_r \mathcal{B} \ , \tag{49.71}$$

where the field gradient $\partial_r B$ along radial direction $r^2 \equiv x^2 + y^2$ in the trap center depends on the applied current and the geometry of the coils. However, the 1:2 aspect ratio is generic for all quadrupolar potentials, as we will see in Exc. 49.4.5.2. We easily verify that,

$$\nabla \cdot \vec{\mathcal{B}} = 0 \qquad \text{but} \qquad \nabla |\vec{\mathcal{B}}| = \frac{\partial_r \mathcal{B}}{\sqrt{r^2 + 4z^2}} \begin{pmatrix} x \\ y \\ 4z \end{pmatrix} \ . \tag{49.72}$$

Thus, the quadrupolar magnetic potential is linear in the spatial coordinates,

$$\boxed{U(\mathbf{r}) = -|\vec{\mu}||\vec{\mathcal{B}}| = \mu_{\rm B} g_J m_J \ \partial_r \mathcal{B} \ \sqrt{r^2 + 4z^2}} \ , \tag{49.73}$$

where $2\partial_r \mathcal{B} = \partial_z \mathcal{B}$.

To calculate the *rms*-radius $\bar{r}$ of a cloud of temperature T confined to this potential, we set,

$$k_{\rm B} T \equiv U(\bar{r}, 0) = \mu_{\rm B} \bar{r} \partial_r \mathcal{B} \ , \tag{49.74}$$

and obtain the density distribution,

$$n(\mathbf{r}) = n_0 e^{-U(\mathbf{r})/k_{\rm B}T} = n_0 e^{-\sqrt{r^2+4z^2}/\bar{r}} \ . \tag{49.75}$$

Normalization requires,

$$\begin{aligned} N &= \int_{R^3} n(\mathbf{r}) \ d^3r = n_0 \int_{-\infty}^{\infty} \int_0^{\infty} e^{-\sqrt{r^2+4z^2}/\bar{r}} 2\pi r \ dr dz \\ &= n_0 2\pi \bar{r}^2 \int_{-\infty}^{\infty} \int_{2|z|/\bar{r}}^{\infty} \xi e^{-\xi} d\xi dz = n_0 2\pi \bar{r}^2 \ \int_{-\infty}^{\infty} e^{-\frac{2|z|}{\bar{r}}} \left(1 + \tfrac{2|z|}{\bar{r}}\right) \ dz \\ &= n_0 2\pi \bar{r}^3 \ \int_0^{\infty} e^{-\zeta}(1+\zeta) \ d\zeta = n_0 4\pi \bar{r}^3 \ . \end{aligned} \tag{49.76}$$

Therefore, the effective volume is, $V_{\text{eff}} = 4\pi\bar{r}^3$. In application example is discussed in Exc. 49.4.5.3.

49.4.1.1 Majorana spin-flips

The quadrupolar trap is the simplest one that can be technically realized. Unfortunately, this trap is not stable because of the phenomenon of *Majorana spin-flips*, which expel atoms from the trapped cloud. Since this field configuration always has a central point, where the magnetic field disappears, non-adiabatic Majorana transitions can occur when the atom passes through the zero point [see Fig. 49.13(c)]. The disappearance of the field leaves the atoms disoriented, that is, ready to reorient their spins. The transitions transfer population from a low-field seeking state to a high-field seeker, which consecutively is expelled from the trap. This problem is particularly severe for hydrogen, where it can induce a so-called *relaxation explosion* [441].

From (49.74) we get the *rms*-radius,

$$\bar{r} = \frac{k_{\text{B}}T}{\mu_{\text{B}}\partial_r\mathcal{B}} \ . \tag{49.77}$$

The average velocity of an atom is,

$$\bar{v} = \sqrt{\frac{k_{\text{B}}T}{m}} \ . \tag{49.78}$$

In order for the atomic motion in the magnetic potential to be adiabatic [so that Eq. (49.73) applies], the *local Larmor frequency*,

$$\omega_{\text{Larmor}}(\mathbf{r}) = \frac{\mu_{\text{B}}}{\hbar}\sqrt{r^2+4z^2}\partial_r\mathcal{B} \tag{49.79}$$

must be faster, than any change the atom might experience due to its motion with velocity $\mathbf{v}$. I.e. we need [728],

$$\omega_{\text{Larmor}}(\mathbf{r}) > \frac{\mathbf{v}\cdot\nabla|\vec{\mathcal{B}}|}{|\vec{\mathcal{B}}|} \ . \tag{49.80}$$

For a quadrupolar trap, this can not be satisfied within a certain volume located at the trap center, since the expression (49.80) divergence near the center. This ellipsoidal volume is delimited by $\mathbf{r}_{\text{sf}}$ given by the condition,

$$\omega_{\text{Larmor}}(\mathbf{r}_{\text{sf}}) \equiv \frac{\mathbf{v}\cdot\nabla|\vec{\mathcal{B}}|}{|\vec{\mathcal{B}}|} \ . \tag{49.81}$$

For our quadrupole trap,

$$\frac{\mathbf{v}\cdot\nabla|\vec{\mathcal{B}}|}{|\vec{\mathcal{B}}|} = \frac{\mathbf{v}\cdot\frac{\partial_r\mathcal{B}}{\sqrt{r_{\text{sf}}^2+4z_{\text{sf}}^2}}}{\partial_r\mathcal{B}\sqrt{r_{\text{sf}}^2+4z_{\text{sf}}^2}}\begin{pmatrix} x_{\text{sf}} \\ y_{\text{sf}} \\ 4z_{\text{sf}}\end{pmatrix} = \frac{x_{\text{sf}}v_x + y_{\text{sf}}v_y + 4z_{\text{sf}}v_z}{r_{\text{sf}}^2+4z_{\text{sf}}^2} \ . \tag{49.82}$$

Considering for simplicity only radial motion, $\mathbf{v} = v\hat{\mathbf{e}}_r$, then by equating (49.79) and (49.81),

$$\frac{\mu_{\text{B}}}{\hbar}r_{\text{sf}}\partial_r\mathcal{B} = \omega_{\text{Larmor}}(r_{\text{sf}}) = \frac{v}{r_{\text{sf}}} \ , \tag{49.83}$$

that is, the spin-flip volume is on the order of,

$$r_{\rm sf} = \sqrt{\frac{\hbar v}{\mu_{\rm B}\partial_r \mathcal{B}}} \ . \tag{49.84}$$

Let us now estimate the spin relaxation rate from the flow of atoms through the volume,

$$\frac{1}{\tau_{\rm sf}} = N\frac{r_{\rm sf}^3}{V_{\rm eff}}\frac{\bar{v}}{r_{\rm sf}} \ , \tag{49.85}$$

where $r_{\rm sf}^3/V_{\rm eff}$ is simply the fraction of the cloud's volume overlapping with the spin-flip volume. Then,

$$\begin{aligned}\frac{1}{\tau_{\rm sf}} &= \frac{N}{4\pi\bar{r}^3}r_{\rm sf}^2\bar{v} = \frac{N}{4\pi\left(\frac{k_{\rm B}T}{\mu_{\rm B}\partial_r\mathcal{B}}\right)^3}\frac{\hbar\bar{v}}{\mu_{\rm B}\partial_r\mathcal{B}}\bar{v} \\ &= \frac{N\hbar}{4\pi(k_{\rm B}T)^3}(\mu_{\rm B}\partial_r\mathcal{B})^2\frac{k_{\rm B}T}{m} = \frac{N\hbar(\mu_{\rm B}\partial_r\mathcal{B})^2}{4\pi m(k_{\rm B}T)^2} \ .\end{aligned} \tag{49.86}$$

That is, the problem gets worse when the cloud is cooled to low temperatures.

49.4.2 Magnetic Ioffe-type traps

The spin-flip problem can be overcome by using a different magnetic field geometries. One example is the so-called *magnetic bottle*, also called the *Ioffe-Pritchard trap* illustrated in Fig. 49.14(a), where the minimum field amplitude has a finite value different from zero. Other methods to eliminate the zero-field point are time-varying potentials, such as the time-orbiting potential (TOP) trap illustrated in Fig. 49.14(b) and discussed in Exc. 49.4.5.4 [297, 412], or the application of an 'optical plug', which consist in an intense dipolar optical laser beam, tuned to the blue of an atomic transition, focused into the center of a quadrupole trap where the magnetic field is zero, and repelling the atoms from this area (see Fig. 49.22). The advantage of Ioffe-Pritchard-type traps is that they are always harmonic sufficiently close to the trap center, which simplifies the theoretical treatment in many respects, as shown in Exc. 49.4.5.5.

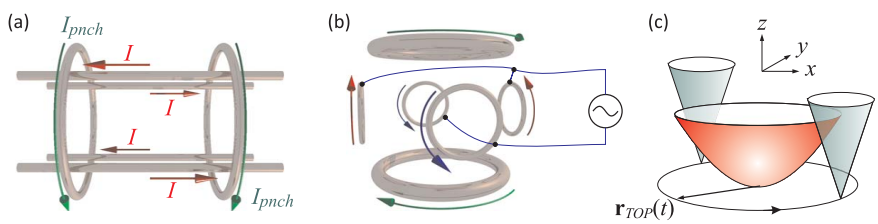

Figure 49.14: (a) Magnetic trap in Ioffe-Pritchard configuration. (b) Time-Orbiting Potential (TOP) trap. (c) Death-circle in a TOP trap.

Close to the trap center Ioffe-Pritchard-type traps are described by,

$$\boxed{U(\mathbf{r}) = \mu_{\rm B} g_F m_F \sqrt{\mathcal{B}_0^2 + (r\partial_r\mathcal{B})^2 + (z\partial_z\mathcal{B})^2}} \ , \tag{49.87}$$

and this magnetic trapping potential can be harmonically approximated by,

$$U(\mathbf{r}) \simeq \mu_{\rm B} g_F m_F \left(\mathcal{B}_0 + \frac{(r\partial_r \mathcal{B})^2}{2B_0} + \frac{(z\partial_z \mathcal{B})^2}{2B_0} \right) \tag{49.88}$$
$$\equiv const + \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 \equiv k_{\rm B}T \left(const + \frac{r^2}{2\bar{r}^2} + \frac{z^2}{2\bar{z}^2} \right) ,$$

where the *rms*-radius $\bar{r} = \omega_r^{-1}\sqrt{k_{\rm B}T/m}$ follow from the normalization of the density $n(\mathbf{r}) = n_0 e^{-U(\mathbf{r})/k_{\rm B}T}$ to the number of atoms,

$$N = \int n(\mathbf{r}) d^3 r = n_0 \int_0^\infty e^{-r^2/2\bar{r}^2} 2\pi dr \int_{-\infty}^\infty e^{-z^2/2\bar{z}^2} dz = n_0 (2\pi)^{3/2} \bar{r}^2 \bar{z} \equiv n_0 V_{\rm eff} . \tag{49.89}$$

The trap frequencies can be calculated as,

$$\omega_{r,z} = \sqrt{\frac{\mu_{\rm B}(\partial_r \mathcal{B}_{r,z})^2}{m\mathcal{B}_0}} . \tag{49.90}$$

The Earth's gravitational field deforms the trapping potential and, in the case of a harmonic potential, causes a gravitational sag without changing the secular frequencies of the potential. Assuming the potential to be given by,

$$U = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 - mgz = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 (z - g/\omega_z^2)^2 - \frac{m}{2} g^2/\omega_z^2 , \tag{49.91}$$

the atoms sag to a height of g/ω_z^2. In time-dependent traps, gravity causes a more complex behavior [407]. Important works have been done by [172, 733, 299, 393, 3, 223, 558, 562, 251]. We study the impact of gravitation in Exc. 49.4.5.6.

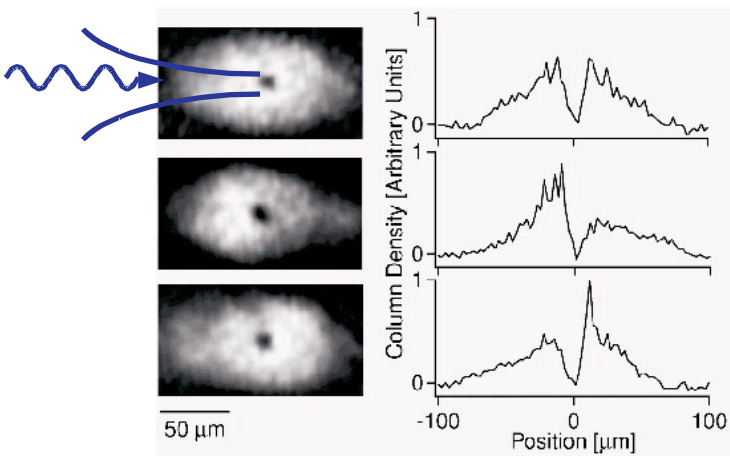

Figure 49.15: Creation of a repulsive hole by light tuned to the blue of an atomic transition.

49.4.2.1 Characterization of Ioffe-type traps

The 'time-of-flight' density distribution is,

$$r_{\rm ToF} = \sqrt{\bar{r}^2 + \bar{v}^2 t_{\rm ToF}^2} = \sqrt{\frac{k_{\rm B}T}{m}}\sqrt{\frac{1}{\omega_r^2} + t_{\rm ToF}^2} \simeq t_{\rm ToF}\sqrt{\frac{k_{\rm B}T}{m}} \ . \tag{49.92}$$

The *phase space density* is,

$$\rho = n_0 \lambda_{\rm dB}^3 = \frac{N}{(2\pi)^{3/2}\bar{r}^2\bar{z}} \left(\frac{2\pi\hbar^2}{mk_{\rm B}T}\right)^{3/2} = N\omega_r^2\omega_z \left(\frac{\hbar}{k_{\rm B}T}\right)^3 = \zeta(3)\left(\frac{T_{\rm c}}{T}\right)^3 \ . \tag{49.93}$$

where $\zeta(3) = 1.202$ and

$$k_{\rm B}T_{\rm c} = \hbar\left(\frac{N\omega_r^2\omega_z}{\zeta(3)}\right)^{1/3} \tag{49.94}$$

is called 'critical temperature'. The *maximum collision rate* is,

$$\gamma_{\rm coll} = n_0\sigma\bar{v} = n_0 4\pi a_s^2\sqrt{\frac{k_{\rm B}T}{m}} \ , \tag{49.95}$$

The average collision rate can be obtained from,

$$\bar{\gamma}_{\rm coll}N = \frac{1}{N}\int \gamma_{\rm coll}(\mathbf{r})n(\mathbf{r})d^3r = \frac{\int \sigma\bar{v}n^2(\mathbf{r})d^3\mathbf{r}}{\int n(\mathbf{r})d^3r} \ . \tag{49.96}$$

49.4.3 Radiative coupling and evaporative cooling

As we saw in the last section, optical cooling becomes ineffective when the density of the gas is high. Hence, we need another dissipation mechanism to cool trapped atoms. A method called *evaporation* has been proposed by Hess [439] for spin-polarized hydrogen (H↑) and was observed by Masuhara et al. [622]. Later, evaporation was used on alkali metals [3, 728, 226]. A detailed review of the subject was published by Ketterle and van Druten [509].

Another collision-based cooling mechanism is *sympathetic cooling*. The technique was originally used in ion traps. Later it was applied to neutral atoms confined in magnetic traps. The idea is to get the cloud under study into thermal contact with a cold buffer gas. In some cases, the buffer gas may be optically or evaporatively cooled. Sympathetic cooling has been used in magnetic traps to create double condensates [681] and to cool fermions until the regime of quantum degeneracy [241].

49.4.3.1 Evaporative cooling

Evaporation always occurs when energetic particles abandon a system with finite bonding energy, removing more than their share of average energy per particle. Here, we consider the case of a finite-sized trapping potential, that is, the potential has an edge or a beak through which hot atoms, with sufficient kinetic energy to reach that region, may leave the trap. In the ideal case, this will lead to a complete truncation of the hot tail of the equilibrium Maxwell-Boltzmann velocity distribution. If the remaining system finds back to thermal equilibrium, it will do at a lower temperature. The redistribution of kinetic energy between atoms leading to *thermalization* occurs through elastic collisions.

Figure 49.16: The basic idea of evaporation consists in removing hot particles from the sample.

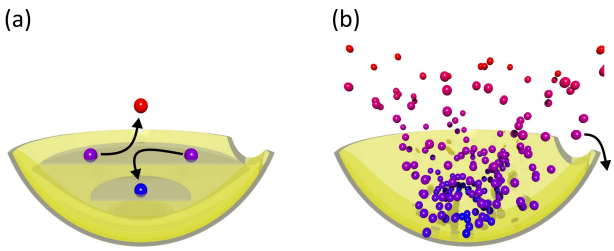

Figure 49.17: Principle of (a) rethermalization due to elastic collisions and (b) evaporation.

49.4.3.2 Truncating the Boltzmann distribution

Let us first explain how the truncation leads to colder temperatures [226].

The objective is to calculate the Boltzmann distribution in a particular trap for a given atom number N and temperature T. The first step is to obtain the density-of-states. For an isotropic harmonic trap $\varepsilon = \frac{p^2}{2m} + V(r)$ with $V(r) = \frac{m}{2}\omega^2 r^2$, it is,

$$\eta(\varepsilon)d\varepsilon = \frac{1}{(2\pi)^3}\int_V d^3r d^3k = \frac{2\pi(2m)^{3/2}}{h^3}\int_V \sqrt{\varepsilon - V(r)}d^3r d\varepsilon = \frac{\varepsilon^2 d\varepsilon}{2(\hbar\omega)^3} \ . \tag{49.97}$$

The atom density is,

$$n(\varepsilon) = e^{(\mu-\varepsilon)/k_{\rm B}T} = w_{T,\mu}(\varepsilon) = Ze^{-\varepsilon/k_{\rm B}T} \ . \tag{49.98}$$

From these expressions we obtain the atom number,

$$N = \int_0^\infty n(\varepsilon)\eta(\varepsilon)d\varepsilon = \int_0^\infty e^{(\mu-\varepsilon)/k_\mathrm{B}T}\frac{\varepsilon^2}{2(\hbar\omega)^3}d\varepsilon = Z\frac{(k_\mathrm{B}T)^3}{(\hbar\omega)^3} \ , \tag{49.99}$$

which we may now use to calibrate the fugacity via

$$Z = N\frac{(\hbar\omega)^3}{(k_\mathrm{B}T)^3} \ , \tag{49.100}$$

which finally allows us to calculate the total energy,

$$E = \int_0^\infty \varepsilon n(\varepsilon)\eta(\varepsilon)d\varepsilon = \int_0^\infty \varepsilon e^{(\mu-\varepsilon)/k_\mathrm{B}T}\frac{\varepsilon^2}{2(\hbar\omega)^3}d\varepsilon = 3Z\frac{(k_\mathrm{B}T)^4}{(\hbar\omega)^3} = 3Nk_\mathrm{B}T \ . \tag{49.101}$$

The evaporation consists in truncating the distribution function $n(\varepsilon)$ at some energy $\hbar\omega_\mathrm{rf}$. We get with $\beta \equiv (k_\mathrm{B}T)^{-1}$,

$$\tilde{N} = \int_0^{\hbar\omega_\mathrm{rf}} n(\varepsilon)\eta(\varepsilon)d\varepsilon = N\left(1 - \frac{2 + 2\beta\hbar\omega_\mathrm{rf} + (\beta\hbar\omega_\mathrm{rf})^2}{2e^{\beta\hbar\omega_\mathrm{rf}}}\right) \tag{49.102}$$

and

$$\tilde{E} = \int_0^{\hbar\omega_\mathrm{rf}} \varepsilon n(\varepsilon)\eta(\varepsilon)d\varepsilon = E\left(1 - \frac{6 + 6\beta\hbar\omega_\mathrm{rf} + 3(\beta\hbar\omega_\mathrm{rf})^2 + (\beta\hbar\omega_\mathrm{rf})^3}{6e^{\beta\hbar\omega_\mathrm{rf}}}\right) \ . \tag{49.103}$$

As the truncation removes the hottest atoms from the cloud, we loose atom number and energy. Assuming the existence of some rethermalization mechanism, we may now use the new values for N and T to calculate the new equilibrium Boltzmann distribution starting all over from Eq. (49.98),

$$N \longleftarrow \tilde{N} \qquad \text{and} \qquad T \longleftarrow \frac{\tilde{E}}{3Nk_\mathrm{B}} \tag{49.104}$$

Repeating this over and over the temperature will gradually reduce. The cooling process can be speed up by readjusting the truncation frequency to the actual temperature. This is called forced evaporation (see Fig. 49.18).

Example 366 (*Truncating in a quadrupole potential*): The formulas (49.102) and (49.102) were derived for a harmonic trap. An analogous calculation for a quadrupole potential yields, with the abbreviation $\varkappa \equiv \beta\hbar\omega_\mathrm{rf}$,

$$N(\varkappa) \approx -2\sqrt{Z}\frac{105 + 70\varkappa + 28\varkappa^2 + 8\varkappa^3}{\sqrt{\pi}105e^\varkappa} + \mathrm{erf}(\sqrt{\varkappa}) \tag{49.105}$$

$$E(\varkappa) \approx -\frac{2}{9}\sqrt{Z}\frac{945 + 630\varkappa + 252\varkappa^2 + 72\varkappa^3 + 16\varkappa^4}{\sqrt{\pi}105e^\varkappa} + \frac{9}{2}\mathrm{erf}(\sqrt{\varkappa}) \ .$$

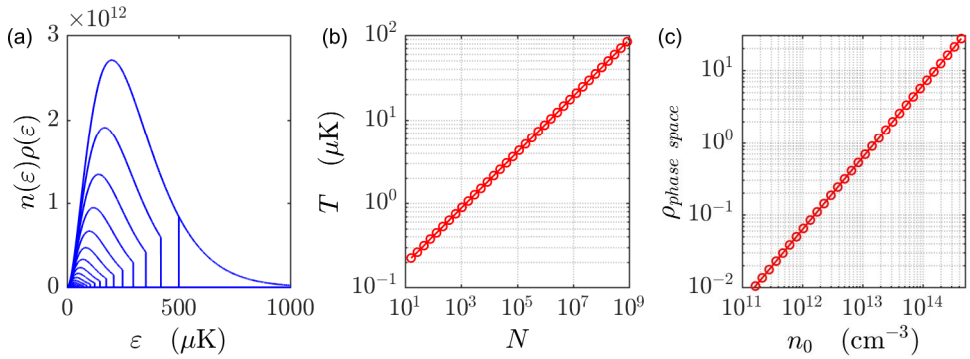

Figure 49.18: (code) (a) Forced evaporation by truncating the Boltzmann distribution over and over again. (b) Evolution of the temperature and (c) of the phase space density with number of remaining atoms.

49.4.3.3 Rethermalization

As already mentioned, rethermalization occurs due to elastic collisions. It needs more or less three collisions per atom to rethermalize a cloud [662, 987], so that the collision rate determines the speed of the evaporation process. A large collision rate is desirable to keep the evaporation process faster than trap loss processes. Evaporation ramps between several seconds and a minute are typical.

The maximum rate of elastic collisions between trapped atoms (in the trap center) is,

$$\gamma_{\rm coll} = n_0 \sigma_{\rm el} \bar{v} \sqrt{2} \propto \rho^3 N^{2/3} \ , \tag{49.106}$$

where n_0 is the peak density,

$$\sigma_{\rm el} = 8\pi a_s^2 \ , \tag{49.107}$$

is the cross-section for elastic collisions and, $\bar{v}$ being the average thermal velocity of the cloud, $\sqrt{2}\bar{v}$ is the average relative velocity between two of its atoms [508]. This formula gives the average collision rate at the *center of the cloud*, where the density is highest. To calculate the total collision rate, we need to integrate over the entire volume of the cloud,

$$\bar{\gamma}_{\rm coll} = \tfrac{1}{N} \int \gamma_{\rm coll}(\mathbf{r}) n(\mathbf{r}) d^3r = \frac{\int \sigma_{\rm el} \bar{v} n^2(\mathbf{r}) d^3r}{\int n(\mathbf{r}) d^3r} \ . \tag{49.108}$$

For harmonic potential we find an average rate reduced by $2\sqrt{2}$, for linear potentials by 8. We verify this in Exc. 49.4.5.7. Finally, the rate for collision events is two times smaller, as it involves two atoms at a time.

Obviously, the evaporation process slows down when the cloud cools more, unless the edge of the potential is lowered, such that the hotter atoms of the colder cloud can be evaporated. By continually lowering the edge of the potential, while the atomic cloud keeps on rethermalizing (this procedure is called *forced evaporation*) very low temperatures in the nano-Kelvin regime can be achieved, and the phase space density can be increased by many orders of magnitude (between a MOT and a BEC there are 6 orders of magnitude) up to the threshold of Bose-Einstein condensation. Of course,

this is only possible by sacrificing many hot atoms. Even with a well optimized evaporation ramp (i.e., a controlled lowering of the potential edge), usually only some 0.1% of the atoms reach the condensation phase after about 500 collisions per atom.

Two aspects should be mentioned regarding the optimization of the evaporation ramp. The first aspect is, that elastic collisions with atoms from the residual background vapor of the vacuum chamber limit the lifetime of the trap. Therefore, the evaporation must be sufficiently fast, which requires either a high rate of elastic collisions or a good vacuum. A compromise must be found between a slow but efficient evaporative cooling and a minimization of the losses, which come into play when the evaporation takes too long. The second aspect is, that the dimensionality of the evaporation surface determines the effectiveness of the cooling. In the first demonstration of evaporation, H↑ atoms of a hot cloud were ejected over a saddle point. The saddle was located a small region away from the trap center, and only atoms with sufficient kinetic energy *along a certain direction*, $E_z > U_{\rm edge}$, could leave the trap. In such cases, evaporation is called one-dimensional. Even though ergodic redistribution due to anharmonicities of the potential will drive, sooner or later, all the atoms to this region, this effect becomes less pronounced when the cloud cools down, because the atoms accumulate at the bottom of the approximately harmonic (and therefore separable) potential. This fact has inhibited efficient evaporation of H↑ below 120 µK [326].

A second evaporative technique has been demonstrated in traps called *time-orbiting potential* (TOP) [728]. It is a feature of TOP traps to display a spatial region called a 'death-circle', where passing atoms are ejected from the trap. This fatal circle can act as a 2-dimensional evaporation surface, provided the radius of the circle is large enough [412]. However, under the influence of gravity the dimensionality is further reduced to 1D [508].

The most successful evaporation technique implemented so far is based on a radiative coupling of confined and free states. We discuss this technique in the following sections. Publications on *evaporative cooling* are [593, 646, 728, 754, 82, 639, 662, 298, 302, 426, 688, 439, 622, 226, 509, 986, 413, 617, 273, 441]. See ([197], Sec. 3.1.4) for an overview.

49.4.3.4 Adiabatic (de-)compression

The condition for *adiabatic decompression* of a trapping potential is,

$$\frac{|\dot{\omega}_{\rm trp}|}{\omega_{\rm trp}} \ll \omega_{\rm trp} \ . \tag{49.109}$$

The population of the quantized levels should not change under adiabatic decompression, $e^{\hbar\omega_i/k_{\rm B}T_i} = e^{\hbar\omega_f/k_{\rm B}T_f}$, and the phase space density remains unchanged, $n_i\lambda_{{\rm dB},i} = n_f\lambda_{{\rm dB},f}$. If this is true, then the temperature and density change as,

$$\frac{\omega_f}{\omega_i} = \frac{T_f}{T_i} = \left(\frac{n_f}{n_i}\right)^{3/2} \ . \tag{49.110}$$

Solve Exc. 49.4.5.8.

49.4.3.5 Radiative coupling of internal state

The most successful evaporation technique implemented so far is based on a radiative coupling of confined and free states. We discuss this technique in the following sections. See ([197], Sec. 3.1.4) for an overview.

The radiative coupling technique originates from an idea proposed by Pritchard et al. [413], who have already had some experience with radiofrequency spectroscopy in magnetically trapped neutral atoms [617, 426]. The spatial dependence of the Zeeman splitting is an intrinsic feature of magnetic traps. Irradiation of a radio wave at a certain frequency couples trapped and untrapped Zeeman substates at a well-defined distance from the trap center. This gives rise to a 3D evaporation surface, where the passing atoms can undergo Landau-Zener transitions and be expelled from the trap. The technical advantages of this technique are substantial: The magnetic trapping potential does not have to be manipulated, for example, by the creation of a nozzle, and the potential edges can be easily controlled by the radiofrequency. If evaporation is forced via a continuous reduction of the radiofrequency and if the evaporation ramp is optimized, the density will increase as well as the collision rate. Rethermalization will accelerate and initiate a self-accelerated evaporation process (*run-away evaporation*). Rf-evaporation was first demonstrated by Ketterle and colleagues [226]. Solve Exc. 49.4.5.9.

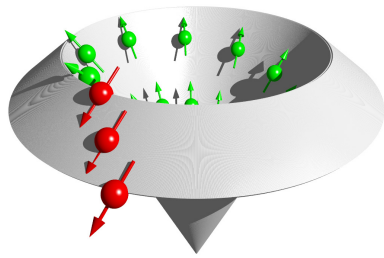

Figure 49.19: Illustration of evaporative truncation.

49.4.3.6 Adiabatic and diabatic limits of rf-induced evaporation

Rf-induced evaporation can be described within the formalism of the dressed atom [185], where the different states m_F of an atom with spin F are coupled to an rf-field [5], which we assume to be linearly polarized:

$$\mathcal{B}(t) = \mathcal{B}\hat{\mathbf{e}}_{\rm rf} \cos \omega t \ . \tag{49.111}$$

The element of the coupling matrix between the levels, $|F, m_F\rangle$ and $|F, m_F \pm 1\rangle$ is,

$$\Omega = \frac{\mu_{\rm B} g}{4\hbar} \left| \vec{\mathcal{B}}_{\rm rf} \times \hat{\mathbf{e}}_B \right| \sqrt{F(F+1) - m_F(m_F+1)} \ , \tag{49.112}$$

where g is the atomic g-factor and $\hat{\mathbf{e}}_B$ the orientation of the local static magnetic field.

The adiabatic potentials $U(r)$ are obtained through the eigenvalues of the atomic states dressed by the local magnetic field $\mathcal{B}(r)$. In the dressed atom picture, we consider the total energy of the atom plus the field of N radiofrequency photons. Without coupling, this simply means that $N\hbar\omega$ is added to the atomic Zeeman energies, resulting in a Zeeman pattern being vertically shifted by $N\hbar\omega$ for $N = 0, \pm 1, ...$ At positions where the rf-field is in resonance, curves with $\Delta N = 1$ intersect. Here, the coupling develops an *avoided crossing*, which determines the pattern of adiabatic energy levels [see Fig. 49.20(b)].

[5] Alternatively, a *microwave* frequency may be used to couple *different hyperfine levels*.

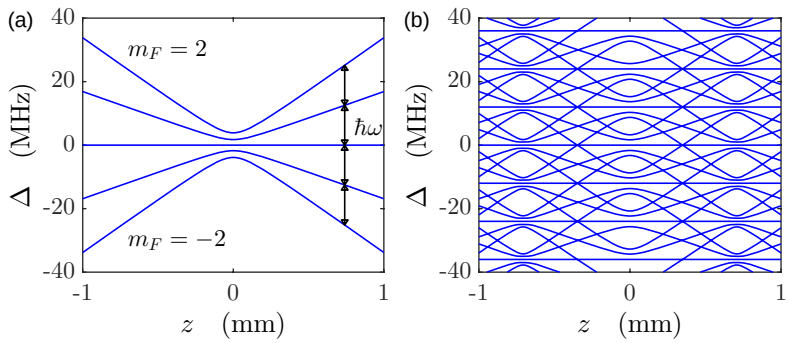

Figure 49.20: (code) (Left) Potentials due to the Zeeman structure of an atom in the ground state with $F = 1$. (Right) Adiabatic potentials resulting from the coupling of Zeeman levels via radiofrequency radiation being resonant with the difference of Zeeman levels at the position 0.7.

A slowly moving atom remains on the curve of an *adiabatic potential*. As an example, let us assume an atom in the hyperfine state $|F, F\rangle$ moving away from the center of the trap. When it comes close to resonance, the rf-field blends this state with other m_F-states, from the $|F, F-1\rangle$ down to the $|F, -F\rangle$ state, which changes the slope of the potential curve. Beyond the resonance point, the atomic state is adiabatically transformed into an untrapped high-field seeking state, and the atom is repelled from the trap. Thus, while passing the avoided crossing, the atom has emitted $2F$ rf-photons in a stimulated manner and inverted the orientation of both the electron and the nuclear spin.

In this way the radiofrequency generates an adiabatic potential surface with a depth of approximately $|m_F|\hbar(\omega - \omega_0)$, where ω_0 is the resonant rf-frequency at the center of the trap. The evaporation process corresponds, then, to the removal of the most energetic atoms out of the trap.

For this adiabatic picture to be valid, an adiabaticity condition must be fulfilled. This condition requires that the energy difference at the avoided crossover be larger than the energy uncertainty related to the limited time that an atom with velocity v spends in the resonance region. For a two-level system coupled by a matrix element V_{12} and an atom moving with velocity v along the z-axis, the transition probability P between the adiabatic curves is given by the *Landau-Zener formula* [792],

$$P = 1 - e^{-\xi} \quad \text{with} \quad \xi = \frac{2\pi|V_{12}|^2}{\hbar g \mu_{\mathrm{B}} \partial_z \mathcal{B} v} \,. \tag{49.113}$$

The Landau-Zener theory is strictly valid only for a two-level system, which we use here only for a qualitative discussion of two following limiting cases.

For a weak rf-field, $\xi \ll 1$, P is much smaller than 1, i.e., the atoms remain predominantly on the diabatic surface shown in Fig. 49.20(a). The probability for a *spin flip* transition is, $P \approx t$, which describes the diabatic limit of rf-induced evaporative cooling: The atomic energy levels are almost unperturbed, the atoms often spill across the resonance surface, and only after $1/P$ oscillations, they spin-flip from the hyperfine state $|F, F\rangle$ to the $|F, F-1\rangle$.

The adiabatic limit is clearly the ideal situation for evaporative cooling. However, the evaporation process in a trap (with oscillation time T_{osc}) saturates at a lower rf-power. The condition for saturation is $P \approx T_{osc}/\tau_{\rm el}$, where $\tau_{\rm el}$ is the average time between two collisions. This means that an energetic atom is evaporated before it collides again.

Only the component of the magnetic field of the rf-radiation which is *perpendicular* to the magnetic trapping field induces spin-flips. In certain geometries of the confinement potential, for example the quadrupole trap, the magnetic field covers the entire solid angle. Consequently, there are two points where the trapping field and the rf-field are parallel and the elements of the transition matrix consequently zero. Within an area around these points, the coupling is diabatic. In practice however, the rf-transition can be sufficiently saturated that this area is small and does not strongly affect the evaporation efficiency.

Note also that gravitation deforms the equipotential surfaces of the confinement potential, which can reduce the evaporation efficiency [508]. Solve Exc. 49.4.5.10.

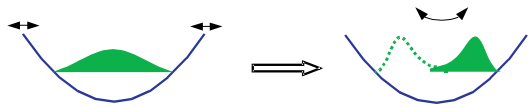

Figure 49.21: Effective potential due to a rapid modulation of the trap's location.

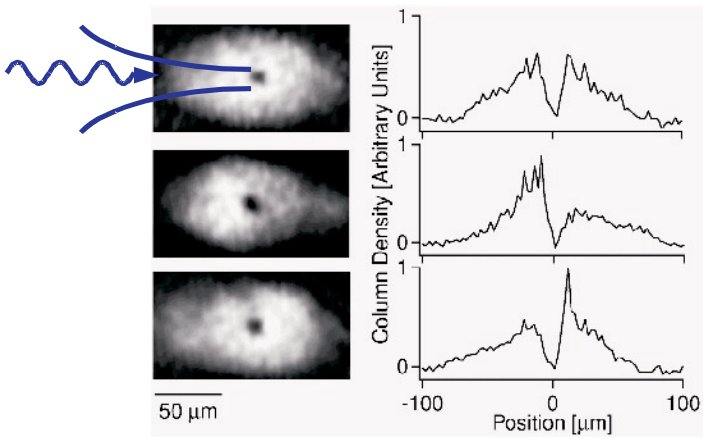

Figure 49.22: Creation of a repulsive hole by light tuned to the blue of an atomic transition.

49.4.4 Sympathetic cooling

The efficiency of evaporative cooling depends on the rate of interatomic collisions. However, there are atomic species with unfavorable, that is, small or even negative scattering lengths. Also, while at low temperatures only s-wave collisions occur (higher partial waves being frozen behind the centrifugal barrier), such collisions are prohibited for fermionic gases. Fermions or species with unfavorable scattering lengths

can not be cooled by evaporation. There is, however, another technique called *sympathetic cooling* by thermal contact with another species. The additional species is, in general, actively cooled (e.g., by evaporation), while the species of interest is passively cooled via elastic collisions with atoms of the additional species. Of course, for this scheme to work the *interspecies scattering length* and the mass ratio must be adequate to ensure adequate thermal coupling.

Following [678] the transfer of kinetic energy between two colliding atoms is reduced by a factor depending on the their mass difference,

$$\xi = \frac{4m_1 m_2}{(m_1+m_2)^2} \ . \tag{49.114}$$

Around $3/\xi$ collisions per atom on average are required for complete thermalization of a gas. For example, for the Rb-Li mixture, we have $3/\xi = 12.4$. The collision rate is,

$$\Gamma_{\text{coll}} = \sigma_{12}\bar{v}\int n_1(\mathbf{r})n_2(\mathbf{r})d^3r \ , \tag{49.115}$$

where the average thermal velocity is,

$$\bar{v} = \sqrt{\frac{8k_{\text{B}}}{\pi}\left(\frac{T_1}{m_1}+\frac{T_2}{m_2}\right)} \ . \tag{49.116}$$

The instantaneous temperature is calculated by,

$$\gamma_{\text{therm}} = -\frac{1}{\Delta T}\frac{d\Delta T}{dt} \ , \tag{49.117}$$

or via simulations: $\Delta T(t+dt) = \Delta T(t) - \Delta T(t)\gamma_{\text{therm}}dt$. Following [240] the rethermalization rate is connected to the collision rate via,

$$\boxed{\gamma_{\text{therm}} = \frac{\xi}{3}\left(\frac{\Delta E_{1\to 2}}{N_1 k_{\text{B}}\Delta T}+\frac{\Delta E_{2\to 1}}{N_2 k_{\text{B}}\Delta T}\right) = \frac{\xi}{3}\left(\frac{\Gamma_{\text{coll}}}{N_1}+\frac{\Gamma_{\text{coll}}}{N_2}\right)} \ . \tag{49.118}$$

Analytic solutions can be derived for harmonic traps. This will be studied in Excs. 49.4.5.11 and Exc. 49.4.5.12.

49.4.5 Exercises

49.4.5.1 Ex: Lack of trapping potentials for strong field seekers

Show that it is not possible to create magnetic trapping potentials for atoms in low-field seeking Zeeman states.

49.4.5.2 Ex: Quadrupolar potential

Show that for a quadrupolar trap always holds $2\partial_r\mathcal{B}_{\text{qua}} = \partial_z\mathcal{B}_{\text{qua}}$.

49.4.5.3 Ex: Magnetic quadrupole trap

a. Consider ^{87}Rb atoms confined in a magnetic trap with $\vec{\mathcal{B}}(x,y,z) = x \quad y \quad -2z \times 200\,\mathrm{G/cm}$. The atoms are in the state $|F=1, m_F=-1\rangle$ with the g-factor $g_F = 1/2$. Check whether it is reasonable to assume constant vibration frequencies for such traps.
b. Assume that the trapped atomic cloud consists of $N = 10^8$ atoms at temperature $T = 100\,\mathrm{K}$. Calculate the atomic density n_0 at the center of the cloud.
c. The cross section for elastic collisions is $\sigma = 10^{-12}\,\mathrm{cm}^2$. How many times do atoms meet in the middle of the trap?

49.4.5.4 Ex: TOP trap

The TOP trap (time-orbiting potential) was the first design to allow for Bose-Einstein condensation in 1995. It consists of the superposition of a quadrupolar magnetic field, with the radial and axial gradients $2\partial_r\mathcal{B}_{\mathrm{qua}} = \partial_z\mathcal{B}_{\mathrm{qua}}$), and a homogeneous magnetic field $\mathcal{B}_{\mathrm{top}}$ rotating in the symmetry plane of the quadrupole field. Atoms which oscillate with an amplitude beyond a given radius r_{d}, called the 'circle of death', undergo Majorana transitions and are expelled from the trap.
a. Calculate the radius of the death circle.
b. Plot the time-averaged 'effective' trapping potential.

49.4.5.5 Ex: Harmonic trap

Calculate the vibration frequencies of ^{87}Rb atoms trapped in a harmonic trap, when the atoms are in the $|F=1, m_F=-1\rangle$ hyperfine level of the ground state.

49.4.5.6 Ex: Gravitational sag in a trap

Consider (a) a quadrupolar trap and (b) an isotropic harmonic trap. What is the gradient, respectively the curvature of the trapping potential required to suspend a cloud of rubidium subject to gravitation? What is the sag of the cloud in the potential due to gravitation?

49.4.5.7 Ex: Mean collision rate

Assuming that the peak collision rate γ_{coll} is known, calculate the average collision rate (a) in a quadrupolar and (b) in a harmonic trap.

49.4.5.8 Ex: Adiabatic compression

How does temperature change upon adiabatic compression of (a) a quadrupole trap and (b) a harmonic trap. How do density, phase space density, and elastic collision rate vary. **Help:** Define the compression for quadrupole trap as $\eta \equiv \partial_r\mathcal{B}_{r,final}/\partial_r\mathcal{B}_{r,initial}$ and for harmonic trap as $\eta \equiv \omega_{r,final}/\omega_{r,initial}$.

49.4.5.9 Ex: RF-antenna for radiative coupling

Calculate the Rabi frequency that can be generated by an rf-antenna consisting of a single square loop with side length $L = 2\,\mathrm{cm}$ on a cloud of trapped ^{87}Rb atoms

located in the center of the loop on transitions between magnetic sublevels of the $F = 1$ ground state hyperfine structure. Assume the antenna to carry an ac-current with $I = 1\,\mathrm{A}$ amplitude.

49.4.5.10 Ex: Landau-Zener transitions

Consider a rubidium-88 cloud in its ground state $^2S_{1/2}, F = 1, m_F = -1$ confined in an isotropic quadrupolar potential with the gradient $200\,\mathrm{G/cm}$. To initiate an efficient radiofrequency evaporation, you want atoms crossing the region where the radiofrequency couples the Zeeman states to make a transition to the untrapped Zeeman state $m_F = 0$ with 95% probability. What is the amplitude of the required magnetic field.

49.4.5.11 Ex: Damping in mixtures of species

From Eq. (49.118) derive the interspecies thermalization rate for harmonic potentials.

49.4.5.12 Ex: Damping in mixtures of species

Describe the damping in mixtures of species, and show how to use a measurement of the damping time for a determination of the interspecies the scattering length.

49.5 Other traps

49.5.1 Ion traps

The electric charge of ions allow for their efficient manipulation and control by electric and magnetic fields exploiting the Coulomb-Lorentz force. In fact, the control is so good, that it is possible to isolate and store individual ions or even arrays of quantum entangled ions and to perform coherent operations on them, which qualifies them as quantum registers. Two different types of traps have been investigated. In *Penning trap*s [725], electrically charged particles are subjected to a radially attractive quadrupolar electrostatic field superimposed to an axial magnetostatic field forcing the particles into closed circular orbitals [6]. In the so-called *radiofrequency trap* or *Paul trap* –*Wolfgang Paul* received the Nobel Prize in 1989 together with Hans Dehmelt and Norman Ramsey– charged particles subjected to an alternating electric field with quadrupolar symmetry. Hyperboloidal electrode configurations produce saddle-shaped potentials, as shown in Fig. 49.24, which are, at any instant of time, parabolically repulsive in the one direction (axial or radial) and parabolically attractive in the other (radial or axial). The alternating electric field causes a periodic reorientation of the Coulomb force, which leads to a time-averaged parabolic quasi-potential $\Phi(\mathbf{r}, t)$. In this potential the particles perform harmonic oscillations at characteristic frequencies, which are independent of the oscillation amplitude [717]:

$$\Phi(r, z) = \Phi_0(t)(r^2 - 2z^2) \quad , \quad r^2 = x^2 + y^2 \ , \tag{49.119}$$

[6] Note that purely electrostatic fields do not lend themselves to trapping, since the necessary condition for the existence of minima in a potential, $\partial_i \partial_j \phi < 0$, does not obey the Laplace equation.

where the polarity is alternated at a radiofrequency Ω_a,

$$\Phi_0(t) = \Phi_{\rm dc} + \Phi_{\rm ac}\cos(\Omega_a t) \ . \tag{49.120}$$

$\Phi_{\rm dc}$ denotes the amplitude of the *dc* part of the voltage, $\Phi_{\rm ac}$ the amplitude of the *ac* part. The potential $\Phi(r,z,t)$ exerts, in the temporal average, a central force on the ion, if the radiofrequency field satisfies specific conditions.

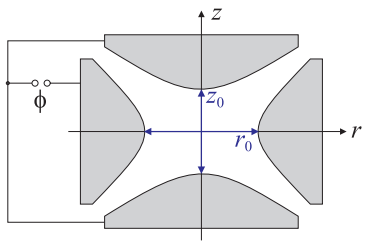

Figure 49.23: Geometry of the Paul trap.

49.5.1.1 Evaluation of the stability diagram

Paul traps do not have to have perfect quadrupolar geometry. To determine the secular frequencies of the pseudo-potential for an arbitrary geometry, we expand the potential around the position $\mathbf{r}_0$ of the potential minimum, which depends on the geometry of the electrodes and the applied voltages,

$$\begin{aligned}\Phi(\mathbf{r}) &= \Phi_a + (\mathbf{r}-\mathbf{r}_0)\nabla\Phi(\mathbf{r}_0) + \tfrac{1}{2}[(\mathbf{r}-\mathbf{r}_0)\nabla]^2\Phi(\mathbf{r}_0) + ... \\ &\equiv \Phi_a[1 + b_r(r-r_0)^2 + b_z(z-z_0)^2] \ .\end{aligned} \tag{49.121}$$

In the last step, we assume that the potential has an almost cylindrical shape. For a given geometry, the curvatures $b_{z,r}$ can be extracted from numerical simulations. From the continuity equation, we find $b_z = -2b_r$. The polarity of the electrodes is modulated with frequency Ω,

$$\Phi(\mathbf{r},t) = \Phi(\mathbf{r})(\zeta - \cos\Omega t) \ . \tag{49.122}$$

The equations of motion are derived from $m\ddot{\mathbf{r}} = -e\nabla\phi(\mathbf{r},t)$,

$$m\ddot{r}_j + 2e\Phi_a b_j(\zeta - \cos\Omega t)r_j = 0 \ . \tag{49.123}$$

Introducing the parameters a and q,

$$a_z = \frac{8e\phi_a b_z\zeta}{m\Omega^2} = -2a_r \qquad \text{and} \qquad q_z = \frac{4e\Phi_a b_z}{m\Omega^2} = -2q_r \ , \tag{49.124}$$

we arrive at the so-called *Mathieu equation* [633, 313],

$$\ddot{r}_j + \tfrac{1}{4}\Omega^2(a_j - 2q_j\zeta\cos\Omega t)r_j = 0 \ . \tag{49.125}$$

These equations predict stable orbits, provided that the parameters a and q are within the so-called stability diagram shown in Fig. 49.25.

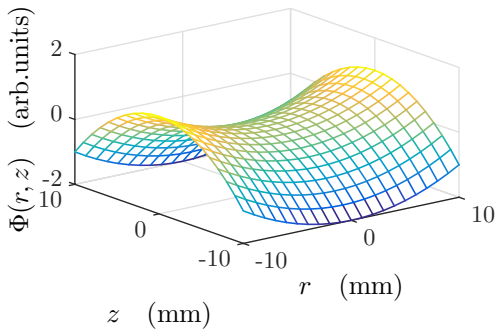

Figure 49.24: (code) Two-dimensional illustration of time-dependent potential: at each instant of time the potential has the form of a saddle. The potential rotates around the vertical axis at an appropriate pace.

According to these equations, the ion goes through oscillatory motions that are defined by the trap parameters a_i and q_i. For the motion of the ion to be finite, its oscillation amplitude may not exceed the boundaries defined by the electrodes. This condition imposes an allowed regime for the trap parameters called *stability diagram* [633].

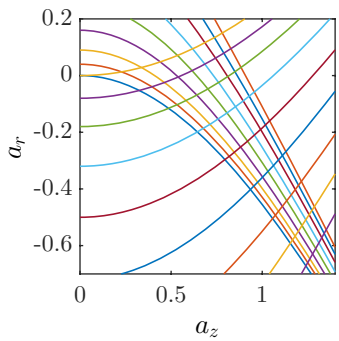

Figure 49.25: (code) Stability diagram.

In the limit $|a_i|, q_i \ll 1$ the ion travels only a short distance $s \ll r_0$ during one modulation period Ω_a. Then the ion undergoes a slow periodic motion called *macromotion* within the trapping potential with the secular frequency ζ_i. This motion is modulated by a rapid oscillation called *micromotion*, which is excited by the modulation field Ω_a. Without *dc* voltage applied between the ring and the endcaps, $a_i = 0$, the motion of the ion is described by the following simple equation:

$$r_i(t) = r_i^0 \left(1 - \tfrac{1}{2} q_i \cos \Omega_a t\right) \cos \zeta_i t \quad , \quad \zeta_i = \tfrac{1}{\sqrt{8}} q_i \Omega_a \quad , \quad i = r, z \ . \tag{49.126}$$

The orbit of the ion is confined to the inner region of the trap, if its kinetic energy is less than $m\zeta_r^2 r_0^2 + M\zeta_z^2 z_0^2$. Since the trap is, at any instant of time, focusing in some directions and defocusing others, it is not a conservative potential. The oscillatory

motion (disregarding micromotion) of the ion, however suggests a model, where the trap is described by a pseudo-potential [313, 96] whose depth is,

$$D_z = \tfrac{q_z}{8} e V_{\rm ac} = 2D_r \qquad \text{if} \qquad a_i = 0 \ . \tag{49.127}$$

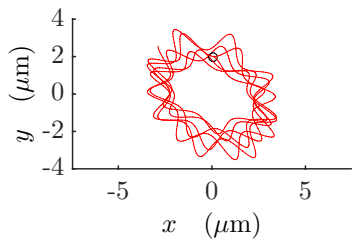

Figure 49.26: (code) Simulated micro- and macromotion of an ion.

Other geometries, deviating from the perfect quadrupole, are possible for the electrodes. These traps are also well described by equation (49.119), as long as the ion is near the trap center. For example, higher order multipolar traps have been used for trapping ion clouds [955], as well as Paul-Straubl traps [826] and storage rings [948]. Particularly important for the storage of arrays of cooled ions with applications in quantum computing is the *linear Paul trap* [751, 316, 750], where immobilized ions are aligned on a linear chain. The advantage of the linear trap, as compared to other traps designed for many ions, is the easier optical access to individual ions by focused laser beams and the possibility of canceling the micromotion.

49.5.2 Micromotion

The motion of an ion in a Paul trap is a superposition of two vibrations with the respective oscillation frequencies Ω_a (modulation frequency) and $\zeta_{r,z}$ (secular frequencies for radial and axial direction vibrations). For an ion in thermal equilibrium (i.e., without active cooling), the mean kinetic energies of the micro- and macromotion are equal [97].

The macromotion can be reduced by cooling, in contrast to the micromotion, which is constantly excited by the modulation of the applied electric field [178]. On the other hand, the amplitude of the micromotion decreases with the distance of the ion from the trap center and, in the minimum of the pseudo potential, disappears completely. Therefore, to suppress the micromotion, it is imperative to cool the macromotion and push the ion to the trap center, if necessary, using additional static electric fields. Since the frequency of the micromotion is much higher than that of the macromotion, the dynamic sidebands can be resolved on a sufficiently narrow optical transition. When the modulation frequency Ω_a is very high, the secular frequencies of the macromotion are also high, so that even large optical transitions are able to resolve the macromotional sidebands. This is called the *strong coupling* regime.

Because of Coulomb repulsion, only a single atom can be at the center of a Paul trap, such that it is difficult to zero micromovement. One solution is to use a linear trap, where the center is smeared out over a straight line. Solve Exc. 49.5.4.1.

Example 367 (*Numerical calculation of the electric field created by a charged surface*): To calculate the trapping potential for a charged particle held on top of a planar microtrap structure, we proceed as follows. The energy of a charge in an electric field is $H = -e\Phi$. The electrostatic potential is given by Coulomb's law,

$$\Phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0}\sum_n \int_{V_n} \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} dV' - \frac{1}{4\pi}\sum_n \int_{S_n} \Phi_n \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3} d\mathbf{f}' + \frac{1}{4\pi}\sum_n \int_{S_n} \frac{\vec{\mathcal{E}}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} \cdot d\mathbf{f}' \ ,$$

where ϕ_n is the voltage applied to the n-th boundary. In practice, electric fields are generated by electrodes set to specific voltages. Using the Dirichlet boundary conditions, we only retain the second term. Furthermore, to account for the planar geometry of the chip electrodes, we only consider surface boundaries in the $y' = 0$ plane,

$$\Phi(\mathbf{r}) = -\frac{1}{4\pi}\sum_n \Phi_n \int_{S_n} \frac{y dx' dz'}{\sqrt{(x-x')^2 + y^2 + (z-z')^2}^3} \ .$$

This implies that the field lines cross the chip surface orthogonally, which in reality is only true if the chip electrodes cover the whole area. Therefore, we

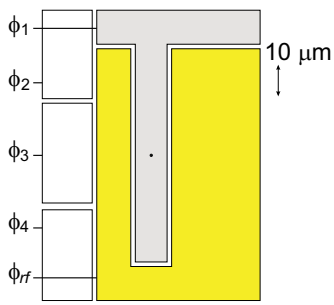

Figure 49.27: Possible design for a microchip ion trap. Φ_n are static potentials except for Φ_0, which is alternates sign with radio frequency.

only consider small gaps between the electrodes. We digitize the integral by dividing every electrode Φ_n into a number of identical surface elements Δf_m,

$$\Phi(\mathbf{r}) = -\frac{1}{4\pi}\sum_{n,m} \Phi_n \frac{y \Delta f_m}{\sqrt{(x-x_m)^2 + y^2 + (z-z_m)^2}^3} \ .$$

This formula can easily be evaluated numerically. A concrete example for a microchip ion trap is shown in Fig. 49.27.

Example 368 (*Numerical calculation of the magnetic field created by a current wire*): Current-carrying wires may exert Lorentz forces on the ions. The magnetostatic field is given by the Biot-Savart law,

$$\vec{\mathcal{B}}(\mathbf{r}) = \frac{\mu_0}{4\pi}\int_V \frac{(\mathbf{r}-\mathbf{r}') \times \mathbf{j}}{|\mathbf{r}-\mathbf{r}'|^3} dV' \ .$$

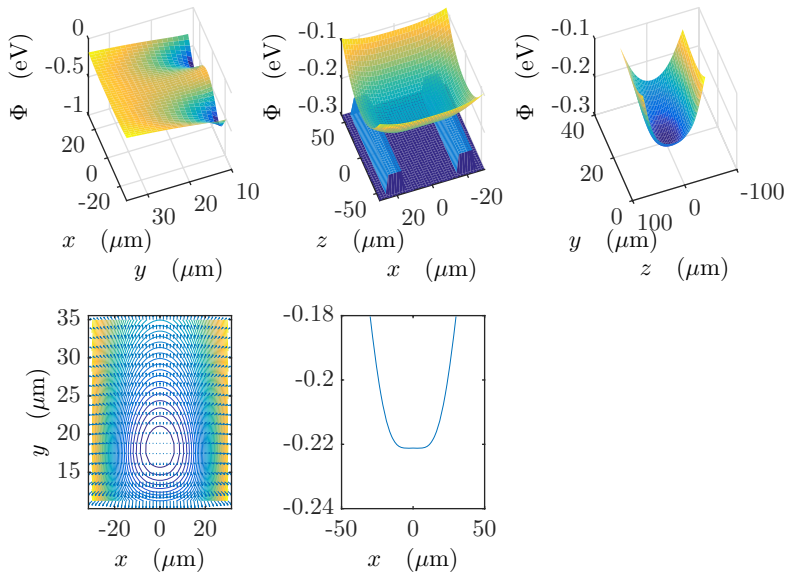

Figure 49.28: (code) Two-dimensional cuts through the electric potential generated by the microchip shown in Fig. 49.27 for $\Phi_{\rm rf} = 100$ V and $\Phi_j = 0$.

In practice magnetic fields are created by current-carrying wires. Those can be parametrized by one-dimensional currents, $\mathbf{j} = I\delta^2 d\mathbf{s}$, so that,

$$\vec{\mathcal{B}}(\mathbf{r}) = \frac{\mu_0 I}{4\pi}\int_C \frac{d\mathbf{s}' \times (\mathbf{r}-\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|^3}$$

$$|\vec{\mathcal{B}}(\mathbf{r})| = \frac{\mu_0 I}{4\pi}\sum_n \frac{\sqrt{ds_{y,n}^2(z-z_n)^2 + ds_{z,n}^2(x-x_n)^2 + ds_{x,n}^2(y-y_n)^2}}{\sqrt{(x-x_n)^2+(y-y_n)^2+(z-z_n)^2}^3} \ .$$

can immediately be numerically solved.

49.5.2.1 Electronic detection of ions

The presence of ions in the trap can be probed through the damping that they induce a coupled electronic resonance circuit [954, 961].

49.5.3 QUEST

Homonuclear atoms and dimers do not have a permanent electrical dipole moment, but they may have a permanent magnetic dipole moment. Therefore, homonuclear dimers must be confined by magnetic field gradients, or else an electric dipole moment must be *induced* by an oscillating electromagnetic field. In the optical regime, this was demonstrated with the quasi-electrostatic trap (*QUEST*).

In contrast, heteronuclear dimers are polar molecules with a permanent electric dipole moment, which can be quite large if the molecules are deeply bound. According to Earnshaw's theorem, there is no static magnetic field maximum in free space. Thus, no 'high-field seeking' state can be trapped. In principle, QUEST-type dipolar optical

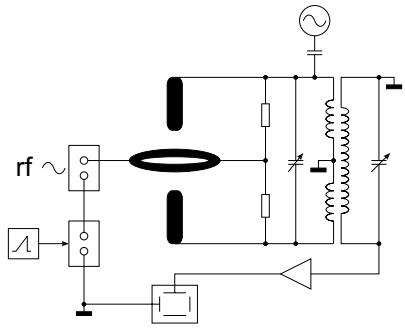

Figure 49.29: Resonance circuit for electronic ion detection. The trap is operated by a radiofrequency, while a DC voltage is scanned across the stability diagram. Simultaneously, an oscillating field is tuned near one of the trap's secular frequencies. When the stability point is such, that the secular frequency coincides with the frequency of the oscillating field, the motion of the ions is parametrically excited and the resonance circuit is damped. This damping is detected by a narrow-band amplifier.

traps can also be used for heteronuclear dimers. The problem is, however, that in contrast to homonuclear molecules, transitions between the vibrational ground state levels are possible. Thus, the light generating the QUEST also induces transitions leading to a redistribution of the population over all vibrational states.

Very far from resonance,

$$U_{\rm dip}(\mathbf{r}) = -\alpha_{\rm stat}\frac{I(\mathbf{r})}{2\varepsilon_0 c} \ . \tag{49.128}$$

Loosely bound homonuclear molecules are subject to the sum of the restoring forces exerted by magnetic traps on the individual atoms, $\mu_m = 2\mu_a$ and $d_m = 2d_a$. This is also true for heteronuclear molecules as long as the trapping potential is much weaker than the binding energy.

Example 369 (*Permanent electric dipole moment of LiRb*): The interaction energy of two dipoles is,

$$\hat{H}_{\rm int} = \frac{1}{4\pi\varepsilon_0}\frac{\mathbf{p}_1\cdot\mathbf{p}_2 - 3(\mathbf{p}_1\cdot\hat{\mathbf{r}})(\mathbf{p}_2\cdot\hat{\mathbf{r}})}{r^3} \ .$$

Thus, two identical dipoles with 1 Debye $= 10^{-27}/2.998\,\mathrm{Cm} = 10^{-19}/c\,\mathrm{Cm}^2\,/\,\mathrm{s} =$ 39.36 $ea_{\rm B}$ parallel oriented at a distance $r = 1\,\mu\mathrm{m}$ have the energy,

$$\hat{H}_{\rm int} = \frac{1}{4\pi\varepsilon_0}\frac{p^2}{r^3} \approx h\times 1.5\,\mathrm{MHz} \approx k_{\rm B}\times 73\,\mu\mathrm{K} \ .$$

For example, LiRb has an electrical dipole moment of between -2 and -4.2 Debye depending on the vibrational state of the molecule.

49.5.4 Exercises

49.5.4.1 Ex: Coulomb repulsion in linear Paul trap

Coulombian repulsion prevents that two ions confined in a linear Paul trap be simultaneously in the ground state. Determine the spatial extent of the ground state

and the depth of the potential in the pseudo-potential approximation. What is the equilibrium distance of the ions?

49.5.4.2 Ex: Motion of ions in a surface Paul trap

Programs on the motion of ions in a surface Paul trap.

49.6 Analysing techniques

To analyze the kinetic state of an atomic gas and, for example, to identify the presence of a Bose-Einstein condensate, it is necessary to measure its spatial or momentum distributions. However, the only way to gather information from the atoms is to throw some kind of particles into them and to detect, where these particles are scattered. The most suitable particle to penetrate an ultra-high vacuum chamber surely is the *photon*. Therefore, apart from few exceptions where electron beams are used, all information on ultra-cold gases has been obtained so far through their reactions to incident laser beams [449, 159, 25, 482, 377].

49.6.1 Time-of-flight imaging

The most common imaging techniques measure the absorption of a laser beam by an atomic cloud after a *time-of-flight* or the dispersion of a laser beam induced by a trapped cloud. The amplitude $\mathcal{E}_0$ of a light wave traversing an atomic cloud of diameter L and characterized by the refractive index η is modified by a factor $e^{\imath\omega L\eta/c}$. For an inhomogeneous cloud, we have,

$$\mathcal{E} = \mathcal{E}_0 e^{\imath\omega L/c} \exp\left(\imath\frac{\omega}{c}\int_{-\infty}^{\infty}(\eta(\mathbf{r})-1)dz\right) . \tag{49.129}$$

We can approximate the refractive index by the atomic susceptibility,

$$\eta = \sqrt{1+\chi} \simeq 1 + \frac{\chi}{2} \qquad \text{with} \qquad \chi = -\frac{4\pi n(\mathbf{r})}{k^3(2\Delta/\Gamma+\imath)} . \tag{49.130}$$

where $n(\mathbf{r})$ is the density distribution of the cloud. The imaginary part of the susceptibility is related to the *absorption coefficient* α and the real part to the *dispersion coefficient* δ,

$$\mathfrak{Im}\,\chi = \frac{\alpha}{\omega/c} \qquad \text{and} \qquad \mathfrak{Re}\,\chi = \frac{2\delta}{\omega/c} . \tag{49.131}$$

Now, the absorption and dispersion coefficients can be related to the optical cross-section $\sigma(\Delta)$ defined in (23.102) [590], where Δ is the detuning of light frequency from an atomic resonance, whose linewidth is Γ. This result is called the *optical theorem*,

$$\alpha = n\sigma(\Delta) \qquad \text{and} \qquad \delta = n\sigma(\Delta)\frac{\Delta}{\Gamma} , \tag{49.132}$$

Finally, we obtain the *Lambert-Beer law*,

$$\boxed{\mathcal{E} = \mathcal{E}_0 e^{\imath\omega L/c} \exp\left[\imath\sigma(\Delta)\left(\frac{\imath}{2}-\frac{\Delta}{\Gamma}\right)\int_{-\infty}^{\infty} n(\mathbf{r})dz\right] \equiv \mathcal{E}_0 e^{\imath\omega L/c} e^{-b/2} e^{\imath\varphi}} . \tag{49.133}$$

For the intensity, $I \propto |\mathcal{E}|^2$, we get,

$$\frac{I}{I_0} = \exp\left[-\sigma(\Delta)\int_{-\infty}^{\infty} n(\mathbf{r})dz\right] \equiv e^{-b} \ . \tag{49.134}$$

The *absorption* b describes the loss of intensity for the laser beam due to scattering by the (disordered) atoms. It is strong near resonance, but diminished quadratically with the detuning Δ. The scattering is necessarily accompanied by radiation pressure accelerating and heating the atoms. The *dispersion* φ describes the refraction of the laser beam by the atomic density distribution (which for this purpose can be considered as continuous) [198, 320]. It disappears in resonance and diminishes slowly with increased detuning ($\propto \Delta$). It is connected to the dipole force and, thus, does not heat the atomic cloud. The coefficient φ describes the phase shift of the electromagnetic wave transmitted through the atomic cloud.

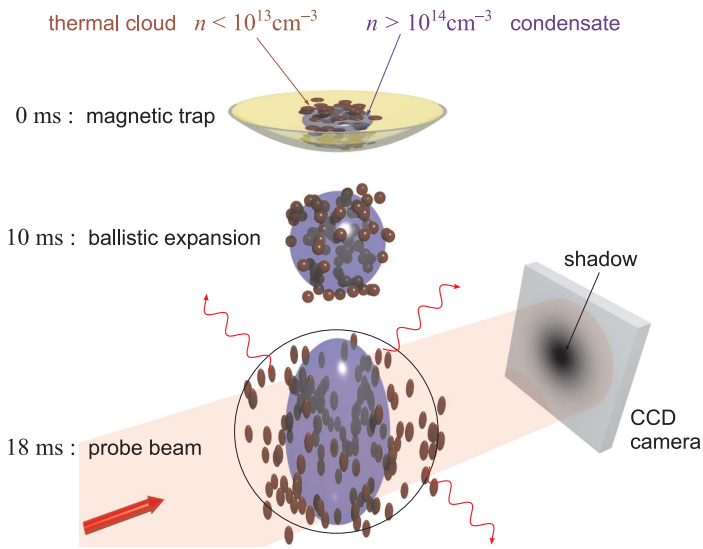

Figure 49.30: Sequence of a typical time-of-flight experiment: As soon as the trapping potential is suddenly switched off, the atomic cloud ballistically expands for 18 ms, before it is illuminated by a short resonant laser pulse. The shadow printed by the cloud onto the beam is photographed by a CCD camera.

49.6.2 Absorption imaging

Let us now detail the experimental process of *absorption imaging* (see Fig. 49.31): The trap confining the atomic cloud is suddenly turned off, thus letting the atoms, accelerated by the Earth's gravitation, fall for a flight time of a few ms. Then a pulse of a resonant laser light, whose diameter is much larger than the size of the cloud, is irradiated. The local attenuation of the beam intensity $I \sim |\mathcal{E}|^2$ can be related through the absorption b (also called *optical density* or *optical depth*) to the atomic density via,

$$-\ln\frac{I(x,y)}{I_0} = b(x,y) = \sigma(\Delta)\int n(\mathbf{r})dz \ . \tag{49.135}$$

The shadow printed by the atomic cloud on the transverse profile of the laser beam is recorded by a CCD camera.

We have already noted that the absorption is accompanied by radiative pressure. After some scattering events, due to the photonic recoil, the atoms have accumulated a sufficiently large velocity, and therefore a sufficiently large Doppler shift, to be out of resonance with the laser beam. Subsequent photons are no longer scattered by the atoms and only contribute to increase the illumination of the CCD camera without carrying any information about the presence of atoms. Consequently, it is advantageous to use very short laser pulses. In addition, the intensity of the laser beam should not saturate the transition in order to guarantee an optical cross-section, which is independent of the intensity, and hence to guarantee the validity of the Lambert-Beer law. Finally, the laser frequency must be tuned perfectly to resonance, $\Delta = 0$. Otherwise, the interaction between the laser beam and the atomic cloud becomes partially dispersive, which leads to a focusing or defocusing of the laser beam by refraction and a distortion of the image making it impossible to estimate the size of the cloud.

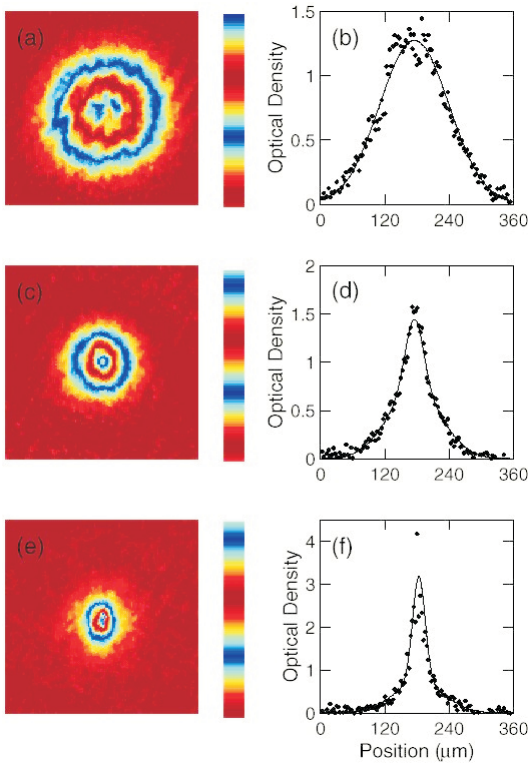

Figure 49.31: Absorption images after a time-of-flight allow to identify the presence of a Bose-condensate through its characteristic momentum distribution. Shown are images (a,b) above, (c,d) slightly below, and (e,f) well below the critical temperature for a Bose-Einstein phase transition (figures [412]).

Fig. 49.31 shows examples of absorption images of an atomic cloud taken at differ-

ent stages of the evaporation process. Fig. 49.31(a,b) was taken at a temperature of 320 nK; the cloud is large and isotropic and therefore purely thermal. At 250 nK [see Fig. 49.31(c,d)] an elliptically shaped part appears in the center of the thermal cloud. And at 180 nK [see Fig. 49.31(e,f)] the thermal cloud almost completely disappeared for the benefit of the condensate. A quantitative evaluation of the condensed fraction is given in Sec. 29.3.2. Solve the Excs. 49.6.6.2 and 49.6.6.1.

49.6.3 Dispersive imaging

The absorption imaging technique is destructive, because of the involved ballistic expansion and also because of the radiative pressure exerted by the resonant imaging beam, which accelerates and heats the atomic cloud. That is, the measurement process messes up the distributions of the cloud, such that a second image taken after the first one will give different results. However, there is a non-destructive imaging technique called *dispersive imaging* or *phase contrast imaging*. In this technique, the laser light is tuned sufficiently far from resonance, $|\Delta| \gg \Gamma$, for spontaneous emission and heating induced by random photonic recoil to be negligible [25]. This permits to take a series of consecutive images and create a *movie* of the temporal evolution of the cloud. Another advantage of this technique is the low off-resonant optical density, which allows to take pictures of very dense clouds *in situ*, that is, *while they are confined in a trap*.

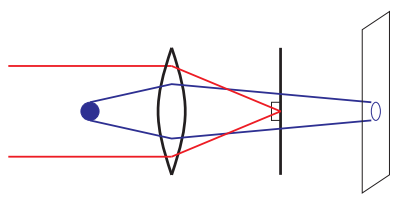

Figure 49.32: Scheme for dispersive images.

The physical quantity which is measured by this method is the local phase shift of the wavefront of the probe laser. Wavefront distortions are difficult to measure. To transform the phase profile into an intensity profile, a method known from classical optics called *Schlieren method* is used. It is based on the interference of the probe beam with its distorted wavefront and a reference plane wave. In practice, there are several possibilities. For *dark-ground imaging*, the part of the incident beam not having interacted with the atoms is blocked behind the interaction zone (see Fig. 49.32)

$$\begin{aligned} \bar{I}_{\mathrm{dg}} = \tfrac{1}{2}|\mathcal{E} - \mathcal{E}_0|^2 &= I_0|e^{-b/2+\imath\varphi} - 1|^2 \\ &\xrightarrow{b\to 0} I_0\varphi^2 = I_0 b\frac{\Delta^2}{\Gamma^2} \ . \end{aligned} \tag{49.136}$$

The intensity signal $\bar{I}_{\mathrm{dg}}$ is quadratic in optical density b.

For *phase contrast imaging*, the part of the beam not having interacted with the atoms receives a phase shift of $\lambda/4$ with respect to the part of the beam having

interacted with the atoms:

$$\bar{I}_{\rm pc} = \tfrac{1}{2}|\mathcal{E} - \mathcal{E}_0 + \mathcal{E}_0 e^{\pm\imath\pi/2}|^2 = I_0|e^{-b/2+\imath\varphi} - 1 + e^{\pm\imath\pi/2}|^2 \overset{b\to 0}{\longrightarrow} I_0(\pm 1+\varphi)^2 \simeq I_0\left(1 \pm b\frac{\Delta}{\Gamma}\right) . \tag{49.137}$$

The intensity $\bar{I}_{\rm pc}$ is linear in b and, consequently, more sensitive to weak signals. Finally, a third technique, called *polarization contrast imaging*, detects the local birefringence of the atomic cloud [123, 798].

The imaging techniques shown so far only allow to visualize the instantaneous density distribution of the atomic cloud $n(\mathbf{r})$. If we are interested in other quantities, we have to conceive the experiment in such a way, that the desired information leaves its signatures in the density distribution. For example, to measure the excitation frequencies of a condensate, which can perturb its shape and observe the subsequent time evolution of $n(\mathbf{r}, t)$ via dispersive imaging [486, 640, 26, 510].

49.6.4 Reconstruction of column-integrated absorption images

Assume cylindrical symmetry $n(\mathbf{r}) = n(r, z)$, with $r = \sqrt{x^2 + y^2}$. Absorption images are *column-integrated*, i.e. they are taken by integration along the x-axis,

$$\frac{I(y,z)}{I_0(y,z)} = e^{-\sigma\int n(r,z)dx} = e^{-\sigma f(y,z)} . \tag{49.138}$$

The radial density can be recovered by tomography [235, 275, 714],

$$n(r,z) = \frac{1}{(2\pi)^2}\int (\mathcal{F}_y f)(\kappa_y, z) J_0(\kappa_y r) d\kappa_y . \tag{49.139}$$

This is called *image reconstruction* or *Fourier reconstruction* or *inverse Abel transform* and will we studied in Exc. 49.6.6.3.

49.6.5 Condensable atomic species

Early work on BEC has been done by [815, 61, 95, 164, 579]. Proposals for atomic gases withe from [420, 896, 892]. An appropriate BEC candidate must fulfill a few conditions: The transition wavelengths must be *accessible by laser light*, the level scheme should exhibit a *closed cycling transition* for laser cooling and have a reasonable pressure in gas phase. Furthermore, it is desirable to have a large HFS, metastable electronic state, no trapping state, large positive scattering length, Feshbach resonances. For sympathetic cooling it may be nice to have several isotopes of the same element.

The most common elements are alkalis, alkali earths and noble gases. The following gases have already been condensed ^{1}H, ^{1}He*, ^{7}Li, ^{23}Na, ^{85}Rb, and ^{87}Rb [23, 225, 124, 123, 799, 201, 412, 416]. Investigations in ^{1}Ne*, ^{39}K, ^{133}Cs, ^{x}Sr, ^{x}Cr and ^{40}Ca are underway [864, 394, 528, 752, 846, 72, 326].

49.6.6 Exercises

49.6.6.1 Ex: Lensing by cold clouds

The interaction of light with two-level atoms generates a susceptibility which gives rise to a refraction index,

$$\eta(\mathbf{r}) = \sqrt{1 - \frac{4\pi n(\mathbf{r})}{k^3(2\Delta/\Gamma + \imath)}} \ ,$$

where $n(\mathbf{r})$ is the cloud's density distribution and $\Gamma/2\pi = 30.5\,\mathrm{MHz}$ for strontium.
a. Calculate the phase-shift suffered by a light beam crossing an ultracold atomic cloud ($N = 10^5$, $T = 1\,\mu\mathrm{K}$) confined in an isotropic harmonic trap ($\omega_{trp} = (2\pi)\ 100\,\mathrm{Hz}$) as a function of detuning.
b. Estimate the focal distance of the cloud for $\Delta = -\Gamma$.

49.6.6.2 Ex: Optical density

A cloud of $N = 10^6$ ^{87}Rb atoms is prepared in a cylindrical harmonic trap characterized by the axial vibration frequencies $\omega_z = (2\pi)\ 50\,\mathrm{Hz}$ and the radial one $\omega_r = (2\pi)\ 200\,\mathrm{Hz}$. The experimenter takes the absorption image after 18 ms time-of-flight, as shown in Fig. 49.31(a). A pixel of the CCD camera corresponds to 5 µm in real space.
a. At what temperature is the phase transition to Bose-Einstein condensate to be expected?
b. Determine the temperature of the sample.
c. Evaluate its density distribution.
d. Evaluate the resonant optical density for the $D2$-transition at 780 nm along the symmetry axis of the trapped cloud.

49.6.6.3 Ex: Inverse Abel transformation

Calculate the inverse Abel transform using Bessel of an arbitrary function in 2D.

Chapter 50

Bose-Einstein condensation

The experimental verification of Bose and Einstein's prediction was for a long time a cherished dream of many physicists. On the one hand, several phenomena have been related to BEC in the past, for example, the phenomenon of superfluidity in liquid helium and superconductivity. On the other hand, these strongly interacting systems are not pure enough to clearly identify the role of BEC. In 1995, however, Bose-Einstein condensation of weakly interacting confined atomic gases was achieved in several laboratories [23, 227, 124, 412]. This success gave rise to a revolution in atom optics documented in an enormous amount of theoretical and experimental work. While initial work focused on the equilibrium thermodynamics of condensates near the phase transition, very soon the dynamic response of condensates to perturbations was the subject of in-depth investigations, followed by the study of superfluid characteristics, quantum transport phenomena, the interaction of condensates with light, of condensed gas mixtures [681, 886], and the behavior of condensates in periodic potentials. To name only a few landmarks, we mention the creation of vortices [623, 607] and quantum turbulence [432], the realization of various types of atom lasers [638, 22, 100, 404] and atom interferometers with condensates [408, 535], the coherent amplification of matter waves [464, 538, 466, 248], the creation of the Mott insulating states in optical lattices [379], the study of condensates in reduced dimensions [670], the Anderson localization of atomic matter waves [163, 780], the observation of Feshbach type collision resonances [200, 463, 947] and Efimov states [539, 66], the creation of homonuclear molecular [380, 488, 208, 1017, 991, 435] and heteronuclear condensates [711] and degenerate Fermi gases [241], the observation of BCS type pairing [446, 381], the observation of matter wave superradiance [464] and the interaction of condensates with optical cavities [857, 146] and with surfaces [76].

It is clearly unthinkable to discuss all matters in this course. Let us, however, give a basic and practical introduction to atomic optics with condensates.

50.1 Bose-Einstein condensation of dilute gases

The challenge of the experimental realization of Bose-Einstein condensation is the preparation of a very dense sample of very cold atoms. In practice, the first step consists in providing an atomic gas, for example, of an alkali metal. This is done by heating the metal in an oven (or sometimes in a dispenser). The atoms being ejected from the metal and forming a hot gas are then forced through a nozzle out of the oven, where they form a hot atomic beam. Some experiments employ a *Zeeman*

slower, which is a device that decelerates the fast atoms of the beam by means of a counterpropagating laser exerting a radiative pressure force. A position-dependent magnetic field applied along the trajectory of the atoms is calculated in order to compensate for the Doppler decreasing shift of the decelerated atoms and to ensure that the laser always stays in resonance with an atomic transition (see Exc. 39.5.6.3). Velocities around 30 m/s are realistic and low enough to allow the capture of the atoms by a magneto-optical (MOT) trap. Usually, some 10^9 atoms are captured in a few seconds.

MOTs do not only trap atoms, but simultaneously cool them down to the Doppler limit of typically some 10 μK. Quasi-resonant optical traps, such as MOT, are afflicted by the problem of radiation trapping (see Sec. 49.3.1), which limits the densities of atomic clouds to typically $10^{11}\,\mathrm{cm}^3$. This corresponds (at temperatures close to the Doppler limit) to phase space densities several orders of magnitude away from the threshold to Bose-Einstein condensation. For this reason, the atoms are transferred from the MOT to a potential exempt of radiative pressure force, for example, an optical dipole potential or a magnetic trap.

Once the atoms are confined in such a conservative potential, all the light beams are turned off, and the technique of evaporative cooling is activated (see Sec. 49.4.3). That is, the effective potential is deformed (for example, by an irradiated radiofrequency) in a way to skim out hot atoms and leave behind a cooler sample. This however supposes that the atomic cloud finds back to thermal equilibrium afterwards. As the rethermalization happens by elastic collisions, a high atomic density is necessary, which is often achieved via a compression of the trapping potential. In general, 99.9% of the atoms must be sacrificed to condense the rest. Finally, the momentum distribution is imaged after a time of free expansion. This is done by irradiation of a probe laser pulse (see Fig. 49.31). The entire process of producing a condensed cloud usually takes between 10 s and 60 s.

50.1.1 Condensate of alkaline gases

The first experimental observation of Bose-Einstein condensation was done with a dilute rubidium gas by Cornell and Wieman at the Joint Institute for Laboratory Astrophysics (JILA) [23]. A group from the University of Texas [412, 201] used rubidium as well. A group led by Ketterle from the Massachusetts Institute of Technology (MIT) created the first sodium condensate. And a group led by Hulet from Rice University opted for lithium [124, 122], which has a slightly negative scattering length, $a = -27.3a_\mathrm{B}$. In this situation, only small condensates are expected to be stable [795, 893], which explains the observation of a limited number of about 1400 condensed lithium atoms. Meanwhile, Bose-Einstein condensation has been achieved with many other species, such as ^{1}H [326], ^{85}Rb [195], ^{4}He* [784], ^{133}Cs [864], ^{39}K [752], ^{4}Ne [72], ^{88}Sr [883], or even molecules [989].

50.1.2 Condensation of hydrogen

Hydrogen is a very interesting element to study condensation, because its short scattering length, $a \approx 1.23a_\mathrm{B}$, makes it an almost ideal gas. Consequently, the three-body collision rate causing losses is weak, even at very high densities. Since the mass of

hydrogen is small, the critical temperature is high. The simplicity of its electronic structure allows precise calculations of the interaction potentials based on fundamental principles, which can thus be tested experimentally.

Twenty years after having started the project of condensing dilute hydrogen gases, Greytak and Kleppner [326] crossed the phase transition at a temperature of 50 μK with an atomic density of $5 \times 10^{15}\,\mathrm{cm}^{-3}$. The number of condensed atoms was 10^9, which corresponds to a condensed fraction below 10% [1]. The condensed cloud had a needle-like shape of 15 μm diameter and 5 mm length. It was detected by an *in situ* measurement technique of the atomic velocity distribution.

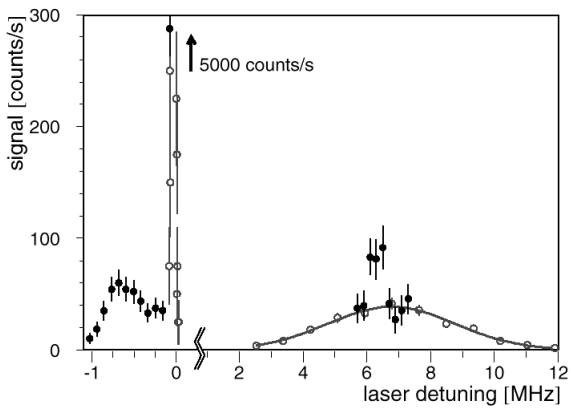

Figure 50.1: Spectrum of condensed hydrogen.

50.1.3 Recognizing Bose-Einstein condensates

'How to recognize the presence of a condensate, what are its signatures?' We have already seen in Sec. 29.3.3 that, trapped inside a confinement potential, an ultracold ideal Bose-gas has a modified density distribution when Bose-Einstein statistics come into play. Below the critical temperature the density distribution is well described by a superposition of a condensed cloud concentrated in the trap's ground state and a thermal cloud distributed over several vibrationally excited states. We thus expect distinct distribution functions for both clouds, and the same is true for the momentum distribution. The splitting of the distribution functions in two fractions occurs abruptly during the phase transition to quantum degeneracy. In a real gas, however, the interatomic collisions have a drastic influence on the distribution functions and the behavior of the gas at the phase transition, and we are obliged to develop a more general theory in order to quantitatively understand the thermodynamic properties (temperature, critical point, heat capacity, ...) through the measured static quantities (density, number of atoms, condensed fraction, ...).

'What observables can be measured in the laboratory?' In fact, with few exceptions, the only accessible quantity is the *spatial density distribution* of the atomic cloud

[1] When the condensed fraction and the density are too high, losses induced by dipolar spin-flip processes predominate over the gain due to evaporative cooling of the thermal cloud [441].

$n(\mathbf{r})$ measured after a time of ballistic expansion. Information on non-trivial properties of the condensate, for example, its dynamic behavior (excitations, superfluidity, turbulence, ...) or its coherent features (phase, correlations, ...), can only be gathered through an observation of the condensate's response to applied perturbations. Solve the Excs. 50.1.5.1 and 50.1.5.2.

50.1.4 Photon condensation

An interesting question is that of the possibility of *photon condensation* and its relationship to the laser. The relationship is not that obvious because, on one hand atomic condensates are produced by evaporating a ensemble in constant thermal equilibrium, while on the other hand the photonic laser requires inversion, which is a highly non-equilibrium situation. And under the constraint of having to reduce its energy, a photon gas trapped in an optical cavity has the simpler alternative to let photons escape into the void by annihilating them on the cavity walls, as it happens for black-body radiation. Since the number of photons in a cavity is not conserved, the chemical potential disappears, $\mu = 0$. The density of states can be written,

$$u(\nu) = \frac{8\pi V}{c^3} \frac{\epsilon^2 d\epsilon}{h^2} \ . \tag{50.1}$$

It is the same as in the Debye model. Planck's formula now follows from,

$$u(\epsilon)d\epsilon = \frac{1}{V}\epsilon f_{\mathrm{BE}}(\epsilon)\rho(\epsilon)d\epsilon \ , \tag{50.2}$$

where f_{BE} is the Bose-Einstein distribution. Hence, the treatment of the photons as indistinguishable particles following the Bose-Einstein distribution is equivalent to assuming a Boltzmann distribution for waves with quantized energies.

Nevertheless, one can imagine a photonic gas in thermal equilibrium with an atomic gas through Compton scattering [510]. In fact, photon condensation was observed experimentally [521]. Also, there are theories about superfluid photon gases [169] [2].

[2] *Bose-Einstein condensation occurs in thermal equilibrium when entropy is maximized by putting a macroscopic population of atoms into the ground state of the system. It might appear counter-intuitive that an apparently highly ordered state as the Bose condensate maximizes entropy. However, only the particles in excited states contribute to the entropy. Their contribution is maximized at a given total energy by forming a Bose condensate in the ground state and distributing the remaining atoms among higher energy states. A macroscopic population of atoms in the ground state of the system is achieved simply by lowering the temperature of the sample. This is in contrast to the optical laser where a non-equilibrium process is necessary to place a macroscopic population of photons in a single mode of the electromagnetic field. This is due to the fact that, unlike photons, the number of atoms is conserved. For bosonic atoms, the lowest entropy state below a certain temperature includes a macroscopic population of the ground state. In contrast, when one cools down a blackbody cavity, the cavity empties. Photons do not Bose condense into the ground state of the cavity, but are absorbed by the walls. The absorbed energy leads to a larger entropy than forming a Bose condensate. The laser phenomenon requires inversion of the active medium characterized by a 'negative' temperature. In that sense, 'lasing' of atoms is a simpler phenomenon than lasing of light –all you need to do is cool a gas! However, if a photon gas would thermalize while the number of photons is conserved, it would be described by a Bose-Einstein distribution with non-zero chemical potential and could form a Bose condensate. Thermalization with number conservation is possible, for example, by Compton scattering with a thermal electron gas [510].*

50.1.5 Exercises

50.1.5.1 Ex: Condensation of ions

Discuss the possibility of creating Bose-Einstein condensates from ionic clouds.

50.1.5.2 Ex: Isobaric impurities

Discuss the possibility of creating Bose-Einstein condensates with isobaric species.

50.2 Quantum theory

As detailed above, interatomic interactions strongly influence the properties of Bose-Einstein condensates, even their density and momentum distributions. For a correct interpretation of the experimental measurements a theoretical many-body treatment taking care of these interactions is compulsory. This is done through a description of the atomic distribution as a *scalar field of matter* called *second quantization*, where the atoms are treated as delocalized Broglie waves. An introduction to this formalism has been provided in Chp. 30 and [953].

50.2.1 Description of the atom as a scalar field

In position space a state with n particles can be described in a canonically quantized way by a *field operator*,

$$\hat{\Psi}(\mathbf{r}_1, ..., \mathbf{r}_n, t) = \hat{\psi}^\dagger(\mathbf{r}_1, t) \cdot ... \cdot \hat{\psi}^\dagger(\mathbf{r}_n, t)\hat{\Psi}_0 \quad , \quad \hat{\psi}(\mathbf{r})\hat{\Psi}_0 = 0 \ , \tag{50.3}$$

where Ψ_0 is the vacuum state. The field operators $\hat{\psi}(\mathbf{r}, t)$ and $\hat{\psi}^\dagger(\mathbf{r}, t)$ annihilate, respectively create, an atom at position $\mathbf{r}$ and time t. This state represents a bosonic Fock state and can be generated from the empty state by a sequence of individual particle creation operators. Applying the notions and rules developed for the harmonic oscillator in Sec. 24.6.1, we can define a coherent state of bosonic matter as,

$$|\hat{\Phi}(t)\rangle = \sum_{n=0}^{\infty} \frac{N^{n/2}}{\sqrt{n!}} |\hat{\Psi}(\mathbf{r}_1, ..., \mathbf{r}_n, t)\rangle \ . \tag{50.4}$$

The field operators for particle creation and annihilation are normalized to the number of atoms and satisfy the following commutation rules,

$$\boxed{\begin{array}{llcl}
\text{(i)} & [\hat{\psi}(\mathbf{r}), \hat{\psi}(\mathbf{r}')]_- & = & 0 \\
\text{(ii)} & [\hat{\psi}(\mathbf{r}), \hat{\psi}^\dagger(\mathbf{r}')]_- = \delta^3(\mathbf{r} - \mathbf{r}') \quad , \quad \hat{\psi}^\dagger(\mathbf{r}) & = & \displaystyle\int d^3r' \hat{\psi}^\dagger(\mathbf{r}')\delta^3(\mathbf{r} - \mathbf{r}') \\
\text{(iii)} & [\hat{\psi}(\mathbf{r}), \hat{N}]_- = \hat{\psi}(\mathbf{r}) \quad , \quad \hat{N} & = & \displaystyle\int d^3r' \hat{\psi}^\dagger(\mathbf{r}')\hat{\psi}(\mathbf{r}') \\
\text{(iv)} & [\hat{\psi}(\mathbf{r}), \hat{\mathbf{p}}]_- = \frac{\hbar}{\imath}\nabla\hat{\psi}(\mathbf{r}) \quad , \quad \hat{\mathbf{p}} & = & \displaystyle\int d^3r' \hat{\psi}^\dagger(\mathbf{r}')(\frac{\hbar}{\imath}\nabla')\hat{\psi}(\mathbf{r}') \\
\text{(v)} & [\hat{\psi}(\mathbf{r}), \hat{H}]_- & = & \imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r})
\end{array}} \tag{50.5}$$

The last equation is the Heisenberg equation of motion and describes the dynamics of a system whose *many-body Hamiltonian* $\hat{H} \equiv \hat{H}_{\rm cm} + \hat{H}_{\rm self}$ for N bosons interacting within an external potential $V_{\rm trp}$ in second quantization is defined by [3],

$$\boxed{\begin{aligned} \hat{H}_{\rm cm} &\equiv \int d^3r \hat{\psi}^\dagger(\mathbf{r}) \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp}(\mathbf{r},t) \right) \hat{\psi}(\mathbf{r}) \\ \hat{H}_{\rm self} &\equiv \int d^3r \int d^3r' \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}^\dagger(\mathbf{r}')V_{\rm coll}(\mathbf{r}-\mathbf{r}')\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r}) \end{aligned}} \ . \tag{50.6}$$

The equations (50.5) and (50.6) represent the foundation of the theory of ultracold bosonic gases. However, to solve the equations, we will need to apply some simplifications, which will be discussed in the following sections. For example, we will generally assume that the temperature of the sample is $T = 0$, and that all atoms are condensed. Also, in a first time, we will neglect quantum fluctuations, replacing field operators with complex numbers. And finally, we will need to handle the nonlinear term appearing in $\hat{H}_{\rm self}$ and which signs responsible for collisions between atoms.

50.2.2 Quantum scattering at low temperatures

To simplify the term $\hat{H}_{\rm self}$, we have to go back to Secs. 36.2.5 (and following) and study the phenomenon of the elastic collisions in the ultracold regime. For simplicity, we consider two particles without internal degrees of freedom with masses m_1 and m_2 approaching each other along the z-axis [184, 962]. Neglecting spin-spin and spin-orbit interactions, the Schrödinger equation in the inertial center-of-mass system is given by (36.115),

$$\left(-\frac{\hbar^2}{2m^*}\nabla^2 + V_{\rm coll}(r) \right) \hat{\psi}(\mathbf{r}) = E\hat{\psi}(\mathbf{r}) \ , \tag{50.7}$$

where $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$ is the momentary interatomic separation, $r = |\mathbf{r}|$, and $m_r \equiv m_1 m_2/(m_1+m_2)$ is the reduced mass of atomic collision partners. We assume that the interatomic potential, $V_{\rm coll}(r)$, is spherically symmetrical. In the asymptotic limit of large separations [4], and in the Born-approximation (36.135), the solution of Eq. (50.7) can be seen as the sum of an incident plane wave and a scattered spherical wave modulated with a certain amplitude $f(\theta)$,

$$\psi(\mathbf{r}) = e^{\imath kz} + f(\theta)\frac{e^{\imath kr}}{r} \ , \tag{50.8}$$

where $k = \sqrt{2m_r E/\hbar^2}$ is the amplitude of the wavevector of the incident and scattered waves and θ the angle between r and z. The function $f(\theta)$ is called *scattering amplitude* and determines the scattering cross-section for s-wave collision through the expression [see (36.123)],

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2 \ . \tag{50.9}$$

[3] Sometimes the Landau potential is used for canonical and macrocanonic ensembles. It defined by, $\hat{\Omega} = \hat{H}_{\rm cm} + \hat{H}_{\rm self} - \int d^3r \hat{\psi}^\dagger(\mathbf{r})\mu\hat{\psi}(\mathbf{r})$, where μ is the chemical potential.

[4] This means, $r \gg r_0$, where r_0 is the range of potential $V(r)$.

where $d\Omega = \sin\theta d\theta d\phi$ is an element of the solid angle. To calculate the scattering amplitude, we expand the wavefunction (50.8) into spherical partial waves of orders ℓ of the angular momentum, as done in (36.136),

$$f_k(\theta) = \frac{1}{k}\sum_{\ell=0}^{\infty}(2\ell+1)P_\ell(\cos\theta)e^{\imath\delta_\ell}\sin\delta_\ell \ . \tag{50.10}$$

The collision cross section has been shown in (36.148) to be given by,

$$\sigma = \frac{4\pi}{k^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\delta_\ell \ . \tag{50.11}$$

For a potential with finite range, that is, a potential falling faster than r^{-3} with the distance (interatomic potentials usually fall as r^{-6} or r^{-7}), the phase shift satisfies,

$$\delta_\ell \propto k^{2\ell+1} \tag{50.12}$$

for small k. In ultra-cold gases, the collision energy is very low and $k \to 0$. Thus the scattering will be dominated by terms with $\ell = 0$. This is the so-called limit of *s-wave scattering*. In this limit the Eqs. (50.10) can be approximated as,

$$f_k(\theta) = \frac{1}{k}e^{\imath\delta_0}\sin\delta_0 \ . \tag{50.13}$$

50.2.3 Scattering length

For $\ell = 0$, taking the limit $k \to 0$, we define the *scattering length* a_s via,

$$\frac{\mathfrak{Im}\, f_k(\theta)}{\mathfrak{Re}\, f_k(\theta)} = \tan\delta_0 \equiv -\tan ka_s \ . \tag{50.14}$$

Therefore, the scattering length and cross section are given at very low temperatures at the asymptotic boundary by,

$$\boxed{a_s = -\frac{\delta_0}{k} \qquad \text{and} \qquad \sigma = 4\pi a_s^2} \ . \tag{50.15}$$

The scattering process can be interpreted as follows: During a collision, the system's wavefunction undergoes a phase shift, δ_0, which may be positive or negative, depending on the sign of a_s. If $a_s < 0$, the phase is 'delayed' by the collision. This corresponds to an attractive interaction. In contrast, if $a_s > 0$, the phase is 'advanced' and the interaction is repulsive. Of course, the intensity of the interaction is proportional to the value of $|a_s|$. The expression for σ in Eq. (50.15) indicates, that the atoms behave like *hard spheres* with radius $|a_s|$. The specific value of a_s will depend on the interaction potential, however, the details of the potential are unimportant, as all information about the collision is already contained in a_s. Consequently, in the low-energy limit, we can assume that the collision is mediated by an effective potential $V_{\text{coll}}(\mathbf{r})$, which has the particularity,

$$\int V_{\text{coll}}(\mathbf{r})d^3r = \frac{4\pi\hbar^2}{m}a_s \equiv g \ . \tag{50.16}$$

This has been shown in Sec. 36.1.2. Consequently, the effective interaction between two particles at positions $\mathbf{r}$ and $\mathbf{r}'$ can be considered as contact interaction given by [5],

$$V_{\rm coll}(\mathbf{r},\mathbf{r}') = \frac{g}{2}\delta(\mathbf{r}-\mathbf{r}') \ . \tag{50.17}$$

The interatomic interaction potential decides on the value of the scattering length a_s: A repulsive potential corresponds to a positive a_s. For a purely attractive potential that does not support bound states a_s is negative, and for an attractive potential that supports bound states a_s may be positive or negative depending on the proximity of the last bound vibrational state of the interaction potential below the dissociation limit.

50.2.4 The mean field approximation

The *mean-field theory* (MFT) or *local density approximation* (LDA) is based on the assumption of *hard sphere collisions* between atoms (as described by the potential (50.17)) propagating through a locally homogeneous mean-field potential, $\frac{g}{2}|\hat{\psi}(\mathbf{r})|^2$. The procedure is also called *regularization of the interaction*.

Thus, the mean-field energy of a condensate is proportional to the density of the gas n and to a single atomic constant, which is the scattering length a_s. Its presence in the Gross-Pitaevskii equation emphasizes its impact on shape, dynamic stability and many other properties of the condensate. For example, the mean-field interaction contributes to the broadening of a condensed wavepacket, and consequently contracts its momentum distribution in comparison with an ideal gas. Homogeneous condensates with a negative scattering length are unstable, because the attempt of such a condensate to lower its self-energy by increasing its density also increases the rate of inelastic three-body collisions until the condensate collapses.

50.2.5 Gross-Pitaevskii equation

The Heisenberg equation [last line of (50.5)] is equivalent to the *variational principle*, as stated by the Ehrenfest theorem,

$$\imath\hbar\frac{d\hat{\psi}}{dt} = \frac{\delta\mathcal{H}}{\delta\hat{\psi}^\dagger} \ . \tag{50.18}$$

This facilitates the derivation of the equation of motion for the atomic field. With the Hamiltonian (50.6) in the mean-field approximation,

$$\mathcal{H}_{\rm atom} \equiv \mathcal{H}_{\rm cm} + \mathcal{H}_{\rm mf} \qquad \text{with} \qquad \mathcal{H}_{\rm mf} \equiv \int d^3r\hat{\psi}^\dagger(\mathbf{r},t)\frac{g}{2}|\hat{\psi}(\mathbf{r},t)|^2\hat{\psi}(\mathbf{r},t) \ , \tag{50.19}$$

we find the *non-linear Schrödinger equation*,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp}(\mathbf{r},t) + g|\hat{\psi}(\mathbf{r},t)|^2\right]\hat{\psi}(\mathbf{r},t) = \imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r},t) \ . \tag{50.20}$$

[5] The *Hartree-Fock-Bogolubov method* (HFB) for the mean-field theory disregards corrections of higher orders, for example, due to the renormalization of the scattering length. It also neglects quantum depletion due to the correlation effects of the order of $N_{out}/N = \frac{5}{8}\sqrt{\pi}\sqrt{a^3n_0}$. The theory mean-field supposes the validity of the *Born approximation*, that is, two-body correlations are neglected, $\hat{\psi}(\mathbf{r}') \approx \hat{\psi}(\mathbf{r})$ and $\int d^3R V_{\rm coll}(\mathbf{R}) = \frac{g}{2}$.

Remember that, despite their symbol $\hat{\psi}$, which usually is associated to wavefunctions, and the fact that they satisfy a non-linear Schrödinger equation the field operators are represented by matrices acting of many-body states. That is, Eq. (50.20) also represents a Heisenberg equation for the field operators.

A common approximation is the *Bogolubov prescription*, where the field operators describing the condensate and its fluctuations are decomposed into a complex function, $\psi_0(\mathbf{r}) \equiv \langle\hat{\psi}(\mathbf{r})\rangle$ called *condensed wavefunction*, which can be chosen as the *order parameter* of the system, and a small perturbation, $\delta\hat{\psi}(\mathbf{r}) \equiv \hat{\psi}(\mathbf{r}) - \psi_0(\mathbf{r})$ describing *thermal excitations*. At zero temperature, we can neglect the excitations [69], and our system is completely described by a single wavefunction, $\psi_0(\mathbf{r}, t)$, obeying the famous *Gross-Pitaevskii equation* (*GPE*),

$$\boxed{\left[\frac{-\hbar^2}{2m}\nabla^2 + V_{\text{trp}}(\mathbf{r}, t) + g|\psi_0(\mathbf{r}, t)|^2\right]\psi_0(\mathbf{r}, t) = \imath\hbar\frac{\partial}{\partial t}\psi_0(\mathbf{r}, t)}\,. \tag{50.21}$$

50.2.5.1 Spontaneous breaking of gauge symmetry

The description of a condensate by a single macroscopic wavefunction means that we attribute a well-defined phase to it. However, the GPE does not allow us to predict, which phase between 0 and 2π this will be, and we have to assume, that the BEC chooses its phase spontaneously when it undergoes the phase transition to quantum degeneracy. This principle is called *spontaneous breaking of gauge symmetry* [6]. In Exc. 50.2.6.2 we study the relation between the fact of having exactly N atoms in a condensate and a well-defined phase φ, knowing that these two quantities are conjugate variables having to satisfy a Heisenberg uncertainty relation.

50.2.6 Exercises

50.2.6.1 Ex: Derivation of the non-linear Schrödinger equation

Derive the non-linear Schrödinger equation using (a) the commutator relation (50.5)(v) and (b) the variational expression (50.18).

50.2.6.2 Ex: Spontaneous breaking of gauge symmetry

One of the primary characteristics of a condensate is its phase coherence. Now, consider a condensate with exactly N atoms. The exact knowledge of the atom number implies a totally uncertain phase of the condensate, according to Heisenberg's uncertainty relation. Explain this contradiction!

[6] An alternative way of modeling the development of a BEC phase is based on measurement theory. See also (37.86) for an analogy to the correct state of a laser.

50.3 Approximate solutions of the Gross-Pitaevskii equation

50.3.1 Stationary GPE

In cases where the external potential is stationary, $V_{\text{trp}}(\mathbf{r},t) = V_{\text{trp}}(\mathbf{r})$, the temporal dependency of the GPE can be removed by the ansatz,

$$\psi_0(\mathbf{r},t) = \psi_0(\mathbf{r})e^{-\imath\mu t/\hbar} \ . \tag{50.22}$$

This gives the stationary Gross-Pitaevskii equation,

$$\boxed{\left[\frac{-\hbar^2}{2m}\nabla^2 + V_{\text{trp}}(\mathbf{r}) + g|\psi_0(\mathbf{r})|^2\right]\psi_0(\mathbf{r}) = \mu\psi_0(\mathbf{r})} \ , \tag{50.23}$$

where μ is called the *chemical potential*. Solve Exc. 50.3.4.1.

50.3.2 Trapped condensates and the Thomas-Fermi limit

50.3.2.1 Free particles

The wavefunction of free particles, $V(\mathbf{r}) = 0$, can be described by a plane wave,

$$\psi(\mathbf{r}) = \sqrt{n}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{50.24}$$

also called the Hartree solution. Inserted it into the equation of Gross-Pitaevskii equation,

$$E(k) = \frac{\hbar^2k^2}{2m} + gn \ , \tag{50.25}$$

we observe a *gap* in the energy spectrum due to the interaction.

50.3.2.2 Ideal gas in a harmonic potential

Most experiments apply non-isotropic (often cylindrical) potentials, which are additionally distorted by the mean-field. Hence, the non-linear term of the GPE is important, and the spatial coordinates can not be separated. However, assuming an ideal gas and a harmonic potential, the dimensions could be separated, as demonstrated in Sec. 24.5.5, even when the potential is not isotropic. It is then sufficient to consider one-dimensional problems with $g = 0$,

$$\left[-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + \frac{m}{2}\omega_x^2\hat{x}^2\right]\psi_n = \mu_n\psi_n \ . \tag{50.26}$$

In this limit, the GPE is nothing more than the usual Schrödinger equation, which has the well-known spectrum (24.119) and the solutions (24.118).

50.3.2.3 Ideal gas in an isotropic potential

In the case of an ideal gas trapped in a spherically symmetric potential, as shown in (25.34), the Schrödinger equation can be reduced to its radial component,

$$\left[\frac{\partial^2}{\partial r^2}+\frac{2}{r}\frac{\partial}{\partial r}-\frac{l(l+1)}{r^2}+V_{\rm trp}(r)\right]f_{nlm}(r)=\mu_{nl}f_{nlm}(r)\ , \tag{50.27}$$

with the solution (25.18),

$$\psi_n(r,\vartheta,\varphi)=\sum_{l,m}f_{nlm}(r)Y_{lm}(\vartheta,\varphi) \tag{50.28}$$

The differential equation (50.27) can be solved numerically by Runge-Kutta type methods,

$$\begin{pmatrix} f'' \\ f' \end{pmatrix}=\begin{pmatrix} \frac{2}{r} & \mu+\frac{l(l+1)}{r^2}-V_{\rm trp}(r) \\ 1 & 0 \end{pmatrix}\begin{pmatrix} f' \\ f \end{pmatrix}\ . \tag{50.29}$$

50.3.2.4 Thomas-Fermi limit for strong interactions

In the case of strong interactions, the kinetic energy term can be neglected, at least in the center of the cloud, where the mean-field energy is stronger. For this case, called *Thomas-Fermi limit*, the GPE solution is easy,

$$|\psi_0(\mathbf{r})|^2=\frac{\mu-V_{\rm trp}}{g}\ . \tag{50.30}$$

The chemical potential follows from the normalization condition,

$$N=\int_{n(\mathbf{r})>0}n(\mathbf{r})d^3\mathbf{r}\ . \tag{50.31}$$

In the case of an cylindrical harmonic oscillator potential, $V_{\rm trp}(r,z)=\frac{m}{2}(\omega_r^2r^2+\omega_z^2z^2)$, the chemical potential is,

$$\mu=\left(\frac{15Ng}{8\pi}\right)^{2/5}\left(\frac{m}{2}(\omega_r^2\omega_z)^{2/3}\right)^{3/5}\ . \tag{50.32}$$

The radial size σ of the condensate follows from $n(r_{\rm hw},0)=\frac{n(0,0)}{2}$,

$$r_{\rm hw}=\sqrt{\frac{\mu}{m\omega_r^2}}\ . \tag{50.33}$$

Solve the Excs. 50.3.4.2 and 50.3.4.3.

50.3.3 Variational treatment of the GPE

The many-body Hamiltonian (50.19) can be used as an *energy functional*,

$$E[\psi_0]\equiv\langle\mathcal{H}[\psi_0]\rangle=\int d^3r\left[\frac{\hbar^2}{2m}|\nabla\psi_0|^2+V_{\rm trp}(\mathbf{r})|\psi_0|^2+\frac{g}{2}|\psi_0|^4\right]\ , \tag{50.34}$$

from which, using the variational condition (50.18), we have derived the Gross-Pitaevskii equation (50.21). Hence, the wavefunction ψ_0 minimizes the functional [266]. By inserting an ansatz for the wavefunction with adjustable parameters, the functional provides conditions to optimize these parameters.

The *variational method* is useful e.g. for finding the ground state wavefunction of a condensate in an arbitrarily shaped trap or to perform a stability analysis of a condensate with attractive interatomic forces.

50.3.3.1 Finding the fundamental state of the GPE

This problem of finding the ground state wavefunction of a condensate consists in finding the ψ for which the energy $\mathcal{H}[\psi]$ goes to a minimum. In general, the functional has the form $\mathcal{H}[\psi] = \int f[\psi, \nabla\psi] d^3r$. The fastest way to the minimum is to reduce the energy by varying ψ in that direction, where the gradient $\delta\mathcal{H}/\delta\psi^*$ is largest, that is,

$$\begin{aligned} \mathcal{H} &\to \mathcal{H}[\psi + \tau \, \tfrac{\delta\mathcal{H}}{\delta\psi^*}] \\ \psi &\to \psi + \tau \tfrac{\delta\mathcal{H}}{\delta\psi^*} \ , \end{aligned} \tag{50.35}$$

with the boundary condition, that the normalization must be preserved. Formally, this problem is similar to a time-dependent Gross-Pitaevskii equation, but with *imaginary time*. Physically, the procedure, called the *steepest descent method*, can be interpreted as applying a heavily 'overdamped' friction force,

$$\frac{\partial\psi}{\partial\tau} = \frac{\delta\mathcal{H}}{\delta\psi^*} \ . \tag{50.36}$$

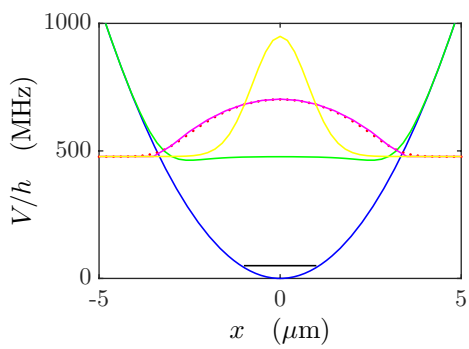

Figure 50.2: (code) Calculation of the BEC wavefunction by the steepest descent method (red dots). Also shown are the ideal gas approximation (yellow line) and the Thomas-Fermi approximation (magenta line), as well as the ground state energy (black line) and the chemical potential (green line).

In practice, the procedure is as follows: we start with a trial wavefunction, for example, the exact solution of the interaction-free case. This function is now propagated in imaginary time, using the complete Hamiltonian including the non-linear term, and then renormalized:

$$\hbar\frac{\partial}{\partial t}\psi(\mathbf{r},t) = \mathcal{H}(\mathbf{r})\psi(\mathbf{r},t) \ . \tag{50.37}$$

Substituting the imaginary unit i in the time-dependent Gross-Pitaevskii equation (50.21) by -1, we obtain,

$$\psi(\mathbf{r}, t+dt) = [1 - \hbar^{-1}\mathcal{H}(\mathbf{r})dt]\psi(\mathbf{r}, t) \tag{50.38}$$
$$\psi'(\mathbf{r}, t) \equiv \frac{\psi(\mathbf{r}, t+dt)}{|\psi(\mathbf{r}, t+dt)|} \to \psi(\mathbf{r}, t) \ .$$

This procedure is repeated until the function converges. Since this method is derived from a variational principle, it only serves to find the ground state of the trapping potential. It can not be used for excited states (with the exception of vortex states, where in cylindrical coordinates the Hamiltonian differs by an additional centrifugal term).

50.3.3.2 Collapse and stabilization of condensates with attractive interactions

Attractive interactions destabilize a Bose-Einstein condensate. Since the interaction energy, $4\pi\hbar^2 a_s n/m$, of a condensate with negative scattering length decreased with increasing density n, the condensate attempts to lower its interaction energy by increasing its density until it succumbs to inelastic two-body spin-changing collisions of to three-body collisions leading to the formation of molecules [893]. Strictly speaking, this only holds true for homogeneous condensates. In the presence of a trapping potential, however, the zero-point energy exerts a kinetic pressure, which counteracts the *condensate collapse* to a certain extent, such that small condensates are stabilized. This can be verified by inserting a Gaussian wavefunction $\psi_0 \propto e^{-r^2/2\bar{r}^2}$ into the energy functional (50.34). Varying the radius $\bar{r}$ of the condensate, we find a local minimum where the condensate is stable. Calculations for spherical traps predict [795, 216],

$$N_{\min} \simeq 0.575 \frac{a_{\text{trp}}}{|a_s|} \ , \tag{50.39}$$

where $a_{\text{trp}} = \sqrt{\hbar/m\omega_{\text{trp}}}$.

The atomic species ^{7}Li has a slightly negative scattering length $a_s = -27.3a_{\text{B}}$. As can be seen in Fig. 50.3, small condensates can survive in a confining trap, since the energy functional has a local minimum [124, 122, 797]. Solve Exc. 50.3.4.4.

50.3.4 Exercises

50.3.4.1 Ex: GPE in dimensionless units

Use the following abbreviations to rewrite the Gross-Pitaevskii equation and its solution for a harmonic isotropic potential in dimensionless units,

$$\begin{array}{llll}
V_1 & \equiv V_{\text{trp}}/\hbar\omega_{\text{trp}} & V_{\text{trp}} & = \frac{m}{2}\omega_{\text{trp}}^2 r^2 \\
\mathbf{r}_1 & \equiv \mathbf{r}/a_{\text{trp}} & a_{\text{trp}} & = \sqrt{\hbar/m\omega_{\text{trp}}} \\
\mu_1 & \equiv \mu/\hbar\omega_{\text{trp}} & T_1 & \equiv k_{\text{B}}T/\hbar\omega_{\text{trp}} \\
\psi_1 & \equiv \psi/a_{\text{trp}}^{3/2} & p_1 & \equiv a_{\text{trp}}p/\hbar \\
g & \equiv 4\pi\hbar^2 a/m & g_1 & \equiv 8\pi N_0 a/a_{\text{trp}}
\end{array}$$

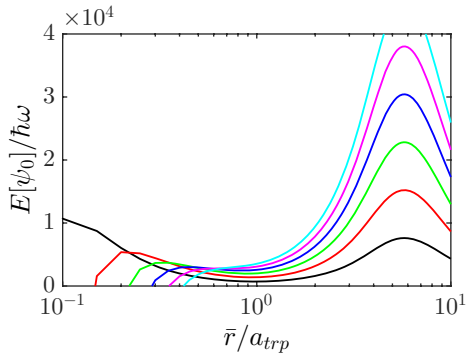

Figure 50.3: (code) Energy of a ^{7}Li condensate in a harmonic isotropic potential with $\omega_{\rm trp} = (2\pi)$ 50 Hz with $N = 500$ atoms (linha inferior) up to $N = 3000$ (linha superior) when the radius $\bar{r}$ of the condensate is varied.

50.3.4.2 Ex: Interacting gas in an isotropic potential

Consider the potential $V(\mathbf{r}) = V(r)$, such that the wavefunction will have radial symmetry, $\psi(\mathbf{r}) = \frac{\phi(r)}{r}$. Rewrite the Gross-Pitaevskii equation for the function ϕ [449].

50.3.4.3 Ex: Interacting gas in a cylindrical potential

Consider the potential $V(\mathbf{r}) = V(\rho, z)$, such that the wavefunction will have rotational symmetry, $\psi(\rho, z, \varphi) = \frac{\phi(\rho,z)}{\rho}$. Rewrite the Gross-Pitaevskii equation for the function ϕ [449].

50.3.4.4 Ex: Collapse of condensate with attractive interactions

A Bose-Einstein condensate of ^{7}Li may become unstable due to attractive interatomic forces, the scattering length being $a_s = -27.3a_{\rm B}$. Consider the radial Gross-Pitaevskii Hamiltonian with an external harmonic potential with the oscillation frequency $\omega_{\rm trp}/(2\pi) = 50$ Hz. Using the variational method, determine the maximum number of atoms allowing for a stable condensate. (Note that the derived minimization condition must be evaluated numerically.)

50.4 Elementary excitations

The dynamics of Bose-Einstein condensates is usually studied by observing the change of their shape in response to temporal variations in the trapping potential. The simplest variation surely consists in suddenly removing the trapping potential altogether. Consequently, the first experiment performed with a BEC was the study of its ballistic expansion [23, 298, 159] (see Sec. 50.7.1).

On the other hand, the temporal variation of the potential can also be a small oscillatory or pulsed perturbation, for example, a small modification of the amplitude of the trapping field, a displacement or a local anisotropy induced by the dipole force

of a laser beam tuned far away from resonance. It is even conceivable to manipulate the self-energy of the condensate or to irradiate electromagnetic waves, which couples internal atomic excitation levels or states of the atomic motion [69, 24, 876, 486, 640, 852, 286, 894, 487, 706, 875, 349]. The response of the condensate to such small perturbations can be understood by a linearized model of the Gross-Pitaevskii equation, which we will present in the following sections.

50.4.1 Bogolubov spectrum of excitations

To analyze the spectrum of a condensate's response to small perturbations, let us follow Bogolubov's treatment of the time-dependent Gross-Pitaevskii equation [873]. We start by substituting Eq. (50.20) [285],

$$\hat{\psi}(\mathbf{r},t) \longrightarrow \hat{\psi}(\mathbf{r},t)e^{-\imath\mu t/\hbar} \ , \tag{50.40}$$

which gives us,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp}(\mathbf{r}) + g|\hat{\psi}(\mathbf{r},t)|^2\right]\hat{\psi}(\mathbf{r},t) = \left[\mu + \imath\hbar\frac{\partial}{\partial t}\right]\hat{\psi}(\mathbf{r},t) \ . \tag{50.41}$$

The *Bogolubov prescription* now consists in approximating the field operators of the condensate by a sum of the equilibrium wavefunction, which is interpreted as a complex number, and a small perturbation, which conserves its operator character,

$$\hat{\psi}(\mathbf{r},t) \simeq \psi_0(\mathbf{r}) + \delta\hat{\psi}(\mathbf{r},t) \ . \tag{50.42}$$

This treatment assumes that most atoms are condensed, $N - N_0 \ll N_0$, and only a few thermal atoms are left out.

Applying the *Bogolubov transform*,

$$\boxed{\delta\hat{\psi}(\mathbf{r},t) \equiv \sum_{\mathbf{k}} u_{\mathbf{k}}(\mathbf{r})\hat{a}_{\mathbf{k}}(t) + v^*_{\mathbf{k}}(\mathbf{r})\hat{a}_{\mathbf{k}}(t)^\dagger} \ , \tag{50.43}$$

the perturbation is expressed as a superposition of amplitudes for annihilation and creation of non-interacting *quasi-particles*. By inserting this ansatz into the Gross-Pitaevskii equation, we obtain a linear system of equations called *Bogolubov-de Gennes equations*.

50.4.1.1 Semi-classical approximation

To simplify the equations, let us neglect the operator character of the quasi-particle by doing the substitutions,

$$\hat{a}_{\mathbf{k}} \to e^{-\imath\omega_{\mathbf{k}}t} \qquad \text{and} \qquad \hat{a}^\dagger_{\mathbf{k}} \to e^{\imath\omega_{\mathbf{k}}t} \ . \tag{50.44}$$

That is, we insert the ansatz (50.42) with,

$$\delta\hat{\psi}(\mathbf{r},t) \equiv u_{\mathbf{k}}(\mathbf{r})e^{-\imath\omega_{\mathbf{k}}t} + v^*_{\mathbf{k}}(\mathbf{r})e^{\imath\omega_{\mathbf{k}}t} \ , \tag{50.45}$$

into the Gross-Pitaevskii equation (50.41), we look for the lowest order,

$$\left(-\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp} + g|\psi_0|^2\right)\psi_0 = \mu\psi_0 \ , \tag{50.46}$$

and we collect the terms of first order in $e^{\pm\imath\omega_{\mathbf{k}}t}$, neglecting terms of order $u_{\mathbf{k}}^2, v_{\mathbf{k}}^{*2}$ or higher,

$$\begin{aligned} -\frac{\hbar^2}{2m}\nabla^2 u_{\mathbf{k}} + V_{\rm trp}u_{\mathbf{k}} + 2g\psi_0^2 u_{\mathbf{k}} - g\psi_0^2 v_{\mathbf{k}}^* &= \mu u_{\mathbf{k}} + \hbar\omega_{\mathbf{k}} u_{\mathbf{k}} \\ \frac{\hbar^2}{2m}\nabla^2 v_{\mathbf{k}} - V_{\rm trp}v_{\mathbf{k}} - 2g\psi_0^2 v_{\mathbf{k}} + g\psi_0^2 u_{\mathbf{k}}^* &= -\mu v_{\mathbf{k}} + \hbar\omega_{\mathbf{k}} v_{\mathbf{k}} \ . \end{aligned} \tag{50.47}$$

Introducing the abbreviations $n = \psi_0^2$ and,

$$\mathcal{L} \equiv \frac{-\hbar^2\nabla^2}{2m} + V_{\rm trp} + 2gn - \mu \ , \tag{50.48}$$

we can write

$$\begin{pmatrix} \mathcal{L} - \hbar\omega_{\mathbf{k}} & gn \\ gn & \mathcal{L} + \hbar\omega_{\mathbf{k}} \end{pmatrix}\begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} = \left[\begin{pmatrix} \mathcal{L} & gn \\ gn & \mathcal{L} \end{pmatrix} - \hbar\omega_{\mathbf{k}}\hat{\sigma}_z\right]\phi_k = 0 \ , \tag{50.49}$$

with $\hat{\sigma}_z$ being the third Pauli matrix. The solution of Eq. (50.49) is given by the requirement, that the determinant of the matrix be 0,

$$\hbar\omega_{\mathbf{k}} = \sqrt{\mathcal{L}^2 - (gn)^2} \ . \tag{50.50}$$

The object

$$\phi_{\mathbf{k}} \equiv \begin{pmatrix} u_{\mathbf{k}}(\mathbf{r}) \\ v_{\mathbf{k}}(\mathbf{r}) \end{pmatrix} \tag{50.51}$$

is called a *normal mode* of the condensate. The normal modes (50.50) are orthonormal,

$$\langle\phi_{\mathbf{k}}|\phi_{\mathbf{k}'}\rangle = \int d\mathbf{r}\phi_{\mathbf{k}}^\dagger(\mathbf{r})\hat{\sigma}_z\phi_{\mathbf{k}'}(\mathbf{r}) = \delta_{\mathbf{k},\mathbf{k}'} \ , \tag{50.52}$$

which means that *the modes do not interact*, that is, the quasi-particles *do not collide*.

For homogeneous systems or at the interior of a large condensate with strong interactions, we can assume that the potential is approximately constant, $V_{\rm trp} \to 0$, and kinetic energy negligible compared to the self-energy, and Eq. (50.41) shows us, $\mu \to gn$. Assuming plane waves,

$$u_{\mathbf{k}}(\mathbf{r}) \equiv ue^{\imath\mathbf{k}\cdot\mathbf{r}} \qquad \text{and} \qquad v_{\mathbf{k}}(\mathbf{r}) \equiv ve^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{50.53}$$

we obtain the *Bogolubov spectrum* of elementary excitations,

$$\boxed{\hbar\omega_{\mathbf{k}} = \sqrt{\frac{\hbar^2\mathbf{k}^2}{2m}\left(\frac{\hbar^2\mathbf{k}^2}{2m} + 2\mu\right)}} \ . \tag{50.54}$$

which corresponds to a *dispersion relation* for Bose-Einstein condensates. For an interacting gas, the collective modes are distortions of the condensate, caused by restoring forces originating in the finite compressibility of the gas.

50.4.1.2 Phonon- and particle-like excitations

The coefficients u and v describe the annihilation and u^* and v^* the creation of *quasi-particles* called *phonons* or *elementary excitations*. Two limits are interesting. In the low energy limit, $\frac{\hbar^2\mathbf{k}^2}{2m} \ll gn(\mathbf{r})$, we create *phonon-like excitations*. The Bogolubov spectrum becomes,

$$\hbar\omega_{\mathbf{k}}^{\mathrm{ph}} \simeq c_{\mathrm{s}}\hbar k \qquad \text{with} \qquad c_{\mathrm{s}} \equiv \sqrt{\frac{ng}{m}} \ . \tag{50.55}$$

Here is c_{s} the *sound velocity* inside the condensate. The fact that, comparing (50.54) and (50.55), we find,

$$\hbar\omega_{\mathbf{k}} > \hbar\omega_{\mathbf{k}}^{\mathrm{ph}} \tag{50.56}$$

for all $\mathbf{k}$ is the *Landau criterion* for the superfluidity of the condensate. It means that, for an object being dragged through the condensate with a velocity less than c_{s}, it does not become energetically favorable to produce excitations, see Fig. 50.4. Therefore, the object will move without dissipation, which is an important characteristic of superfluids. Experiments demonstrated this manifestation of superfluidity by slowly stirring a strongly focused blue-detuned laser through a condensate. We will come back to this in Sec. 51.1.1.

In the high energy limit, $\frac{\hbar^2\mathbf{k}^2}{2m} \gg gn(\mathbf{r})$, we create *particle-like excitations*. The Bogolubov spectrum becomes,

$$\hbar\omega_{\mathbf{k}}^{\mathrm{pa}} = \frac{\hbar^2\mathbf{k}^2}{2m} \ . \tag{50.57}$$

In this limit, we recover the quadratic dispersion relation of free particles, as seen in Fig. 50.4.

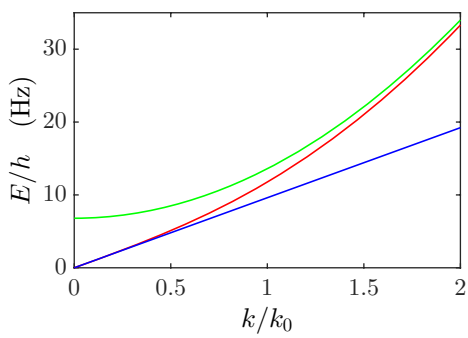

Figure 50.4: (code) Bogolubov spectrum (red), phonon limit (blue line) and particle limit (green line).

Experimentally, the complete Bogolubov spectrum (50.54) can be measured by Bragg spectroscopy [885, 874] (see Sec. 52.2). Solve Exc. 50.4.3.1.

50.4.2 Excitation of normal modes

In the simplest case, we generate a perturbation as a weak additional potential in the Gross-Pitaevskii equation (50.41),

$$\left[\mathcal{L} - gn + f_+(\mathbf{r})e^{-\imath\omega_p t} + f_-(\mathbf{r})e^{\imath\omega_p t}\right]\hat{\psi} = \imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r},t) \ . \tag{50.58}$$

After the Bogolubov transform (50.45) we now have,

$$\left[\begin{pmatrix}\mathcal{L} & gn\\ gn & \mathcal{L}\end{pmatrix} - \hbar\omega_{\mathbf{k}}\sigma_3\right]\begin{pmatrix}u(\mathbf{r})\\ v(\mathbf{r})\end{pmatrix} = -\begin{pmatrix}f_+(\mathbf{r})\psi_0(\mathbf{r})\\ f_-^*(\mathbf{r})\psi_0^*(\mathbf{r})\end{pmatrix} \ . \tag{50.59}$$

The solution of this equation is found by expanding the amplitudes $u(\mathbf{r})$ and $v(\mathbf{r})$ into normal modes,

$$\begin{pmatrix}u(\mathbf{r})\\ v(\mathbf{r})\end{pmatrix} = \sum_{\mathbf{k}} c_{\mathbf{k}}\phi_{\mathbf{k}}(\mathbf{r}) \qquad \text{and} \qquad \begin{pmatrix}f_+(\mathbf{r})\psi_0(\mathbf{r})\\ f_-^*(\mathbf{r})\psi_0^*(\mathbf{r})\end{pmatrix} = \sum_{\mathbf{k}} g_{\mathbf{k}}\phi_{\mathbf{k}}(\mathbf{r}) \ , \tag{50.60}$$

where $g_{\mathbf{k}}$ is given by the overlap integral,

$$g_{\mathbf{k}} = \int d\mathbf{r}\phi_{\mathbf{k}}^\dagger(\mathbf{r})\sigma_3\begin{pmatrix}f_+(\mathbf{r})\psi_0(\mathbf{r})\\ f_-^*(\mathbf{r})\psi_0^*(\mathbf{r})\end{pmatrix} \ . \tag{50.61}$$

To calculate the response of the condensate to a given perturbation $f_\pm(\mathbf{r})$, we must first calculate the normal mode spectrum $\phi_{\mathbf{k}}(\mathbf{r})$ from the Bogolubov equation (50.49). After that, we can calculate the coefficients (50.61). Inserting the expansions into the Eq. (50.59), we obtain the response of the condensate,

$$\begin{pmatrix}u(\mathbf{r})\\ v(\mathbf{r})\end{pmatrix} = -\sum_{\mathbf{k}}\frac{g_{\mathbf{k}}/\hbar}{\omega_{\mathbf{k}} - \omega}\phi_{\mathbf{k}} \ . \tag{50.62}$$

The deviation, which is observed for resonant excitation, is due to the neglected losses and non-linear effects.

50.4.2.1 Classification of normal modes

BECs often have cylindrical symmetry, $\psi(\mathbf{r}) = \psi_0(r,z)$. In this case, similar calculations to those shown above, result in analytical expressions for the frequencies of the elementary excitations. These frequencies were derived by [215] [7]. The modes can be classified by their main quantum numbers n_r and by their multipolar moment ℓ. Examples are the *surface excitation* or *shape oscillation* ($n_r = 0$) and the *compression oscillation* ($n_r \neq 0$). Special cases are called *shaking mode*, *breathing mode* ($n_r = 1, \ell = 0$), and *swirling mode*. In the case of cylindrical symmetry, the projection of the angular momentum onto the symmetry axis m is the relevant quantum

[7] It is worth mentioning that the linearized theory applies to *small perturbations*. Strong disturbances render the dynamics chaotic, since the energy is coupled to many modes of excitation.

number. The dispersion relations are,

$$\begin{aligned}
&\omega(\ell, \mp m = \ell) = |m|\omega_r^2 \\
&\omega(\ell, \mp m = \ell - 1) = |m|\omega_r^2 + \omega_z^2 \\
&\omega(\ell, \mp m = \ell - 2) = \omega_r^2 \left[2|m| + 2 + \tfrac{3}{2}\lambda^2 \mp \sqrt{(|m| + 2 - \tfrac{3}{2}\lambda^2)^2 + 2\lambda^2(|m| + 1)}\right] \\
&\omega(\ell, \mp m = \ell - 3) = \omega_r^2 \left[2|m| + 2 + \tfrac{7}{2}\lambda^2 \mp \sqrt{(|m| + 2 - \tfrac{5}{2}\lambda^2)^2 + 6\lambda^2(|m| + 1)}\right] \ ,
\end{aligned} \tag{50.63}$$

where λ is the aspect ratio $\lambda = \omega_z/\omega_r$. Obviously, higher excitation orders depend on the trap geometry. Moreover, we can easily see, that occasional degeneracies must arise for specific aspect ratios. For example, when $\omega_+(2,0) = 2\omega(2,2)$, we derive from (50.63) the condition $\lambda = \sqrt{16/7}$, and when $\omega_+(2,0) = 2\omega_-(2,0)$, we derive $\lambda = \frac{1}{6}\sqrt{77 + 5\sqrt{145}}$.

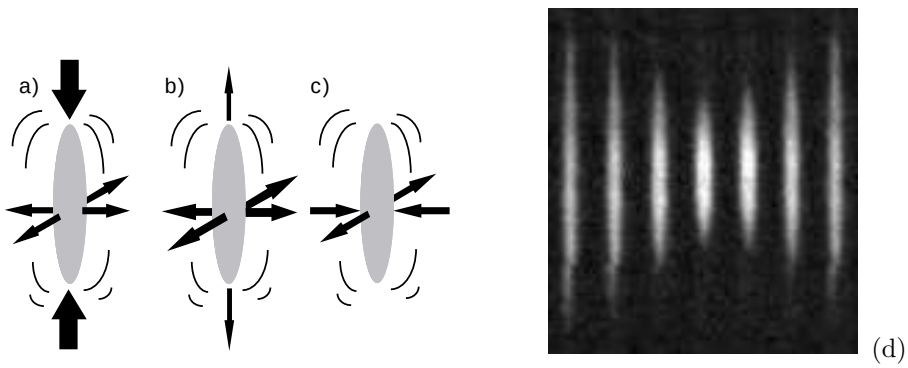

Figure 50.5: Normal modes of a BEC. (a) Shape oscillation, (b) breathing oscillation, and (c) quadrupole oscillation. (d) Non-destructive measurements of quadrupolar vibrations of a BEC [875].

50.4.2.2 Quantum depletion

Following Bogolubov's theory the *quantum depletion* is given by,

$$\frac{\delta N}{N} = \frac{1}{N}\sum_{\mathbf{k}} \int d^3r |v_{\mathbf{k}}(\mathbf{r})|^2 \ . \tag{50.64}$$

50.4.2.3 Fluctuations in BECs

Fluctuations in condensates are reduced as compared to thermal ensembles. Non-linearities are always very sensitive to fluctuations (see the laser). Therefore, we have to look at closer at collisions. For 3-body decay in a thermal source, $\langle\rho(\mathbf{r})^3\rangle \sim 6\langle\rho(\mathbf{r})\rangle^3$, and in a coherent source: $\langle\rho(\mathbf{r})^3\rangle \sim \langle\rho(\mathbf{r})\rangle^3$ [141, 864].

50.4.3 Exercises

50.4.3.1 Ex: Sound velocity in the Thomas-Fermi regime

Consider a condensate of $N = 10^5$ ^{87}Rb atoms confined to an isotropic harmonic potential with secular frequency $\omega_{\rm trp} = (2\pi)$ 50 Hz. Remember $a_s = 110 a_{\rm B}$ and use the Thomas-Fermi approximation.
a. Evaluate the chemical potential.
b. Calculate the sound velocity at the center of the condensate.

50.5 Hydrodynamics and the propagation of sound

The question arises how the elementary excitations relate to the phenomenon of *sound*, well known from the hydrodynamic theory of superfluid ^{4}He proposed by Landau [553]. The *hydrodynamic regime* is characterized by the dominance of collisions [8]. On the other hand, Bogolubov's theory describes elementary excitations in the *collisionless regime*, where *quasi-particles* do not interact [9]. There is, therefore, a great motivation to study excitations with condensates in a very dense regime, where one can expect to recover predictions of hydrodynamic theory.

The hydrodynamic regime is reached, when the *free path* of the particles is smaller than the wavelength of the sound, that is [10],

$$l_{\rm mfp} < \lambda/2\pi \ . \tag{50.65}$$

50.5.1 Zero, first and second sound

The occurrence of several types of sound was related by Tisza and London to the existence of superfluid and normal components in ^{4}He [692]. The *second sound* is a quantum phenomenon, where the heat transfer occurs as an *wave-like motion* instead of being diffusive. Heat takes the place of pressure in normal sound waves called *first sound*. This induces a very high thermal conductivity. At temperatures below the λ-point, ^{4}He has the highest known conductivity of all materials (a few hundred times higher than copper).

The *zero sound* was introduced by Landau to name quantum vibrations in Fermi quantum liquids. This sound can not be seen as a simple wave of compression and rarefaction. In gaseous condensates, the zero sound corresponds to the elementary excitation called *phonon-like*.

Finally, the excitation called *particle-like* or *ballistic*, observed in gaseous condensates has no correspondence in dense superfluids, since the mean free path there is too short. The various regimes accessible in condensed gasses are listed in the following table [24, 26, 385, 507, 843, 876, 875, 317]:

[8] Collisions prevent condensation, because they localize the particles. This is the reason for the large quantum depletion, which in ^{4}He is of the order of 10% and hides effects of quantum statistics. Quantum depletion prevents any form of long-range order, as this requires delocalization.

[9] Bogolubov's theory assumes that the only impact of collisions is to deform the dispersion relationship, keeping the collective modes orthogonal.

[10] Note the similarity to the Ioffe-Regel criterion.

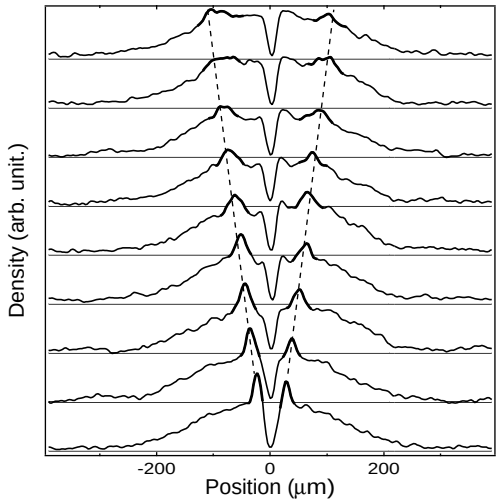

Figure 50.6: (code) Consecutive measurements of the BEC density profile showing the propagation of zero sound. The sound was excited by a blue-detuned laser tuned focused into the middle of the BEC (lower curve). The other curves show how the perturbation propagates towards the edges of the BEC.

regime	range scale	energy range	condensate	thermal cloud
collision-less	$k^{-1} < \xi < l_{\rm mfp}$	$\frac{\hbar^2}{2ml^2_{\rm mfp}} < gn_0 < \frac{\hbar^2 k^2}{2m}$	ballistic	ballistic
collision-less	$\xi < k^{-1} < l_{\rm mfp}$	$\frac{\hbar^2}{2ml^2_{\rm mfp}} < \frac{\hbar^2 k^2}{2m} < gn_0$	zero sound	ballistic
hydrodynamic	$\xi < l_{\rm mfp} < k^{-1}$	$\frac{\hbar^2 k^2}{2m} < \frac{\hbar^2}{2ml^2_{\rm mfp}} < gn_0$	second sound	first sound

(50.66)

normal modes			$qR \ll 1$
macroscopic			$qa \ll 1$
beyond Bogolubov			$qa > 1$
superfluid (TF limit, LDA)	$E_{\rm self} \gg E_{\rm kin}$	$8\pi Na \gg a_{\rm ho}$	$a_{\rm ho} \gg \xi$
???	$E_{\rm self} \ll E_{\rm kin}$	$8\pi Na \ll a_{\rm ho}$	$a_{\rm ho} \ll \xi$
collision-less	$\gamma_{\rm coll} \ll \frac{\hbar q^2}{2m}$		$ql_{\rm mfp} \ll 1$
hydrodynamic	$\gamma_{\rm coll} > \frac{\hbar q^2}{2m}$		$ql_{\rm mfp} > 1$

(50.67)

With $l_{\rm mfp} \simeq 1/n_{\rm therm}\sigma$. Typical values are,

$$\begin{aligned}
&a = 0..1000 a_{\rm B} && = 0..50\,{\rm nm} \\
&n^{-1/3} && = 20..200\,\mu{\rm m} \\
&2\pi/q && = 0.2..\infty\,\mu{\rm m} \\
&\xi = \sqrt{8\pi n a}^{-1} && = 0.03..30\,\mu{\rm m} \\
&a_{\rm ho} = \sqrt{\hbar/m\omega_{\rm trp}} && = 0.1..3\,\mu{\rm m} \\
&2\pi/k_F = 2\pi a_{\rm ho}(48N)^{-1/6} && = 30..70\,\mu{\rm m}
\end{aligned} \tag{50.68}$$

The various regimes of sound are distinguished by frequency shifts and damping rates of the collective modes, which depend on the density (determining the mean-field energy and the mean free path) and the temperature (controlling the ratio between condensed and normal fraction). The quantity

$$\xi \equiv \frac{1}{\sqrt{8\pi a_s n}}\ , \tag{50.69}$$

is called *healing length*.

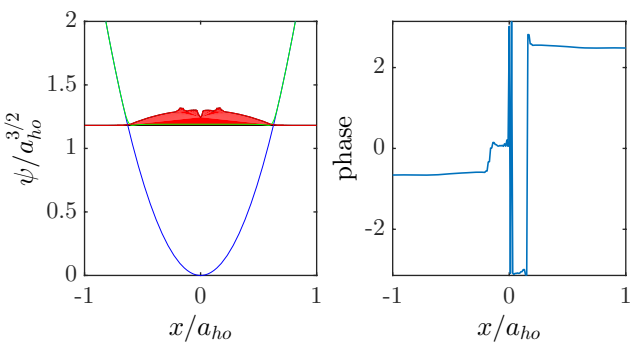

Figure 50.7: Simulation of the propagation of sound toward the edges of the condensate.

50.6 Momentum representation

We showed in Sec. 23.5.7, that the wavefunctions can be represented in the spatial or the momentum domain. These notions can be extended to the second quantization procedure by generalizing the equations (23.214),

$$\boxed{\hat{a}_{\mathbf{k}} \equiv \frac{1}{\sqrt{(2\pi)^3 V}} \int \hat{\psi}(\mathbf{r}) e^{-\imath \mathbf{k}\cdot\mathbf{r}} d^3r \quad , \quad \hat{\psi}(\mathbf{r}) \equiv \sqrt{\frac{V}{(2\pi)^3}} \int \hat{a}_{\mathbf{k}} e^{\imath \mathbf{k}\cdot\mathbf{r}} d^3k} \ . \tag{50.70}$$

Differently from (23.214) we chose here a normalization, which leaves the field operators $a_{\mathbf{k}}$ without unit.

50.6.1 Confined particles

In the case of confined atoms, $\mathcal{H} = \mathcal{H}_{\rm cm} + V_{\rm trp}(\mathbf{r}) + \mathcal{H}_{\rm self}$, we get sharp eigenvalues,

$$\hat{a}_{\mathbf{k}} = \frac{1}{V}\sum_{\mathbf{k}'} \hat{a}_{\mathbf{k}'}\delta^{(3)}(\mathbf{k}-\mathbf{k}') \ . \tag{50.71}$$

We insert this in equation (50.70),

$$\begin{aligned}\hat{\psi}(\mathbf{r}) &= \sqrt{\tfrac{1}{(2\pi)^3 V}}\sum_{\mathbf{k}'} \hat{a}_{\mathbf{k}'}\int \delta^{(3)}(\mathbf{k}-\mathbf{k}')e^{\imath\mathbf{k}\cdot\mathbf{r}}d^3k \\ &= \sqrt{\tfrac{1}{(2\pi)^3 V}}\sum_{\mathbf{k}'} \hat{a}_{\mathbf{k}}e^{\imath\mathbf{k}\cdot\mathbf{r}} = \sum_{\mathbf{k}} u_{\mathbf{k}}(\mathbf{r})\hat{a}_{\mathbf{k}} \ ,\end{aligned} \tag{50.72}$$

thus making an expansion of the condensate into plane waves,

$$u_{\mathbf{k}}(\mathbf{r}) = \tfrac{1}{\sqrt{(2\pi)^3 V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{50.73}$$

which is particularly adapted to the 3D box potential, $V_{\rm trp}(\mathbf{r}) \equiv \infty$ se $r > R$. Also, we calculate,

$$\hat{a}_{\mathbf{k}} = \sqrt{\tfrac{1}{(2\pi)^3 V}}\int \hat{\psi}(\mathbf{r})e^{-\imath\mathbf{k}\cdot\mathbf{r}}d^3r = \int \hat{\psi}(\mathbf{r})u^*_{\mathbf{k}}(\mathbf{r})d^3\mathbf{r} \ . \tag{50.74}$$

We obtain the observable commutation rules from (50.5),

$$[\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = \delta_{\mathbf{k}\mathbf{k}'} \quad , \quad [\hat{a}_{\mathbf{k}}, \hat{a}_{\mathbf{k}'}] = 0 \quad , \quad \hat{N} = \sum_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}}\hat{a}_{\mathbf{k}} \ . \tag{50.75}$$

Using the following mathematical relationships,

$$\tfrac{1}{(2\pi)^3 V}\sum_{\mathbf{k}} e^{-\imath\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} = \delta^3(\mathbf{r}-\mathbf{r}') \quad \text{and} \quad \tfrac{1}{(2\pi)^3 V}\int d^3\mathbf{r}e^{\imath(\mathbf{k}'-\mathbf{k})\cdot\mathbf{r}} = \delta_{\mathbf{k},\mathbf{k}'} \ , \tag{50.76}$$

and easy to show for plane waves,

$$\sum_{\mathbf{k}} u^*_{\mathbf{k}}(\mathbf{r})u_{\mathbf{k}}(\mathbf{r}') = \delta^3(\mathbf{r}-\mathbf{r}') \quad \text{and} \quad \int u^*_{\mathbf{k}}(\mathbf{r})u_{\mathbf{k}'}(\mathbf{r})d^3\mathbf{r} = \delta_{\mathbf{k}\mathbf{k}'} \ . \tag{50.77}$$

In Exc. 50.6.4.1 we will check the validity of the commutation rules (50.75), and in Exc. 50.6.4.2 we derive the following representation of the Hamiltonian:

$$\boxed{\begin{aligned}\mathcal{H} &= \int d^3r\hat{\psi}^\dagger(\mathbf{r})\left(-\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp}(\mathbf{r})\right)\hat{\psi}(\mathbf{r}) \\ &\quad + \frac{g}{2}\int d^3r\int d^3r'\hat{\psi}^\dagger(\mathbf{r})\hat{\psi}^\dagger(\mathbf{r}')\delta(\mathbf{r}-\mathbf{r}')\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r}) \\ &= \sum_{\mathbf{k}}\frac{\hbar^2\mathbf{k}^2}{2m}\hat{a}^\dagger_{\mathbf{k}}\hat{a}_{\mathbf{k}} + \sum_{\mathbf{k},\mathbf{k}'}\hat{a}^\dagger_{\mathbf{k}}V_{\mathbf{k},\mathbf{k}'}\hat{a}_{\mathbf{k}'} + \frac{g}{2}\sum_{\mathbf{k},\mathbf{k}',\mathbf{k}''}\hat{a}^\dagger_{\mathbf{k}}\hat{a}^\dagger_{\mathbf{k}'}\hat{a}_{\mathbf{k}''}\hat{a}_{\mathbf{k}+\mathbf{k}'-\mathbf{k}''}\end{aligned}} \ , \tag{50.78}$$

with the abbreviation,

$$V_{\mathbf{k},\mathbf{k}'} = \int u^*_{\mathbf{k}}(\mathbf{r}) V_{\rm trp}(\mathbf{r}) u_{\mathbf{k}'}(\mathbf{r}) d^3\mathbf{r} = \tfrac{1}{(2\pi)^3} \int V_{\rm trp}(\mathbf{r}) e^{\imath(\mathbf{k}'-\mathbf{k})\mathbf{r}} d^3\mathbf{r} \ . \tag{50.79}$$

The equation of motion for the momentum wavefunction now becomes,

$$\imath\hbar \frac{\partial}{\partial t} \hat{a}_{\mathbf{k}} = [\hat{a}_{\mathbf{k}}, \mathcal{H}] = \frac{\hbar^2 \mathbf{k}^2}{2m} \hat{a}_{\mathbf{k}} + \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \hat{a}_{\mathbf{k}'} + g \sum_{\mathbf{k}',\mathbf{k}''} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}''} \hat{a}_{\mathbf{k}+\mathbf{k}'-\mathbf{k}''} \ . \tag{50.80}$$

50.6.1.1 Harmonically confined particles

In harmonic traps, $V_{\rm trp}(r) = \frac{m}{2}\omega^2_{\rm trp} r^2$, the motion can be canonically quantized,

$$\hat{a} = \frac{1}{\sqrt{2}} \left(\frac{\hat{r}}{a_{\rm trp}} \mp \imath a_{\rm trp} \hat{p} \right) \qquad , \qquad \mathcal{H}_{\rm cm} = \sum_{\mathbf{k}} \hbar\omega_{\rm trp} \hat{a}^\dagger_{\mathbf{k}} \hat{a}_{\mathbf{k}} \ , \tag{50.81}$$

with the size of the ground state,

$$a_{\rm trp} \equiv \sqrt{\frac{\hbar}{m\omega_{\rm trp}}} \ . \tag{50.82}$$

As an alternative notation we could introduce,

$$|\mathbf{r}\rangle \equiv \hat{\psi}^\dagger(\mathbf{r}) \qquad \text{and} \qquad |\mathbf{k}\rangle \equiv \hat{a}^\dagger_{\mathbf{k}} \ . \tag{50.83}$$

Hence, just considering the ground state of the trap, that is, assuming that the atomic motion be frozen, our Hamiltonian becomes:

$$\mathcal{H}_{\rm cm} + \mathcal{H}_{\rm self} = \hbar\omega_{\rm trp} \hat{a}^\dagger \hat{a} + \frac{g}{2} \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} \ . \tag{50.84}$$

50.6.2 Thomas-Fermi limit

In the limit of negligible kinetic energy (that is, in the middle of a large condensate) with the analytical form of the condensate wavefunction,

$$\hat{\psi}(\mathbf{r}) \propto \sqrt{n_0} \left(1 - \frac{\mathbf{r}^2}{\mathbf{r}_0^2} \right) \ , \tag{50.85}$$

the transformation (50.70) allows us to derive an expression for the momentum distribution,

$$|a(\mathbf{k})| \propto \frac{J_1(\mathbf{k}\cdot\mathbf{r}_0)}{(\mathbf{k}\cdot\mathbf{r}_0)^2} \ . \tag{50.86}$$

50.6.2.1 Width of the momentum distribution

It is interesting to compare the size of an ideal gas condensate with the size of an interacting condensate. We can express the Thomas-Fermi radius as,

$$\Delta r_{\rm TF} = a_{\rm trp} \sqrt{\frac{\mu}{\hbar\omega_{\rm trp}}} \ . \tag{50.87}$$

The Heisenberg limit requires,

$$\Delta p_{\rm TF} = \frac{\hbar}{\Delta r_{\rm TF}} \ . \tag{50.88}$$

Since $\sqrt{\mu/\hbar\omega_{\rm trp}} > 1$, the interaction increases the volume of the condensate, but restricts the distribution of its velocities. For a hypothetical thermal Boltzmann gas having the same temperature,

$$\Delta r_{\rm therm} = a_{\rm trp}\sqrt{\frac{k_{\rm B}T}{\hbar\omega_{\rm trp}}} \qquad \text{and} \qquad \Delta p_{\rm therm} = \frac{\hbar}{a_{\rm trp}}\sqrt{\frac{k_{\rm B}T}{\hbar\omega_{\rm trp}}} \ . \tag{50.89}$$

The thermal cloud *is not at the Heisenberg limit*, because $\sqrt{k_{\rm B}T/\hbar\omega_{\rm trp}} > 1$.

These relationships were experimentally confirmed [885] by measurements of the velocity distributions of condensates using a Bragg spectroscopy technique (see Sec. 52.2). It is interesting to note that the measured widths of velocity distributions were *lower than the photonic recoil limit*, $\hbar k/m \simeq 30$ mm/s for ^{87}Rb.

50.6.3 Master equation approach

The Hamiltonian that describes a BEC in second quantization in an orthonormal set of energy eigenfunctions reads:

$$\begin{aligned}
\mathcal{H} &= \sum\nolimits_{i,j} \mathcal{H}^{(ij)}_{\rm atom}\hat{a}^\dagger_i\hat{a}_j + \sum_{i,j,k,l} \tfrac{1}{2}W^{(ijkl)}\hat{a}^\dagger_i\hat{a}^\dagger_j\hat{a}_k\hat{a}_l \\
\mathcal{H}^{(ij)}_{\rm atom} &= \langle\phi_i|\tfrac{1}{2m}\mathbf{p}^2 + V_{\rm trp}(\mathbf{r})|\phi_j\rangle \\
W^{(ijkl)} &= g\int \phi_i(\mathbf{r})\phi_j(\mathbf{r})\phi_k(\mathbf{r})\phi_l(\mathbf{r})d^3r \ .
\end{aligned} \tag{50.90}$$

The inclusion of spontaneous processes (one-body-loss, dephasing) requires a master equation including a *Lindblad term* within a density matrix formalism. The von Neumann equation for the density operator reads:

$$\begin{aligned}
\frac{d}{dt}\hat{\rho} &= -\imath[V,\hat{\rho}] + \mathcal{L}\hat{\rho} \\
\mathcal{L}_{\text{one-body loss}} &\equiv \kappa(2\hat{a}\hat{\rho}\hat{a}^\dagger - \hat{a}^\dagger\hat{a}\hat{\rho} - \hat{\rho}\hat{a}^\dagger\hat{a}) \\
\mathcal{L}_{\text{one-body feeding}} &\equiv \kappa(2 + 2\hat{a}^\dagger\hat{\rho}\hat{a} - \hat{a}\hat{a}^\dagger\hat{\rho} - \hat{\rho}\hat{a}\hat{a}^\dagger) \\
\mathcal{L}_{\text{two-body loss}} &\equiv \kappa\left(2\hat{a}^2\hat{\rho}\hat{a}^{\dagger 2} - \hat{a}^{\dagger 2}\hat{a}^2\hat{\rho} - \hat{\rho}\hat{a}^{\dagger 2}\hat{a}^2\right) \ .
\end{aligned} \tag{50.91}$$

50.6.4 Exercises

50.6.4.1 Ex: Commutators in momentum space

Demonstrate the validity of the commutation rules (50.75).

50.6.4.2 Ex: Commutators in momentum space

Derive the representation (50.78) of the Hamiltonian.

50.7 Condensates at finite temperature

50.7.1 Ballistic expansion of a bosonic gas

As discussed in Sec. 49.6, the atomic density distributions are revealed through their interaction with a laser beam. The problem with imaging a confined condensate is, on the one hand, its very high optical density, which inhibits the penetration of resonant light and, on the other hand, its very small size, which is often below the diffraction limit and prevents its optical resolution. As discussed in Sec. 49.6, both problems can be avoided by the time-of-flight imaging technique, which consists in quickly switching off the trap and dropping the atomic cloud (see Fig. 49.30). If the switching-off process is fast enough, the potential energy is lost, but in the course of ballistic expansion, the self-energy is transformed into kinetic energy. Both the self-energy transformed to kinetic energy and the inherent initial kinetic energy contribute to blow up the size of the atomic cloud, so that the density rapidly decreases. After a few 10 ms, when the optical density is sufficiently low (on the order of 1), the cloud can be imaged via its absorption of a resonant laser beam. The condensate, which is about 10 times denser than the thermal cloud, has a much larger repulsive self-energy. When the condensate is suddenly released from its trap, its explosion is accelerated by this self-energy, and the acceleration is faster in those directions, where the confining potential was stronger [449, 159]. Therefore, the aspect ratio of the condensate's shape is inverted during the flight time [510, 159]. In contrast, the self-energy of the thermal cloud is relatively insignificant. Therefore, its spatial density after a time of free expansion reflects the pure velocity distribution of the atomic cloud while it was trapped. This allows the interpretation of the spatial distribution of the expanded cloud in terms of a *temperature* of the trapped cloud.

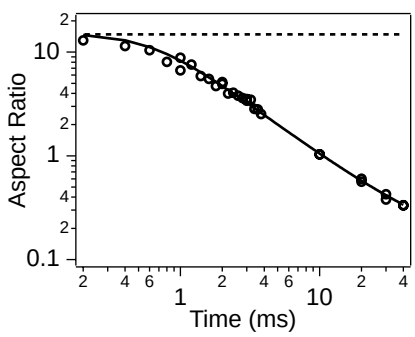

Figure 50.8: Inversion of aspect ratio during time-of-flight. The frequencies of the harmonic trap were $\omega_r = (2\pi) \cdot 248$ Hz and $\omega_r = (2\pi) \cdot 16$ Hz [510].

50.7.1.1 Popov approximation

The Popov decomposition separates the condensed part, described by a c-number $\phi \equiv \langle \hat{\psi} \rangle$ and normalized to the number of condensed atoms N_0 from the thermal part

$\tilde{\psi} \equiv \hat{\psi} - \phi$, which keeps track of the quantum nature of the Bose-gas [268],

$$\begin{aligned}
\mathcal{K} &= \mathcal{K}_0 + \mathcal{K}_1 + \mathcal{K}_1^\dagger + \mathcal{K}_2 \\
\mathcal{K}_0 &= \int d^3\mathbf{r}\phi^*(\mathbf{r}) \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp}(\mathbf{r}) + \frac{g}{2}|\phi|^2 - \mu \right) \phi(\mathbf{r}) \\
\mathcal{K}_1 &= 0 \qquad \text{if} \qquad [\mathcal{L} - gn_0(\mathbf{r})]\phi(\mathbf{r}) = 0 \\
\mathcal{K}_2 &= \int d^3r \left[\tilde{\psi}^+(\mathbf{r})\mathcal{L}\tilde{\psi}(\mathbf{r}) + \frac{g}{2}\left(\phi(\mathbf{r})^2\tilde{\psi}^+(\mathbf{r})\tilde{\psi}^+(\mathbf{r}) + \phi^*(\mathbf{r})^2\tilde{\psi} + (\mathbf{r})\tilde{\psi}(\mathbf{r}) \right) \right] \\
\mathcal{L} &\equiv -\frac{\hbar^2}{2m}\nabla^2 + V_{\rm trp}(\mathbf{r}) - \mu + 2gn(\mathbf{r}) \\
n(\mathbf{r}) &= n_0(\mathbf{r}) + n_T(\mathbf{r}) = |\phi(\mathbf{r})|^2 + \langle \tilde{\psi}^\dagger(\mathbf{r})\tilde{\psi}(\mathbf{r}) \rangle \ .
\end{aligned} \tag{50.92}$$

We perform the Bogolubov transform to the diagonalized Hamiltonian,

$$\begin{aligned}
\mathcal{K}_{Popov} &= \mathcal{K}_0 + \sum\nolimits_j \varepsilon_j \hat{b}_j^+ \hat{b}_j \\
\tilde{\psi}(\mathbf{r}) &= \sum\nolimits_j u_j(\mathbf{r})\hat{b}_j - v_j^*(\mathbf{r})\hat{b}_j^+ \\
\delta_{jk} &= \int d^3r \left(u_j u_k^* - v_j v_k^* \right) \\
\delta_{jk} &= [\hat{b}_j, \hat{b}_k^+] \ .
\end{aligned} \tag{50.93}$$

This yields a set of equations for elementary excitations (quasi-particle excitations in a diagonalized energy space),

$$\begin{aligned}
N_j &= [\exp(\varepsilon_j/k_{\rm B}T) - 1]^{-1} \\
n_T(\mathbf{r}) &= \sum\nolimits_j \left[\left(|u_j|^2 + |v_j|^2 \right) N_j + |v_j|^2 \right] \\
\mathcal{L}u_j(\mathbf{r}) - gn_0(\mathbf{r})v_j(\mathbf{r}) &= \varepsilon_j u_j(\mathbf{r}) \ , \\
\mathcal{L}v_j(\mathbf{r}) - gn_0(\mathbf{r})u_j(\mathbf{r}) &= -\varepsilon_j v_j(\mathbf{r}) \ .
\end{aligned} \tag{50.94}$$

The quantum depletion at $T = 0$ [last term in the density $n(\mathbf{r})$] may be neglected. In this zero-temperature limit, the equations simplify to yield the Gross-Pitaevskii equation. We may separate these equations using auxiliary functions [461],

$$\begin{aligned}
\tilde{\psi}_j^{(\pm)}(\mathbf{r}) &\equiv u_j(\mathbf{r}) \pm v_j(\mathbf{r}) \\
\hat{h}_0 &\equiv \mathcal{L} - gn_0(\mathbf{r}) \\
\hat{h}_0\tilde{\psi}_j^{(+)}(\mathbf{r}) &= E_j\tilde{\psi}_j^{(-)}(\mathbf{r}) \ .
\end{aligned} \tag{50.95}$$

The eigenvalue equations that one gets after substituting (III.2.5) into (III.2.4) may be solved by expanding in a set of eigenfunctions of $\hat{h}_0$:

$$\begin{aligned}
\tilde{\psi}_j^{(\pm)}(\mathbf{r}) &\equiv \sum\nolimits_\alpha c_\alpha^{(j)}\phi_\alpha(\mathbf{r}) \\
\hat{h}_0\phi_\alpha(\mathbf{r}) &\equiv \varepsilon_\alpha\phi_\alpha(\mathbf{r}) \\
\sum\nolimits_\beta (M_{\alpha\beta} + \varepsilon_\alpha\delta_{\alpha\beta})\varepsilon_\beta c_\alpha^{(j)} &= E_j^2 c_\alpha^{(j)} \\
M_{\alpha\beta} &= 2g\int \phi_\alpha^*(\mathbf{r})n_0(\mathbf{r})\phi_\beta(\mathbf{r})d^3r \ .
\end{aligned} \tag{50.96}$$

50.7.2 Hartree-Fock approach

50.7.2.1 Two-gas model for $T > 0$

The two phases of a condensate above $T = 0$ have a specific interdependence, which makes it possible to treat the problem with an approximation, where only the condensed part influences the non-condensed and not vice versa [267]. The HFB equation is solved for the condensed part alone, assuming $n_{\rm therm} = 0$. The condensate wavefunction and the chemical potential are derived from that, f.e. using numerical methods like the method of steepest descent. The effective potential for the thermal cloud in the presence of a condensate is:

$$V_{1,\rm eff}(\mathbf{r}_1) = V_{1,\rm trap}(\mathbf{r}_1) + g_1|\psi_1(\mathbf{r}_1)|^2 \ . \tag{50.97}$$

Next, we diagonalize the Schrödinger equation:

$$[-\nabla_1^2 + V_{1,\rm eff}(\mathbf{r}_1)]\psi_{1,j}(\mathbf{r}_1) = 2E_{1,j}\psi_{1,j}(\mathbf{r}_1) \ , \tag{50.98}$$

maintaining the normalization,

$$1 = \int |\psi_{1,j}(\mathbf{r}_1)|^2 d^3\mathbf{r}_1 \ . \tag{50.99}$$

This provides us with the energy eigenvalues of the excited trap states and their eigenfunctions. One can f.e. guess an eigenvalue and numerically solve the Schrödinger equation using Runge-Kutta integration routines. The eigenfunction will probably diverge. In this case, we vary the eigenvalue until the solution converges.

Finally, we can calculate the thermal density distribution:,

$$\begin{aligned} N_j &\equiv [\exp((E_{1,j} - \mu_1)/k_{\rm B}T_1) - 1]^{-1} \\ n_{\rm therm}(\mathbf{r}_1) &= \sum\nolimits_j N_j|\psi_{1,j}(\mathbf{r}_1)|^2 \ , \end{aligned} \tag{50.100}$$

and all thermodynamic potentials, as shown in Sec. 29.3.2.

A more sophisticated method uses self-consistent recursion [461]. Here, the thermal density is plugged back into the HFB equation, and the whole procedure is repeated until it converges.

50.7.2.2 Hartree-Fock approximation

We have already seen that, inside a trap the condensate occupies the lowest vibrational level, whereas the atoms of the thermal gas are distributed among all levels. The trapping potential is often harmonic, $U_{\rm trp}(\mathbf{r}) = \frac{m}{2}\omega_r^2 r^2$, with secular frequencies ω_r typically on the order of several tens or hundreds of Hz. The spatial (radial) extent of the vibration levels varies a lot with their quantum number, $r_j = \sqrt{(2j+1)\hbar/m\omega_r}$. This naturally produces a *separation of the thermal (or normal) and condensate fractions* at $T > 0$, which does not exist for a homogeneous gas and which allows (up to a certain degree) an individual treatment of the two fractions. The details of the interaction between the two fractions are very complicated and are still under intense theoretical investigation. However, to understand the shape of a trapped atomic cloud and other characteristics, we can use a simple approximate model [**?**, 461], assuming

that the condensate is only weakly disturbed by the thermal cloud. In contrast, the presence of the condensate dramatically modifies the potential for the thermal atoms. Therefore, we must *first* calculate the density of the condensate $n_0(\mathbf{r})$, *before* calculating that of the thermal cloud. If this procedure is applied iteratively, it is called *Hartree-Fock method*:

i. We start with $n_{\rm therm}(\mathbf{r}) = 0$;

ii. we solve the GPE $\left(-\frac{\hbar^2}{2m}\Delta + V_{\rm trp}(\mathbf{r}) - \mu + g\left[|\psi(\mathbf{r})|^2 + n_{\rm therm}(\mathbf{r})\right]\right)\psi(\mathbf{r})$ numerically with the steepest descent method, we derive μ and ψ, and also $n(\mathbf{r}) = |\psi(\mathbf{r})|^2 + n_{\rm therm}(\mathbf{r})$;

iii. assuming that collisions between atoms of the thermal cloud, the density of which is weak, can be neglected, we can view the cloud as an ideal gas in a potential modified by the strongly anharmonic mean field of the condensate, $V_{\rm trp}(\mathbf{r}) + 2gn(\mathbf{r})$, we calculate the thermal density $n'_{\rm therm}(\mathbf{r}) = \lambda_{\rm dB}^{-3} g_{3/2}\left(\exp\frac{V_{\rm trp}(\mathbf{r})-\mu+2gn(\mathbf{r})}{k_{\rm B}T}\right)$;

iv. we start over at (ii) using the new thermal density.

We can now calculate the total energy,

$$U = \int d^3r\left(\psi(\mathbf{r})\frac{-\hbar^2\nabla^2}{2m}\psi(\mathbf{r}) + V_{\rm trp}(\mathbf{r})n(\mathbf{r}) + \frac{g}{2}[2n(\mathbf{r})^2 - n_0(\mathbf{r})] - \frac{1}{h^3}\int d^3k\frac{\hbar^2k^2}{2m}n(\mathbf{r},\mathbf{k})\right) \tag{50.101}$$

$$= \int d^3\mathbf{r}\left(\psi(\mathbf{r})\frac{-\hbar^2\nabla^2}{2m}\psi(\mathbf{r}) + V_{\rm trp}(\mathbf{r})n(\mathbf{r}) + \frac{g}{2}[2n(\mathbf{r})^2 - n_0(\mathbf{r})] + \frac{3k_{\rm B}T}{2\lambda_{\rm dB}^3}g_{3/2}\left[\exp\frac{V_{\rm trp}(\mathbf{r})-\mu+2gn(\mathbf{r})}{k_{\rm B}T}\right]\right)$$

and other thermodynamic quantities.

50.7.3 Ideal gas limit

Consider the ideal gas in an isotropic harmonic potential. The excitation spectrum then takes the form:

$$f(\mathbf{k},\mathbf{r}) = n(\mathbf{k},\mathbf{r}) \tag{50.102}$$

$$\varepsilon_{\rm HF}(\mathbf{k},\mathbf{r}) = \mathcal{L}(\mathbf{k},\mathbf{r}) = \frac{\hbar^2\mathbf{k}^2}{2m} + V(\mathbf{r}) - \mu\ .$$

We can immediately calculate:

$$
\begin{aligned}
g &\longrightarrow 0 \\
\mu &\stackrel{g\to 0}{\longrightarrow} \tfrac{3}{2}\hbar\omega \\
\phi(\mathbf{r}) &\stackrel{g\to 0}{\longrightarrow} \frac{\sqrt{N_0}}{\pi^{3/4}a_{\rm trp}^{3/2}}\exp(-\frac{\mathbf{r}^2}{2a_{\rm trp}^2}) \\
E_{\rm kin} &= \int \phi(\mathbf{r})\frac{-\hbar^2\Delta}{2m}\phi(\mathbf{r})d^3r = -\tfrac{9}{4}N_0\hbar\omega \\
n_{\rm therm}(\mathbf{r}) &\stackrel{g\to 0}{\longrightarrow} \int f(\mathbf{r}\cdot\mathbf{k})d^3\mathbf{k} = \frac{1}{\lambda_{\rm dB}^3}g_{3/2}\left[\exp\left(\tfrac{V_{\rm trp}(\mathbf{r})-\mu}{k_{\rm B}T}\right)\right] \\
N_{\rm therm} &\stackrel{g\to 0}{\longrightarrow} \int n_{\rm therm}(\mathbf{r})d^3\mathbf{r} = \left(\frac{k_{\rm B}T}{\hbar\omega}\right)^3 g_3\left[\exp\left(\tfrac{\mu}{k_{\rm B}T}\right)\right] \\
U &\stackrel{g\to 0}{\longrightarrow} \int \varepsilon_{HF}f(\mathbf{r}\cdot\mathbf{k})d^3\mathbf{r}\cdot\mathbf{d}^3k = 3k_{\rm B}T\left(\frac{k_{\rm B}T}{\hbar\omega}\right)^3 g_4\left[\exp\left(\tfrac{\mu}{k_{\rm B}T}\right)\right] \ .
\end{aligned}
\tag{50.103}
$$

50.7.4 Exercises

50.7.4.1 Ex: Ballistic expansion of a condensate

Calculate the ballistic expansion of a ^{87}Rb BEC initially confined in a cylindrically symmetric trap with secular frequencies $\omega_z = 20\,\mathrm{Hz}$ and $\omega_r = 100\,\mathrm{Hz}$.

50.8 Numerical simulations of the Gross-Pitaevskii equation

To simulate the one-dimensional evolution of a wavepacket following the Gross-Pitaevskii equation,

$$
\imath\hbar\frac{\partial}{\partial t}\psi(z,t) = \left[\frac{-\hbar^2}{2m}\frac{d^2}{dz^2} + V_{\rm trp}(z) + |\psi(z,t)|^2\right]\psi(z,t) \ . \tag{50.104}
$$

we solve iteratively [744],

$$
\psi(z,t+dt) = \psi(z,t) + dt\dot{\psi}(z,t) \ . \tag{50.105}
$$

As initial state we choose, $\psi(z,0) = e^{-z^2/2\bar{z}^2}e^{\imath kz}$, where $k \equiv \sqrt{2mE}/\hbar$ is the wavevector.

The numerical propagation is conveniently performed using the *time-splitting spectral algorithm* [59, 58, 57, 338], which can be easily extended to two dimensions.

50.8.1 Crank-Nicholson-Crout algorithm

50.8.1.1 Crank-Nicholson-Crout algorithm for the time-dependent Schrödinger equation

The *Crank-Nicholson algorithm* goes as follows. The time-dependent Schrödinger equation in one dimension,

$$\frac{\partial}{\partial t}\psi(x,t) = \frac{\imath\hbar}{2m}\frac{\partial^2}{\partial x^2}\psi(x,t) - \frac{\imath V(x)}{\hbar}\psi(x,t) \tag{50.106}$$

is a parabolic partial differential equation. We usually seek a solution on an interval $x \in [a,b]$ and $t > 0$. The solution is uniquely determined from boundary conditions: $\psi(a,t) = \psi(b,t) = 0$ and $\psi(x,0) = g(x)$. One method for numerical solution solves for the values of the wavefunction on a regular grid of dimension $h = (b-a)/N_x$ in x and τ in t:,

$$\psi_j^k = \psi(a + jh, k\tau) \ . \tag{50.107}$$

The derivatives are replaced by simple finite differences. The r.h.s. of the equation at the grid point (i,j) is then,

$$\frac{\imath\hbar}{2mh^2}\left(\psi_{j+1}^k - 2\psi_j^k + \psi_{j-1}^k\right) - \frac{\imath V(a+jh)}{\hbar}\psi_j^k = \sum_{m=0}^{N} \imath H_{jm}\psi_j^k \ , \tag{50.108}$$

where H is a real symmetric tridiagonal matrix (provided $V(x)$ is real). The l.h.s. of the equation can be replaced either by a forward or backward difference,

$$\frac{\psi_j^{k+1} - \psi_j^k}{\tau} \qquad \text{or} \qquad \frac{\psi_j^k - \psi_j^{k-1}}{\tau} \ , \tag{50.109}$$

which, when combined with the r.h.s. gives the explicit algorithm,

$$\psi^{k+1} = (1 + \imath H\tau)\psi^k \qquad \text{or} \qquad \psi^k = (1 - \imath H\tau)\psi^{k+1} \ . \tag{50.110}$$

The Crank Nicholson Algorithm averages both,

$$(1 - \imath H\tau/2)\psi^{k+1} = (1 + \imath H\tau/2)\psi^k \ . \tag{50.111}$$

This method is a second order algorithm in t, i.e. the discretization error decreases as τ^2. The finite difference representation of the second derivative d^2/dx^2 is also good to second order in h^2. The Crank-Nicholson Algorithm also gives a unitary evolution in time. That is especially useful for quantum mechanics where unitarity assures that the normalization of the wavefunction is unchanged over time. The algorithm steps the solution forward in time by one time unit, starting from the initial wavefunction at $t = 0$. According to the Crank-Nicholson scheme, the time stepping process is half explicit and half implicit. The implicit part involves solving a tridiagonal system. That solution is accomplished by Crout reduction, a direct method related to Gaussian elimination and LU decomposition.

To simplify the algorithm we have chosen units in which the Planck constant $\hbar = 1$, time step $\tau = 1$ and the spatial separation $h = 1$. This can always be arranged by an appropriate redefinition of mass and potential: $m = m_{SI}\ h^2/\tau\hbar$ and $V = V_{SI}\ \tau/h$.

50.8.1.2 Crank-Nicholson algorithm for the time-dependent Gross-Pitaevskii equation

The Crank-Nicholson algorithm [6],

$$\frac{\imath\left(\varphi_j^{n+1}-\varphi_j^n\right)}{\Delta} = -\frac{\varphi_{j+1}^{n+1}-2\varphi_j^{n+1}+\varphi_{j-1}^{n+1}+\varphi_{j+1}^n-2\varphi_j^n+\varphi_{j-1}^n}{2h^2} + \frac{1}{2}\left(\frac{c(x_j)^2}{4}+n\frac{|\varphi_j^n|^2}{(x_j)^2}\right)\left(\varphi_j^{n+1}+\varphi_j^n\right) . \tag{50.112}$$

Introducing abbreviations,

$$B(\varphi_j^{n+1}-\varphi_j^n) = -A\left(\varphi_{j+1}^{n+1}-2\varphi_j^{n+1}+\varphi_{j-1}^{n+1}+\varphi_{j+1}^n-2\varphi_j^n+\varphi_{j-1}^n\right)+C_j^n\left(\varphi_j^{n+1}+\varphi_j^n\right) . \tag{50.113}$$

Can be rewritten as,

$$A\varphi_{j+1}^{n+1}+\left(-2A+B-C_j^n\right)\varphi_j^{n+1}+A\varphi_{j-1}^{n+1} = -A\varphi_{j+1}^n+\left(2A+B+C_j^n\right)\varphi_j^n-A\varphi_{j-1}^n = X_j^n . \tag{50.114}$$

The set of equations,

$$\begin{pmatrix} -2A-B-C_1^n & A & 0 & \cdots & 0 \\ A & -2A-B-C_2^n & A & \cdots & 0 \\ 0 & A & -2A-B-C_3^n & \ddots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & A & -2A-B-C_j^n \end{pmatrix} \begin{pmatrix} \varphi_1^{n+1} \\ \varphi_2^{n+1} \\ \varphi_3^{n+1} \\ \vdots \\ \varphi_j^{n+1} \end{pmatrix} = \begin{pmatrix} X_1^n \\ X_2^n \\ X_3^n \\ \vdots \\ X_j^n \end{pmatrix} \tag{50.115}$$

can be solved by inverting tridiagonal matrix. Set $\varphi_0^{n+1}=\varphi_{J+1}^{n+1}=0$. Run a loop $j=1,..,J$. Assume given $\varphi_1^{n+1}=\varphi_j^{n+1}$,

$$\varphi_{j+1}^{n+1} = \frac{X_j^n}{A}+\frac{2A-B+C_j^n}{A}\varphi_j^{n+1}-\varphi_{j-1}^{n+1} . \tag{50.116}$$

50.8.2 Time-splitting spectral algorithm: Coherent propagation

We write the one-dimensional GPE in the form,

$$\imath\hbar\frac{\partial\psi(x,t)}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2\psi(x,t)+V(x)\psi(x,t)+\frac{4\pi\hbar^2 a_s}{m(2r_h)^2}|\psi(x,t)|^2\psi(x,t) \tag{50.117}$$

for $a<x<b$. Choose periodic boundary conditions, $\psi(a,t)=\psi(b,t)$ and $\psi_x(a,t)=\psi_x(b,t)$. Various methods are known to solve the GPE numerically, such as the *Crank-Nicholson algorithm*. The *time-splitting spectral algorithm* (TSSA) consists in solving the first and the second of the following equations in two distinct steps [59, 58, 57, 338],

$$\frac{\partial\psi(x,t)}{\partial t} = -\imath\frac{V(x)}{\hbar}\psi(x,t)-\imath\frac{g_{1D}}{\hbar}|\psi(x,t)|^2\psi(x,t) \tag{50.118}$$
$$\frac{\partial\psi(x,t)}{\partial t} = i\frac{\hbar}{2m}\psi_{xx}(x,t) ,$$

i.e. we discretize in space using $x = a + j(b-a)/M$ and $k = 2\pi l/(b-a)$ such that $k\,(x-a) = 2\pi l j/M$. We propagate half the way, $\Delta t/2$, in time,

$$\varphi_x \equiv e^{-\frac{\imath}{\hbar}(V(x)+g_{1D}|\psi(x,t)|^2)\frac{\Delta t}{2}}\psi(x,t) \tag{50.119}$$

for $j = 0, .., M-1$. Now we propagate the spectral components, $(\mathcal{F}\varphi)_k \equiv \sum_{j=0}^{M-1}\varphi_x e^{-2\pi\imath l j/M}$, in momentum space and transform back, $(\mathcal{F}^{-1}\varphi)_x \equiv M^{-1}\sum_{l=-M/2}^{M/2-1}\varphi_k e^{2\pi\imath l j/M}$,

$$\phi_x \equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi)_k\right] \ . \tag{50.120}$$

for $l = -M/2, .., M/2-1$. Finally, we propagate the remaining time, $\Delta t/2$,

$$\psi(x, t+dt) = e^{-\frac{\imath}{\hbar}(V(x)+g_{1D}|\phi_x|^2)\frac{\Delta t}{2}}\phi_x \ . \tag{50.121}$$

Compared to the Crank-Nicholson algorithm time-splitting spectral algorithm has several advantages:

- TSSA is much much faster, especially, for large arrays;
- No divergence, perfect reversibility;
- Imaginary version yields same density shape as steepest descent.

But there are problems:

- The coherent version changes shape, maybe it's due to ifft(fft(x))!=x;
- The imaginary version mixes up real and imag parts;
- Don't know how to generalize to coupled GPEs.

50.8.2.1 Time-splitting spectral algorithm for coupled GPEs

Write the one-dimensional GPE in the form,

$$\begin{aligned}
\imath\hbar\frac{\partial\psi_1(x,t)}{\partial t} &= -\frac{\hbar^2}{2m}\nabla^2\psi_1(x,t) + V(x)\psi_1(x,t) + \frac{4\pi\hbar^2 a_s}{m(2r_h)^2}|\psi_1(x,t)|^2\psi_1(x,t) \\
&\quad + \frac{\hbar}{2}\Omega_{\rm mw}\psi_2(x,t) + \hbar\Delta_{\rm mw}\psi_1(x,t) \\
\imath\hbar\frac{\partial\psi_2(x,t)}{\partial t} &= -\frac{\hbar^2}{2m}\nabla^2\psi_2(x,t) + V(x)\psi_2(x,t) + \frac{4\pi\hbar^2 a_s}{m(2r_h)^2}|\psi_2(x,t)|^2\psi_2(x,t) \\
&\quad + \frac{\hbar}{2}\Omega_{\rm mw}\psi_1(x,t)
\end{aligned} \tag{50.122}$$

for $a < x < b$. Choose periodic boundary conditions, $\psi(a,t) = \psi(b,t)$ and $\psi_x(a,t) = \psi_x(b,t)$. We generalize the *time-splitting spectral algorithm*,

$$\begin{aligned}
\frac{\partial \psi_1(x,t)}{\partial t} &= -\frac{\imath}{\hbar} V(x)\psi_1(x,t) - \frac{\imath}{\hbar} g_{1D}|\psi_1(x,t)|^2\psi_1(x,t) - \imath\Delta_{\rm mw}\psi_1(x,t) - \frac{\imath}{2}\Omega_{\rm mw}\psi_2(x,t) \\
\frac{\partial \psi_2(x,t)}{\partial t} &= -\frac{\imath}{\hbar} V(x)\psi_2(x,t) - \frac{\imath}{\hbar} g_{1D}|\psi_2(x,t)|^2\psi_2(x,t) - \frac{\imath}{2}\Omega_{\rm mw}\psi_1(x,t) \\
\frac{\partial \psi_1(x,t)}{\partial t} &= \imath\frac{\hbar}{2m}\psi_{xx1}(x,t) \\
\frac{\partial \psi_2(x,t)}{\partial t} &= \imath\frac{\hbar}{2m}\psi_{xx2}(x,t) \ ,
\end{aligned} \tag{50.123}$$

i.e. we discretize in space and propagate half the way, $\Delta t/2$, in time,

$$\begin{aligned}
\varphi_{x1} &\equiv \psi_1(x,t) - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\psi_1(x,t)|^2 + i\Delta_{\rm mw}\right)\psi_1(x,t) - \frac{\imath}{2}\Omega_{\rm mw}\psi_2(x,t)\right]\frac{\Delta t}{2} \\
\varphi_{x2} &\equiv \psi_1(x,t) - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\psi_2(x,t)|^2\right)\psi_2(x,t) - \frac{\imath}{2}\Omega_{\rm mw}\psi_1(x,t)\right]\frac{\Delta t}{2} \ .
\end{aligned} \tag{50.124}$$

Since we here use the first order Taylor expansion of the exponential function, we introduce an error that we have to keep low by renormalizing the wavefunction after each step. Now we propagate the spectral components in momentum space and transform back,

$$\begin{aligned}
\phi_{x1} &\equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi_{x1})_k\right] \\
\phi_{x2} &\equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi_{x2})_k\right] \ ,
\end{aligned} \tag{50.125}$$

for $l = -M/2, .., M/2 - 1$. Finally, we propagate the remaining time, $\Delta t/2$,

$$\begin{aligned}
\psi_1(x,t+dt) &= \phi_{x1} - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\phi_{x1}|^2 + \frac{\imath}{2}\Delta_{\rm mw}\right)\phi_{x1} - \frac{\imath}{2}\Omega_{\rm mw}\phi_{x2}\right]\frac{\Delta t}{2} \\
\psi_2(x,t+dt) &= \phi_{x1} - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\phi_{x2}|^2\right)\phi_{x2} - \frac{\imath}{2}\Omega_{\rm mw}\phi_{x1}\right]\frac{\Delta t}{2} \ .
\end{aligned} \tag{50.126}$$

50.8.2.2 Spinor notation

It may be possible to simplify the notation by writing the wavefunction as a spinor, $\vec{\psi} \equiv \begin{pmatrix}\psi_1 \\ \psi_2\end{pmatrix}$. Now the non-kinetic part of the coupled GPE can be written,

$$\frac{\partial \vec{\psi}(x,t)}{\partial t} = M\vec{\psi}(x,t) \ , \tag{50.127}$$

with the matrix,

$$M = \begin{pmatrix} -\frac{\imath}{\hbar}V(x) - \frac{\imath}{\hbar}g_{1D}|\psi_1(x,t)|^2 - \imath\Delta_{\rm mw} & -\frac{\imath}{2}\Omega_{\rm mw} \\ -\frac{\imath}{2}\Omega_{\rm mw} & -\frac{\imath}{\hbar}V(x) - \frac{\imath}{\hbar}g_{1D}|\psi_2(x,t)|^2 \end{pmatrix} \ , \tag{50.128}$$

and the solution,

$$\vec{\psi}(x,t) = e^{Mt}\vec{\psi}(x,0) \ . \tag{50.129}$$

Let us now abbreviate the matrix by,

$$M = \begin{pmatrix} A & B \\ B & D \end{pmatrix} \ . \tag{50.130}$$

The matrix is diagonalized with the unitary transforms,

$$\mathcal{U} = \frac{1}{\sqrt{2\Delta}} \begin{pmatrix} \frac{A-D}{2B} + \Delta & \frac{A-D}{2B} - \Delta \\ 1 & 1 \end{pmatrix} \quad \text{and} \quad \mathcal{U}^{-1} = \frac{1}{\sqrt{2\Delta}} \begin{pmatrix} 1 & -\frac{A-D}{2B} + \Delta \\ -1 & \frac{A-D}{2B} + \Delta \end{pmatrix} \ . \tag{50.131}$$

The eigenvalue matrix is,

$$\mathcal{U}^{-1} M \mathcal{U} = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \tag{50.132}$$

with $E_{1,2} = \frac{1}{2}A + \frac{1}{2}D \pm B\Delta$. Here we used the abbreviation $\Delta = \sqrt{\left(\frac{D-A}{2B}\right)^2 + 1}$. The formal solution now reads,

$$\vec{\psi}(x,t) = \exp\left[\mathcal{U} \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \mathcal{U}^{-1} t\right] \vec{\psi} = \mathcal{U} \begin{pmatrix} e^{E_1 t} & 0 \\ 0 & e^{E_2 t} \end{pmatrix} \mathcal{U}^{-1} \vec{\psi}(x,0) \ . \tag{50.133}$$

This formula can easily be computed, because the block matrices of transform U are diagonal in x.

50.8.3 Wavepacket propagation

50.8.3.1 1D simulations

We want to describe the one-dimensional evolution of an atomic wavepacket according to the Schrödinger equation. The problem is fully described by [744],

$$\imath\hbar \frac{\partial}{\partial t}\psi(z,t) = \frac{-\hbar^2}{2m}\frac{d^2}{dz^2}\psi(z,t) + V(z)\psi(z,t) \ . \tag{50.134}$$

Numerically the Schrödinger equation is integrated via,

$$\psi(z, t+dt) = \psi(z,t) + dt\,\dot{\psi}(z,t) \ . \tag{50.135}$$

The initial state of the wavepacket is set to $\psi(z,0) = e^{-z^2/2\bar{z}^2} e^{\imath kz}$, where $k \equiv \sqrt{2mE}/\hbar$ is its wavevector.

The numerical propagation is conveniently done with the time-splitting spectral algorithm [59, 58, 57, 338].

The flux is,

$$\psi \nabla \psi = 0 \ . \tag{50.136}$$

50.8.3.2 2D simulations

We want to describe the two-dimensional evolution of an atomic wavepacket according to the Schrödinger equation. The problem is fully described by,

$$\frac{-\hbar^2}{2m}\left(\frac{d^2}{dx^2}+\frac{d^2}{dz^2}\right)\Psi(x,z,t)+V(x,z)\Psi(x,z,t)=\imath\hbar\frac{\partial}{\partial t}\Psi(x,z,t)\ . \tag{50.137}$$

Since the potential is conservative, we separate the time-evolution,

$$\Psi(x,z,t)=\psi(x,z)e^{-\imath Et/\hbar} \tag{50.138}$$

The initial shape of the wavefunction moving along the y coordinate could be a Gaussian,

$$\psi(x,z)=\psi_x(x,0)\psi_z(0,z)=(2\pi\sigma_x\sigma_z)^{-1/2}\,e^{-x^2/4\sigma_x^2-z^2/4\sigma_y^2}\ . \tag{50.139}$$

We can assume $\sigma_z \gg \sigma_x$ and obtain an effectively one-dimensional model, $E=E_{kz}$. Set,

$$\psi(x,z,0)=\phi(x,z)e^{-\imath k_z z} \tag{50.140}$$

and,

$$-\frac{d^2}{dz^2}\phi(x,z)+2\imath k_z\frac{d}{dz}\phi(x,z)=\frac{d^2}{dx^2}\phi(x,z)+\left[\frac{2m}{\hbar^2}E_{kz}-\frac{2m}{\hbar^2}V(x,z)-k_z^2\right]\phi(x,z)\ , \tag{50.141}$$

and,

$$\frac{d}{dz}\phi(x,z)=\frac{d^2}{dx^2}\phi(x,z)-\frac{2m}{\hbar^2}V(x,z)\phi(x,z) \tag{50.142}$$

$$\frac{d}{dz}\phi(x,z)=\frac{1}{2\imath k_z}\frac{1}{dx^2}[\phi(x-dx,z)-2\phi(x,z)+\phi(x+dx,z)]-\frac{m}{\imath k_z\hbar^2}V(x,z)\phi(x,z)\ .$$

Discretize in steps dz.

50.8.3.3 Reflection from a potential barrier

Now we allow for a change of direction. We assume that a matter wave with wavevector $\mathbf{k}_0=k_{0x}\hat{\mathbf{e}}_x+k_{0y}\hat{\mathbf{e}}_y=k_0\hat{\mathbf{e}}_x\sin\alpha+k_{0y}\hat{\mathbf{e}}_y\cos\alpha$, runs towards a potential step. If the step is sharp, $V(x)=V_1\theta(-x)+V_2\theta(x)$, the following ansatz is reasonable,

$$\begin{aligned}\psi_0(x,y)&=e^{\imath xk_x+\imath yk_y}\\ \psi_1(x,y)&=re^{-\imath xk_x+\imath yk_y}\\ \psi_2(x,y)&=te^{\imath xk'_x+\imath yk_y}\end{aligned} \tag{50.143}$$

and we have to solve the equations,

$$\begin{aligned}\frac{-\hbar^2}{2m}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)(\psi_0+\psi_1)&=(E-V_1)(\psi_0+\psi_1)\\ \frac{-\hbar^2}{2m}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)\psi_2&=(E-V_2)\psi_2\ .\end{aligned} \tag{50.144}$$

In the step is smooth, $V(x\to-\infty)=V_1<V_2=V(x\to\infty)$, the situation is more complicated. Let us set $V(x)=(V_1-V_2)\frac{1}{\pi}\arctan x+\frac{1}{2}(V_1+V_2)$.

Superfluid and coherent properties of Bose-Einstein condensates

Superfluid liquids or gases are distinguished by their ability to sustain flow without dissipation, i.e. flow which is free of viscous damping. The phenomenon of superfluidity is a well-known property of liquid ^{4}He, but the relationship between superfluidity and Bose-Einstein condensation in this strongly interacting system is not trivial. The situation is much simpler in weakly interacting Bose gases, where the superfluid fraction is almost identical with the condensed fraction and the normal phase of the fluid with the thermal fraction. The availability of dilute gas Bose-Einstein condensates now offers the unique opportunity to study the complicated interdependence between superfluidity and condensation.

51.1 Superfluidity in quantum gases

The *superfluidity* of a gaseous condensate, which is one of its most apparent properties, is intrinsically linked to interatomic collisions. To characterize this phenomenon, it is useful to define some parameters. In the local-density approximation, the *homogeneity* of a gas of N atoms with the thermal de Broglie wavelength (49.9) confined inside a harmonic trap with the ground state size defined by (24.94), is characterized by,

$$\frac{k_B T}{\hbar\omega_{\rm trp}} = \frac{2\pi a_{\rm trp}^2}{\lambda_{\rm therm}^2} \ . \tag{51.1}$$

For a typical experimental situation, $k_B T/\hbar\omega_{\rm trp} \approx N^{1/3} \approx 100$. This shows that the assumption of a locally homogeneous gas is generally a good approximation. With the definition of the *healing length* (50.69), the degree of superfluidity of a condensate with density n can be cast into the form,

$$\frac{gn}{\hbar\omega_{\rm trp}} = \frac{a_{\rm trp}^2}{\xi^2} \ . \tag{51.2}$$

For a typical experimental situation, $a_{\rm trp}^2/\xi^2 \approx 100$. A parameter that well characterizes the importance of interatomic forces within a condensate is the gas *dilution*,

$$na_s^3 = \frac{a_s^2}{8\pi\xi^2} \ . \tag{51.3}$$

The typical numerical value $na_s^3 \approx 10^{-5}$ shows, that atomic gases are usually very dilute, although interatomic forces play an important role in the dynamics of condensates. In contrast, three-body collisions can be totally neglected, because the probability to have three atoms close to each other is even lower than the probability for two atoms.

There are several manifestations of phenomena linked to superfluidity, such as the behavior of collective elementary excitations, superfluid flow of non-circulating topological modes, quantized flux in vortices and matter wave solitons, which will be discussed in the following sections.

51.1.1 Landau's criterion for superfluidity

According to Landau, the phenomenon of superfluidity is rooted in the particular character of the Bogolubov spectrum of elementary excitations (50.54). Let us consider a bosonic fluid at a given temperature moving with velocity v. A macroscopic obstacle in the path of the superfluid can generate elementary excitations. That is, a fraction of the kinetic energy of the fluid is transferred to these excitations, thereby decelerating the fluid and causing *viscosity*. With the excitation energy $\mathcal{E}(p)$ and the momentum $\mathbf{p}$, the total energy of the fluid interacting with the obstacle is,

$$E = \mathcal{E}(p) + \frac{(\mathbf{p}+M\mathbf{v})^2}{2M} = \mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v} + \tfrac{1}{2}Mv^2 + \frac{p^2}{2M} \simeq \mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v} + \tfrac{1}{2}Mv^2 \ , \tag{51.4}$$

where M is the total mass of the superfluid. Since the term $Mv^2/2$ is the initial kinetic energy of the fluid, $\mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v}$ represents the excitation energy. And since the kinetic energy of the superfluid can only be diminished by the excitation, we need $\mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v} < 0$. Finally, as $\mathcal{E}(p)$ must be positive, the condition for generating elementary excitations is,

$$\mathcal{E}(p) \leq pv \ , \tag{51.5}$$

where $\mathbf{p}$ and $\mathbf{v}$ are antiparallel.

Therefore, there is a relative *minimum velocity* between the fluid and the obstacle, called *critical Landau velocity*, for creating excitations,

$$v_c = \min\left(\frac{\mathcal{E}(p)}{p}\right) \ . \tag{51.6}$$

For velocities below v_c, it is impossible to generate excitations, and there is no mechanism to decrease the kinetic energy of the fluid. As a result, the system becomes superfluid [553].

The spectrum of elementary excitations for a weakly interacting condensate, is the Bogolubov spectrum (50.54). The graph Fig. 51.1 shows, that for velocities below the sound velocity given by (50.56), $v < c_s$, the curve representing the propagation of

the perturbation does not cross the Bogolubov spectrum. That is, the perturbation can not be converted into excitations, which is only possible when $v > c_s$.

In an ideal condensate without interactions, $a_s = 0$, the Bogolubov spectrum reduces to the quadratic dispersion relation of free particles, which means that there is no critical velocity, $v_c = c_s$. Consequently, it is always possible to excite the condensate, that is, an ideal condensate can not be superfluid, and, as first pointed out by Landau: *superfluidity and Bose-Einstein condensation are different phenomena.*

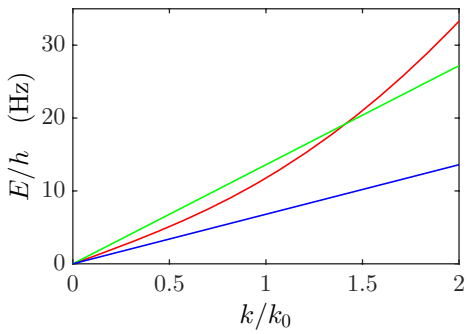

Figure 51.1: (code) Landau's criterion for superfluidity. Slow perturbations (blue line) do not cross the Bogolubov spectrum (red line) and do not generate excitations. Rapid perturbations (green line) cross the spectrum and can be dissipated.

51.1.2 Impurity scattering

A first hint for the superfluid nature of Bose-Einstein condensates is the fact that the hydrodynamic theory of superfluidity describes well the collective excitations (see Sec. 50.5). Moreover, several experiments provided direct evidence for the superfluid nature of condensates. For example, via a calorimetric measurement [763]: A condensate, stirred around by a rotating far blue-detuned laser beam, dissipated atoms to the thermal fraction of the atomic cloud, provided the stirring velocity exceed a certain *critical velocity* v_c: At lower velocities, the perturbation did not lead to dissipation. At higher velocities, phonons were excited and the cloud was heated. In a subsequent experiment, perturbation-induced density fluctuations were observed *in vivo* and *in situ* [707]. When the stirring speed was below the critical velocity, the density was almost homogeneous, thus indicating superfluid flow. When, however, the stirring speed exceeded v_c, atoms piled up in front of the stirring beam, and the resulting pressure gradients led to a turbulent flow around the perturbation and to dissipation.

The critical velocity v_c found in the stirring experiments was about ten times smaller than the local sound velocity c_s,

$$c_s \equiv \sqrt{\frac{gn}{m}} = \frac{\hbar}{\sqrt{2}m\xi} \ . \tag{51.7}$$

In fact, while the onset of dissipation is accelerated by turbulence around the *macroscopic object* traversing the superfluid, the local sound velocity (51.8) is derived for

a *microscopic object*. Puzzled by this discrepancy, Chikkatur *et al.* [170] studied the motion of microscopic atomic impurities through a condensate. The *impurity* was created by transferring a few atoms out of the original BEC from the trapped state $|F = 1, m_F = -1\rangle$ to the free state $|F = 1, m_F = 0\rangle$ via induced Raman transitions. The initial velocity was adjusted by the laser beams exciting the Raman transition (polarization, incident angle and relative detuning) to satisfy the Bragg condition (see Sec. 52.2). After the free impurity passed through the BEC, the trap was switched off, a Stern-Gerlach magnetic field gradient was pulsed to separate atoms in different Zeeman states, and finally the atoms were detected via time-of-flight imaging (see Sec. 49.6.1). When the initial velocity of the impurity was well above a critical value given by the local velocity of sound, ultracold s-wave collisions between impurity atoms and the stationary condensate distributed the momenta of the collision partners uniformly. In TOF images this appeared as a *circular halo* centered around the center-of-mass momentum of the collision partners (see Fig. 51.2). When, however, the initial velocity of the impurity was reduced, its collision rate with the stationary condensate was suppressed and the trajectory became superfluid.

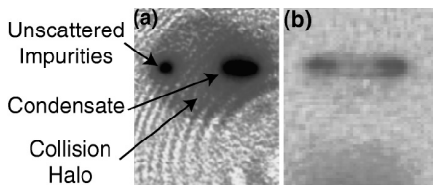

Figure 51.2: (a) Scattering of impurities at velocities above the critical velocity. The presence of a halo indicates the occurrence of collisions between the impurity and the condensate dissipating the relative kinetic energy. (b) For velocities below the critical velocity the halo disappears.

51.1.3 Hydrodynamic theory of superfluidity

For the description of superfluidity a hydrodynamic theory is adequate. Therefore, we will rewrite the time-dependent Gross-Pitaevskii equation (50.21). We consider the general case, in which the external potential $V_{\rm trp}(\mathbf{r}, t)$ depends on time. The wavefunction can be written by defining the density and the velocity fields,

$$\phi(\mathbf{r}, t) = \sqrt{n_0(\mathbf{r}, t)} e^{\imath\theta(\mathbf{r},t)} \tag{51.8}$$
$$\mathbf{v}_s(\mathbf{r}, t) = \frac{\mathbf{j}(\mathbf{r}, t)}{n_0(\mathbf{r}, t)} = \frac{1}{2\imath m} \frac{1}{n(\mathbf{r}, t)} \left[\phi^*(\mathbf{r}, t)\nabla\phi(\mathbf{r}, t) - \nabla\phi^*(\mathbf{r}, t)\phi(\mathbf{r}, t)\right] \ .$$

This gives,

$$\mathbf{v}_s(\mathbf{r}, t) = \tfrac{\hbar}{m}\nabla\theta(\mathbf{r}, t) \ . \tag{51.9}$$

From the GPE we derive the continuity and the Navier-Stokes equations:

$$\frac{\partial n}{\partial t} + \nabla(\mathbf{v}_s n) = 0 \tag{51.10}$$
$$m\frac{\partial \mathbf{v}_s}{\partial t} + \nabla\left(V_{\rm trp} + gn - \frac{\hbar^2 a}{2m\sqrt{n}}\nabla^2\sqrt{n} - \mu + \frac{m}{2}\mathbf{v}_s^2\right) = 0 \ .$$

We can see that the hydrodynamic behavior of a BEC depends greatly on the quantum phase θ. When the kinetic pressure is small compared to the mean-field energy,

$$m\frac{\partial \mathbf{v}_s}{\partial t} + \nabla\left(V_{\text{trp}} + gn + \frac{m}{2}\mathbf{v}_s^2\right) = 0 \ . \tag{51.11}$$

This is the *Euler equation* for a fluid with a potential flow. This equation and the *continuity equation* have the typical structure of equations describing superfluids at $T = 0$. This is due 1. to the presence of a Bose-Einstein condensate allowing us to formulate an equation for a complex *order parameter*, and 2. to the presence of interactions, included via the pressure term in the Euler equation, which are necessary condition for superfluidity.

At zero temperature, the entire fluid is superfluid. Moreover, in the Gross-Pitaevskii approximation, the whole fluid is condensed. Therefore, $\mathbf{v}_s(\mathbf{r}, t)$ is the velocity flow of the superfluid [1].

51.2 Topological modes

Significant manifestations of superfluidity are associated with rotational phenomena. An example is the occurrence of *scissor modes* [395], which are excited, when an angular momentum is suddenly applied to a condensate confined in an anisotropic trap. This can be done via a sudden reorientation of the symmetry axis of the trap [614, 613]. The condensate responds to this perturbation by an oscillation of its inclination implemented by an *irrotational superfluid flow*. The excitation spectrum reflects the strong reduction of the inertial momentum for superfluids.

The most rigorous manifestation of superfluidity, however, is the occurrence of a quantized and persistent current, called *quantized vortex*. In contrast to the elementary excitations, which must be created by perturbations, the vortex is a *stationary* (or *topological mode*) solution of the Gross-Pitaevskii equation Eq. (50.21).

Work on vortices has been done by [624, 607, 763, 707, 170, 395, 614, 608, 168, 21, 789, 265, 472, 145, 1007].

51.2.1 Vortices

From Eq. (51.9) it is easy to see, that the superfluid is non-rotational, that is,

$$\nabla \times \mathbf{v}_s(\mathbf{r}, t) = 0 \ . \tag{51.12}$$

This raises the question, how vortices are possible. The solution to this apparent contradiction is, that Eq. (51.12) does not apply, when the phase exhibits a singularity. Consider, for example, a closed loop C around the singularity. In a vortex, the superfluid current is pulled by the phase gradient, $\mathbf{v} = \frac{\hbar}{m}\nabla\theta$. For the condensate wavefunction to be well defined, the phase variation $\Delta\theta$ around the loop must be a multiple of 2π, that is,

$$\Delta\theta = \oint_C \nabla\theta \cdot d\mathbf{l} = 2\pi\ell \ . \tag{51.13}$$

[1] This is not the case for strongly interacting superfluids, such as superfluid helium, where the normal fluid fraction is considerable.

where ℓ is an integer. Therefore, we can calculate the *circulation* Γ around the closed loop, that is,

$$\Gamma = \oint_C \mathbf{v}_s(\mathbf{r}, t) \cdot d\mathbf{l} = \frac{h}{m}\ell \ . \tag{51.14}$$

Apparently, the superfluid circulation is quantized in units of $\hbar/m$. The parameter ℓ is called *charge of the vortex* and measures, in unit of h, the quantized angular momentum of the vortex.

In addition, the flow must be persistent, because its circulation can only be changed in a discontinuous way, by overcoming a discrete energy barrier, which requires energy coming e.g. from thermal excitations. Clearly, the normal (thermal) fraction of a gas can also have a circular flow. However, the disordered microscopic motion of each individual particle causes a viscous drag that prevents the persistence of the flow in the absence of a torque. This is in contrast to superfluid flow, which persists even without external torque. The issues of vortex stability, formation, and topology were addressed in recent experiments [623, 607, 608, 168, 21]. Solve the Excs. 51.2.6.1 and 51.2.6.2.

The kinetic energy per unit vortex length can be estimated from a semi-classical approach. First, we define as the mass density ρ_m of the superfluid. If n is the particle density, $\rho_m = nm$. The kinetic energy of a flux line at the radius r is,

$$\mathcal{E}_{\text{kin}} = \tfrac{1}{2}\rho_m v_s^2 = \frac{\hbar^2\ell^2}{2m}\frac{n}{r^2} \ . \tag{51.15}$$

To obtain the kinetic energy per unit length, we integrate the expression (51.21) over a plane perpendicular to the vortex axis. Note, however, that the velocity field is $v_s \propto r^{-1}$ and, therefore, can not be integrated from zero. Instead, we begin the integration at a radius given by the *healing length* ξ, which represents a measure of the vortex core size. Now, the kinetic energy per unit length is,

$$E_{\text{semi}} = \int_0^{2\pi}\int_\xi^R \mathcal{E}_{\text{kin}}(\mathbf{r}) r dr d\theta = \pi n \frac{\hbar^2\ell^2}{m}\ln\frac{R}{\xi} \ . \tag{51.16}$$

Note, that a multiply charged vortex carrying the entire angular momentum $\ell = \ell_0$ of the superfluid is energetically less favorable than an ensemble of ℓ_0 vortices with unit charge $\ell = 1$. Therefore, a multiply charged vortex is unstable and may decay to several single charge vortices.

To calculate exactly the energy of a vortex, we do the following ansatz,

$$\Phi_0(\mathbf{r}) = \phi(r, z)e^{\imath\ell\vartheta} \ , \tag{51.17}$$

we then solve the Gross-Piatevskii equation (50.21) numerically, and calculate the expectation value of the energy of the vortex through the expression,

$$\langle\Phi_0|\hat{H}|\Phi_0\rangle = \int d^3\mathbf{r}\left[\tfrac{\hbar^2}{2m}|\nabla\Phi_0(r,z)|^2 + V_{\text{trp}}|\phi(r,z)|^2 + g|\phi(r,z)|^4\right] \ , \tag{51.18}$$

where $\hat{H}$ is the Gross-Pitaevskii Hamiltonian.

The calculation yields for energy per unit length of a single charge vortex in a uniform cylindrical condensate [727],

$$E_{\text{unif}} = \pi n \tfrac{\hbar^2}{m}\ln\left(1.464\tfrac{R}{\xi}\right) \ , \tag{51.19}$$

which is very close to our semi-classical prediction. Although the wavefunction $|\phi(r,z)|$ has no analytic form, it can be shown by a variational approach, that the trial wavefunction,

$$|\phi(r,z)| = \frac{nr}{\sqrt{2\ell^2\xi^2 + r^2}} \tag{51.20}$$

is a good approximation [727]. Note that the healing length ξ characterizes the size of the vortex. For a superfluid, we can calculate the total energy of the vortex exactly, because the fluid is confined in all directions,

$$E_{\text{tot}} = \tfrac{4\pi n_0}{3}\tfrac{\hbar}{m}\ln\left(0.671\tfrac{R_r}{\xi_0}\right) \ , \tag{51.21}$$

where n_0 and ξ_0 are, respectively, the density and healing length at the center of the fluid. R_z and R_r are, respectively, the extensions of the cloud along the axial and radial directions within the Thomas-Fermi approximation.

51.2.1.1 Creation and detection of vortices

The first superfluid vortex was observed 1979 in ^{4}He [999]. For gaseous condensates, two approaches have been employed to produce vortices. Either one stirs the atomic cloud in order to impart an angular momentum to it. This can be done by rotating the (anisotropic) trap during the process of forced evaporation with time-orbiting magnetic fields or with an optical spoon. The vortex state is formed when the critical temperature for condensation is crossed. An alternative method is to imprint a 2π circular phase gradient into a previously created condensate. Indeed, the local phase of a matter wave can be manipulated via a local modification of the potential depth, which can be achieved by a Stark shift induced by a far-detuned laser beam [265]. Focused into a tiny spot which is moved across the condensate, the laser beam will create a phase gradient, which in turn will cause a velocity flow. It is important to force the local density at the center of the vortex to zero, which can be achieved via a proper design of the trapping potential (e.g., a Mexican hat-shaped potential), and let the BEC then relax to the vortex state.

A variation of this method [972] avoids the need for relaxation processes. In this configuration the phase gradient is created through a *local* Raman coupling between two internal atomic states (for example, in ^{87}Rb the two trappable Zeeman states $|F, m_F\rangle = |1,-1\rangle$ to $|2,1\rangle$). At the spots, where the focused Raman beams hit the condensate, atoms were dynamically converted from the ground state to the excited state. The circular trajectory of the spots and the rotation speed were calculated such as to generate a toroidal topology for the adiabatic population transfer. The process was coherent and allowed to directly construct and shape the vortex wave function. We study this experiment in more detail in the Exc. 51.2.6.3.

In confined single-species condensates the diameter of the vortex core is on the order of the healing length, 2ξ. With typical values of $2\xi \approx 0.4$ μm it is thus way too small to be imaged *in situ*, and ballistic expansion times of several 10 ms are necessary. On the other hand, in double condensates formed by two repelling species (e.g. the two states $|2,1\rangle$ and $|1,-1\rangle$ in ^{87}Rb), one of the species can form a vortex around the second. In this case, the diameter of the vortex core, is determined by the diameter of the condensate of the second species and, hence, much larger. When

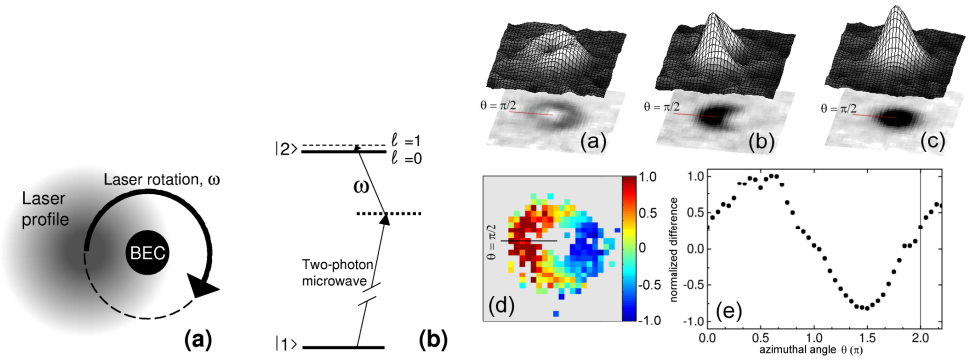

Figure 51.3: (Left) Scheme of the experiment [623]. (Medium) Level system used. (Right) Density distribution of a vortex state: (a) (the visible atoms are in the upper hyperfine state), (b) after a $\pi/2$-pulse and (c) after a π-pulse (the visible atoms are in the lower hyperfine state). The images (d) and (e) visualize the phase slip around the vortex.

the second species is selectively removed (e.g. by the radiative pressure exerted by a resonant laser), and the vortex in the first species can be studied by *in situ* imaging of the confined density distribution [624].

A particularly smart detection method for vortices is based on matter wave interferometry (see Sec. 51.3.3). Here, two matter waves, that is, the vortex state in $|2,1\rangle$ and a (reference) ground state BEC in $|1,-1\rangle$ are coherent mixed via a resonant two-photon radiofrequency $\pi/2$-pulse. The resulting matter wave interference patterns reveals the phase profile of the vortex (see Fig. 51.3).

51.2.1.2 Stability

In a topologically 'singly-connected' trap, for example a potential harmonic, vortices do not represent the lowest energy eigenstate, and they must decay to the ground state. If the mean-field energy of the condensate is weak compared to the kinetic energy, $gn_0/\hbar\omega_z \ll 1$, the healing length will exceed the size of the BEC, $\xi \gg a_{\rm trp}$, and the vortex rapidly decays by dissipating its excess energy to thermal excitation. Such BECs can not be considered superfluid. If the mean-field interaction is strong, the vortex spontaneously breaks azimuthal symmetry, moves away from the center and exits the condensate on a spiral-shaped trajectory [789]. Nevertheless, the decay time may be quite long.

On the other hand, a vortex can be the ground state of a 'multiply-connected' trap (for example, a toroidal potential). Such a potential can be realized as the temporal average of a harmonic potential with a small rotating anisotropy [607]. In such geometries vortices are extremely stable.

51.2.1.3 Vortex precession

A radial force acting on a vortex results in a radial displacement and a precession about the symmetry axis. The effect, known as *Magnus effect* [472], is due to pressure

imbalances on the vortex surface. A radial force naturally arises, when the core is displaced from the center, because local pressure gradients will force the vortex out of the center toward regions with lower densities. Experimentally, a slow precession ($\sim$ 1 Hz) spiraling the vortex toward the rim of the condensate has been observed [21] by taking a succession of nondestructive images.

51.2.2 Vortex lattices

Superfluid ^{4}He in a rotating bucket spontaneously develops symmetrically organized vortex patterns. Similar phenomena can be observed, when a dilute gas Bose-Einstein condensate is forced to rotate [145] at a given frequency Ω. The energy in the rotating system receives an additional contribution from the centrifugal term, $U_{rot}(\mathbf{r}) = U_{\rm trp}(\mathbf{r}) - \Omega L_z$, where $L_z = \hbar N l_z$, and $l_z = \imath(y\partial_x - x\partial_y)$ is the angular momentum of the individual atoms. If the rotation is slow, the energy ΩL_z is too small to force the condensed wavefunction to rotate. If the rotation frequency is beyond a critical value Ω_c, the *time-averaged* potential, $U_{rot}(\mathbf{r})$ eventually develops a local minimum in the center, thus adopting the toroidal shape. For non-interacting gases, the critical frequency coincides with the radial secular frequency, $\Omega_c = \omega_r$. Then the radial restoring force of the trap does not balance the centrifugal force, such that atoms can escape from the trap. However, for superfluid gases the critical frequency is reduced, $\Omega_c < \omega_r$. Between the rotation frequencies $\Omega = \Omega_c$ and $\Omega = \omega_r$, the state with the lowest energy in the toroidal potential is the vortex, whose filament is pinned to the symmetry axis. For even higher rotation frequencies, we could expect a single vortex with a larger winding number (more than the phase winding of 2π for a single turn). However, individual multiple-order vortices in harmonic traps are unstable. Instead, vortex lattices [145] called *Abricosov lattices* will form. For a given trapping potential and mean-field energy, the symmetry of the lattice and the number of vortices depend on the rotation frequency Ω. Counter-intuitively, the angular momentum of individual particles l_z *is not quantized*. When we vary Ω, regimes of forbidden l_z (i.e. when no vortex pattern is formed) alternate with allowed regimes. The discontinuous transition from one vortex pattern to another is a first-order phase transition, which spontaneously breaks one symmetry to form another. An upper limit for the rotation speed is given by the equilibrium between the centrifugal force and the radial restoring force of the trapping potential at $\Omega = \omega_r$.

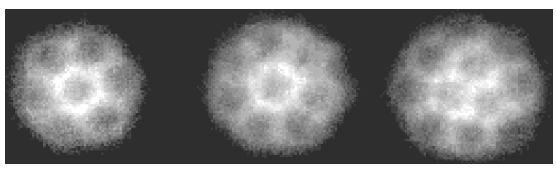

Figure 51.4: Abricosov vortex lattice.

These patterns of vortex lattices were observed in experiments using the *stirring method*, which consists in brushing a far-detuned focused laser ('optical spoon') around the rim of a condensate [607] at a certain frequency Ω. In this experiment, the ratio of the mean-field energy to the kinetic energy was $gn_0/\hbar\omega_z = a_{\rm trp}^2/2\xi^2 > 100$. Beyond a certain critical rotation frequency, $\Omega_c \approx 2\pi \times 150$ Hz, a single central vortex

was formed. At even higher frequency, a symmetrical vortex lattice appeared in a transverse plane (see Fig. 51.4). Finally, at rotation frequencies near the radial trap frequency ω_r, the condensate wavefunction became turbulent and finally disappeared. As soon as the optical spoon was removed, the vortex lattice gradually decayed losing the vortices one by one.

51.2.3 Solitons

Work on solitons has been done by [1005, 971, 623, 972, 668, 773, 471, 680, 142, 48, 280, 137, 250].

51.2.3.1 Dark solitons

Solitons are non-singular solutions of any equation satisfying,

$$|\psi(\mathbf{r}, t)| = |\psi(\mathbf{r} - \mathbf{v}t)| \ . \tag{51.22}$$

Solitons are well known to occur in non-linear optical media, for example in optical fibers, when dispersion is counterbalanced by self-phase modulation, such that optical signals propagate without spreading. The Gross-Pitaevskii equation is another example for a nonlinear wave equation supporting soliton-like solutions. States called *dark soliton* or *twisted state* with a dynamically stable density dip are expected in condensates with repulsive interactions [668, 773, 471, 680]. In contrast to topologically stable states, for example, vortices, dark solitons are pseudo-defects, the decay of which, even though it may be slow, is topologically trivial. Due of the greater freedom of movement of their wavefunctions, solitons can be distorted by complex deformations [142]. Soliton-like matter wave states were initially observed in superfluid ^{3}He-B [48]. In dilute gases, the size of the solitons is of the order of healing length.

The first dark solitons in dilute gases were created by applying an inhomogeneous phase shift to a condensate [137, 250]. One half of the condensate was irradiated by a far-detuned laser pulse (detuning Δ, Rabi frequency Ω, duration $\tau \ll \hbar/gn_0$) in order to advance the phase of this part of the condensate by $\varphi = \Omega^2\tau/4\Delta$. When the phase shift was set to π, an abrupt phase gradient developed at the boundary delimiting the two halves. The condensate reacted to the phase gradient by developing a deep density minimum all along the boundary corresponding to a soliton (see Fig. 51.5). The phase distribution can also be imaged by interferometric techniques based on Bragg diffraction (see Sec. 52.2). In one dimension, the density dip of the soliton corresponds to a node of the dipolar topological mode [972, 668, 680].

The abrupt phase gradient at the boundary plane exerts a force trying to increase the gap, while repulsive interactions work to heal it. At zero temperature, this balance ensures the dynamic stability of the soliton. While a perfect dark soliton should be stationary, experiments [137, 250] revealed that solitons with finite contrast propagate along the direction of the plane's normal vector with a velocity, which must always be less than the local sound velocity,

$$v_{\rm sol} = c_s \sqrt{\frac{n_{\rm sol}}{n}} \ , \tag{51.23}$$

where n is the peak density of the condensate and n_{sol} the density at the bottom of the dark soliton [773, 471]. Fig. 51.5 shows that the soliton develops a curvature when

it propagates. One reason for this is a slower sound velocity, $c_s = \sqrt{gn_0/m}$, on the edges of the condensate, where the density is lower. The second reason is, that the density in the dip, $n_{\rm sol}$, goes to zero at the edges. In the presence of a thermal cloud, dissipation reduces the contrast of the density dip and accelerates the soliton, until it reaches the sound velocity c_s and finally disappears.

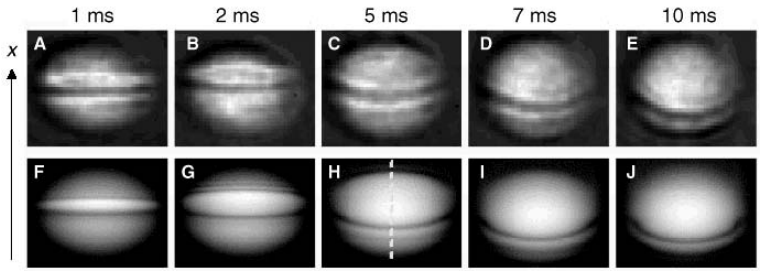

Figure 51.5: Solitons.

51.2.3.2 Bright solitons

In condensates with attractive interactions *bright solitons* have been observed, as well [513, 500].

51.2.4 Description of general topological modes

A coherent *topological mode* is a stationary solution of the *Gross-Pitaevskii equation*,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + U_{\rm trp}(\mathbf{r}) + \frac{4\pi\hbar^2 a_s}{m}N|\phi_n|^2\right]\phi_n(\mathbf{r}) = E_n\Phi(\mathbf{r}) \ . \tag{51.24}$$

These modes can be calculated using an *optimized perturbation theory* [197]. We separate the Hamiltonian into an unperturbed part and a perturbed part, $\hat{H} = \hat{H}_0 + \Delta\hat{H}$, where the unperturbed part now depends on variational parameters,

$$\hat{H} = \hat{H}_0(u, v, ..) + \Delta H \ . \tag{51.25}$$

As usual, the first-order energy correction is,

$$E_n^{(1)}(u, v, ..) = E_n^{(0)}(u, v, ..) + \langle\Phi_n^{(0)}|\Delta\hat{H}|\Phi_n^{(0)}\rangle \ , \tag{51.26}$$

where the $\Phi_n^{(0)} = \Phi_n^{(0)}(u, v, ..)$ are the solutions of the unperturbed Hamiltonian $\hat{H}_0$. Once the energies are found, we must minimize them in terms of the variational parameters,

$$\frac{\partial E_n}{\partial u} = 0 \quad , \quad \frac{\partial E_n}{\partial v} = 0... \ . \tag{51.27}$$

With these parameters, we obtain the energies and the wavefunctions [2].

[2] Excited modes can be understood stationary matter waves with the trap serving as a cavity.

51.2.4.1 Creation of topological modes

One possibility of creating topological modes is to apply a temporal modulation to the trapping potential [1005]. The modulation frequency must be resonant with the energy difference between the excited mode and the ground state. Another possibility is to vary the interaction energy via a modulation of the scattering length in the vicinity of a *Feshbach resonance* [201].

The steady-state situation of a cloud in a stationary trap is *thermal equilibrium*, that is, inversion is not possible. At a time-dependent (e.g. shaking) potential however, for example, transitions to excited vibrational levels can be driven. These can generate inversion, provided collision-induced relaxation is not too fast [3].

51.2.5 Turbulence

The issue of turbulence is one of the most important problems of classical physics yet to be solved [311]. In superfluids, restrictions imposed by quantum mechanics constrain the emergence of turbulence, which is then called *quantum turbulence*. On the other hand, the study of quantum turbulence can improve our understanding of *classical turbulence* [272]. Recently, the study of the dynamics of a ensemble of vortices in a Bose-Einstein condensate allowed the identification of signatures of quantum turbulence [432, 415].

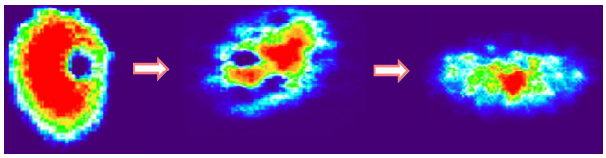

Figure 51.6: Turbulence.

51.2.6 Exercises

51.2.6.1 Ex: Comparison between the quantum and the classical vortex

Consider a vortex around a straight line along the z-axis at $r = 0$. Compare the radial velocity variation of a quantum vortex with that of a classical one.

51.2.6.2 Ex: Singularity in vortices

Show for the above simple example,

$$\nabla \times \mathbf{v}_s(\mathbf{r}, t) = \hat{\mathbf{z}} \frac{\ell h}{m} \delta(x)\delta(y) \ .$$

[3] The dynamics of atoms trapped in a harmonic potential is similar to the Jaynes-Cummings dynamics of an optical mode. However, the non-linear condensate self-interaction changes the situation and makes the collisions being collective.

51.2.6.3 Ex: Phase-engineering of a vortex state

The first vortex in a dilute gas was created at the JILA [624]. Study the paper and explain in detail, how the vortex was created.

51.3 Atom optics

Unlike the photons [551], there is no doubt about the fact that atoms are particles. On the other hand, the deep analogy between light and matter, resulting from the particle-wave duality, prompted de Broglie in 1924 to ascribe a *wave* to each massive particle, whose wavelength would be a function of the particle's momentum. Whether an atom behaves more like a particle or a wave depends on the specific experimental situation. For example, interferometers emphasize its wave nature: Atoms are able to interfere with *themselves*, when their Broglie wavelength is coherently split and then recombined. (Bosonic) atoms are able to interfere with other atoms, if their de Broglie wavelengths are greater than their distances. For this to happen, it requires high densities and very low temperatures, that is, high phase space densities. When the phase space densities are so high that the Broglie waves come into contact, effects of quantum statistics begin to influence the dynamics of the atoms, and fermions will behave differently from bosons.

Analogously to the distinction between classical and laser optics, we can separate the area of conventional atomic optics working with individual, mutually incoherent atoms, from the area of coherent atomic optics working with Bose-Einstein condensates. Unlike for the study of phenomena related to superfluidity, gases with weak interatomic interactions are generally more useful for the study of the coherent properties of condensates and for application in atomic optics. Nevertheless, interatomic collisions increase the complexity of the dynamics of matter waves interacting with atom optical devices, by introducing non-linarities analogous to those known from nonlinear optics and thus raising the field of *nonlinear atom optics*.

51.3.1 Atomic optical tools

The basic equipment of an atomic optics laboratory [655, 4, 735, 324, 756] comprises atomic beams, atom traps, lenses and waveguides, various types of mirrors and resonators, Stern-Gerlach type matter wave polarizers, de Broglie wave phase shifters based on Bragg diffraction, and a multitude of atomic beam gratings. Obviously, gratings allow the construction of atom interferometers, which are used in experiments and high precision devices, for example, atomic gyroscopes and gravimeters. Other applications for atomic beams controlled by atom optical elements are in atomic holography for the projection of complex pattern into integrated semiconductor circuits [669], in lithography [920], and in microscopy [264].

An important feature of atoms (as compared to light) is the existence of a rich internal structure providing a wealth of additional degrees of freedom, whose dynamics (of the Bloch vector) is frequently entangled with the motional dynamics (of the de Broglie wave). This allows to monitor (e.g. in matter wave interferometers) the evolution of the motional state of the matter wave via an observation of the internal

excitation. Moreover, in some interferometers, the de Broglie wave is not even split, and one does interferometry with completely immobile atoms or ions [459].

The epitome of a coherent light source is the laser, and we may ask whether there is a material analogue, which would be a source of coherent matter [979, 115, 870, 448, 676, 522] serving for *coherent atom optics*. In fact, we may already consider a trapped condensate as a stationary *atom laser* pulse with the trapping potential playing the role of the laser resonator. While most atom optical devices (including conventional atomic interferometers) do not require mutual coherence of atoms, certain applications take advantage of an intense, highly directional, monochromatic, and coherent atom source. In this respect, atom lasers are much superior to thermal atomic beams. While a thermal beam contains about 10^{-12} atoms per mode and a magneto-optical trap about 10^{-6}, a condensed mode may contain more than 10^6 atoms. Condensates offer the advantage of large de Broglie wave amplitudes and de Broglie wavelengths as long as their actual size (which can be much longer than optical wavelengths). And for an atom laser, the coherence length can even be longer than that of the condensate from which it emerged. This obviously has a major impact on the sensitivity and resolution of atom optical elements, in particular those, where atomic coherence is important, for example, atom interferometers. Without doubt atom lasers will replace conventional atomic beams in precision measurement of fundamental constants and tests of fundamental symmetries ([Phys. World (mar,97) p.43]). Finally, atom lasers are crucial for nonlinear optics.

Also of interest are the references [869, 669, 764, 556, 794, 55, 431, 276, 755, 249, 444, 776, 470, 820, 86, 264, 964].

51.3.2 The atom laser

A large number of techniques for making an *atom laser* has already been developed [638, 27, 645, 22, 100, 404, 618] and theories on atom lasers have been formulated [401, 674, 977, 951, 460]. The following sections are devoted to explaining, why the term atom laser is justified. For the reasoning we will let as guide by the optical laser.

We already mentioned the *trapping potential* (replacing the resonator in lasers) as a major ingredients of an atom laser [4]. Another necessary feature would be the availability of an *output coupling* mechanism, which we still need to discuss in the following. Apart from these more practical aspects, we need to prove, that atom lasers are indeed *phase-coherent*, and we have to clarify the role of *bosonic stimulation* and of *irreversibility* in the production process of a BEC.

51.3.2.1 Bosonic stimulation and irreversibility

The gain mechanism for optical lasers is photonic stimulation of atoms inciting them to emit other photons into the stimulating mode. The atomic laser operates in a similar way. Atoms trapped in a potential constitute a thermal reservoir. Binary collisions redistribute the atoms among the vibrational energy levels of the potential. If a vibrational level already contains an atomic population, Bose-Einstein quantum

[4] Coherent reflection of atom laser beams has been demonstrated [108, 30, **?**], and an atom laser cavity with efficient transverse focusing has been built [102]

statistics will encourage atoms involved in a collision process to join this level. Ultimately, this comes down to an irreversible pumping of a single level, where the atoms accumulate to build a single degenerate quantum state. Bose condensation is always the result of *bosonic stimulation*. However, the dynamics and time scale for the formation of a condensate have been controversially discussed, until some experiments [645] could directly visualize *in vivo* the process of nucleation and the exponential amplification at the center of a thermal cloud (see Fig. 51.7).

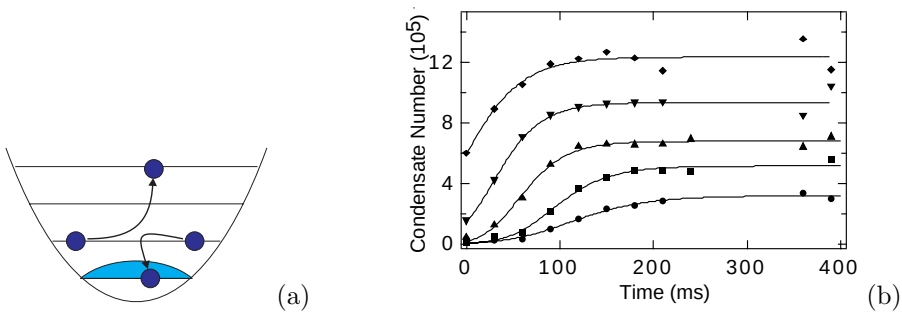

Figure 51.7: (a) Illustration of the idea of bosonic stimulation. (b) The curves show the growth of a condensate toward thermal equilibrium for different initial numbers of condensed atoms.

The very high concentration of population in a single phase space cell during the creation of a condensate represents a dramatic reduction of entropy. Since the total entropy can not decrease, the condensate must be coupled to a thermal reservoir receiving the excess entropy. This coupling is necessarily irreversible. In practice, the reservoir is the cloud of thermal atoms, whose energy is spread over many vibrational states. Irreversibility is introduced by collisions and the subsequent removal of the hottest atoms.

51.3.2.2 Phase of a condensate and first and higher-order coherences

First-order coherence and long-range order are necessary conditions for assigning a single global phase to the condensate. The existence of a single phase, and the possibility of measuring it, were questioned in the past. Certainly, the phase of a BEC is not observable *by itself*, but only *the relative phase* of two condensates.

The intrinsic phase-coherence of condensates has demonstrated in many experiments. An early example [409] employed internal state interferometry by splitting and remixing ^{87}Rb condensates trapped in the different Zeeman states $|F, m_F\rangle = |1, -1\rangle$ and $|2, 1\rangle$. They found that the phase was remembered for times longer than 150 ms. In another experiment [24, 510, 951], illustrated in Fig. 51.8, a condensate was spatially split in two halves and then recombined. The interpenetration of the two halves at a well-defined relative velocity gave rise to a clear matter wave interference pattern. This ability of ballistically expanding condensates to interfere demonstrated the absence of a random phase lag during the expansion process and that the preservation of the condensates' long range order. However, under the repulsive influence of the mean-field energy, the phase profile of a released condensate evolves in a non-uniform

but well-defined manner [851].

The homogeneity of the phase of a *confined* condensate was also confirmed experimentally [884, 403, 101] through interferometric techniques based on Bragg diffraction (see Sec. 52.2.2). The spatial coherence of an output coupled atom laser has been verified with a double-slit experiment [101]. And the temporal coherence of an atom laser beam was shown to be Fourier-limited by the finite output coupling time [**?**].

Similar to Young's double slit experiment in optics, the observation of matter wave interference only indicates first-order coherence, i.e. amplitude fluctuations in the matter field. Signatures for the presence of higher-order coherences in condensates were discovered in other experiments: The second-order correlation function, which represents a measure for intensity fluctuations (number of particles) in the matter field, was derived from measurements of the condensate's release energy [512]. And the third-order coherence can be deduced from a comparison of the three-body recombination rates for condensed and thermal clouds [141].

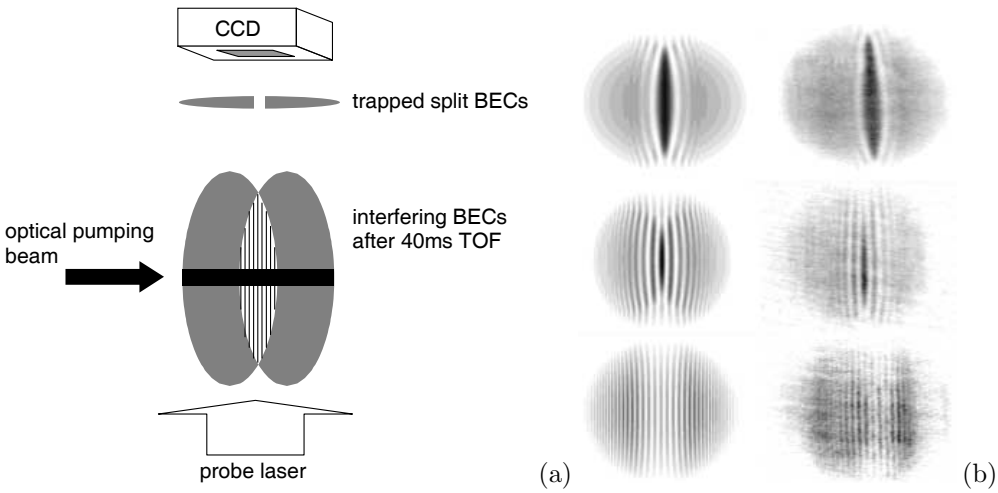

Figure 51.8: (a) Scheme for observation of matter wave interference. (b) Interference fringes.

A reliable characterization of atom number fluctuations and matter wave phase fluctuations in condensates is important for the simple reason, that these fluctuations will limit ultimately the resolution of atom interferometers, analogous to the *Schawlow-Townes limit* in lasers.

51.3.2.3 Output coupling

The *output coupler* for a trapped condensate plays a role similar to that of the partially reflecting mirror of a laser resonator. It transfers a fraction of condensed atoms out of the trapping potential through a coherent coupling to untrapped states. The coupling can be conveniently implemented via adiabatic potentials (see 43.1.3 and 49.4.3) generated by radiation (e.g. radiofrequency pulses [638] or continuous radiofrequency [100]). Also, pairs of laser beams in Raman configuration can create a coherent quasi-

continuous and well-collimated atomic beam [404] and tunneling can give rise to a pulsed mode-locked atom laser (*mode-locked laser*) [22].

A trapped condensate represents a *finite reservoir* from which an atom laser can be fed. For a really cw atom laser, an incoherent pumping mechanism, continuously feeding the BEC, while it delivers atoms to the atom laser, is still lacking [610].

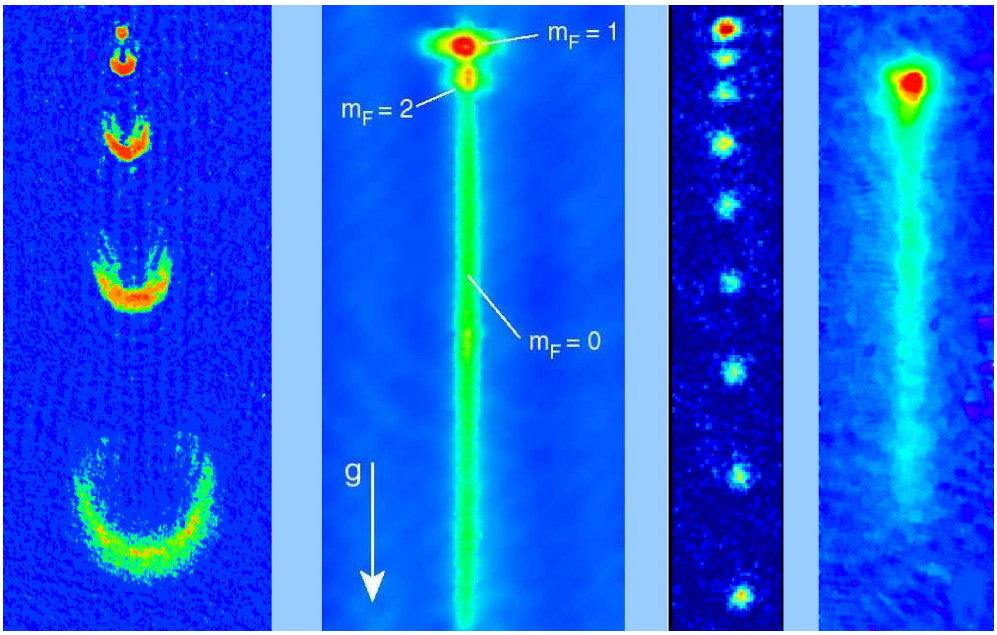

Figure 51.9: Several types of atomic lasers realized, from left to right at the MIT in 1997, in Munich in 1999, at Yale in 1998, and at NIST in 1999. The vertical sizes of the images are, from left to right: 5, 2, 0.5, and 1 mm.

51.3.3 Atomic interferometry with Bose-Einstein condensates

The most obvious use of an atom laser is within an atomic interferometer [885, 872, 109, 403, 101, 851, 512, 141, 713, 247, 652, 671]. Many types of interferometers have been developed over the years. First of all, we note that the interferometric idea can be realized in the spatial domain (e.g. an atomic beam passing through a light wave) or in the time domain (e.g. a trapped atomic cloud or an immobile trapped ion irradiated by a pulsed light) [114, 459, 765, 358].

Furthermore, depending on the involved degree of freedom (kinetic or internal excitation), we may distinguish two types of interferometers. Matter wave interferometers operating with the kinetic degree of freedom often use beam splitters based on Bragg diffraction [535, 713, 403, 851]. Matter wave interferometers involving internal degrees of freedom generally couple two species of condensates, that is, two condensates in different states of internal excitation, for example, in different Zeeman [886], hyperfine [681, 409, 652], or dressed states [561]. The phases of two BECs in different internal states, which we will call $|\pm\rangle$, evolve according to their respective chemical

potentials, $\varphi_{|\pm\rangle}(t) = \mu_{|\pm\rangle}t$. The accumulated phases are not directly observable, but their difference, $\Delta\varphi(t)$, can be measured by *Ramsey interferometry*.

51.3.4 Non-linear atomic optics

In classical nonlinear optics, the interaction between matter (e.g. dilute gases) and light is described by Maxwell's equations. The electromagnetic field $\mathbf{E}$ creates a macroscopic polarization,

$$\mathbf{P}(\mathbf{r},t) = \chi(\mathbf{E})\mathbf{E}(\mathbf{r},t) = \chi^{(1)} \cdot \mathbf{E} + \chi^{(3)} : \mathbf{EEE} + \dots \,. \tag{51.28}$$

which in turn acts back onto the field. Higher-order processes, such as *self-focusing*, *second-harmonic generation*, *four-wave mixing*, etc. are described by the non-linear susceptibility $\chi^{(3)}$. These processes require the presence of a non-linear medium (the vacuum polarization itself being too small [501, 392]).

The role of binary collisions in coherent matter wave optics, as described by the nonlinear term in the Gross-Pitaevskii equation (50.21), is very similar to the role of the third-order nonlinear susceptibility in quantum optics [565, 535, 248, 363, 926, 502, 417, 504, 568, 215, 419]. For example, if the atomic interaction is repulsive, the nonlinear term tries to increase the size of the condensate as much as possible within the limits imposed by the trapping potential. This behavior is analogous to the phenomenon of *self-defocusing* known in non-linear optics.

Small-amplitude elementary oscillations are well described by the *Bogolubov-de Gennes equations*, which are a linearized version of the Gross-Pitaevskii equation [197]. On the other hand, large-amplitude oscillations, which are sensitive to the nonlinear mean-field interaction [861], showed a splitting of the frequency for quasi-particle excitation, in analogy with the generation of the second-harmonic (*SHG*) in quantum optics [419].

Other phenomena, such as matter wave *phase conjugation* and four waves mixing (*4WM*) [363] have been observed in experiments [248]. The three matter wave modes for the nonlinear mixing were produced out of a single condensate by applying two short consecutive sequences of Bragg diffraction pulses. The condensates are created in the same spatial region, but at different times. The nonlinear mixing during the process of spatial separation was observed by time-of-flight images.

The geometry of the laser beams is shown in Fig. 51.10(a) in the laboratory system. A first standing wave light pulse is generated by lasers $\mathbf{k}_1$ and $\mathbf{k}_2$ detuned from each other by an amount, such that the Bragg condition is satisfied and the momentum $\mathbf{p}_2 = \hbar\mathbf{k}_1 - \hbar\mathbf{k}_2$ is transmitted to the diffracted atoms. Then, a second standing wave light pulse formed by lasers $\mathbf{k}_1$ and $\mathbf{k}_3 = -\mathbf{k}_1$ transmits to the diffracted atoms the momentum $\mathbf{p}_3 = 2\hbar\mathbf{k}_1$. The duration and intensity of the standing waves are adjusted such as to create an approximately equal distribution of N_j^0 atoms in all three condensate momentum modes, each mode having a different momentum, $\mathbf{p}_1 = 0$, $\mathbf{p}_2$, and p_3. Initially, the three wavepackets $\hat{\psi}_j \equiv \hat{\psi}_0(\mathbf{r})e^{i\mathbf{p}_j\mathbf{r}/\hbar}$ overlap. The nonlinear term in the Gross-Pitaevskii equation mixes the wavepackets while they separate to

form other wavepackets, $\hat{\psi}_4 \sim g\hat{\psi}_j^+\hat{\psi}_m\hat{\psi}_n e^{i\mathbf{p}_4\cdot\mathbf{r}/\hbar}$, where,

$$N_4 = -N_j + N_j^0 = N_m - N_m^0 = N_n - N_n^0 = \sum\nolimits_{\kappa=1}^{3}(N_\kappa^0 - N_\kappa) \tag{51.29}$$
$$\mathbf{p}_4 = -\mathbf{p}_j + \mathbf{p}_m + \mathbf{p}_n$$
$$p_4^2 = -p_j^2 + p_m^2 + p_n^2 \ .$$

To produce the new momenta, $\mathbf{p}_4 \neq \mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3$, the corresponding wavepackets must gather atoms from all three initial packets $\mathbf{p}_1 \neq \mathbf{p}_2 \neq \mathbf{p}_3$.

The experimental observation of a newly emerging wavepacket $\hat{\psi}_4$ has two complementary interpretations: In the inertial system defined by $\mathbf{p}_1 = -\mathbf{p}_3$ [see Fig. 51.10(b)], the wavepackets $\hat{\psi}_1$ and $\hat{\psi}_3$ suffer elastic collisions. The direction in which the condensates are scattered is, a priori, isotropic. The injection of a third condensate $\hat{\psi}_2$ bosonically stimulates the formation of a forth one, $\hat{\psi}_4$, in a predefined direction $\mathbf{p}_4 = -\mathbf{p}_2$. The laws of conservation for the particle numbers, momenta, and energies (51.29) only allow processes, which can be interpreted as degenerate 4WM in this inertial system. Each of the wavepackets $\hat{\psi}_1$ and $\hat{\psi}_3$ sacrifice N_4 atoms to create a new wavepacket $\hat{\psi}_4$ and to amplify the wavepacket $\hat{\psi}_2$. The redistribution of atoms is a coherent process.

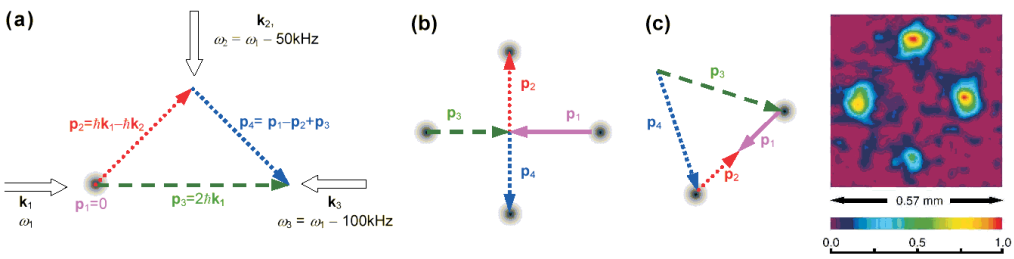

Figure 51.10: Matter wave 4WM can be illustrated (a) in the laboratory system, or (b) in the inertial system defined by $p_1 = -p_3$, or (c) in the system defined by $p_1 = -p_2$. In each system the process has a different physical interpretation (see text). The right image shows the experimental result.

The second interpretation becomes clear in the inertial system, in which $\mathbf{p}_1 = -\mathbf{p}_2$ [see Fig. 51.10(c)]. The conservation of energy only allows scattering products satisfying $p_4 = p_3$, that is, $\hat{\psi}_1^+\hat{\psi}_2\hat{\psi}_3$ and $\hat{\psi}_2^+\hat{\psi}_1\hat{\psi}_3$. In this system, the process can be interpreted as Bragg diffraction of the wavepacket $\hat{\psi}_3$ by the matter wave lattice formed by $\hat{\psi}_1$ and $\hat{\psi}_2$. The wavepacket $\hat{\psi}_4$ is nothing more than the first diffraction order. Unlike the Bragg diffraction in an optical lattice (see Sec. 52.2), the Bragg diffraction by a matter wave lattice requires nonlinear mixing through binary atomic collisions. Thus, the number of redistributed atoms depends on parameters such as the interatomic interaction strength, the size of the condensate, and the collision time between the wavepackets, i.e. the time that the wavepackets spend together before separating.

Despite the similarity with the optical counterpart, matter wave 4WM is fundamentally different: The number of particles must be conserved and the energy-momentum dispersion relation is not linear. Furthermore, while photons require the

presence of a nonlinear medium in order to participate in higher-order processes, atomic matter waves mix through binary collisions.

51.4 Quantum atom optics

When describing a condensate by the Gross-Pitaevskii equation, we specify a phase and an atom number. However, both are conjugate quantities, which can not be specified without uncertainty. So, what does the BEC really look like: a Glauber state or rather a Fock state? We need to be careful. Certainly, it makes no sense talking about the absolute phase of a single BEC. Only the *relative phase* between *two* BECs matters. The condition for interference is, that we do not know, from which condensate the interfering atom came $\Delta N \Delta\varphi \geq 1$. So, the relative atom number must be uncertain.

51.4.1 Quantum transport

Now, let us imagine two BECs in a double-well potential. Atoms may be move between the wells via *Josephson tunneling*, even if the height of the barrier is higher than the atomic energy. Hence, the motion is a type of *quantum transport*. Be $\psi(\mathbf{r},t) = \psi_1(\mathbf{r})e^{\imath\mu_1 t/\hbar} + \psi_2(\mathbf{r})e^{\imath\mu_2 t/\hbar}$. In elongated traps the Josephson current is obtained as the expectation value of the *flux operator*,

$$I(z,t) = \frac{\imath\hbar}{2m}\int\left(\psi(\mathbf{r},t)\frac{d}{dz}\psi^*(\mathbf{r},t) - c.c.\right)dxdy\ . \tag{51.30}$$

One obtains,

$$I(z,t) = \frac{\imath\hbar}{2m}\int\left(\psi_1\frac{d\psi_1^*}{dz} + \psi_2\frac{d\psi_2^*}{dz} + \psi_1\frac{d\psi_2^*}{dz}e^{\imath(\mu_1-\mu_2)t/\hbar} + \psi_2\frac{d\psi_1^*}{dz}e^{\imath(\mu_2-\mu_1)t/\hbar} - c.c.\right)dxdy\ . \tag{51.31}$$

Choosing the original phase of the two condensates equal to zero, the time-independent terms are real and cancel each other, leaving,

$$\begin{aligned} I(z,t) &= \frac{\imath\hbar}{2m}\int\left(\psi_1\frac{d\psi_2}{dz} - \psi_2\frac{d\psi_1}{dz}\right)2\imath\sin\tfrac{(\mu_1-\mu_2)t}{\hbar}dxdy \\ &\equiv I_0\sin\tfrac{(\mu_1-\mu_2)t}{\hbar}\ . \end{aligned} \tag{51.32}$$

This shows that the current oscillates in time. This feature is well-known for *Josephson junction* in superconductors.

The question is now, what will be the steady-state of the two BECs [710]. Experiments have shown, that the BECs will gradually evolve into a superposition of number states, until they are coherent. The time scale is set by Josephson tunneling. The same interference pattern would result from BECs initially having well-defined phases [5].

[5] If two Josephson-coupled BECs are initially in Fock-states, the current must initially be a quantum superposition of all currents corresponding to all possible atom number differences. This quantum superposition decoheres rapidly, leaving behind a semi-classical oscillation.

51.4.2 Optical lattices and the Mott insulator

We have already pointed out in Sec. 49.3.2, that laser beams tuned far away from resonances serve to construct trapping potentials for atoms. Laser beams incident on the atomic cloud under various angles allow the engineering of a large diversity of geometries for attractive potentials (with red tuned lasers) or repulsive potentials (with blue tuned lasers). Various cooling methods can be combined with dipolar traps, for example, Doppler cooling [462], Raman cooling [411], evaporative cooling [3], or gravitational Sisyphus cooling [688]. A particularly interesting geometry is that of are optical lattice, which we will discuss in the following sections.

51.4.2.1 Bloch bands with mean field interaction

The deformation of Bloch bands in the presence of mean field interaction has been discussed in [983, 985]. Under certain circumstances, the bands develop loops at the edges of a Brillouin zone. This is due to superfluidity overwhelming Bragg reflection.

51.4.2.2 The Hubbard model in 1D

The *Hubbard model* gives an approximate description of the physics of interacting *particles* in a lattice. Depending on the type of particle one distinguishes the *Bose-Hubbard model* from the *Fermi-Hubbard model* used in solid state physics for the description of superconducting systems and the hopping of electrons between the atoms of a solid crystalline lattice.

The foundations of the Hubbard model lie in the Bloch-Wannier formalism exposed in Sec. 26.2.3 for the case one-dimensional sinusoidal potentials. Although we already define particle creation and annihilation operator in both, the Bloch and the Wannier basis, there we restricted to individual particles, which dispensed us from taking into account symmetrization constraints and inter-particle interactions. The presence of many particles is best described in a second-quantized Fock state notation for Bloch and Wannier states,

$$|n,q\rangle \longrightarrow |N_{n,q}\rangle \qquad \text{respectively,} \qquad |n,j\rangle \longrightarrow |N_{n,j}\rangle \ , \tag{51.33}$$

where we drop the index n when it is clear that the particles stays in the nth band. In the Wannier basis, the bosonic field operators must satisfy the commutation relation,

$$[\hat{w}_j, \hat{w}^\dagger_{j'}]_- = 1 \quad \text{with} \quad \begin{aligned} \hat{w}^\dagger_{j'}|N_j\rangle &= \sqrt{N_j+1}|N_j+1\rangle \\ \hat{w}_{j'}|N_j\rangle &= \sqrt{N_j}|N_j-1\rangle \end{aligned} \ , \tag{51.34}$$

while the fermionic field operators must satisfy,

$$[\hat{w}_j, \hat{w}^\dagger_{j'}]_+ = 0 \quad \text{with} \quad \begin{aligned} \hat{w}^\dagger_{j'}|N_j\rangle &= \sqrt{1-N_j}|N_j+1\rangle \\ \hat{w}_{j'}|N_j\rangle &= \sqrt{N_j}|N_j-1\rangle \end{aligned} \ . \tag{51.35}$$

In Sec. 26.2.3 we have derived the number operator and Hamiltonian for a given band n,

$$\hat{N}^{(n)}_j = \hat{w}^\dagger_j \hat{w}_j \quad , \quad \hat{H}^{(n)} = -\sum_{j,j'} \mathfrak{J}(\Delta j)\hat{w}^\dagger_j \hat{w}_{j'} \ , \tag{51.36}$$

where,

$$\begin{aligned}\mathfrak{J}(\Delta j) &= -\langle n, z_{j'}|\hat{H}^{(n)}|n, z_j\rangle \\ &= \int_{\mathbb{R}}\int_{\mathbb{R}} \langle n, z_{j'}|z'\rangle\langle z'|\left(\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} - V_0\cos^2 k_1\hat{z}\right)|z\rangle\langle z|n, z_j\rangle dz dz' \\ &= \int_{\mathbb{R}} \langle n, z_{j'}|z\rangle\left(\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} - V_0\cos^2 k_1\hat{z}\right)\langle z|n, z_j\rangle dz \ .\end{aligned} \tag{51.37}$$

In the tight-binding limit, we only consider tunneling between neighboring sites, $\mathfrak{J}(j-j') = \mathfrak{J}\,\delta_{j,j\pm1}$, setting $\mathfrak{J} = \mathfrak{J}(1)$.

Example 370 (*Link between particle field operators and Wannier states*): Many-particle field operators have been introduced in Sec. 50.2.1,

$$\hat{\psi}(z) = \sum_{n,j}\langle z|n, z_j\rangle\hat{w}_j^{(n)} \ .$$

We verify the commutator,

$$\begin{aligned}[\hat{\psi}(z), \hat{\psi}^\dagger(z')]_- &= \delta^{(3)}(z-z') = \sum_{n,j}\langle z|n, z_j\rangle\langle n, z_j|z'\rangle \\ &= \sum_{n,j,n',j'}\langle z|n, z_j\rangle\langle n', z_{j'}|z'\rangle\delta_{n,n'}\delta_{j,j'} = \sum_{n,j,n',j'}\langle z|n, z_j\rangle\langle n', z_{j'}|z'\rangle[\hat{w}_j, \hat{w}_{j'}^\dagger]_- \ ,\end{aligned}$$

the particle number operator,

$$\begin{aligned}\hat{N} &= \int \hat{\psi}^\dagger(z)\hat{\psi}(z)dz = \sum_{n,j,n',j'}\hat{w}_{j'}^\dagger\hat{w}_j\int\langle n', z_{j'}|z\rangle\langle z|n, z_j\rangle dz \\ &= \sum_{n,j,n',j'}\langle n', z_{j'}|n, z_j\rangle\hat{w}_{j'}^\dagger\hat{w}_j = \sum_{n,j}\hat{w}_j^\dagger\hat{w}_j \ ,\end{aligned}$$

and the Hamiltonian,

$$\begin{aligned}\hat{H} &= \int \hat{\psi}^\dagger(z)\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + V_0\cos^2 k_1\hat{z}\right)\hat{\psi}(z)dz \\ &= \sum_{n,j,n',j'}\hat{w}_{j'}^\dagger\hat{w}_j\int\langle n', z_{j'}|z\rangle\left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + V_0\cos^2 k_1\hat{z}\right)\langle z|n, z_j\rangle dz = -\sum_{n,j,n',j'}J(\Delta j)\hat{w}_{j'}^\dagger\hat{w}_j \ .\end{aligned}$$

51.4.2.3 Additional trapping potential

The presence of an additional trapping potential can also be considered,

$$\begin{aligned}\hat{\mathcal{V}} &= \int \hat{\psi}^\dagger(z)V_{\text{trp}}(z)\hat{\psi}(z)dz \\ &= \sum_{n_1,j_1,n_2,j_2}\hat{w}_{j_1}^\dagger\hat{w}_{j_2}\int V_{\text{trp}}(z)\langle n_1, z_{j_1}|z\rangle\langle z|n_2, z_{j_2}\rangle dz \ .\end{aligned} \tag{51.38}$$

To simplify this expression, we assume that the potential depth of V_{trp} *does not vary much between adjacent sites*,

$$\hat{\mathcal{V}} \simeq \sum_j \hat{w}_j^\dagger\hat{w}_j\int V_{\text{trp}}(z)|\langle z|0, z_j\rangle|^2 dz \simeq \sum_j V_{\text{trp}}(z_j)\hat{w}_j^\dagger\hat{w}_j \ . \tag{51.39}$$

51.4.2.4 s-wave collisions between bosons

The short-range interaction Hamiltonian (s-wave for bosons) reads, in the pseudo-potential approximation,

$$\hat{H}_{coll} = \frac{g}{2}\int \hat{\psi}^\dagger(z)\hat{\psi}^\dagger(z)\hat{\psi}(z)\hat{\psi}(z)dz \tag{51.40}$$
$$= \frac{g}{2}\sum_{n_1,j_1,n_2,j_2,n_3j_3,n_4,j_4} \hat{w}^\dagger_{j_1}\hat{w}^\dagger_{j_2}\hat{w}_{j_3}\hat{w}_{j_4}\int \langle n_1, z_{j_1}|z\rangle\langle n_2, z_{j_2}|z\rangle\langle z|n_3, z_{j_3}\rangle\langle z|n_4, z_{j_4}\rangle dz \ .$$

To simplify this complicated expression, we assume (i) that the *energy of a collision be too low to excite interband transitions*, so that atoms being in the lowest band $n_\alpha = 0$ stay there. (ii) The lattice is so deep, that the *Wannier functions of adjacent sites do not overlap*, so that only on-site collisions contribute,

$$\hat{H}_{coll} \simeq \frac{g}{2}\sum_j \hat{w}^\dagger_j\hat{w}^\dagger_j\hat{w}_j\hat{w}_j\int |\langle z|0, z_j\rangle|^4 dz \tag{51.41}$$
$$= \frac{g}{2}\sum_j \hat{N}_j(\hat{N}_j - 1)\int |\langle z|0, z_j\rangle|^4 dz = \frac{U}{2}\sum_j \hat{N}_j(\hat{N}_j - 1) \ ,$$

where we defined,

$$U \equiv \frac{g}{2}\sum_j \int |\langle z|0, z_{j=0}\rangle|^4 dz \ . \tag{51.42}$$

In the limit of very deep lattices, when the Wannier function can be approximated by the ground state wavefunction of a harmonic oscillator, $\langle 0|0, z_{j=0}\rangle \simeq (\pi a^2_{\rm ho})^{-1/4}e^{-z^2/2a^2_{\rm ho}}$, we find,

$$U = g\int \langle z|0, z_{j=0}\rangle^4 dz \simeq \frac{g}{\pi a^2_{\rm ho}}\int e^{-2z^2/a^2_{\rm ho}}dz = \frac{g}{\sqrt{2\pi}a_{\rm ho}} \ . \tag{51.43}$$

51.4.2.5 The Bose-Hubbard model in 3D

The Hubbard model in the tight-binding limit can readily be generalized to 3D [710, 379]. Collecting the Hamiltonian terms (51.36), (51.39), and (51.41), we arrive at,

$$\boxed{\hat{H} = -\mathfrak{J}\sum_{j,j'} \hat{w}^\dagger_j\hat{w}_{j'} + \sum_j \varepsilon_j\hat{N}_j + \frac{1}{2}U\sum_j \hat{N}_j(\hat{N}_j - 1)} \ , \tag{51.44}$$

where

$$\mathfrak{J} = \int d^3r \ w^*(\mathbf{r} - \mathbf{r}_j)\left[-\frac{\hbar}{2m}\nabla^2 + V_0(\mathbf{r})\right] w(\mathbf{r} - \mathbf{r}_j) \ . \tag{51.45}$$

and

$$U \equiv \frac{4\pi a_s\hbar^2}{m}\int |w^*(\mathbf{r})|^4 d^3r \ , \tag{51.46}$$

and in the presence of an additional external trap,

$$\varepsilon_j \equiv \int V_{\rm trp}(\mathbf{r})|w(\mathbf{r} - \mathbf{r}_j)|^2 d^3r \simeq V_{\rm trp}(\mathbf{r}_j) \ , \tag{51.47}$$

and $w(\mathbf{r}) = w(x)w(y)w(z)$ are the *Wannier functions* for an individual particle. We assume for the moment a homogeneous condensate.

The Hilbert space dimension of the Bose-Hubbard model grows exponentially with the number of atoms N and the number of sites L,

$$D_b = \binom{N_b + L - 1}{N_b} , \tag{51.48}$$

according to the partition function derived in quantum statistics, see Sec. 29.2.2. For the Fermi-Hubbard model, the Pauli exclusion principle leads to the Hilbert space dimension,

$$D_f = \binom{L}{N_f} . \tag{51.49}$$

In three dimensional lattices the Hilbert space grows even faster. Therefore, it is a difficult computational task to model or simulate such systems, and generally not possible for more than 20 atoms and 20 lattice sites.

51.4.2.6 The Mott insulator

At zero temperature, the Bose-Hubbard model (in the absence of disorder) predicts the atomic ensemble to be an a Mott insulating state (MI) when $\mathfrak{J} \ll U$, a superfluid state (SF) when $\mathfrak{J} \gg U$, or a *supersolid phase* (SS), where both solid and superfluid phases (diagonal and off-diagonal) coexist. Mott insulation phases are characterized by integer site occupation numbers, by the existence of an energy gap for particle-hole excitations, and zero compressibility. In the presence of disorder, a third phase, the *Bose glass* exists. This phase is insulation because of the Anderson localization effects. Bose glass is characterized by a finite compressibility, the absence of a gap, and an infinite superfluid susceptibility [315]. See also (watch talk).

In the Mott insulating state, the atoms are *localized* at individual sites of an optical lattice. On one hand, the localization impedes any phase relation between atoms at different sites, that is, at a given site the phase uncertainty $\Delta\phi$ is complete. But at the same time, there is a perfect correlation of the atom number at each site known as *spin squeezing* [6], because (in a homogeneous lattice) every site contains exactly the same number of atoms, that is, the atom number uncertainty ΔN tends to zero. At a given lattice site, the number of atoms and the phase of the wavefunction can not be simultaneously fixed: $\Delta N \Delta\phi > 1$.

The absence of relative coherence between different sites and of the ability to interfere prohibits the description of the system by a single global wavefunction and the use of the Gross-Pitaevskii equation. Nevertheless, the Mott insulating state is not equivalent to a completely randomized sample. On the contrary, the coherence only changes its character [7].

The *Mott transition* of a condensate from a superfluid state and to state of a *Mott insulator* occurs as a *quantum phase transition*, because it is driven by quantum fluc-

[6] The spin squeezing feature makes the Mott insulator interesting for spectroscopy at the *Heisenberg limit* and for quantum computation.

[7] Remember, that the Fock state is a complicated superposition of Glauber states. The disappearance and reappearance of coherence is reminiscent to the phenomenon of collapse and revival in the Jaynes-Cummings model.

tuations rather than of thermal noise. Therefore, it is a direct result of Heisenberg's uncertainty relation.

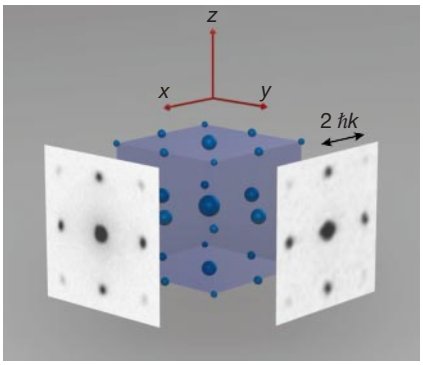

Figure 1 Schematic three-dimensional interference pattern with measured absorption images taken along two orthogonal directions. The absorption images were obtained after ballistic expansion from a lattice with a potential depth of $V_0 = 10E_r$ and a time of flight of 15 ms.

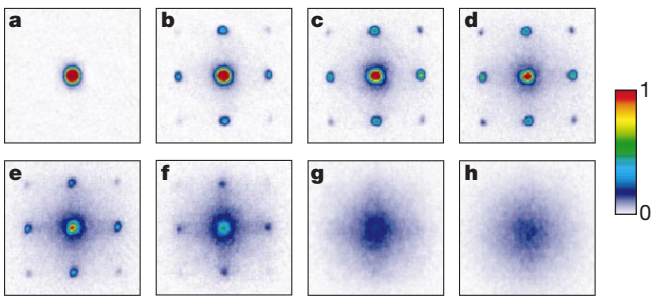

Figure 2 Absorption images of multiple matter wave interference patterns. These were obtained after suddenly releasing the atoms from an optical lattice potential with different potential depths V_0 after a time of flight of 15 ms. Values of V_0 were: **a**, 0 E_r; **b**, 3 E_r; **c**, 7 E_r; **d**, 10 E_r; **e**, 13 E_r; **f**, 14 E_r; **g**, 16 E_r; and **h**, 20 E_r.

Figure 51.11: Signature of the Mott phase.

In the limit of strong tunneling and weak interactions, $\mathfrak{J} \gg U$, the matter wave function looks like a *Bloch state*,

$$|\psi_{SF}\rangle \sim \left(\sum_{i=1}^{M} \hat{a}_i^\dagger\right)^N |0\rangle \ . \tag{51.50}$$

The variance of the number of particles per site is Poissonian, $\sigma_{SF} \sim \sqrt{N_i}$, that is, the wavefunction per lattice site is (quasi)-coherent. However, the total wavefunction is delocalized over all lattice sites, the local wavefunctions have a rigid phase relationship and no long-range coherence. Otherwise, the matter wave function is an independent

product of *Fock states*,

$$|\psi_{MI}\rangle \sim \prod_{i=1}^{M} (\hat{a}_i^\dagger)^n |0\rangle \ . \tag{51.51}$$

The momentum distribution in terms of Wannier functions is [396, 984],

$$n(\mathbf{k}) = |w(\mathbf{k})|^2 \sum_{i,j} e^{\imath \mathbf{k}(\mathbf{r}_i - \mathbf{r}_j)} \langle \hat{a}_i^\dagger \hat{a}_j \rangle \ . \tag{51.52}$$

The atoms are localized in individual sites and there is a perfect correlation of the particle number in each site, known as *spin-squeezed state*, i.e. the variance tends to zero, $\sigma_{MI} \to 0$. The Mott transition is characterized by $\sigma = \frac{1}{2}$. In a given site, the atom number and the phase of the wavefunction cannot be known simultaneously: $\Delta N \Delta \phi < 1$. Therefore, the on-site wavefunction loose their relative coherence and capability to interfere. They cannot be described by a single global wavefunction and do not follow the Gross-Pitaevskii equation. However, this state is not equivalent to a completely randomized ensemble. Rather the *coherence is transferred from inter-site correlations to inner-site correlations* (keep in mind that a Fock state is a complicated superposition of Glauber states). This is somehow analogous to collaps and revival in the Jaynes-Cummings model.

The Mott transition between the superfluid and the *Mott insulator* phase is a *quantum phase transition*, since it is driven by quantum fluctuations rather than themal noise. Thus it is a direct result of Heisenberg's incertainty relation.

These features make optical lattices in the Mott insulating phase interesting for spectroscopy at the *Heisenberg limit* and quantum computing.

Example 371 (*Practical Aspects*): Normal MOT loaded $3D$ lattices have filling factors of 1/10 per site. Sophisticated Raman-sideband cooling schemes are necessary to achieve higher factors. Alternatively, one may fill $1D$ or $3D$ lattices from a BEC, which offers low temperatures and high densities, so large filling factors, but quantum degeneracy is not a requirement (what matters is that only the lowest band is populated).
We may go to $1D$ configurations. In order to get good signal contrast despite the small number of sites, large filling factors are necessary. Even though spin-squeezing is possible, the weak lateral confinement makes it hard to reach the Mott insulating regime. An improvement could be the use of $1D$ arrays of annular traps, because of the tighter lateral confinement. Alternatively, we may fill a $3D$ lattice with 1 to 3 atoms per site and some 150000 sites. Low atom numbers make it easier to resolve the Mott transition. Typical numbers are $\nu_{\text{trp}} \approx 50\,\text{Hz}$, $\nu_{Gauss} \approx 60\,\text{Hz}$, $\nu_{lattice} \approx 30\,\text{kHz} \ \approx 22 E_{rec}$.
For quantum gate application, spin squeezing is important since the entangling

pulse area depends on the on-site interaction energy $\frac{4\pi a_s \hbar^2}{m} n$, but it is not necessary to have only a single atom per site. What is the deeper relationship of the Mott spin-squeezing and the entanglement achievable by quantum gates [474]?
Probing is simply done by free expansion and observation of the interference patterns as the image of the momentum space distribution. The periodic structure of the density distribution causes a periodic pattern in momentum space,

and since in the superfluid phase the ....
For inhomogeneous systems, superfluid and Mott insulating phases with different (integral atom number) populations may coexist. The Mott insulating phase is characterized by a gap in the excitation spectrum (precisely the one that inhibits the atomic mobility). This may be probed by applying potential gradients designed to overcome the gap.
The Mott insulating phase is not equivalent to random dephasing in the sites. The latter one causes a broadening of the interference patterns. If all atoms at all sites had the same phase (which is possible in a single realization, but highly unlikely, because such a state cannot be generated on purpose since this would violate the uncertainty principle) they could constructively interfere.
An important signature of is the *incompressibility of a Mott insulator*. This distinguishes it from a superfluid. Even more fundamental [350] is the fact that particle-hole pairs are localized. The $\mu - J/U$ phase diagram is most significant...

Example 372 (*Band insulator, Fermi-Hubbard model*): The Pauli principle gives rise to an energy gap in a Fermi gas and makes it a *band insulator* [527], *antiferromagnetic phases*. Transfer a pure Fermi gas in an optical lattice [447].

51.4.3 Schrödinger cat BECs

Ruostekoski *et al.* [793] proposed a double BEC system consisting of two momentum sidemodes and a far-off resonance laser beam that constantly spontaneously redistributes the atoms between the sidemodes. Homodyne detection of the scattered photons established *relative phase* information in such a way, that the relative number information is blurred in such a way that both sidemodes evolve into a simultaneous superposition of phase and number states. They disregard thermal excitations and two-body collisions. The cats are very sensitive to decoherence.

Cirac *et al.* [177] and Gordon *et al.* [369] consider Josephson double species condensates. The relative atom numbers Rabi flop. Mediated by the mean-field the systems may evolve into cats. The proposals have been reexamined by Dalvit *et al.* [221]. Other contributions come from [362, 440, 800, 766, 474]. First experiments on spin-squeezed states have been made by [710].

51.4.4 Exercises

51.4.4.1 Ex: Superfluid to Mott insulator transition

Consider a condensate trapped in a 3D *simple cubic* optical lattice with lattice spacing l. The Hamiltonian can be written as,

$$\hat{H} = -J \sum_{i,j} \delta_{ij}^{(1)} \hat{a}_i^\dagger \hat{a}_j + \tfrac{U}{2} \sum_i \hat{a}_i^\dagger \hat{a}_i^\dagger \hat{a}_i \hat{a}_i \ ,$$

where $\hat{a}_i$ ($\hat{a}_i^\dagger$) is the operator annihilating (creating) one boson in the lattice site i; $\delta_{ij}^{(1)} = 1$ only when i and j are nearest neighbors, otherwise it is zero. Assume a total

of $M \gg 1$ sites, periodic boundary conditions in the x, y, and z directions, and $U > 0$. On this lattice we consider the construction operator $\hat{b}_s^\dagger$ defined in the following way:

$$\hat{b}_s^\dagger = \frac{1}{\sqrt{M}} \sum_i \hat{a}_i^\dagger \ .$$

a. Describe the action of this construction operator.
b. Derive the commutation relation,

$$[\hat{a}_\alpha, \hat{b}_s^\dagger] = \frac{1}{\sqrt{M}} \ .$$

c. Derive the commutation relation,

$$[\hat{a}_\alpha, (\hat{b}_s^\dagger)^N] = \frac{N}{\sqrt{M}} (\hat{b}_s^\dagger)^{N-1} \ .$$

d. Suppose that the following N-atom state exists:

$$|N, SF\rangle \equiv \frac{1}{\sqrt{N!}} (\hat{b}_s^\dagger)^N |0\rangle \ ,$$

where SF stands for a name label (and not for quantum numbers). Show that for $N = M$ we have $\hat{a}_\alpha |N, SF\rangle = |N-1, SF\rangle$.
e. Define the density operator for the site i as $\hat{n}_i = \hat{a}_i^\dagger \hat{a}_i$. Calculate the density fluctuation,

$$\Delta n_i = \sqrt{\langle \hat{n}_i^2 \rangle - \langle \hat{n}_i \rangle^2}$$

of the state $|N, SF\rangle$ with $N = M$.
f. Calculate the total energy $\langle H \rangle$ with the state $|N, SF\rangle$.
g. Next consider the state,

$$|N, MI\rangle \equiv \prod_j \hat{a}_j^\dagger |0\rangle \ .$$

Calculate $\langle \hat{a}_i^\dagger \hat{a}_j \rangle$ and the density fluctuations Δn_i for this state.
h. Calculate the total energy $\langle H \rangle$ with the state $|N, MI\rangle$.
i. Discuss the energy for the states $|N, SF\rangle$ and $|N, MI\rangle$. Which one is the ground state? How to make a ground state change from $|N, SF\rangle$ to $|N, MI\rangle$?

Chapter 52

Interaction of Bose-Einstein condensates with light

Light can essentially be used in two ways for the manipulation of matter waves: 1. Tuned *far from resonance*, light serves to create conservative optical dipole potentials (see Secs. 49.3.2 and 51.4.2). In such circumstances the states of internal atomic excitation can be adiabatically eliminated from the description of the center-of-mass dynamics. 2. *Close to resonance* the situation is quite different, but even then, the coherent excitation of internal states may allow for a controlled manipulation of the atomic motion. Among the examples discussed in the following sections are the adiabatic sweeps, the Raman output coupler, Bragg pulses, photoassociation, and matter wave superradiance (see Fig. 52.1).

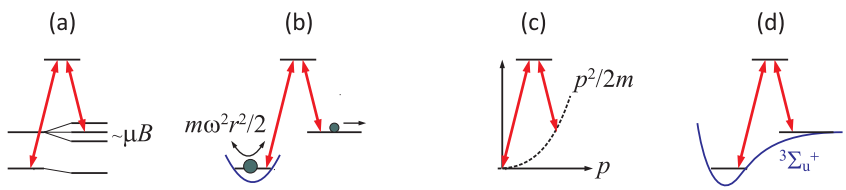

Figure 52.1: Different types of coherent coupling: (a) coherent coupling of hyperfine levels, (b) coupling from a confined state to the continuum of free states, (c) mutual coupling of different velocity states of an atom, and (d) coupling between a (collisional) state of two free atoms with a bound molecular state.

52.1 Scattering of light by degenerate gases

52.1.1 The structure factor for degenerate quantum gases

We introduced in Sec. 44.1.1 the notion of the structure factor, where it was used to characterize the scattering of light by thermal distributions of atoms. To characterize the scattering of matter waves, we must generalize the notion of the structure factor. We wrote in (44.3) the Fourier transform of the density distribution, which now becomes, after inserting $\hat{n}(\mathbf{r}) = \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r})$ and the plane wave expansion (50.70),

$$\hat{\rho}^\dagger(\mathbf{q}) = \int \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r})e^{\imath\mathbf{q}\cdot\mathbf{r}}d^3r = \tfrac{V}{(2\pi)^3}\iiint \hat{a}^\dagger_{\mathbf{k}'}\hat{a}_{\mathbf{k}}e^{\imath(\mathbf{k}-\mathbf{k}'+\mathbf{q})\cdot\mathbf{r}}d^3k'd^3kd^3r\ . \qquad (52.1)$$

With (50.76) and assuming sharp momenta (50.71),

$$\hat{\rho}^\dagger(\mathbf{q}) = V^2 \iint \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}} \delta_{\mathbf{k}',\mathbf{k}+\mathbf{q}} d^3k' d^3k = \sum_{\mathbf{k}',\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}} \delta_{\mathbf{k}',\mathbf{k}+\mathbf{q}} \ . \tag{52.2}$$

Finally,

$$\boxed{\hat{\rho}^\dagger(\mathbf{q}) = \sum_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}+\mathbf{q}} \hat{a}_{\mathbf{k}} = \sum_{\mathbf{k}} |\mathbf{k}+\mathbf{q}\rangle\langle\mathbf{k}|} \ . \tag{52.3}$$

Hence, $\hat{\rho}^\dagger(\mathbf{q})$ describes the scattering of an atom with the momentum $\mathbf{k}$ to $\mathbf{k}+\mathbf{q}$. We also find,

$$\hat{\rho}^\dagger(\mathbf{q}) = \hat{\rho}(-\mathbf{q}) \ . \tag{52.4}$$

Understanding the fundamental state $|g\rangle$ as the state without excitations, we define the *static structure factor* (44.5) now normalized to the number of particles [872],

$$\boxed{S(\mathbf{q}) \equiv \tfrac{1}{N} \langle g|\hat{\rho}(\mathbf{q})\hat{\rho}^\dagger(\mathbf{q})|g\rangle} \ , \tag{52.5}$$

as a generalization of the classical structure factor. The static structure factor describes the probability to excite a condensate by creating a quasi-particle with momentum $\mathbf{k}$. We will need these notions in the Sec. 52.2.3.

The *dynamic structure factor* is obtained from $S(\mathbf{q}) = \int S(\mathbf{q},\omega)d\omega$ and measures the density of correlations in the ground state with 0 momentum. The formula describes, how an atom probes its environment by scattering quasi-particles back and forth,

$$S(\mathbf{q},\omega) = \tfrac{1}{N} \sum_f \langle g|\hat{\rho}(\mathbf{q})|f\rangle\langle f|\hat{\rho}(\mathbf{q})|g\rangle \hbar\delta(\hbar\omega - E_f + E_g) \ . \tag{52.6}$$

Solve the Excs. 52.1.6.1 to 52.1.6.5.

Example 373 (*Spatial coherence and the correlation function*): The *spatial coherence* can be defined by [CCT & Aspect],

$$\boxed{F(\mathbf{x}) \equiv \int \langle\mathbf{r}|\hat{\rho}|\mathbf{r}+\mathbf{x}\rangle d^3r = \int e^{\imath\mathbf{k}\cdot\mathbf{x}} \langle\mathbf{k}|\hat{\rho}|\mathbf{k}\rangle d^3k} \ . \tag{52.7}$$

We will demonstrate this relationship in Exc. 52.1.6.6. The *coherence length* ξ is given by $F(\xi) = \frac{1}{e}F(0) = \frac{1}{e}$. A *second order correlation function* is defined by,

$$\boxed{\begin{aligned} g^{(2)}(\mathbf{r}_1,\mathbf{r}_2) &= \frac{\langle\hat{\psi}^\dagger(\mathbf{r}_1)\hat{\psi}^\dagger(\mathbf{r}_2)\hat{\psi}(\mathbf{r}_2)\hat{\psi}(\mathbf{r}_1)\rangle}{\langle\hat{n}(\mathbf{r}_1)\rangle\langle\hat{n}_2(\mathbf{r})\rangle} \\ g^{(2)}(\mathbf{r}) &\equiv g^{(2)}(\mathbf{r}_1,\mathbf{r}_1+\mathbf{r}) \end{aligned}} \ .$$

52.1.2 The structure factor in Bragg spectroscopy

52.1.2.1 The Hamiltonian of the Rayleigh scattering process

In Sec. 23.7.3 we saw the Galilei-boost (23.320),

$$|\mathbf{k}+\mathbf{q}\rangle = e^{\imath\mathbf{q}\cdot\hat{\mathbf{r}}}|\mathbf{k}\rangle \ . \tag{52.8}$$

In the second quantization we generalize to,

$$|\mathbf{k}+\mathbf{q}\rangle = \int \hat{\psi}^\dagger(\mathbf{r}) e^{\imath \mathbf{q}\cdot\mathbf{r}} \hat{\psi}(\mathbf{r}) d^3r |\mathbf{k}\rangle = \hat{\rho}^\dagger(\mathbf{q})|\mathbf{k}\rangle \ . \tag{52.9}$$

Thus, we can implement the second quantization by simply replacing $e^{\imath \mathbf{q}\cdot\mathbf{r}}$ by $\hat{\rho}^\dagger(\mathbf{q})$. Now, the Hamiltonian for the process of a photon absorption from the mode $\hat{c}_{\mathbf{k}_i}$, taking into account the photonic recoil, was introduced in (43.6),

$$\hat{H}_{int} = \hbar\Omega(\hat{\mathbf{r}}) e^{-\imath \mathbf{k}_i\cdot\hat{\mathbf{r}}} \hat{c}_{\mathbf{k}_i} \hat{\sigma}^+ + c.c. \ . \tag{52.10}$$

If the process is followed by the reemission of a photon to the mode $\hat{c}_{\mathbf{k}_f}$,

$$\boxed{\hat{H}_{int} = \hbar\Omega(\hat{\mathbf{r}}) e^{\imath(\mathbf{k}_f-\mathbf{k}_i)\cdot\mathbf{r}} \hat{c}^\dagger_{\mathbf{k}_f} \hat{c}_{\mathbf{k}_i}} \ . \tag{52.11}$$

Going to second quantization, as done in (52.9), and doing the Fourier transform [1],

$$\tilde{H}_{int} = C \sum_{\mathbf{p}_f,\mathbf{p}_i} \hat{c}^\dagger_{\mathbf{k}_f} \hat{c}_{\mathbf{k}_i} \hat{a}^\dagger_{\mathbf{p}_f} \hat{a}_{\mathbf{p}_i} \delta_{\mathbf{k}_f-\mathbf{k}_i+\mathbf{p}_f-\mathbf{p}_i} \ . \tag{52.12}$$

We assume here, that the light modes $\mathbf{k}_i$ and $\mathbf{k}_f$ are predefined, but the velocities $\mathbf{p}_i$ are distributed. Otherwise, in the expression (52.12), we must also sum over light modes [2],

$$\boxed{\tilde{H}_{int} = C \sum_{\mathbf{k}_i,\mathbf{k}_f,\mathbf{p}_i,\mathbf{p}_f} \hat{c}^\dagger_{\mathbf{k}_f} \hat{c}_{\mathbf{k}_i} \hat{a}^\dagger_{\mathbf{p}_f} \hat{a}_{\mathbf{p}_i} \delta_{\mathbf{k}_f-\mathbf{k}_i+\mathbf{p}_f-\mathbf{p}_i}} \ , \tag{52.13}$$

where C is a normalization constant. This Hamiltonian describes the elementary scattering process as a process of four wave mixing (4WM) [510, 873]. The light and the atoms are treated on equal footings as modes which can receive (quasi-)particle populations, and the scattering corresponds to a redistribution of populations between the modes [3].

The Hamiltonian (52.13) can be applied to various situations, such as spontaneous or stimulated Rayleigh scattering or Bragg scattering, depending on which ones of the modes $\mathbf{k}_f$, $\mathbf{k}_i$, $\mathbf{p}_f$, and $\mathbf{p}_i$ are populated or filtered by imposed boundary conditions.

Using momentum conservation $\mathbf{q} \equiv \mathbf{k}_f - \mathbf{p}_i = -\mathbf{p}_f + \mathbf{p}_i$, we obtain the cross section,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\mathbf{k}_i\to\mathbf{k}_f} = C^2 \sum_f |\langle f|\hat{H}_{int}|i\rangle|^2 = C^2 \sum_f |\langle f| \sum_{\mathbf{p}_i} \hat{c}^\dagger_{\mathbf{k}_i+\mathbf{q}} \hat{c}_{\mathbf{k}_i} \hat{a}^\dagger_{\mathbf{p}_i-\mathbf{q}} \hat{a}_{\mathbf{p}_i} |i\rangle|^2 \ , \tag{52.14}$$

Example 374 (*Description of Bragg scattering via the structure factor*): In this example we irradiate two plane waves in directions $\mathbf{k}_1$ and $\mathbf{k}_2$ into a Bose-Einstein condensate. The total intensity will be,

$$I_{mod}(\mathbf{r},t) = I\cos(\mathbf{q}\cdot\mathbf{r} - \omega t) \qquad \text{with} \qquad \mathbf{q} = \mathbf{k}_1 - \mathbf{k}_2 \ . \tag{52.15}$$

[1] $\hat{a}_{\mathbf{p}}$ and $\hat{a}^\dagger_{\mathbf{p}}$ are the operators of the quantized atomic field, while $\hat{c}_{\mathbf{k}}$ and $\hat{c}^\dagger_{\mathbf{k}}$ are the operators of the light fields.

[2] Note the different form of this Hamiltonian as compared to (44.10).

[3] This is analogous to the way, in which a 'collision' redistributes atomic populations between momentum modes. We will discuss this general concept of 4WM in Secs. 52.3.4 and 51.3.4.

and the optical potential,

$$V_{mod} = \frac{\hbar\Gamma^2}{8\Delta} I \cos(\mathbf{q}\cdot\mathbf{r} - \omega t) = \frac{\hbar\Gamma^2}{8\Delta}\frac{I}{2I_{sat}}(e^{\imath\mathbf{q}\cdot\mathbf{r}-\imath\omega t} + e^{-\imath\mathbf{q}\cdot\mathbf{r}+\imath\omega t}) \tag{52.16}$$
$$\rightarrow \hat{V}_{mod} = \frac{V}{2}[\hat{\rho}^\dagger(\mathbf{q})e^{-\imath\omega t} + \hat{\rho}^\dagger(-\mathbf{q})e^{\imath\omega t}] \ .$$

Now, the transition rate is [873],

$$\frac{W}{N} = 2\pi\Omega_R^2 S(\mathbf{q},\omega) = \frac{2\pi}{N\hbar}\left(\frac{V}{2}\right)^2 \sum_f |\langle f|\hat{\rho}^\dagger(\mathbf{q})|g\rangle|^2 \delta(\hbar\omega - (E_f - E_g)) \ , \tag{52.17}$$

with $\frac{V}{2} = \hbar\Omega_R$.

Resolve Exc. 52.1.6.7.

52.1.3 Bosonic stimulation

We assume in the following weak light intensities (and hence a negligible contribution of the Mollow fluorescence spectrum). That is, without cooperative effects the light would be elastically scattered by Rayleigh scattering. Now, we adopt a notation labeling the multimodal state by the numbers of photons and atoms distributed over the available light and momentum modes. That is, the initial state consists of $n_{\mathbf{p}}$ atoms distributed over momentum atomic states $\mathbf{p}$ and $N_{\mathbf{k}}$ photons distributed over wave vector modes $\mathbf{k}$ denoted by $|...N_{\mathbf{k}}...\rangle_{rad} \otimes |...n_{\mathbf{p}}...\rangle_{at}$:

$$|i\rangle \equiv |...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}...\rangle_{at} \ \otimes |...N_{\mathbf{k}_i}...N_{\mathbf{k}_f}...\rangle_{rad} \equiv \left|\begin{matrix}...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}...\\ ...N_{\mathbf{k}_i}...N_{\mathbf{k}_f}...\end{matrix}\right\rangle \ , \tag{52.18}$$

where we introduced the vector-like notation for notational compactness.

A particular scattering process can be treated like a 'collision' by redistributing the initial populations to final populations:

$$|f\rangle = \left|\begin{matrix}...n_{\mathbf{p}_i} - 1...n_{\mathbf{p}_f} + 1...\\ ...N_{\mathbf{k}_i} - 1...N_{\mathbf{k}_f} + 1...\end{matrix}\right\rangle \ . \tag{52.19}$$

We write the matrix element,

$$\langle f|\hat{H}_{int}|i\rangle \propto \left\langle\begin{matrix}...n_{\mathbf{p}_i''}...n_{\mathbf{p}_f''}...\\ ...N_{\mathbf{k}_i''}...N_{\mathbf{k}_f''}...\end{matrix}\right| C \sum_{\mathbf{k}_i',\mathbf{k}_f',\mathbf{p}_i',\mathbf{p}_f'} \hat{c}^\dagger_{\mathbf{k}_f'}\hat{c}_{\mathbf{k}_i'}\hat{a}^\dagger_{\mathbf{p}_f'}\hat{a}_{\mathbf{p}_i'}\delta_{\mathbf{k}_f'-\mathbf{k}_i'+\mathbf{p}_f'-\mathbf{p}_i'} \left|\begin{matrix}...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}...\\ ...N_{\mathbf{k}_i}...N_{\mathbf{k}_f}...\end{matrix}\right\rangle \ . \tag{52.20}$$

Assuming that all modes are not degenerate, such that $[\hat{a}_{\mathbf{p}_f}, \hat{a}^\dagger_{\mathbf{p}_i}] = \delta_{\mathbf{p}_f,\mathbf{p}_i}$, that is, $\hat{a}^\dagger_{\mathbf{p}_f}$ and $\hat{a}_{\mathbf{p}_f}$ only act on the mode $|n_{\mathbf{p}_f}\rangle_{at}$, etc.,

$$\sum_{\mathbf{p}_i'} \hat{a}_{\mathbf{p}_i'}|...n_{\mathbf{p}_i}...\rangle_{at} = \sum_{\mathbf{p}_i} \sqrt{n_{\mathbf{p}_i}}|...n_{\mathbf{p}_i} - 1...\rangle_{at} \tag{52.21}$$
$$\text{and} \quad \sum_{\mathbf{p}_f'} \hat{a}^\dagger_{\mathbf{p}_f'}|...n_{\mathbf{p}_f}...\rangle_{at} = \sum_{\mathbf{p}_f} \sqrt{n_{\mathbf{p}_f} + 1}|...n_{\mathbf{p}_f} + 1...\rangle_{at} \ ,$$

as well as,

$$\sum_{\mathbf{k}'_i} \hat{c}_{\mathbf{k}'_i} |...N_{\mathbf{k}_i}...\rangle_{rad} = \sum_{\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} |...N_{\mathbf{k}_i} - 1...\rangle_{rad} \tag{52.22}$$

$$\text{and} \quad \sum_{\mathbf{k}'_f} \hat{c}^\dagger_{\mathbf{k}'_f} |...N_{\mathbf{k}_f}...\rangle_{rad} = \sum_{\mathbf{k}_f} \sqrt{N_{\mathbf{k}_f} + 1} |...N_{\mathbf{k}_f} + 1...\rangle_{rad} \ .$$

Let us now assume for a moment, that the photon is scattered to the vacuum, that is, the final mode of light is initially empty, $N_{\mathbf{k}_f} = 0$ [4],

$$\begin{aligned}
&\langle f|\hat{H}_{int}|i\rangle_{inel} \qquad (52.23)\\
&\propto \left\langle \begin{matrix} ...n_{\mathbf{p}''_i}...n_{\mathbf{p}''_f}... \\ ...N_{\mathbf{k}''_i}...N_{\mathbf{k}''_f}... \end{matrix} \middle| \sum_{\mathbf{p}_f,\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} \sqrt{n_{\mathbf{p}_f} + 1} \sqrt{n_{\mathbf{p}_i}} \middle| \begin{matrix} ...n_{\mathbf{p}_i} - 1...n_{\mathbf{p}_f} + 1... \\ ...N_{\mathbf{k}_i} - 1...1_{\mathbf{k}_f}... \end{matrix} \right\rangle \\
&= \sum_{\mathbf{p}_f,\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} \sqrt{n_{\mathbf{p}_f} + 1} \sqrt{n_{\mathbf{p}_i}} \delta_{N_{\mathbf{k}''_i},N_{\mathbf{k}_i}-1} \delta_{N_{\mathbf{k}''_f},N_{\mathbf{k}_f}+1} \delta_{n_{\mathbf{p}''_i},n_{\mathbf{p}_i}-1} \delta_{n_{\mathbf{p}''_f},n_{\mathbf{p}_f}+1} \\
&= \sqrt{N_{\mathbf{k}_i}} \sqrt{n_{\mathbf{p}_f} + 1} \sqrt{n_{\mathbf{p}_i}} \ .
\end{aligned}$$

Obviously, the differential scattering cross-section,

$$\boxed{\left(\frac{d\sigma}{d\Omega}\right)_{inel} \propto N_{\mathbf{k}_i}(n_{\mathbf{p}_f} + 1) n_{\mathbf{p}_i}} \ . \tag{52.24}$$

depends, in addition to the numbers of provided photons $N_{\mathbf{k}_i}$ and atoms $n_{\mathbf{p}_i}$ in the initial mode, also on the *number of atoms in the final mode* $n_{\mathbf{p}_f}$. This amplification of the probability of the scattering process is called *bosonic stimulation*.

Now, we consider the degenerate case, where the initial atomic momentum mode coincides with the final mode, $n_{\mathbf{p}_f} = n_{\mathbf{p}_i}$. In this case,

$$\sum_{\mathbf{p}'_f = \mathbf{p}'_i} \hat{a}^\dagger_{\mathbf{p}'_f} \hat{a}_{\mathbf{p}'_i} |...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}...\rangle_{at} = \sum_{\mathbf{p}'_i} \hat{a}^\dagger_{\mathbf{p}'_i} \hat{a}_{\mathbf{p}'_i} |...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}...\rangle_{at} = \sum_{\mathbf{p}_i} n_{\mathbf{p}_i} |...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}...\rangle_{at} \ , \tag{52.25}$$

and a calculus analogous to (52.23) yields,

$$\begin{aligned}
&\langle f|\hat{H}_{int}|i\rangle_{el} \propto \left\langle \begin{matrix} ...n_{\mathbf{p}''_i}...n_{\mathbf{p}''_f}... \\ ...N_{\mathbf{k}''_i}...N_{\mathbf{k}''_f}... \end{matrix} \middle| \sum_{\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \middle| \begin{matrix} ...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}... \\ ...N_{\mathbf{k}_i} - 1...1_{\mathbf{k}_f}... \end{matrix} \right\rangle \qquad (52.26)\\
&= \sum_{\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \ {}_{rad}\langle ...N_{\mathbf{k}''_i}...N_{\mathbf{k}''_f}...|...N_{\mathbf{k}_i} - 1...1_{\mathbf{k}_f}...\rangle_{rad} \ {}_{at}\langle ...n_{\mathbf{p}''_i}...n_{\mathbf{p}''_f}...|...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}...\rangle_{at} \\
&= \sum_{\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \delta_{N_{\mathbf{k}''_i},N_{\mathbf{k}_i}-1} \delta_{N_{\mathbf{k}''_f},N_{\mathbf{k}_f}+1} \delta_{n_{\mathbf{p}''_i},n_{\mathbf{p}_i}} \delta_{n_{\mathbf{p}''_f},n_{\mathbf{p}_i}} = \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \ .
\end{aligned}$$

Now, the differential scattering cross-section,

$$\boxed{\left(\frac{d\sigma}{d\Omega}\right)_{el} \propto N_{\mathbf{k}_i} n^2_{\mathbf{p}_i}} \ , \tag{52.27}$$

[4] We will discuss later the case, where the scattering is (bosonically) stimulated by the number of photons already present in the final mode prior to the scattering process.

only depends on the number of provided photons $N_{\mathbf{k}_i}$ and the number of atoms $n_{\mathbf{p}_i}$ in the initial mode.

52.1.3.1 Elastic and inelastic scattering

The interpretation of the result is the following: Light can be scattered in two ways: (i) with or (ii) without change of atomic moment distribution. The event of a photon scattering (52.19) then it consists of two terms (52.24) and (52.27) [742],

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{el} + \left(\frac{d\sigma}{d\Omega}\right)_{inel} . \tag{52.28}$$

The first term of (52.28) occurs when the momentum of the scattering atom does not change, $\mathbf{p} = \mathbf{q}$, that is, when the populations of the momentum states $n_{\mathbf{p}}$ and $n_{\mathbf{q}}$ do not change. The corresponding term (52.27) describes elastic Rayleigh scattering. This process is coherent, that is, the phase relationship between the incident wave and the outgoing wave is fixed, because the photon emission is self-stimulated. I.e. it decays to the original mode via *forward scattering* within the angle defined by the *phase matching condition* $\vartheta < \lambda/d$, where d is the size of the atomic sample [510]. This contribution is dispersive, reversible, and conservative, and it is at the origin of the dipole force.

The second term of (52.28) is the inelastic part of Rayleigh scattering, where an atom with the initial momentum $n_{\mathbf{p}}$ is scattered to the momentum state $n_{\mathbf{q}}$. This term is absorptive, dissipative, and spontaneous. The frequency of the photons is shifted, a momentum is imparted to the atom, such that the process is incoherent. Hence, a suggestive way of expressing the differential scattering cross-section (52.19) is,

$$\frac{d\sigma}{d\Omega} \propto \left|\sum_i n_i \langle i|\hat{H}_{int}|i\rangle\right|^2 + \sum_{i\neq f} n_i(1+n_f)|\langle i|\hat{H}_{int}|f\rangle|^2 , \tag{52.29}$$

where $|i\rangle$ and $|f\rangle$ denote momentum states of the atomic sample.

The bosonic stimulation of inelastic Rayleigh scattering represents a way to overcome, on one hand the restrictive phase matching condition, and on the other the incoherence of the scattering into large angles. For non-interacting systems of localized bosons $S(\mathbf{q},\omega)$ can be expressed using single particle states $|i\rangle$ with energy E_i and population N_i [see (44.3) and (44.6)],

$$S(\mathbf{q},\omega) = N\left|\sum_i n_i \langle i|\hat{H}_{int}|i\rangle\right|^2 \delta(\omega) + N\sum_{i\neq f} |\langle f|\hat{H}_{int}|i\rangle|^2 n_i(n_f+1)\delta[\omega-(E_f-E_i)/\hbar] , \tag{52.30}$$

with $S_0(\mathbf{q}) = |\langle\hat{\rho}^\dagger(\mathbf{q})\rangle|^2 = \left|\sum_i n_i\langle i|\hat{H}_{int}|i\rangle\right|^2$.

52.1.4 Playing with bosonic and fermionic states

Here, we want to address the question, whether scattering processes are influenced by bosonic stimulation or cooperative enhancement. Let us consider the case of N atoms (bosons or fermions) generated from vacuum by operators $\hat{a}^\dagger_m(\mathbf{q})|0\rangle$, where m

indicates some additional quantum number (for example, the vibrational state of a loose trapping potential) helping us to enumerate fermionic states, and $\mathbf{q}$ indicates the momentum (considered independent from the trapping potential for short enough times). The operators respect the rules,

$$\begin{aligned} &[\hat{a}_m(\mathbf{0}), \hat{a}_n(\mathbf{q})]_\mp = 0 = [\hat{a}^\dagger_m(\mathbf{0}), \hat{a}^\dagger_n(\mathbf{q})]_\mp \\ \text{and} \quad &[\hat{a}_m(\mathbf{0}), \hat{a}^\dagger_n(\mathbf{q})]_\mp = \delta_{m,n}\delta_{\mathbf{0},\mathbf{q}} \quad \text{and} \quad \hat{a}_m(\mathbf{q})|0\rangle = 0 \ , \end{aligned} \tag{52.31}$$

where upper signs hold for bosons and lower signs for fermions. Initially the N atoms are in the bosonic, respectively, fermionic many-body state [666],

$$\boxed{|\Psi^{(N)}_b(\mathbf{0})\rangle = \tfrac{1}{\sqrt{N!}}\hat{a}^\dagger_0(\mathbf{0})^N|0\rangle \quad \text{resp.} \quad |\Psi^{(N)}_f(\mathbf{0})\rangle = \prod_{n=0}^{N-1}\hat{a}^\dagger_n(\mathbf{0})|0\rangle} \ . \tag{52.32}$$

Note that $|\Psi^{(N)}_b(\mathbf{0})\rangle = |N\rangle$ is a Fock state satisfying $\langle\Psi^{(N)}_b(\mathbf{0})|\Psi^{(N)}_b(\mathbf{0})\rangle = 1$, while $|\Psi^{(N)}_f(\mathbf{0})\rangle$ is a product state being normalized as well, $\langle\Psi^{(N)}_f(\mathbf{0})|\Psi^{(N)}_f(\mathbf{0})\rangle = 1$.

Probing the number of atoms in a many-body state is done by,

$$N = \langle\Psi|\hat{N}|\Psi\rangle \quad \text{where} \quad \hat{N} = \int \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r})d^3r = \sum_{m,\mathbf{k}}\hat{a}^\dagger_m(\mathbf{k})\hat{a}_m(\mathbf{k}) \ , \tag{52.33}$$

or if we are only interested in a particular momentum state $\mathbf{k}$ and vibrational state m,

$$\langle\Psi|\hat{N}_m(\mathbf{k})|\Psi\rangle = \langle\Psi|\hat{a}^\dagger_m(\mathbf{k})\hat{a}_m(\mathbf{k})|\Psi\rangle = \|\hat{a}_m(\mathbf{k})|\Psi\rangle\|^2 \ . \tag{52.34}$$

Other possible many-body states are bosonic or fermionic product states,

$$\boxed{|\Psi^{(N_1)}(\mathbf{0})\rangle|\Psi^{(N_2)}(\mathbf{q})\rangle} \ . \tag{52.35}$$

We will see in 52.1.6.9 that product states are normalized if the partial states are normalized. Explicitly,

$$\begin{aligned} |\Psi^{(N_1)}_b(\mathbf{0})\rangle|\Psi^{(N_2)}_b(\mathbf{q})\rangle &= \frac{1}{\sqrt{N_1!N_2!}}\hat{a}^\dagger_0(\mathbf{0})^{N_1}\hat{a}^\dagger_0(\mathbf{q})^{N_2}|0\rangle \\ |\Psi^{(N_1)}_f(\mathbf{0})\rangle|\Psi^{(N_2)}_f(\mathbf{q})\rangle &= \prod_{n=0}^{N_1-1}\hat{a}^\dagger_n(\mathbf{0})\prod_{n=0}^{N_2-1}\hat{a}^\dagger_n(\mathbf{q})|0\rangle \ . \end{aligned} \tag{52.36}$$

Note, that product states in the same mode need renormalization when merged,

$$|\Psi^{(N_1)}_b(\mathbf{0})\Psi^{(N_2)}_b(\mathbf{0})\rangle = \frac{1}{\sqrt{N_1!N_2!}}\hat{a}^\dagger_0(\mathbf{0})^{N_1+N_2}|0\rangle = \sqrt{\binom{N_1+N_2}{N_1}}|\Psi^{(N_1+N_2)}_b(\mathbf{0})\rangle \ , \tag{52.37}$$

for example, $|\Psi^{(N)}_b(\mathbf{0})\Psi^{(1)}_b(\mathbf{0})\rangle = \sqrt{N+1}|\Psi^{(N+1)}_b(\mathbf{0})\rangle$.

A $\pi/2$-Bragg pulse has the faculty to transfer 50% of the atoms into a momentum mode $\mathbf{q}$, thus creating a new state where every single atom lives in a coherent

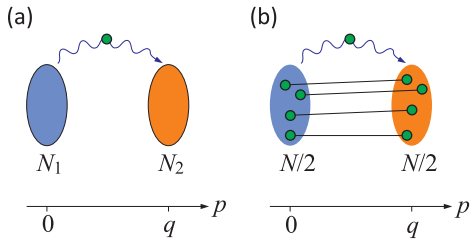

Figure 52.2: Cartoon of (a,b) bosonic stimulation and (c,d) cooperative enhancement.

superposition of two momenta,

$$\boxed{\begin{aligned} |\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \frac{[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^N}{\sqrt{2^N N!}}|0\rangle = \sum_{n=0}^{N}\binom{N}{n}\frac{\hat{a}_0^\dagger(\mathbf{0})^N\hat{a}_0^\dagger(\mathbf{q})^{N-n}}{\sqrt{2^N N!}}|0\rangle \\ |\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \prod_{n=0}^{N-1}\frac{[\hat{a}_n^\dagger(\mathbf{0})+\hat{a}_n^\dagger(\mathbf{q})]}{\sqrt{2^N}}|0\rangle \end{aligned}} \ . \tag{52.38}$$

In the following, we will study scattering processes, that is, fluctuations, in the presence of the states (52.35) or (52.38).

52.1.4.1 Bosonic stimulation versus cooperative enhancement by a Bragg grating

Now, we scatter a photon, whose fate is not of interest here, but which triggers possible transitions of an atom sitting together with N_1 atoms in the momentum state $\mathbf{0}|0\rangle$ towards another momentum state $\mathbf{q}|0\rangle$ initially populated with N_2 atoms via the operator,

$$\hat{H} = \sum_m \hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{0}) \ , \tag{52.39}$$

which in fact is nothing else than the static structure factor. Applying this process to bosonic or fermionic clouds, as defined in (52.32), we find *bosonic stimulation* only in the case of bosons,

$$\boxed{\langle\Psi^{(N_1-1)}(\mathbf{0})\Psi^{(N_2)}(\mathbf{q})|\hat{H}|\Psi^{(N_1)}(\mathbf{0})\Psi^{(N_2-1)}(\mathbf{q})\rangle = \delta_{\mathbf{k},\mathbf{q}}\begin{cases}\sqrt{N_1N_2} & \text{for bosons}\\ 1 & \text{for fermions}\end{cases}} \ , \tag{52.40}$$

as will be shown in Exc. 52.1.6.10(a). The transition probabilities are then,

$$\frac{d\sigma}{d\Omega} = |\langle f|\hat{H}|i\rangle|^2 = \delta_{\mathbf{k},\mathbf{q}}\begin{cases}N_1N_2 & \text{for bosons}\\ 1 & \text{for fermions}\end{cases} \ . \tag{52.41}$$

Note, that these results does not change in the presence of a Bragg grating not participating in the dynamics:

$$\langle\Psi_b^{(M-1)}(\mathbf{0})\Psi_b^{(brgg,N+1)}(\mathbf{0},\mathbf{q})|\hat{H}|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle = 1 \ . \tag{52.42}$$

However, applying the same scattering process between a BEC with M atoms and the Bragg state defined in (52.38) consisting of N atoms, we identify two interesting possibilities for which we find,

$$\boxed{\begin{aligned}\langle\Psi_b^{(M-1)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})|\hat{H}|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\rangle &= (\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\sqrt{MN}\\ \langle\Psi_b^{(M)}(\mathbf{q})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})|\hat{H}|\Psi_b^{(M-1)}(\mathbf{q})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \delta_{\mathbf{k},\mathbf{q}}\sqrt{MN}\end{aligned}} \quad . \tag{52.43}$$

Interestingly, we find the same expression for bosons and for fermions,

$$\boxed{\langle\Psi_{b,f}^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\Psi_{b,f}^{(1)}(\mathbf{q})|\hat{H}|\Psi_{b,f}^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle = \sqrt{\tfrac{N}{2}}\left[\delta_{\mathbf{k},\mathbf{0}} \pm \tfrac{N-1}{2}(\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\right]} \quad . \tag{52.44}$$

as will be shown in Exc. 52.1.6.10(b). The transition probabilities are then for boson and for fermions,

$$\frac{d\sigma}{d\Omega} = |\langle f|\hat{H}|i\rangle|^2 = \delta_{\mathbf{k},\mathbf{q}}\frac{N}{2}\frac{(N-1)^2}{4} \quad . \tag{52.45}$$

This means that, if $\mathbf{k}=\mathbf{0}$ or $\mathbf{k}=\mathbf{q}$, the scattering is subject to *cooperative enhancement* by a factor of $N/2$ (which is the number of atoms in each of the momentum state $\mathbf{0}$ and $\mathbf{q}$) independently on the quantum nature of the atom (boson or fermion). That is, the probability that the scattered atoms joins one of the two momentum goes, for large N, like N^2, but for $N=1$ there is no enhancement possible. Do Exc. 52.1.6.11.

52.1.4.2 Interpretation of bosonic stimulation as cooperative enhancement

The distinction between spontaneous and stimulated processes is not always obvious, as there is a whole world of cooperative processes in between those two concepts, for instance, superradiance, Bragg scattering, and enhanced spontaneous emission into a resonant cavity. All those processes have in common that they are amplified by fluctuations.

Example 375 (*Stimulated emission versus spontaneous emission: Cooperativity in a cavity*): Let us first discuss the case of a cavity. Vacuum fluctuations (VF) are structured by a cavity (finesse F) leading to a modified DOS becoming anisotropic and developing spectral resonances. In resonance the VFs are enhanced (we get a standing wave of VFs), while off resonance they are suppressed. Therefore, an excited atom placed inside a cavity will suffer 'spontaneous stimulation' to decay into the cavity mode. Alternatively, we may say that the atom not only reacts to the local VFs but to all VFs reflected F times by the cavity mirrors provided these VFs are in phase (which is the case when the cavity is resonant). That is, *cavity-enhanced VFs amplify scattering into cavity modes* and, as we argued in Sec. 38.3 the VFs are measured by the structure factor (38.85).
Note, that the presence of photons in the cavity does not stimulate 'additionally', because stimulated emission and absorption are reversible processes.

Example 376 (*Bragg scattering: Cooperativity in a lattice*):

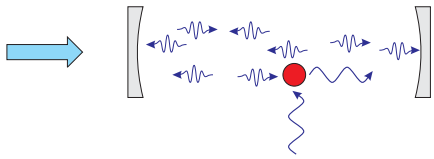

Figure 52.3: Cartoon of cooperative enhancement in a cavity.

Example 377 (*Matter wave superradiance and CARL: Cooperativity in a BEC*): We have seen that the stimulated processes mentioned above do not rely on quantum statistics, but rather on symmetry and coherence. Let us start with a naive picture of bosonic stimulation, a concept which can be applied to matter waves [511]. The physical process behind bosonically stimulated scattering is, that the presence of a macroscopically occupied state increases the density fluctuations of the system, and bosonically enhanced scattering is simply the diffraction of particles from these density fluctuations measured by $S(\mathbf{q}, \omega)$.

52.1.5 Collective scattering for condensates with interactions

Until now we totally disregarded interactions between particles. Correlations are introduced in a BEC by interactions between the atoms. Therefore, collective scattering effects are influenced by interactions, while on the other hand an ideal gas ($gn \to 0$) scatters like an ultra-cool non-degenerate thermal cloud. In this sense, particle-like excitations ($\mathbf{p}^2/2m \gg gn$) in an interacting BEC behave like thermal atoms. The mean-field energy can be seen as resulting from excitations of phonon pairs. These pairwise excitations populate the momentum modes, which modify the scattering of light via bosonic stimulation. That is, an interacting condensate ($gn > 0$) gives a collective response to an incident light beam. Note that $\mu > 0$ is possible when $V(\mathbf{r}) \neq 0$ and $gn \neq 0$ even if $T \to 0$, which is the case here considered.

What is the nature of the collective behavior? 1. The Bogolubov spectrum is modified. In the phononic regime, the absence of dispersion allows the definition of a speed of sound. 2. The scattering of light can be suppressed by excitation of phonon pairs. This effect is anisotropic and more pronounced in forward direction. That is, the resonance at which the light is scattered is shifted and broadened. The latter effect is understood via destructive interference of two processes: Scattering from a BEC to the momentum mode $\mathbf{k}$ and from the momentum mode $-\mathbf{k}$ to a BEC.

It is important to be aware that the notion of *bosonic stimulation* $\sim n_i(1+n_f)$ and *fermionic inhibition* $\sim n_i(1-n_f)$ also has its limitations, when interatomic interactions are not negligible, that is, when the quantum depletion is remarkable [371, 627]. The effect of interatomic collisions can be taken into account as contributions of pair correlations to the ground state of the BEC,

$$|\psi_0, n_0\rangle = |n_0, 0, 0\rangle - \sum_{\mathbf{k}} (v_{\mathbf{k}}^2/u_{\mathbf{k}}^2)|n_0 - 2, 1, 1\rangle + \sum_{\mathbf{k}} (v_{\mathbf{k}}^2/u_{\mathbf{k}}^2)^2 |n_0 - 4, 2, 2\rangle - \dots , \quad (52.46)$$

where $|n_0, n_{\mathbf{k}}, n_{-\mathbf{k}}\rangle$ denotes the state with n_0 atoms in the trap's ground state and $n_{\pm\mathbf{k}}$ atoms in the momentum mode $\mathbf{k}$, where $v_{\mathbf{k}}^2$ is the average population of momentum

mode $\mathbf{k}$. The populated recoil modes result in a increase of spontaneous emission by a factor of $v_{\mathbf{k}}^2 = 1 + u_{\mathbf{k}}^2$. We can also understand the modification of the scattering rate as resulting from small scale inhomogeneities generated by pair correlations. The effect is strongest at small scattering angles, that is in forward direction.

52.1.6 Exercises

52.1.6.1 Ex: Sum rules for the dynamic structure factor

Derive the following sum rules for the norm, the kinetic energy, and the compressibility,

$$\begin{aligned} S(\mathbf{q}) &= \int S(\mathbf{q},\omega)d\omega \\ \frac{\hbar^2 q^2}{2m} &= \int \hbar\omega S(\mathbf{q},\omega)d\omega \\ \frac{\kappa^2}{2} &= \int \frac{S(\mathbf{q},\omega)}{\hbar\omega}d\omega\Big|_{\mathbf{q}\to 0} \ . \end{aligned}$$

52.1.6.2 Ex: Interaction energy of a condensate via spatial coherence

Show that the total energy of a condensate is given by $\langle U\rangle = \frac{1}{2}\int n(\mathbf{r}_1)U(\mathbf{r}_1 - \mathbf{r}_2)g^{(2)}(\mathbf{r}_1,\mathbf{r}_2)n(\mathbf{r}_2)d^3r_1 d^3r_2$.

52.1.6.3 Ex: Structure factor of a condensate in the local density approximation

Calculate the structure factor of a condensate in the local density approximation (LDA) [132, 872].

52.1.6.4 Ex: Structure structure of a Fermi gas

Calculate the structure factor for Bragg scattering on a Fermi gas.

52.1.6.5 Ex: Structure factor of a heteronuclear mixture

In this exercise we discuss the structure factor of a heteronuclear mixture (specifically contemplating ^{6}Li mixed with ^{87}Rb) generalizing the available theory for Li spin mixtures to heteronuclear mixtures [192, 330, 331, 936]. The total dynamic structure factor is,

$$S(q,\omega) = S_{87,87}(q,\omega) + S_{6,6}(q,\omega) + S_{6,87}(q,\omega) + S_{87,6}(q,\omega) \ .$$

Exciting the Bragg resonance for Li, the Rb cloud would stay unaffected,the such that around $\omega/2\pi = 295$ kHz, $S_{87,87}(q,\omega) = 0$, as well as, $S_{6,87}(q,\omega) = S_{87,6}(q,\omega) = 0$. For Fermi gas $S_{6,6}(q,\delta) \to 1$, except if Bose gas induces Li-Li correlations, as in the case of BCS-pairing of phonon-mediated Efimov states.
How does Rb influence the Bragg scattering of Li? Via a variation of the apparent

mass as a displacement of the Bragg resonance or as a second peak appearing at a specific detuning of the Bragg beams at $\omega_{6,6} * 6/(6+87)$?

52.1.6.6 Ex: Spatial coherence of a condensate

Derive the relationship (52.7).

52.1.6.7 Ex: Structure factor for Bragg scattering

Demonstrate the following relationships,

$$\frac{dp_{cm}(\mathbf{q},\omega)}{dt} = -m\omega_z^2 z_{cm} + \hbar q \frac{\Omega_{br}^2}{2} \int d\delta' [S(\mathbf{q},\omega') - S(-\mathbf{q},-\omega')] \frac{\sin(\omega-\omega')t_{br}}{\omega-\omega'}$$

$$\ddot{p}_{cm}(q,\omega) + \omega_z^2 p_{cm} = \hbar q \frac{\Omega_{br}^2}{2} \int d\omega' [S(\mathbf{q},\omega') - S(-\mathbf{q},-\omega')] \cos(\omega-\omega')t_{br} \longrightarrow 0 \ .$$

52.1.6.8 Ex: Commutation expressions for bosons and fermions

Verify the following useful commutation relations:
a. For bosons,

$$\hat{a}_m(\mathbf{k})\hat{a}_n^\dagger(\mathbf{q})^N = N\delta_{m,n}\delta_{\mathbf{k},\mathbf{q}}\hat{a}_n^\dagger(\mathbf{q})^{N-1} + \hat{a}_n^\dagger(\mathbf{q})^N \hat{a}_m(\mathbf{k}) \ , \tag{52.47}$$

which can be generalized to,

$$\begin{aligned} &\hat{a}_m(\mathbf{k})[\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)]^N \\ &\quad = N\delta_{m,n}\left(\delta_{\mathbf{k},\mathbf{q}_1} + \delta_{\mathbf{k},\mathbf{q}_2}\right)[\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)]^{N-1} + [\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)]^N \hat{a}_m(\mathbf{k}) \ . \end{aligned} \tag{52.48}$$

b. For fermions do not support macroscopic populations of the type $\hat{a}_n^\dagger(\mathbf{q})^N$. Performing a number P of permutations of the operators and assuming that one fermion of the product state is in the internal state n, we calculate,

$$\hat{a}_n(\mathbf{k}) \prod_{m=0}^{N-1} \hat{a}_m^\dagger(\mathbf{q}) = (-1)^P \left[\delta_{\mathbf{k},\mathbf{q}} \prod_{m\neq n}^{N-1} \hat{a}_m^\dagger(\mathbf{q}) - \prod_{m=0}^{N-1} \hat{a}_m^\dagger(\mathbf{q})\hat{a}_n(\mathbf{k}) \right] \ . \tag{52.49}$$

If none of the fermions of the product state is in state n the first part of the sum simply vanishes. This expression can also be generalized to,

$$\begin{aligned} \hat{a}_n(\mathbf{k}) \prod_{m=0}^{N-1} [\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)] &= (-1)^P \prod_{m\neq n}^{N-1} [\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)]\hat{a}_n(\mathbf{k})[\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)] \\ &= (-1)^P \left[(\delta_{\mathbf{k},\mathbf{q}_1} + \delta_{\mathbf{k},\mathbf{q}_2}) \prod_{m\neq n}^{N-1} [\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)] - \prod_{m=0}^{N-1} [\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)]\hat{a}_n(\mathbf{k}) \right] \ . \end{aligned} \tag{52.50}$$

52.1.6.9 Ex: Extracting the atom number from many-body states

Verify the normalization of (a) the bosonic Fock state (52.32), (b) the fermionic product state (52.32), (c) the bosonic product state (52.35), (d) the bosonic Bragg grating state (52.37), and (e) the fermionic Bragg grating state (52.37). **Help:** Speed up the calculations by using the results of 52.1.6.8.

52.1.6.10 Ex: Bosonic stimulation and cooperative enhancement by lattices of bosons and fermions

Compare bosons and fermions with respect to (a) bosonic stimulation and (b) cooperative enhancement.

52.1.6.11 Ex: Cooperative enhancement versus bosonic stimulation

CARL amplification comes from cooperativity not from bosonic stimulation [666, 511, 825], that is, it should work for fermions and boltzons. To demonstrate this proceed as follows:
a. Set up the single-atom Hamiltonian for a 3D harmonic potential in which the atoms (bosons or fermions) are initially placed allowing for the possibility of momentum recoil by photon scattering. This disregards the trap's inhomogeneity, but is a good assumption for short times. What are the eigenfunction of this Hamiltonian? Calculate the expectation value for the density distribution. Express the field operators in momentum space. Express the lowest energy states for a bosonic/fermionic cloud in momentum representation.
b. Now apply a $\pi/2$-Bragg-pulse imparting the recoil $\mathbf{K}$ to the cloud. What is the resulting state? Recalculate the expectation value for the density distribution.
c. Now, assume the presence of another free (test) atom (or photon). Write down the Hamiltonian and the wavefunction for this atom. It is supposed to interact with the atomic cloud via the (perturbatively treated) interaction potential,

$$\hat{V} = \lambda \int d^3r \hat{\psi}_1^\dagger(\mathbf{r})\hat{\psi}_2^\dagger(\mathbf{r})\hat{\psi}_2(\mathbf{r})\hat{\psi}_1(\mathbf{r}) \ .$$

Calculate the probability that the atom is scattered at a particular wavevector, i.e. determine the cooperative enhancement factor.
d. Is cooperative enhancement possible with just one atom?
e. How about cooperative enhancement in a cavity, when cooperativity is ensured by a single atom plus all its mirror images?

52.2 Bragg diffraction

An important technique for manipulating the atomic motion is by *Bragg diffraction* [5]. It allows the coherent transfer of atoms to other states of motion or to superpositions of motional states, and is extremely useful for applications, such as the realization of

[5] The idea is analogous to the manipulation of the $\mathbf{k}$-vector of light waves by acousto-optic modulators.

matter wave beamsplitters [535] and atomic lasers, or for the targeted excitation of quasi-particles [535, 884, 872].

To implement Bragg diffraction, we consider two laser pulses with different frequencies and propagation directions $\omega, \mathbf{k}_\omega$ and $\omega - \Delta\omega, \mathbf{k}_{\omega-\Delta\omega}$, detuned from an atomic resonance and intersecting at the position of atoms under an angle ϑ, as shown in Fig. 52.4(a). The superposition of the electric fields of the light beams,

$$\begin{aligned} E &= E_0 e^{\imath(\mathbf{k}_\omega\cdot\mathbf{r}-\omega t)} + E_0 e^{\imath[\mathbf{k}_{\omega-\Delta\omega}\cdot\mathbf{r}-(\omega-\Delta\omega)t]} = E_0 e^{\imath(\mathbf{k}_\omega\cdot\mathbf{r}-\omega t)}\left(1 + e^{-\imath(\mathbf{q}\cdot\mathbf{r}-\Delta\omega t)}\right) \\ &= 2E_0 e^{\imath(\mathbf{k}_\omega\cdot\mathbf{r}-\omega t)} e^{-\frac{\imath}{2}(\mathbf{q}\cdot\mathbf{r}-\Delta\omega t)} \cos\frac{\mathbf{q}\cdot\mathbf{r}-\Delta\omega t}{2} \ , \end{aligned} \tag{52.51}$$

where $\mathbf{q} \equiv \mathbf{k}_\omega - \mathbf{k}_{\omega-\Delta\omega}$, produces a standing light wave with an intensity proportional to,

$$|E|^2 = 4E_0^2 \cos^2\frac{\mathbf{q}\cdot\mathbf{r}-\Delta\omega t}{2} = 2E_0^2[1 + \cos(\mathbf{q}\cdot\mathbf{r} - \Delta\omega t) \ , \tag{52.52}$$

with which the atoms interact.

The Bragg diffraction technique has proven extremely efficient: up to 100% of the atoms can be transferred to well-defined momentum sidemodes. In general, the components of a cloud with different momentum modes overlap during the time scale of the Bragg pulses. They only separate spatially after a ballistic flight time, which then allows their identification via absorption imaging.

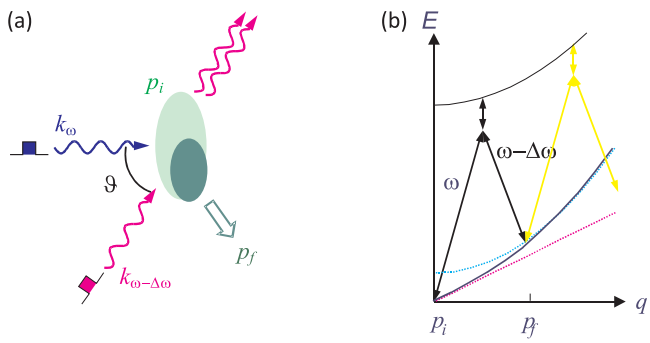

Figure 52.4: Bragg scattering of atoms at a standing light wave. (a) Geometric layout: Short pulses of two laser beams in Raman configuration enclosing an angle of ϑ and detuned from each other by $\Delta\omega$ are simultaneously irradiated into the cloud. (b) Bogolubov dispersion relation for interacting condensates (blue line). The quadratic dispersion relation (cyan) holds for free particles, and the linear dispersion relation (magenta) for phonon excitations.

52.2.1 Interpretations of the Bragg diffraction process

Bragg's diffraction can be treated within the formalism developed in Sec. 52.1.2, as will be shown later, in Sec. 52.2.3. But before that, let us present a simplified approach and several simple pictures illustrating the dynamics of Bragg diffraction.

52.2.1.1 Bragg diffraction picture

The *first interpretation* of this phenomenon is as *matter wave Bragg diffraction* at a standing light wave (i.e. an one-dimensional optical lattice) formed by two crossing

pulsed laser beams [6]. We consider atoms initially at rest exposed to the standing wave (52.51) with $\Delta\omega = 0$ and $\mathbf{q} \equiv q\hat{\mathbf{e}}_z$, such that the dipolar potential $U \propto |E|^2$ is, with (52.52),

$$U(z) = U_0 \cos^2 \tfrac{qz}{2} \ . \tag{52.53}$$

Assuming a given finite interaction time τ, the modulation of the local phase of the atoms becomes [7],

$$\boxed{\psi_\tau(z) = \psi_0(z) e^{\imath U(z)\tau/\hbar} = \psi_0(z) e^{\frac{\imath}{2\hbar} U_0 \tau(\cos qz + 1)} = \psi_0(z) e^{\imath U_0 \tau/2\hbar} \sum_n \imath^n J_n(\tfrac{U_0\tau}{2\hbar}) e^{inqz}} \ , \tag{52.54}$$

where J_n are the Bessel functions of the first kind [8].

The condensed wavefunction evolves into a superposition of motional modes, which correspond to the diffraction orders of Bragg scattering and their amplitudes through the Bessel functions J_n. The diffraction efficiency increases with laser intensity and with time.

Now, we need to generalize this result to the propagating standing wave of the expression (52.52). The intensity generates a dipole potential,

$$U(z,t) \approx U_0 \cos^2 \tfrac{q_z z - \Delta\omega t}{2} \ , \tag{52.55}$$

so that the condensate now evolves according to,

$$\psi(z,t) = \psi_0(z) e^{\imath/\hbar \int_{t_0}^{t_0+\tau} U(z,t) dt} = \psi_0(z) e^{\imath/\hbar \int_{t_0}^{t_0+\tau} U_0 \cos^2 \frac{q_z z - \Delta\omega t}{2} dt} \ . \tag{52.56}$$

For short interaction times, $\tau \ll 2\pi/\Delta\omega$, ...

52.2.1.2 Compton scattering picture

The *second interpretation* is that of *Compton scattering*: Spontaneous Rayleigh scattering of a photon from a mode $\mathbf{k}_\omega$ into a solid angle around $\mathbf{k}_{\omega-\Delta\omega}$ leaves an atom with the recoil momentum $\hbar\mathbf{q} \equiv \mathbf{p}_f \cdot \mathbf{p}_i$. Of course, one can *stimulate* the Rayleigh scattering process by providing the laser mode $\mathbf{k}_\omega - \Delta\omega$ at the entrance. By replacing the spontaneous output mode with a stimulated input mode, we increase the probability for an atomic recoil in the momentum mode $\hbar\mathbf{q}$, which is thus pre-selected by the choice of $\mathbf{k}_{\omega-\Delta\omega}$. Since the elementary scattering process must conserve energy and total momentum,

$$\begin{aligned} \hbar\omega + \frac{p_i^2}{2m} &= \hbar(\omega - \Delta\omega) + \frac{p_f^2}{2m} \\ \hbar\mathbf{k}_i + \mathbf{p}_i &= \hbar\mathbf{k}_f + \mathbf{p}_f \ , \end{aligned} \tag{52.57}$$

we obtain the *Bragg condition*,

$$\boxed{E = \Delta\omega = \frac{p_f^2}{2m} - \frac{p_i^2}{2m} = \frac{(\mathbf{p}_f - \mathbf{p}_i)^2}{2m} + \frac{(\mathbf{p}_f - \mathbf{p}_i)\cdot\mathbf{p}_i}{m} = \frac{q^2}{2m} + \frac{\mathbf{q}\cdot\mathbf{p}_i}{m}} \ . \tag{52.58}$$

[6] Note, that the initial population of the recoil mode should be small. Otherwise, since Bragg diffraction is a coherent and thus reversible process, atoms initially in the recoil mode are transferred back to the original matter wave mode.

[7] Using the Jacobi-Anger expansion, $e^{\imath\beta\cos x} = \sum_n \imath^n J_n(\beta) e^{\imath nx}$.

[8] Andreas got $\psi_0(z) \sum_n J_n^2(U_0\tau/2\hbar) e^{inqz/2}$.

Expressed by the Bragg angle, the condition reads,

$$q = \sqrt{(\mathbf{p}_f - \mathbf{p}_i)^2} = \sqrt{\hbar^2\mathbf{k}_i^2 + \hbar^2\mathbf{k}_f^2 - 2\hbar^2\mathbf{k}_i\mathbf{k}_f} \simeq \hbar\mathbf{k}_i\sqrt{2 - 2\cos\theta} = 2\hbar k_i \sin\vartheta/2 \ . \tag{52.59}$$

The efficiency for transferring atoms to the recoil mode depends on the fulfillment of this condition. The Bragg condition can be employed to select higher diffraction orders.

52.2.1.3 Stimulated Raman scattering picture

A *third interpretation* is as *stimulated Raman scattering* between two different kinetic states of the atom [see 52.4(b)]. In fact, the momentum modes $\mathbf{p}_i$ and $\mathbf{p}_f$ have different energies, which, for a condensate, are determined by the Bogolubov spectrum [359]. By varying the angle ϑ in the Bragg condition (52.58), we can choose the amount of energy to be transferred and thus probe the spectrum, i.e. measure the excitation energy $E(\mathbf{q}, \mu)$ as a function of the momentum $\mathbf{q}$ and the chemical potential μ in the particle regime $\mathbf{q}^2/2m \gg \mu$, as well as in the phonon regime $\mathbf{q}^2/2m \ll \mu$. On the other hand, varying the detuning $\Delta\omega$ in the Bragg condition (52.58), we selectively address different velocity classes of a gas or condensate, which allows us to probe its velocity distribution. This procedure is called spectroscopy of *recoil-induced resonances* (RIR) [204, 884]. RIR spectroscopy also provides detailed information on the mean-field energy and the (inhomogeneous) density distribution of a condensate. Note, finally, that Bragg scattering is closely related to *Kapitza-Dirac* scattering of atomic beams, well-known in conventional atom optics [499, 375].

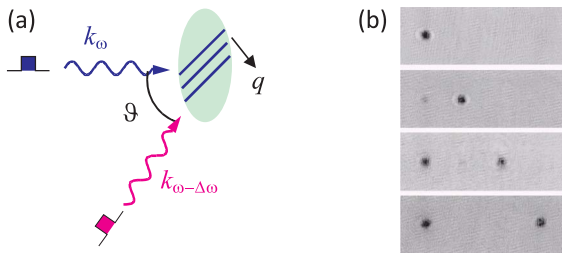

Figure 52.5: Bragg scattering of atomic clouds. (a) Geometric layout as in 52.4. Here, we assume $p_i = 0$. (b) Experiment showing coherent splitting by a Bragg pulse.

52.2.1.4 Coherent splitting

There is a general interest in the possibility of dividing phase space by coherent coupling of otherwise independent modes. We are talking, of course, about double slits or beamsplitters, which represent an essential tool of quantum mechanics. Bragg diffraction realizes a beamsplitter for atomic clouds analogous to the optical beamsplitter. In fact, Bragg diffraction has been used for the realization of output couplers for atom lasers and for atom interferometers. A suggestion that is sometimes made is the following: 'A condensate is a macroscopically populated momentum mode. The Bragg beamsplitter divides the phase space into two entangled output modes. Shouldn't it

be possible to generate a macroscopic superposition of two condensates, i.e. a really macroscopic Schrödinger cat?' of the type

$$(|\Psi_+\rangle + |\Psi_-\rangle) \ . \tag{52.60}$$

Their is an obvious fundamental interest to study such states and the mechanisms leading to their decoherence (see Sec. 41.1.1).

To clarify the situation, we first have to say, what we mean by *Schrödinger cat*. A Schrödinger cat is a quantum superposition of many-body states. A perfect cat made of N two-level atoms can be expressed as $|++...\rangle \pm |--...\rangle$. The Einstein-Podolsky-Rosen (EPR) and the Greenberger-Horne-Zeilinger states (GHz) belong to this category. The degree of entanglement of the cat is measured by the information entropy defined as $S = -\langle \log_2 \hat{\rho} \rangle$, where $\hat{\rho}$ is the density operator. The information entropy measures the amount of classical information that can be encoded in the quantum state. For example, the entropy of a perfect cat state is $S = 1$ bit, because if we find one of the atoms in the state $|+\rangle$, we know that all others are in the same state.

Second, we have to explain, what we mean by a *beamsplitter*. Subject to a beam splitting process, every individual atom has the choice between one of two output ports. However, if the process is coherent, every atom will evolve into a coherent superposition, but it does so independently from the other atoms. That is, we can write the state of the atomic cloud as a product state of *Schrödinger kittens* $(|+\rangle \pm |-\rangle)^N$, but no real cat. The information entropy is $S = N$ bit, as for independent atoms. *Clearly, the state (52.60) is NOT the state generated by a beamsplitter!* Nevertheless, the beamsplitter creates a certain correlation between the two modes (see Sec.37.5).

It may come as a surprise, that a condensate composed of totally delocalized atoms coherently interacting with a homogeneous light field (the photons of the Bragg beams are totally delocalized over the field mode including the condensate volume) increases its entropy from 1 to N bits. This argument, however, would be the same for a non-condensed *thermal* cloud being sufficiently cold that the thermal de Broglie wavelengths exceeds the size of the cloud. That is, even in condensates the photons are scattered by individual atoms. The interaction with the light *localizes* one atom in the condensate before removing it from there by recoil. Nevertheless, cooperative interaction of several atoms with a light mode is possible, e.g. in superradiance or when the photons are recycled by means of an optical cavity, as in the Jaynes-Cummings model.

52.2.2 Bragg interferometry of a thermal gas

Even above the critical temperature the momentum distribution of a dilute thermal gas is (slightly) modified by quantum statistics, i.e. by the classical, bosonic or fermionic nature of the gas. The momentum distributions have been calculated in Chp. 29.3 and 29.4. We have already emphasized that Bragg interferometry can be used to measure the momentum distribution of a gas via RIR spectroscopy, whether the gas is condensed or thermal. Now, let us discuss Bragg interferometry on a thermal gas, based on the articles [621] and [237].

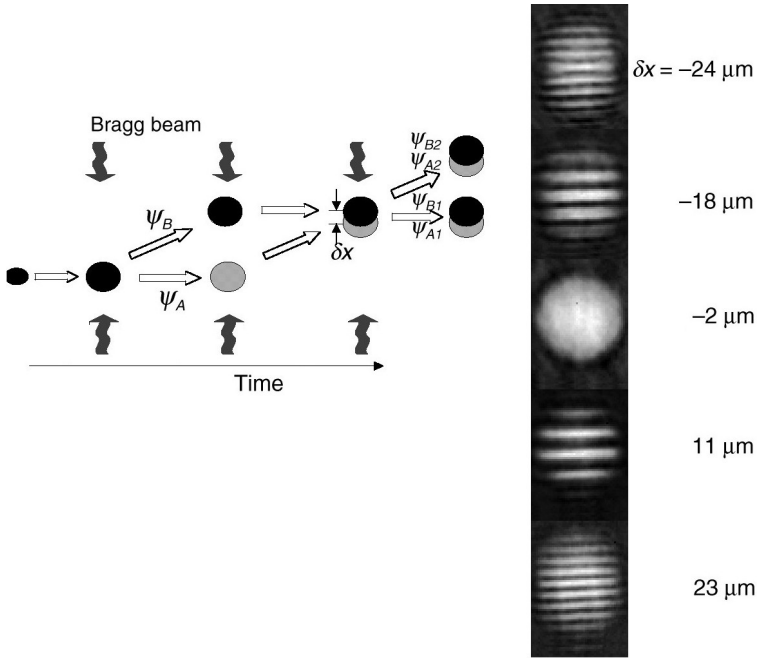

Figure 52.6: Bragg interferometer.

52.2.2.1 Free evolution of a thermal cloud

To describe the Bragg scattering process quantitatively, we interpret it as a *Raman transition between discrete atomic momentum states governed by a Schrödinger equation.* On the other hand, as long as no radiation is incident the atomic center-of-mass wavefunctions evolve freely or under the constraint of an external potential. That is, both processes concern the same motional degree of freedom. In order to derive a complete quantum model, let us first develop the formalism for the description of the free evolution of a thermal cloud, then we explain how a resonant radiation can be included.

We consider a thermal atomic cloud initially distributed over many momentum classes according to the Maxwell-Boltzmann velocity distribution,

$$D(k_z) = \frac{\hbar}{(2\pi m k_B T)^{1/2}} e^{-\hbar^2 k_z^2/2mk_BT} = \frac{e^{-\pi k_z^2/k_{therm}^2}}{k_{therm}} \ , \tag{52.61}$$

using $k_{therm} \equiv 2\pi/\lambda_{therm}$ and (49.9). Because of the inhomogeneity of the distribution, any evolution of atoms belonging to specific momentum classes caused by velocity-selective radiation pulses, must be calculated with individual atoms. The final momentum distribution (e.g. after a pulse sequence) can then be obtained by weighing with the individual evolution with the initial momentum distribution [9].

[9] The procedure neglects interatomic interactions, which is always a good presumption, for example, for an ultracold Fermi gas [241] or for ^{88}Sr atoms, which have a very small scattering length.

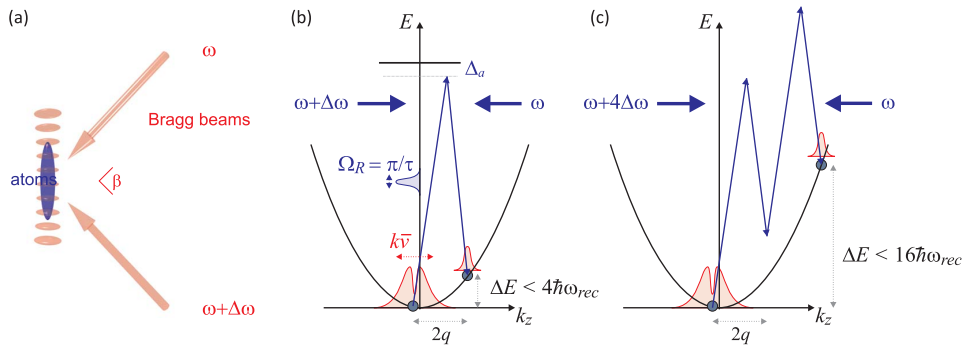

Figure 52.7: (a) Geometry for Bragg diffraction. (b) Illustration of a Raman transition between two points of the free-particle dispersion curve, when the atoms are initially thermally distributed. (c) Same as (a), but now the detuning $\Delta\omega$ is adjusted for second-order Bragg diffraction.

We describe the quantum state of a thermal atom $|\psi\rangle$ as a plane wave, $\langle z|\psi\rangle \propto e^{\imath k_z z}$, which in momentum space corresponds to a Dirac distribution, $\langle k_z|\psi\rangle \propto \delta(z - z_0)$. Without radiative coupling, we describe the evolution in momentum space by the solution of the Schrödinger equation (or propagator),

$$\langle k_z|\psi(t)\rangle = e^{\imath \hat{H} t/\hbar}\langle k_z|\psi(0)\rangle \ . \tag{52.62}$$

In free space, with the Hamiltonian $\hat{H}_{free} = \hbar^2 k_z^2/2m$, the wavefunction is obviously constant.

In order to couple two intervals of momentum distribution by resonant radiation, we first need to duplicate the Hilbert space,

$$a_{i,k_z}(t) \equiv \langle i|\psi_{k_z}(t)\rangle = \langle i|\langle k_z|\psi(t)\rangle \tag{52.63}$$

with $i = 1, 2$. Note that, in this case, the Hilbert spaces are not disjunct.

To obtain the atomic momentum distribution after the application of a pulse sequence, we calculate the evolution of the amplitudes a_{j,k_z} for a variety of initial momenta and weigh the final populations of the momentum states with the distribution function $D(k_z)$. The number of atoms expected in the zeroth and first Bragg diffraction order is, therefore,

$$N_j(t) = \int D(k_z)|a_{j,k_z}(t)|^2 dk_z \ . \tag{52.64}$$

52.2.2.2 Bragg scattering and RIR

For large momentum distributions, $T \gg T_{rec}$, the atomic cloud occupies many momentum states, such that the Bragg scattering produces a RIR-like signal. That is, the scattering probability is proportional to the *population difference* of the initial and final momentum states, as discussed in Sec. 48.3.1. The number of scattered atoms/photons is, therefore,

$$\dot{N}_{brg} \propto \Omega_R \left.\frac{\partial D(k_z)}{\partial k_z}\right|_{k_z = \hbar m \Delta\nu/q} \ . \tag{52.65}$$

where,

$$\Omega_R = \frac{\Omega_1\Omega_2}{2\Delta_a} = \frac{1}{\Delta_a}\frac{3\lambda^2}{4\pi}\frac{\Gamma}{\hbar\omega}\sqrt{I_1 I_2} = \frac{3\pi c^2 I}{\hbar\omega^3}\frac{\Gamma}{\Delta_a} \tag{52.66}$$

is the two-photon Rabi frequency. For very narrow momentum distributions, $T \ll T_{rec}$, we may assume the atomic cloud to occupy only a single momentum state,

$$\dot{N}_{brg} \propto \Omega_R D(k_z) \ . \tag{52.67}$$

The transition rate per atom is then given by [873],

$$\frac{W}{N} = \frac{2\pi\hbar}{N}\Omega_R^2 \sum_f |\langle f|\hat{\rho}^\dagger(\mathbf{k})|g\rangle|^2 \delta(\hbar\nu - E_f + E_g) \equiv 2\pi\Omega_R^2 S(\mathbf{k},\nu) \ . \tag{52.68}$$

As illustrated in Fig. 52.7, to scatter an atom with the initial wavevector k_z to the next higher momentum state $k_z + 2q$, the Bragg condition requires,

$$\Delta\nu_R = \nu_{R2} - \nu_{R1} = \frac{\hbar(k_z+2q)^2}{2m} - \frac{\hbar k_z^2}{2m} = \frac{2\hbar q}{m}(k_z+q) \ . \tag{52.69}$$

If we tune $\Delta\nu(\pm\Delta k_z)$ until the Bragg signal $\dot{N}_{brg}$ drops to $e^{-1/2}$,

$$\Delta\nu_R(\Delta k_z) - \Delta\nu_R(-\Delta k_z) = \frac{4\hbar\Delta k_z q}{m} = \frac{4\hbar q}{m}\frac{\sqrt{m k_B T}}{\hbar} = 4q\sqrt{\frac{k_B T}{m}} \ . \tag{52.70}$$

52.2.2.3 Bragg scattering by free atoms

Let us first assume that during the Bragg pulse only two discrete atomic momentum states $j = 0, 1$ are coupled [503, 94, 621, 237], and that trapping potentials are absent or can be neglected. This is justified for Bragg pulse sequences much shorter than an oscillation period of the trap. We denote the probability amplitudes for the two momentum states by momentum space wavefunctions a_{j,k_z}. They correspond to atoms with initial momenta $\hbar k_z$ that are coupled to states with momentum $\hbar k_z' = \hbar(k_z + 2q)$. The temporal evolution of the amplitudes under the action of the Bragg light is given by the solutions of the Schrödinger equation [621, 237],

$$\begin{pmatrix} a_{0,k_z}(t) \\ a_{1,k_z}(t) \end{pmatrix} = e^{-\imath\hat{H}_R t/\hbar} \begin{pmatrix} a_{0,k_z}(0) \\ a_{1,k_z}(0) \end{pmatrix} \ , \tag{52.71}$$

with the Hamiltonian,

$$\boxed{\hat{H}_R = \begin{pmatrix} \frac{\hbar^2}{2m}k_z^2 & \frac{\hbar}{2}\Omega_R \\ \frac{\hbar}{2}\Omega_R & \frac{\hbar^2}{2m}k_z'^2 - \hbar\delta \end{pmatrix}} \ , \tag{52.72}$$

where $\Delta = 2\hbar q^2/m - \delta$ is the detuning of the Bragg lasers from the recoil shift. When the Bragg light is switched off, the Hamiltonian simplifies to,

$$\hat{H}_{free} = \begin{pmatrix} \frac{\hbar^2}{2m}k_z^2 & 0 \\ 0 & \frac{\hbar^2}{2m}k_z'^2 - \hbar\delta \end{pmatrix} \ . \tag{52.73}$$

Concatenating temporal evolutions described by $e^{-\imath\hat{H}_R t/\hbar}$ and $e^{-\imath\hat{H}_{free} t/\hbar}$, the phase evolution of individual atoms in momentum state superpositions can be calculated for arbitrary sequences of pulses separated by intervals of free evolution, for example, Ramsey-type sequences.

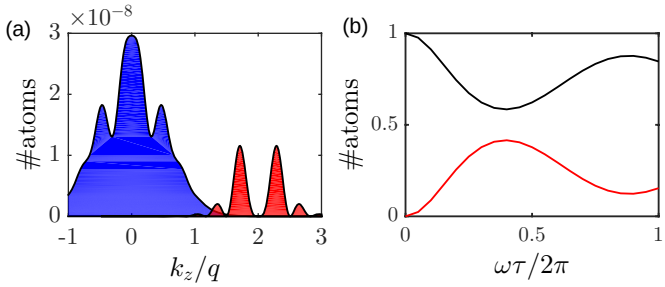

Figure 52.8: (code) (a) Distribution of momentum classes in the direction of k_z after irradiation of a 2π Bragg pulse. The width of the structure is determined by the power broadening of the Raman transition. (b) Temporal evolution of the populations of the momentum states 0 and $2q$.

52.2.2.4 Bragg scattering by trapped particles

When trapped atoms are considered, the problem arises that the Hilbert space of momentum states is simultaneously coupled by two interactions: a moving optical lattice (generated by the Bragg lasers) and the (harmonic) trap. However, the situation gets simpler if a separation of the scales is possible. In general, the duration of a pulse is very short, $\tau \ll 2\pi/\omega_z$. In contrast, the duration of a free evolution period Δt (e.g. in a Ramsey cycle) may be such, that it is no more negligible compared to a trap oscillation period, so that we need to account for the action of the trapping potential explicitly.

As the trap couples the atomic momenta with the atomic positions ($E_{kin} + E_{pot} = const$), the initial spatial distribution of the atoms must now be considered. For simplicity, we describe it as a thermal Gaussian, similarly to what has been done in Eq. (52.61) for the momentum distribution,

$$G(z) = \sqrt{\frac{m\omega_z^2}{2\pi k_B T}} e^{-m\omega_z^2 z^2/2k_B T} = \frac{e^{-\pi z^2/a_z^4 k_{therm}^2}}{a_z^2 k_{therm}} \ . \tag{52.74}$$

Beginning with the positions z and initial momenta k_z, after a diffraction pulse transferring the recoil $2q$ to part of the atoms and being short enough not to change their positions, the atoms follow classical trajectories. The atomic momenta (now depending on time) are simply the solution of the equation of motion $\hbar \dot{k}_z = -m\omega_z^2 z$ with the initial conditions $z(0) = z$ and $k_z(0) = k_z$, respectively, $k_z'(0) = k_z + 2q$,

$$\begin{aligned} \tilde{k}_z(t) &= k_z \cos\omega_z t - \frac{m\omega_z}{\hbar} z \sin\omega_z t \\ \tilde{k}_z'(t) &= (k_z + 2q)\cos\omega_z t - \frac{m\omega_z}{\hbar} z \sin\omega_z t \ , \end{aligned} \tag{52.75}$$

where the first expression holds for non-diffracted atoms and the second for diffracted atoms. These momenta are substituted for k_z and k_z', respectively, in the Hamiltonians (52.72) and (52.73). As the Bragg pulses are short compared to the oscillation period, $\tau \ll 2\pi/\omega_z$, the effect of the trapping potential may be neglected during Bragg scattering. This means that the Hamiltonian $\hat{H}_R$ depends on $\tilde{k}_z(t)$, but can be

treated as time-independent for the short intervals τ. In contrast, the Hamiltonian for free propagation $\hat{H}_{free}$ depends on the time, if Δt is long. In this case, the phase evolution of the atoms in both coupled states can be described by the time evolution operator as,

$$\boxed{e^{-\imath \hat{H}_{free} t/\hbar} = \begin{pmatrix} \exp\left(-\imath \int_0^t dt \frac{\hbar}{2m} \tilde{k}_z^2(t)\right) & 0 \\ 0 & \exp\left(-\imath \int_0^t dt \left[\frac{\hbar}{2m} \tilde{k}_z'^2(t) - \delta\right]\right) \end{pmatrix}} \ . \tag{52.76}$$

Since the amplitudes a_{j,z,k_z} now also depend on the initial atomic positions, the final populations of the momentum states must be additionally weighted with the initial spatial distribution. Therefore, the Eq. (52.64) for the expected the numbers of diffracted and non-diffracted atoms must be replaced by,

$$N_j(t) = \iint D(k_z) G(z) \left|a_{j,z,k_z}(t)\right|^2 dk_z dz \ . \tag{52.77}$$

In practice, however, it might be a good approximation to assume small displacements around a δ-shaped position distribution. Note, that the transformation (52.75) must be repeated for every free evolution pulse of a sequence.

Example 378 (*Approximation for small displacements*): In practice, we may neglect the displacements, $z \simeq 0$. Then the equations (52.75) simplify to,

$$\tilde{k}_z(t) = k_z \cos \omega_z t \qquad \text{and} \qquad \tilde{k}_z'(t) = (k_z + 2q) \cos \omega_z t \ .$$

Inserting them in (52.76) we obtain for the propagator,

$$e^{-\imath \hat{H}_{free} t/\hbar}$$
$$= \exp\left(-\frac{\imath \hbar k_z^2}{4m\omega_z}(\cos \omega_z t \sin \omega_z t + \omega_z t)\right) \begin{pmatrix} 1 & 0 \\ 0 & \exp\left(-\frac{\imath \hbar q k_z}{2m\omega_z}(\cos \omega_z t \sin \omega_z t + \omega_z t)\right) \end{pmatrix} \ .$$

In Exc. 52.2.4.1 we will study the behavior of an ultracold atomic cloud subject to a gravitational potential during a Ramsey-Bordé sequence.

52.2.2.5 Bloch equations approach

Experimentally, we observe decoherence of the dynamics described above on a very slow time scale. This phenomenon can be included in a description based on Bloch equations,

$$\frac{d}{dt} \vec{\rho}_{k_z}(\tau) = M_j \vec{\rho}_{k_z}(\tau) \ , \tag{52.78}$$

with

$$\vec{\rho}_{k_z}(\tau) = \begin{pmatrix} \rho_{00,k_z}(\tau) \\ \rho_{01,k_z}(\tau) \\ \rho_{10,k_z}(\tau) \\ \rho_{11,k_z}(\tau) \end{pmatrix} \qquad \text{and} \qquad M_j = \begin{pmatrix} 0 & \Gamma & \frac{\imath}{2}\Omega_R & -\frac{\imath}{2}\Omega_R \\ 0 & -\Gamma & -\frac{\imath}{2}\Omega_R & \frac{\imath}{2}\Omega_R \\ \frac{\imath}{2}\Omega_R & -\frac{\imath}{2}\Omega_R & -\gamma - \imath\Delta_j & 0 \\ -\frac{\imath}{2}\Omega_R & \frac{\imath}{2}\Omega_R & 0 & -\gamma + \imath\Delta_j \end{pmatrix} \tag{52.79}$$

with the solution,

$$\vec{\rho}_{k_z}(\tau) = e^{M_3 t} e^{M_2 t} e^{M_1 t} \vec{\rho}_{k_z}(0) \tag{52.80}$$

with,

$$\begin{aligned} \Delta_1 &= \frac{\hbar}{2m}(k_z + 2q)^2 - \Delta\nu - \frac{\hbar}{2m}k_z^2 \\ \Delta_3 &= \frac{\hbar}{2m}\left[(k_z + 2q)\cos\omega_{tr}\tau\right]^2 - \frac{\hbar}{2m}\left[(k_z + 2q)\cos\omega_{tr}\tau - 2q\right]^2 - \Delta\nu \ . \end{aligned} \tag{52.81}$$

We weigh populations with the initial momentum distribution,

$$N_j(\tau) \equiv \int D(k_z)\rho_{jj,k_z}(\tau)dk_z \ . \tag{52.82}$$

52.2.2.6 Kapitza-Dirac scattering

An atomic beam with longitudinal de Broglie wavelength $\lambda_{dB} = h/p$ diffracted by a solid periodic grating with a slit distance of d receives a transverse amplitude modulation. In the far field, this generates focuses at angles defined by $n\lambda_{dB}/d = \sin\vartheta$. Alternatively, the grating may consist of a standing light wave detuned from resonances. The standing wave will create a periodic optical potential, which imprints a transverse phase modulation on the atomic beam. In the far field, the result will be the same as for the solid grating. Each atom will evolve into a superposition of momentum sidemodes $\pm n2\hbar k$, without any momentum having been transferred to the atoms. The diffraction angle is again $\sin\vartheta = \pm n2\hbar k/p = \pm n\lambda_{dB}/(\lambda/2)$, where $\lambda/2 = d$ is the periodicity of the standing light wave. However, this is only true if the phase shift is much smaller than π. This scheme is called the *Raman-Nath regime* or the regime of *Kapitza-Dirac scattering*. An equivalent condition for this regime is, that the interaction time is less than a period of oscillation in the optical potential, $\tau \ll \sqrt{\hbar/\omega_{rec}/U}$, or $v_{trans}\tau \ll \lambda$.

The Raman-Nath regime is realized by a very focused optical standing wave. A wave that is not plane can be considered a superposition of many spatial modes. Since (off-resonant) scattering (absorption followed by induced emission) corresponds to a photon redistribution between spatial modes, in a tight waist the phase matching condition is somewhat relaxed and minor corrections to the energy balance are possible. In a certain sense, Kapitza-Dirac scattering is the inverse process of 'forward scattering' of a laser beam passing through an atomic cloud: the roles of light and atoms are exchanged. The requirement that the interaction time be short implies, that the light grating is 'optically dilute' for the atomic beam [10].

For larger Rabi frequencies,

$$\Omega_R \gg \frac{2\hbar q\sigma_{k_z}}{m} \ , \tag{52.83}$$

with $\sigma_{k_z} = \sqrt{mk_{\mathrm{B}}T/\hbar^2}$ being the width of the momentum distribution, the Doppler broadening is dominated by power broadening, meaning that Bragg diffraction occurs

[10] Note, that we usually employ the term of *optical diluteness* the other way round, i.e. an atomic cloud can be optically dilute (or dense) for a laser beam.

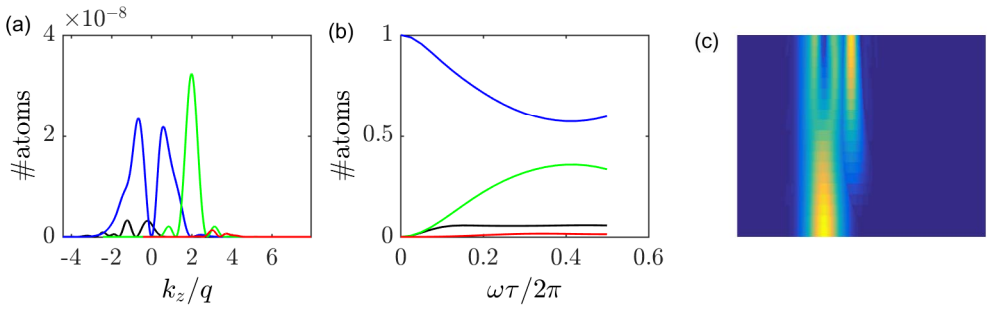

Figure 52.9: (code) (a) Distribution of momentum classes in the direction of k_z after irradiation of a π Bragg pulse. (b,c) Temporal evolution of the populations of the momentum states nq.

all over the atomic cloud. At some point, however, the Rabi frequency becomes comparable to the energy difference between adjacent momentum states, and Kapitza-Dirac scattering sets in. According to [94] the scattering will stay two-state like as long as the Rabi frequency fulfills the condition,

$$\Omega_R \ll \frac{\hbar}{m}(4q^2 - 2q\sigma_{k_z}) \ . \tag{52.84}$$

In the Kapitza-Dirac regime, the large energy uncertainty, connected with the fast coupling rate, allows several momentum states to be coupled simultaneously. In particular the Bragg Hamiltonian is replaced by,

$$\hat{H}_\tau = \begin{pmatrix} \ddots & \ddots & & & \\ \ddots & \frac{\hbar(k_z-2q)^2}{2m} + \delta & \frac{\Omega_R}{2} & & \\ & \frac{\Omega_R}{2} & \frac{\hbar k_z^2}{2m} & \frac{\Omega_R}{2} & \\ & & \frac{\Omega_R}{2} & \frac{\hbar(k_z+2q)^2}{2m} - \delta & \ddots \\ & & & \ddots & \ddots \end{pmatrix} \ . \tag{52.85}$$

The crossover from the Bragg-diffraction regime to Kapitza-Dirac scattering is a smooth transition. As we will see below, for intermediate Rabi frequencies (here $1\,\mathrm{MHz} > \Omega_R/2\pi > 100\,\mathrm{kHz}$) the neighboring diffraction states, corresponding to momentum shifts of $4\hbar q$ and $-2\hbar q$ (second and minus first order), are scarcely populated. For higher and higher Rabi frequencies, $\Omega_R/2\pi > 1\,\mathrm{MHz}$, the scattering populates more and more diffraction orders.

52.2.2.7 Higher-order Bragg scattering

Higher-order Bragg scattering is possible as well. Then the $2n$-photon Rabi frequency must be calculated and inserted in the second diagonal of (52.85).

52.2.3 Bragg spectroscopy of a condensate

To measure the Bogolubov spectrum, we need to excite perturbations in a condensate and study its reaction [873].

Let us now imagine that the potential has the form of a standing wave. Technically this can be done by two laser beams having the same frequency crossing at the position of the atoms,

$$V_{trap}(\mathbf{r},t) \equiv \tfrac{V}{2} e^{\imath \mathbf{q}_1 \cdot \mathbf{r} - \imath\omega t} + \tfrac{V}{2} e^{\imath \mathbf{q}_2 \cdot \mathbf{r} - \imath\omega t} \ . \tag{52.86}$$

Choosing the coordinate system such that, $\mathbf{q}_1 \equiv (k_x, 0, k_z)$ and $\mathbf{q}_1 \equiv (k_x, 0, -k_z)$,

$$V_{trap}(\mathbf{r},t) = \tfrac{V_x}{2} e^{\imath k_z z - \imath\omega t} + \tfrac{V_x}{2} e^{-\imath k_z z + \imath\omega t} \ , \tag{52.87}$$

with $V_x \equiv V e^{ik_x x}$. With this weak perturbation applied to the atoms, we make the ansatz,

$$\psi(\mathbf{r},t) = e^{-\imath\mu t/\hbar} \left(\psi_0(\mathbf{r},t) + u(t) e^{\imath k_z z - \imath\omega t} - v(t) e^{-\imath k_z z + \imath\omega t} \right) \ , \tag{52.88}$$

where the amplitudes of the perturbation, $u(t)$ and $v(t)$, only vary slowly in time. Assuming that ψ_0 is fairly homogeneous, i.e. $\langle \psi_0 | \nabla_z | \psi_0 \rangle \simeq 0$, the momentum transferred to the BEC is,

$$\langle \psi(\mathbf{r},t) | -\imath\hbar\nabla_z | \psi(\mathbf{r},t) \rangle = \hbar k_z (|u|^2 - |v|^2) \ . \tag{52.89}$$

We can now solve the Gross-Pitaevskii equation (50.20) in the same way as in Sec. 50.4.1 inserting the ansatz (52.88). The terms proportional to $e^{\imath k_z z - \imath\omega t}$ are,

$$\frac{\hbar^2 \mathbf{k}_z^2}{2m} u + \frac{V}{2}\psi_0 + g\left(|\psi_0|^2 + |u|^2 + |v|^2\right) u + g\psi_0^2 v + g|v|^2 u + g|\psi_0|^2 u = \left(\imath\hbar\frac{\partial}{\partial t} + \hbar\omega + \mu\right) u \ , \tag{52.90}$$

and the analogously for $e^{-\imath k_z z + \imath\omega t}$. Using $\mu = gn = g|\psi_0|^2$ and assuming that the perturbation is weak, $|u|, |v| \ll |\psi_0|$, we obtain,

$$\begin{aligned} \left(\frac{\hbar^2 k^2}{2m} + gn\right) u + \frac{V}{2}\psi_0 - gnv &= \left(\imath\hbar\frac{\partial}{\partial t} + \hbar\omega\right) u \\ -\left(\frac{\hbar^2 k^2}{2m} + gn\right) v - \frac{V}{2}\psi_0 + gnu &= \left(-\imath\hbar\frac{\partial}{\partial t} + \hbar\omega\right) v \ . \end{aligned} \tag{52.91}$$

This effect is called *Bragg diffraction* of atoms by a standing light wave.

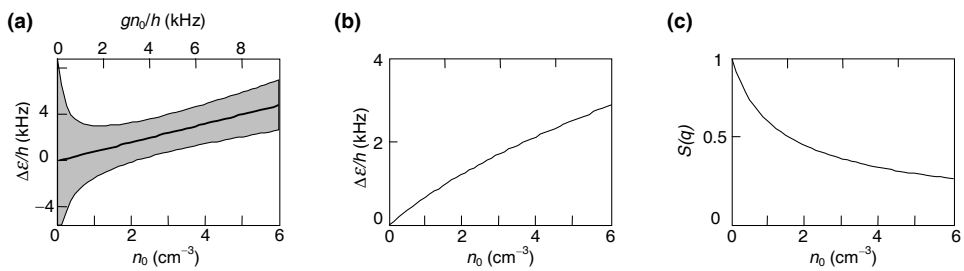

Figure 52.10: Spectrum of elementary excitations.

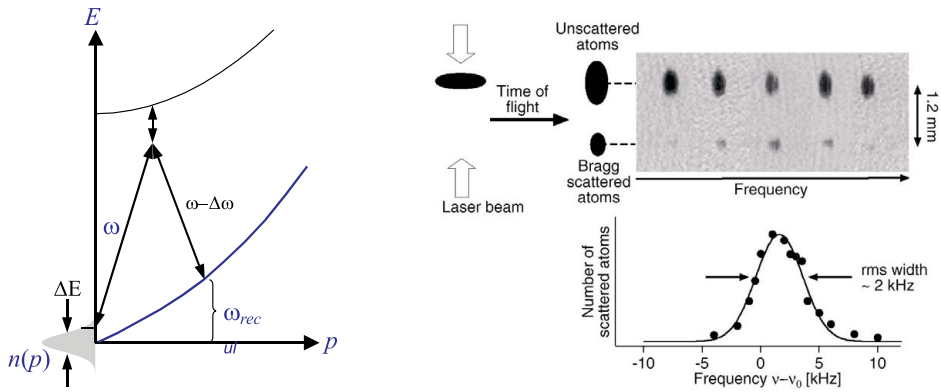

Figure 52.11: Spectrum of elementary excitations.

Using $\mathcal{L} \equiv \frac{\hbar^2 \mathbf{k}^2}{2m} + V_{trap} + 2gn - \mu - \imath\hbar\frac{\partial}{\partial t}$, we can write,

$$\begin{pmatrix} \mathcal{L} - \hbar\omega_{\mathbf{k}} & -gn \\ -gn & \mathcal{L} + \hbar\omega_{\mathbf{k}} \end{pmatrix} \begin{pmatrix} u \\ v^* \end{pmatrix} = 0 \ . \tag{52.92}$$

These equations can be decoupled using the Bogolubov transform.

We calculate the momentum transferred to the BEC, assuming ψ_0 to be fairly homogeneous,

$$\langle \psi(\mathbf{r}, t)| - \imath\hbar\nabla|\psi(\mathbf{r}, t)\rangle = \hbar\mathbf{q}(|u|^2 - |v|^2) \ . \tag{52.93}$$

52.2.4 Exercises

52.2.4.1 Ex: Bragg diffraction in a Ramsey-Bordé interferometer

A Ramsey-Bordé interferometer consists of a $\frac{\pi}{2}$-π-$\frac{\pi}{2}$ laser pulse sequence of Bragg diffraction pulses leading to a splitting and recombination of an atomic wavefunction in momentum space. Simulate the behavior of a cold atomic cloud subject to a gravitational potential during a Ramsey-Bordé sequence using the formalism developed in Sec. 52.2.2. See also Excs. 23.7.6.2 and 23.7.6.3.

52.3 Matter wave superradiance

52.3.1 Classical superradiance

The Bragg beam splitter introduced in the last section does not give rise to collective scattering, even when the atoms are as strongly correlated as in a condensate. On the other hand, collective scattering is known to occur in a classical gas: When two atoms excited to an internal energy level, $\sim hc/\lambda$, are separated by a distance R too large to form a molecule, but smaller than the wavelength of the excited transition, $a_B \ll R \ll \lambda$, the atoms are coupled to the electromagnetic continuum by the same radiation that they emit (see Fig. 52.12). The dipole moments of the atoms stimulate each other to emit, and we observe a synchronized and accelerated relaxation, resulting in a coherent

and directional burst of radiation [256, 768]. The directionality of the radiation is due to a destructive interference of the dipolar radiation patterns emitted by the atoms in all directions except the direction chosen by the first emitted photon. This direction is random (except when bosonically stimulated). The atomic sample evolves, during this time, to a state of coherent superposition, until all the atoms are deexcited. This phenomenon is called *Dicke superradiance*. A similar effect exists for matter waves, and will be discussed in the following sections [464].

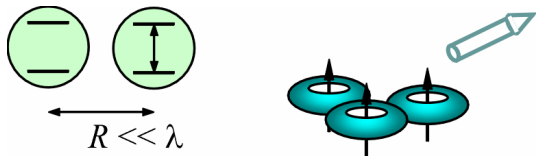

Figure 52.12: Superradiance assumes small interatomic distances compared to the wavelength of the excited dipole. Toroidal interference patterns interfering constructively in only one direction.

52.3.2 Matter wave superradiance & CARL

We consider the process of Rayleigh scattering from a condensate. The scattering rate obviously depends on the number of atoms and the laser intensity. The crucial point now is, that this rate can be stimulated by populations in the output modes, that is, the modes of scattered light and the atomic recoil modes. Matter and light participate in the scattering process as equal partners. In Sec. 52.2.1 we showed that Bragg scattering can be interpreted as *optical stimulation of matter wave scattering*. By analogy, it is possible to imagine a process of *wave matter stimulation of light scattering*. We will now discuss such a process, called *superradiant Rayleigh scattering* or *matter wave superradiance* (MWSR) [464], with the help of the small cartoon shown in Fig. 52.13. See also (watch talk).

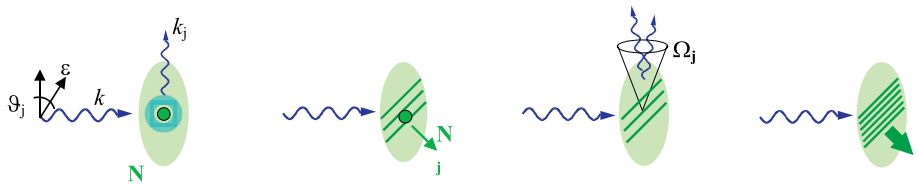

Figure 52.13: Cartoon for MWSR (see text).

Let us imagine an elongated condensate, subject to a magnetic field directed along its long axis and illuminated perpendicularly to the long axis by a linearly polarized laser beam. The scattered light is emitted into a (toroidal) dipolar radiation pattern. The fraction of the light scattered into the solid angle Ω_j, which is inclined by angle ϑ_j with respect to the polarization of the incident laser is $\Omega_j \sin^2 \vartheta_j/(8\pi/3)$. Of course, the number of scattered photons also depends on the optical cross section σ and the number of scattering atoms N_0. When an atom, recoiling due to the transfer of one unit of photonic momentum, moves with a speed of a few centimeters per second

through the condensate, it interferes with other atoms of the condensate, thus forming a wave matter grating. The grating, the lifetime of which is long in comparison to the scattering rate, now stimulates subsequent photons to follow the same path Ω_j and receives, in turn, the scattering atoms. In other words, the bosonic stimulation of the scattering process by the N_j atoms already populating the recoil mode amplifies the photon scattering rate by a factor of $N_j + 1$. The differential optical cross section (power P_j scattered into the direction Ω_j divided by the laser intensity I) is [464],

$$\frac{d\sigma}{d\Omega_j} = \frac{P_j}{I} = \frac{\Omega_j \sin^2 \vartheta_j}{8\pi/3} \sigma N_0 (N_j + 1) \ . \tag{52.94}$$

Each scattering event of a photon into the mode Ω_j transfers an atom to the recoil mode N_j:

$$\dot{N}_j = P_j/\hbar\omega \equiv G_j N_j \qquad \text{where} \qquad G_j = \frac{I}{\hbar\omega} \sigma \frac{\Omega_j \sin^2 \vartheta_j}{8\pi/3} N_0 \ . \tag{52.95}$$

The phase matching condition is satisfied for a solid angle of approximately $\Omega_j = \lambda^2/A_j$, where A_j is the cross-sectional area of the condensate. If l_j is the length of condensate, we can write,

$$G_j = \frac{I}{\hbar\omega} \sigma \frac{\sin^2 \vartheta_j}{8\pi/3} n_0 \lambda^2 l_j \ . \tag{52.96}$$

With the atomic density $n_0 = N_0/(A_j l_j)$, the factor $n_0 \lambda^2 l_j$ describes the optical density of the BEC in the direction of the scattering. Therefore, we obtain *exponential gain* for the atom number N_j, that is, the process is self-amplifying.

Using the terms of the *dressed atom* picture, we would say that the excited state of our system is formed by the BEC and the laser mode. This state relaxes to a state formed by the recoiled atoms and the scattered photons. The exponential gain occurs, when this system exhibits inversion. The inversion is maintained, until the BEC is completely transferred to the momentum recoil modes [11].

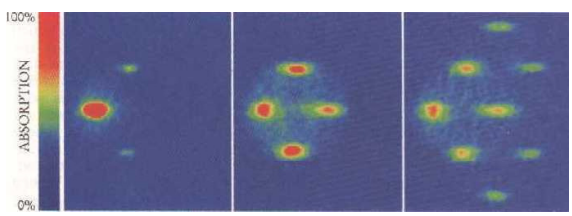

Figure 52.14: Observation of matter wave superradiance.

[11] Superradiant scattering is due to a nonlinear coupling between two matter waves and two optical waves in a *four-wave mixing* process (4WM) interpreted as scattering of light *from* a wave matter *stimulated* by a wave matter mode. The process does not require nonlinearity due to collisions, but it works with an ideal gas, $g \to 0$. This distinguishes it from the 4WM of four matter waves, studied in Sec. 51.3.4 and interpreted as a scattering of atoms by a matter wave stimulated by matter wave mode, and 4WM in quantum optics involving four photons. But in all cases bosonic stimulation is crucial.

It is instructive to compare Dicke superradiance and matter wave superradiance. Dicke superradiance is induced by an electronic coherence between adjacent atoms. It requires a sufficiently long coherence time for the atomic dipoles. On the other hand, MWSR is a coherence effect between two states of the atomic center-of-mass motion, i.e. the condensed state and a momentum sidemode. A long lifetime of this coherence is necessary to allow for correlations between successive scattering events. The coherence lifetime corresponds to a coherence length, which for a condensate is equal to its physical size, whereas for a thermal cloud, it only corresponds to its thermal Broglie wavelength. This explains why it is difficult to observe MWSR with non-condensed atomic clouds.

Since the scattered photons quickly leave the BEC, there is no feedback or bosonic stimulation by the optical output mode. This can be interpreted as a fast decaying cavity mode, and the regime is called the *bad cavity limit*. Let us now imagine, that the photons were recycled, for example, via an optical cavity constructed around the BEC and reflecting back the photons emitted in the solid angle Ω_j [12]. The mirrors of the cavity create reflection images of the radiating atoms, which increase the *density of states*, the scattering rate, and the gain G_j increase by a factor of $8F/\pi$. An interesting question now is, what happens in the limit $F \to \infty$. If the decay of the cavity mode, and therefore the removal of photons from the coherent interaction zone (which is precisely the volume occupied by the BEC) is slow, the MWSR process seems to be doubly stimulated, optically and atomically. However, in this case we also expect the inverse process, where photons are scattered back to the original mode, to occur and to be stimulated by the number of atoms N_0 in the condensate. We see that the simple picture of bosonic stimulation does not work in this case, and a more complete model including the possibility of Rabi oscillations amplified by stimulated emission is necessary [13].

52.3.3 Amplification of matter and light waves

The feedback-induced exponential gain giving rise to the phenomenon of MWSR can be used to construct a phase-coherent amplifier of matter and light waves. After all, the momentum side modes observed in the MWSR process [464] already represent amplified vacuum fluctuations. To experimentally realize a *coherent matter wave amplifier* [538, 466], it is sufficient to replace the vacuum fluctuations of the original MWSR experiment with a small *seed condensate*: $\sim 0.1\%$ of the 'mother condensate' proved sufficient to stimulate the matter wave amplifier. The seed condensate was created by Bragg diffraction transferring atoms from the mother BEC to another momentum state (see Sec. 52.2). The matter wave grating formed by interference of the seed condensate and the mother BEC was subsequently amplified by a MWSR pulse. The gain for the atom number in the seed condensate was 10 to 100 depending on the

[12] Alternatively, we may imagine a scheme decelerating of the group velocity of the light pulse.

[13] The phenomenon of the matter wave superradiance can be understood without quantization of the atomic motion [**?**] and, in particular, without quantum degeneracy. A cold and dense thermal cloud can show the phenomenon of MWSR [1003]. The scattered light forms together with the pump light, a propagating standing light wave, from which the atoms are scattered by Bragg diffraction. Atoms are accelerated by the CARL effect [204, 111, 557, 665, 664, 538, 466, 465] through a coherent redistribution of photons between the pump and scattered modes. However, as was shown later-on, the different recoil modes of the condensate exhibit phase-coherence, which is not explained by a theories treating the atomic motion semi-classically.

intensity and duration of the MWSR pulse. Finally, the coherence of the amplification process was demonstrated by *active atom interferometry* using the Ramsey scheme: One of the interferometer arms consisted of the amplified seed condensate and the other of a reference condensate (local oscillator) especially created by Bragg diffraction from the mother condensate. The observation of interference between these two matter waves proved the coherence of the amplification process and the existence of a well-defined phase relationship between the input and the output of the matter wave amplifier.

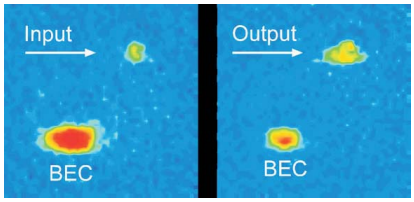

Figure 52.15: Matter wave amplification of a 'seed condensate' at the expense of a 'mother condensate'. Time-of-flight imaging visualizes the condensate's momentum distribution.

In analogy to electronics, we may consider the coherent matter wave amplifier as an *active device* complementing the atom optical toolbox of *passive devices* (see Sec. 51.3.1).

52.3.4 Four-wave mixing of optical and matter waves

We will now make an attempt to categorize the various scattering processes involving condensates. Let us first return to the radiation pressure [Fig. 52.16(a)], where an incident photon is spontaneously scattered into a random direction. The isotropy of the scattering process can, however, be broken when certain directions (i.e. spatial modes) are favored by bosonic stimulation. The symmetry of the roles of matter wave modes and light modes allows us to treat both on the same footing, for example, we can stimulate scattered modes either by matter of light waves.

Let us first have a look at stimulation by optical modes [Fig. 52.16(b) and (c)]. Fig. (b) describes optical four-wave mixing (4WM) in nonlinear optical media, i.e. *optically stimulated scattering of photons* from a standing light wave, which is a 4WM process of 4 photons. Fig. (c) describes Bragg scattering, i.e. an *optically stimulated scattering of atoms* by a standing light wave, which is a 4WM process of 2 photons and 2 atoms.

Similarly, a scattering process can also be stimulated by a macroscopic number of atoms in a recoil mode [Fig. 52.16(d) and (f)]. Fig. (d) describes superradiant Rayleigh scattering and matter wave amplification, i.e. scattering of photons *stimulated by a de Broglie wave*, which again corresponds to 4WM of 2 photons and two atoms. Fig. (e) describes amplification of a laser pulse by superradiant Rayleigh scattering, i.e. scattering of photons in a matter wave with *double stimulation by light waves and de Broglie waves*, which once again is a 4WM process of 2 photons and 2 atoms. Finally, Fig. (f) describes the basic process of nonlinear atom optics, i.e. the scattering of atoms by a matter wave *stimulated by de Broglie waves*, which is a 4WM process of 4 atoms.

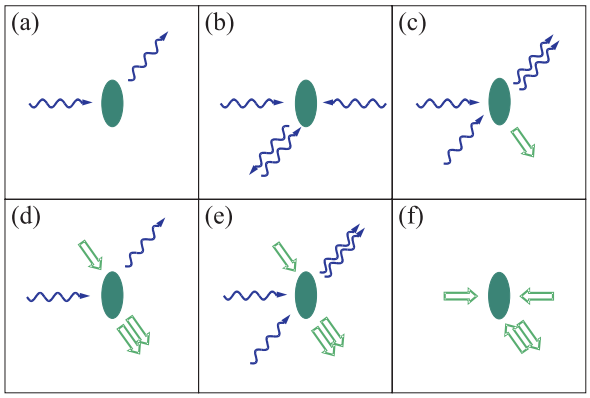

Figure 52.16: Schematic comparison of 4WM processes between light and matter wave modes. (a) Spontaneous emission, (b) classical 4WM of light modes, (c) Bragg scattering, (d) superradiant Rayleigh scattering, respectively, matter wave amplification, (e) optical amplification, and (f) 4WM of matter waves.

52.4 Condensates in electronically excited states

The interaction between condensates and light has, so far, been treated in the limit where the *population of excited states can be neglected or adiabatically eliminated.* An example was the coherent coupling of different kinetic states of an atom by a method called *Bragg diffraction* discussed in Sec. 52.2.

On the other hand, atoms can have metastable excited states, which can introduce new degrees of freedom, and a whole world of new problems emerges that need to be addressed: How do condensed atoms move, when they are in different states of internal excitation (or superposition of states), and how do atoms in different states interact with each other? We will now turn our attention to coherent coupling of internal states [14].

In Sec. 52.4.1 we will show how to generalize the second-quantized formalism introduced in 50.2.1 in order to deal with coupled condensates in different states of internal excitation.

In Sec. 52.4.2 we will discuss examples of how coherent coupling of two states can be accomplished either by radiofrequency/microwave radiation or by two laser beams in Raman configuration. In order to avoid spontaneous relaxation, we often choose state with low excitation energy, for example, within the hyperfine structure ($\hat{H} \sim \mathbf{I}\cdot\mathbf{J}$) or the Zeeman structure ($\hat{H} \sim \mu \cdot B$) of the electronic ground state. But one can also consider the coupling between different *kinetic states* of free atoms $\hat{H} \sim \mathbf{p}^2/2m$, or the *output coupling* of atoms confined to a trapping potential ($\hat{H} \sim \frac{m}{2}\omega^2\mathbf{r}^2$), or even a chemical coupling between a vibrational state of two atoms bound together to form

[14] We will disregard, for the moment, possible effects due to inhomogeneous broadening caused by the finite volume of the cloud inside the potential (Zeeman shift in magnetic traps or dynamic Stark shift optical traps) or effects due to interatomic interactions. But we have to keep in mind, that interatomic interaction can have a big impact on the dynamics, because the chemical potential of each condensate depends on its number of atoms. Thus, in view of the inhomogeneity of the trapping potential, the transfer of atoms can excite oscillations and sound waves in the condensates.

a molecular and a state, where the same two atoms are free and involved in an elastic collision.

Finally, in Sec. 52.4.3 we will show how to harness the forces induced by atom-light coupling in order to design new geometries of trapping potentials.

52.4.1 Theory of the interaction of condensates with light

Let us consider two Bose-Einstein condensates in the mean-field approximation consistent of atoms in two different internal excitation states, ψ_1 and ψ_2, separated by the energy $\hbar\omega_0$. We illuminate the BEC by a plane wave of monochromatic light with the frequency ω. The formal procedure consists of constructing the Hamiltonian of individual atoms, as done in Eq. (43.2), and then quantizing the field of matter [738],

$$\hat{H}_{atom} = |1\rangle \hat{H}^{(1)}_{cm} \langle 1| + |2\rangle (\hat{H}^{(2)}_{cm} + \hbar\omega_0)\langle 2| \qquad \text{where} \qquad \hat{H}^{(j)}_{cm} = \frac{\hat{\mathbf{p}}^2}{2m} + V^{(j)}_{trap}(\hat{\mathbf{r}}) \ , \tag{52.97}$$

where we allow for the fact that the trapping potentials can be different for the two excitation states. We assume that atoms in different states of excitation are distinguishable, such that their respective wavefunctions commute:

$$\hat{\psi}_j(\mathbf{r}) \equiv |j\rangle\langle j|\hat{\psi}(\mathbf{r}) \quad , \quad [\hat{\psi}_j(\mathbf{r}), \hat{\psi}_{j'}(\mathbf{r})] = \delta_{jj'}\delta^3(\mathbf{r}-\mathbf{r}') \ . \tag{52.98}$$

However, we need to consider interatomic collisions which, in the mean-field approximation (50.19) are described by,

$$\hat{H}^{(j)}_{mf} = \int \hat{\psi}^\dagger_j(\mathbf{r}) \frac{2\pi\hbar^2 a_s}{m} \hat{\psi}_j(\mathbf{r}) d^3r \ . \tag{52.99}$$

The total atomic Hamiltonian is then a generalization of the many-body Hamiltonian (50.6),

$$\boxed{\mathcal{H}_{atom} = \int \hat{\psi}^\dagger_1(\mathbf{r}) \left(\hat{H}^{(1)}_{cm} + \hat{H}^{(1)}_{mf}\right) \hat{\psi}_1(\mathbf{r}) d^3r + \int \hat{\psi}^\dagger_2(\mathbf{r}) \left(\hat{H}^{(2)}_{cm} + \hat{H}^{(2)}_{mf} + \hbar\omega_0\right) \hat{\psi}_2(\mathbf{r}) d^3r} \ . \tag{52.100}$$

52.4.1.1 Interaction with a single light mode

The normalized annihilation operator for a photon in mode $\mathbf{k}$ is,

$$\vec{\mathcal{E}}^+(\mathbf{r}) = \sqrt{\tfrac{\hbar\omega}{2\varepsilon_0 V}} \vec{\epsilon} \hat{a} e^{\imath \mathbf{k}\cdot\mathbf{r}} \ . \tag{52.101}$$

The semi-classical Hamiltonian (the light not being quantized) of individual particles is, in the rotating wave approximation,

$$\hat{H}_{field} = \hbar\omega \hat{a}^\dagger \hat{a} \qquad \text{and} \qquad \hat{H}_{int} = -\hat{\mathbf{d}} \cdot \hat{\vec{\mathcal{E}}} = -|2\rangle \hat{\mathbf{d}}^+ \cdot \hat{\vec{\mathcal{E}}}^+ \langle 1| - |1\rangle \hat{\mathbf{d}}^- \cdot \hat{\vec{\mathcal{E}}}^- \langle 2| \ . \tag{52.102}$$

For a condensate we still need to second-quantize the interaction part of the Hamiltonian which, disregarding collisions gives [15],

$$\boxed{\mathcal{H} = \hat{H}_{field} + \mathcal{H}_{atom} - \int \left(\hat{\mathbf{d}}^{+} \cdot \hat{\vec{\mathcal{E}}}^{+} \hat{\psi}_2^{\dagger}(\mathbf{r})\hat{\psi}_1(\mathbf{r}) + \hat{\mathbf{d}}^{-} \cdot \hat{\vec{\mathcal{E}}}^{-} \hat{\psi}_1^{\dagger}(\mathbf{r})\hat{\psi}_2(\mathbf{r})\right) d^3r} \ . \tag{52.103}$$

With the Hamiltonian (52.103) we derive the Heisenberg equations for the condensate respecting the commutation rules (52.98) [16],

$$\begin{aligned} \dot{\hat{\psi}}_2 &= -\tfrac{\imath}{\hbar}(\hat{H}_{cm} + \hbar\omega_0)\dot{\hat{\psi}}_2 + \tfrac{\imath}{\hbar}\hat{\mathbf{d}}^{+} \cdot \hat{\vec{\mathcal{E}}}^{+}\hat{\psi}_1 \\ \dot{\hat{\psi}}_1 &= -\tfrac{\imath}{\hbar}\hat{H}_{cm}\dot{\hat{\psi}}_1 + \tfrac{\imath}{\hbar}\hat{\mathbf{d}}^{-} \cdot \hat{\vec{\mathcal{E}}}^{-}\hat{\psi}_2 \ . \end{aligned} \tag{52.104}$$

We transform to the non-rotating coordinate system by $\tilde{\psi}_2 \equiv \psi_2 e^{\imath\omega t}$ and $\tilde{\vec{\mathcal{E}}}^{+} \equiv \hat{\vec{\mathcal{E}}}^{+} e^{\imath\omega t}$ introducing the detuning $\Delta \equiv \omega - \omega_0$:

$$\partial_t \tilde{\psi}_2 = \imath(\Delta - \tfrac{1}{\hbar}\hat{H}_{cm})\tilde{\psi}_2 + \tfrac{\imath}{\hbar}\hat{\mathbf{d}}^{+} \cdot \tilde{\vec{\mathcal{E}}}^{+}\tilde{\psi}_1 \ . \tag{52.105}$$

Making the adiabatic approximation $\partial_t \tilde{\psi}_2 = 0$ and disregarding the external degree of freedom, $\hat{H}_{cm} = 0$, we obtain,

$$\tilde{\psi}_2 = \frac{\imath\hat{\mathbf{d}}^{+} \cdot \tilde{\vec{\mathcal{E}}}^{+}}{\hbar\Delta}\tilde{\psi}_1 \ . \tag{52.106}$$

52.4.1.2 Heisenberg equation for the light field

Similarly, we can write the Heisenberg equation for the light mode,

$$\frac{d\hat{a}}{dt} = \frac{\imath}{\hbar}[\mathcal{H}, \hat{a}] = -\imath\omega\hat{a} + \imath\sqrt{\tfrac{\omega}{2\varepsilon_0 V}} \int \hat{\mathbf{e}}_{\mathbf{k}} e^{-\imath\mathbf{k}\cdot\mathbf{r}} \cdot \left(\hat{\mathbf{d}}^{+}\hat{\psi}_2^{\dagger}\hat{\psi}_1 + \hat{\mathbf{d}}^{+}\hat{\psi}_1^{\dagger}\hat{\psi}_2\right) d^3r \ . \tag{52.107}$$

The integration of this gives the distribution of the fields (incident and scattered), such that,

$$\tilde{\vec{\mathcal{E}}}^{+}(\mathbf{r}) = \tilde{\vec{\mathcal{E}}}_{in}^{+}(\mathbf{r}) + \int K(\mathbf{d}, \mathbf{r} - \mathbf{r}')\hat{\psi}_1^{+}(\mathbf{r}')\hat{\psi}_1(\mathbf{r}')d^3\mathbf{r}' \ , \tag{52.108}$$

with the kernel:

$$K(\mathbf{d}, \mathbf{r}) = \frac{1}{4\pi\varepsilon_0}\left[k^2(\mathbf{R} \times \mathbf{d}) \times R\frac{e^{\imath kR}}{R} + [3\mathbf{R}(\mathbf{R} \cdot \mathbf{d} - \mathbf{d})]\left(\frac{1}{R^3} - \frac{\imath k}{R^2}\right)e^{\imath kR}\right] \ . \tag{52.109}$$

We focus on the first term dominating in the far-field, and neglect the second term by letting $R \approx r - \hat{\mathbf{e}}_R \cdot \mathbf{r}'$ and $\hat{R} \approx r$. We also define $\mathbf{k}_s \equiv k\hat{\mathbf{e}}_R$, and we only retain the term of order $1/R$. In this Born approximation for optically thin media, we obtain,

$$K(\mathbf{d}, \mathbf{r}) \simeq \frac{1}{4\pi\varepsilon_0}\frac{e^{ikR}}{r}k^2(\mathbf{r} \times \mathbf{r}) \times \mathbf{d}e^{-\imath\mathbf{k}_s\mathbf{r}'} \ . \tag{52.110}$$

[15] Or, by defining the Rabi frequency g_1 generated by a single photon, $\mathcal{H}_{int} = -\imath\hbar g_1 \hat{a} \int d^3\mathbf{r}\hat{\psi}_2^{\dagger}(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}}\hat{\psi}_1(\mathbf{r}) + h.c.$.

[16] In the first quantization, these equations would simply be the equations of motion for the amplitudes of the fundamental and excited states.

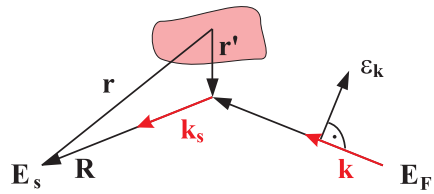

Figure 52.17: Scheme for the light scattering off a condensate.

52.4.1.3 Incident plane waves

When we now excite the condensate by a plane wave,

$$\hat{\vec{\mathcal{E}}}^{+}_{in}(\mathbf{r}) = \tfrac{1}{2}\vec{\epsilon}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{52.111}$$

we derive in the Born approximation of the equation (52.108):

$$\tilde{\vec{\mathcal{E}}}^{+}_{s}(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0}\frac{e^{\imath kR}}{r}k^2\mathbf{r}\times(\mathbf{r}\times\hat{\mathbf{d}}^{-})\int e^{-\imath\mathbf{k}_s\mathbf{r}'}\hat{\psi}^{\dagger}_1(\mathbf{r}')\hat{\psi}_2(\mathbf{r}')d^3r' \ , \tag{52.112}$$

and from this the fluorescence spectrum.

52.4.2 STIRAP & adiabatic sweep

A frequent problem for experimenters is the need to transfer a magnetically trapped atomic cloud from one Zeeman or hyperfine state to another. We will present here two techniques called STImulated Raman Adiabatic Passage and *adiabatic sweep*.

52.4.2.1 Adiabatic sweep

To discuss the adiabatic sweep, we consider the example of a ^{87}Rb cloud trapped in the state $|F, m_F\rangle = |2, -2\rangle$. The application of resonant radiofrequency radiation to the transition $|2, -2\rangle$-$|2, -1\rangle$ also couples all other m_F states and causes a diffusion of the atomic populations toward an uncontrollable mixture of states. An alternative is the application of a ramp sweeping the radiofrequency from red to blue (or vice versa). Such a ramp is able to transfer the entire population toward the opposite Zeeman state $|2, +2\rangle$. To see this, we solve the Schrödinger equation, $|\psi(t + dt)\rangle = e^{\imath H\ dt}|\psi(t)\rangle$, iteratively,

$$H = \begin{pmatrix} 0 & \frac{1}{2}\Omega & 0 & 0 & 0 \\ \frac{1}{2}\Omega & -\Delta & \frac{1}{2}\Omega & 0 & 0 \\ 0 & \frac{1}{2}\Omega & -2\Delta & \frac{1}{2}\Omega & 0 \\ 0 & 0 & \frac{1}{2}\Omega & -3\Delta & \frac{1}{2}\Omega \\ 0 & 0 & 0 & \frac{1}{2}\Omega & -4\Delta \end{pmatrix} \ . \tag{52.113}$$

The initial population distribution is $|\psi(t)\rangle = \begin{pmatrix}1 & 0 & 0 & 0 & 0\end{pmatrix}^t$. Ω is the Rabi frequency generated by the radiofrequency, $\Delta(t)$ is the instantaneous detuning. The curves of Fig. 52.18 show the temporal evolution of populations $|\langle k|\psi(t)\rangle|^2$.

The disadvantage of this method is that only the external (fully stretched) states $|m_F| = F$ can be interconverted.

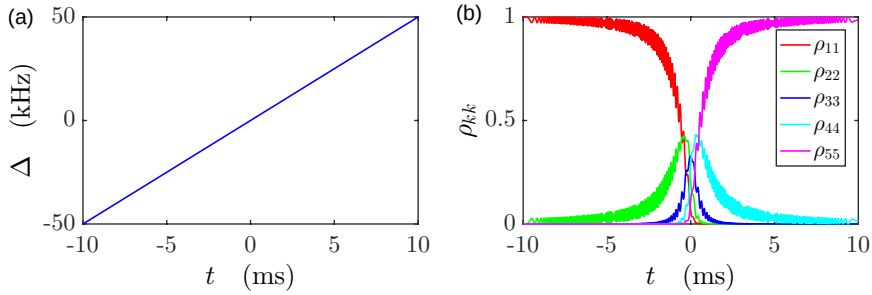

Figure 52.18: (code) Adiabatic sweep through the ground state ^{87}Rb $F = 2$. The Rabi frequency is $\Omega = (2\pi)8$ kHz. The frequency ramp is $\Delta(t) = \frac{t}{t_m}\,(2\pi)50$ kHz with $t_m = 10$ ms. The red line shows the evolution of the population in the state $|2, -2\rangle$, the green line of state $|2, +2\rangle$, and the blue line is the sum of the populations of all other states.

52.4.2.2 Sweep through a dark resonance

To discuss STIRAP, let us think of how to transfer atoms from the state $|1\rangle \equiv |2, 2\rangle$ to $|2\rangle \equiv |2, 1\rangle$. The general idea consists in applying two radiation fields with Rabi frequencies Ω_{13} and Ω_{23}, tuned a bit out of resonance with an intermediate state $|3\rangle$, $\Delta_{13} = \Delta_{23} \neq 0$, in a counterintuitive pulse sequence. That is, the field Ω_{23} is applied first and then adiabatically turned down, while the field Ω_{13} is ramped up. This method is capable of transferring all atoms.

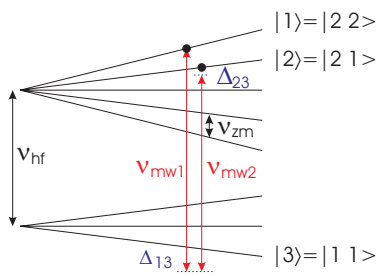

Figure 52.19: STIRAP.

Considering the example of the preceding section, we will discuss here another option (see Fig. 52.19). We consider continuous microwave fields with fixed tunings Δ_{13} to the red of the state $|3\rangle \equiv |1, 1\rangle$ state. Now, we apply a ramp to the second microwave field Δ_{23}, such that the two radiation fields, at some point, cross the Raman resonance, for example,

$$\nu_{mw1} = \nu_{hf} + 3\nu_{zm} + \Delta_{13} \qquad \text{and} \qquad \nu_{mw2}(t) = \nu_{hf} + 2\nu_{zm} + \Delta_{23}(t)\ . \tag{52.114}$$

The evolution of the populations can be simulated by iterative solution of the Schrödinger

equation, $|\psi(t+dt)\rangle = e^{iH\ dt}|\psi(t)\rangle$ with,

$$\hat{H} = \begin{pmatrix} 0 & 0 & \frac{1}{2}\Omega_{13} \\ 0 & \Delta_{23} - \Delta_{12}(t) & \frac{1}{2}\Omega_{23} \\ \frac{1}{2}\Omega_{13} & \frac{1}{2}\Omega_{23} & \Delta_{23} \end{pmatrix} . \tag{52.115}$$

The initial population distribution is $|\psi(t)\rangle = \begin{pmatrix} 1 & 0 & 0 \end{pmatrix}^t$. The curves of Fig. 52.20 show the temporal evolution of the populations $|\langle k|\psi(t)\rangle|^2$.

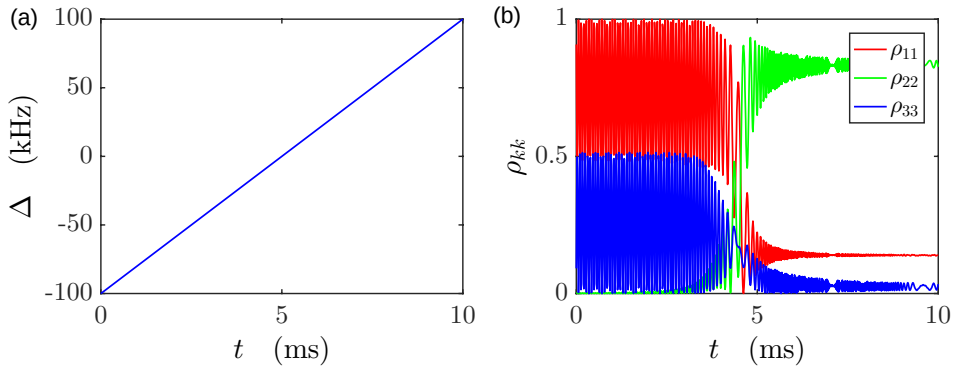

Figure 52.20: (code) STIRAP ramp through a dark resonance. Here, the Rabi frequencies are $\Omega_{13} = \Omega_{23} = 2\pi 10$ kHz. The frequency of the first microwave is $\Delta_{13} = (2\pi)10$ kHz and the frequency ramp of the second microwave is given by $\Delta_{23}(t) = \frac{2t-t_m}{t_m}\ (2\pi)100$ kHz, where $t_m = 10$ ms.

52.4.3 Condensate in adiabatic potentials

Adiabatic potentials have already been introduced in Secs. 43.1.3 and 49.4.3. Here, we will focus on the dynamics of condensed atoms in different states of electronic excitation, when these states are subject to different potentials and radiation fields that can induce transitions between the states. In particular, we consider paramagnetic atoms in different Zeeman states placed in inhomogeneous static magnetic fields and subject to single-mode or multi-mode radiofrequency radiation fields [199]. To simplify the problem, let us concentrate on two-level systems, e.g. a system with the total spin $F = \frac{1}{2}$ [1015], and only consider the one-dimensional case.

52.4.3.1 Coupled Gross-Pitaevskii equations

For a single atom the Hamiltonian is the one given in (43.13),

$$\hat{H}(\mathbf{r}) = |1\rangle \left(\tfrac{1}{2}\mu_B g_F B(\mathbf{r}) - \tfrac{1}{2}\hbar\omega\right) \langle 1| + |2\rangle \left(-\tfrac{1}{2}\mu_B g_F B(\mathbf{r}) + \tfrac{1}{2}\hbar\omega\right) \langle 2| + |1\rangle \tfrac{1}{2}\hbar\Omega \langle 2| + |2\rangle \tfrac{1}{2}\hbar\Omega \langle 1| . \tag{52.116}$$

With the definition,

$$\hat{\psi}_k(\mathbf{r}) \equiv \langle k|\hat{\psi}(\mathbf{r})\rangle \ , \tag{52.117}$$

and the abbreviation $\hbar\Delta(\mathbf{r}) \equiv \mu_B g_F B(\mathbf{r}) - \hbar\omega(\mathbf{r})$ we proceed to the second quantization via,

$$\boxed{\begin{aligned} \mathcal{H} &= \sum_{k\neq m} \int d^3r\ \hat{\psi}_k^\dagger \left[\frac{-\hbar^2\nabla^2}{2m} + \tfrac{1}{2}u_{kk}\hat{\psi}_k^\dagger\hat{\psi}_k + \tfrac{1}{2}u_{k,m}\psi_m^\dagger\hat{\psi}_m \right] \hat{\psi}_k \\ &+ \left[(-1)^k \tfrac{\hbar}{2}\Delta(\mathbf{r})\hat{\psi}_k^\dagger\hat{\psi}_k + \tfrac{\hbar}{2}\Omega(\mathbf{r})(\hat{\psi}_k^\dagger\hat{\psi}_m + \psi_m^\dagger\hat{\psi}_k) \right] \end{aligned}} \ . \tag{52.118}$$

The total energy of the system is the sum of the energies of the individual condensates (kinetic, potential, and collisional interaction) *plus* the interspecies collisional interaction energy. The coefficients $u_{kl} = 4\pi\hbar^2 a_{kl}/m$ with the scattering lengths a_{kl} govern the impact of the collisions.

The interaction with the radiofrequency field leads to Rabi oscillations with frequency Ω [17] The tuning of the radiofrequency depends on the position, due to the non-homogeneous Zeeman shift Δ. Also, to simplify the model, we assume $u_{kl} = 0$ for $k \neq l$,

$$\hat{H} = \sum_{k\neq m} \int d^3r\ \hat{\psi}_k^\dagger \left[\frac{-\hbar^2\nabla^2}{2m} + \tfrac{1}{2}u_{kk}\hat{\psi}_k^\dagger\psi_k \right] \psi_k + \left[(-1)^k \tfrac{\hbar}{2}\Delta(\mathbf{r})\hat{\psi}_k^\dagger\hat{\psi}_k + \tfrac{\hbar}{2}\Omega \left(\hat{\psi}_k^\dagger\psi_m + \hat{\psi}_m^\dagger\hat{\psi}_k \right) \right] \ . \tag{52.119}$$

From the Heisenberg equations of motion for the field operators of the matter wave and the light, we obtain [1015],

$$\begin{aligned} \imath\dot{\hat{\psi}}_1 &= -\tfrac{1}{\hbar}[\hat{H}, \hat{\psi}_1] = \frac{\delta\hat{H}}{\hbar\delta\hat{\psi}_1^\dagger} = \left(\frac{-\hbar^2\nabla^2}{2m} + u_{11}\hat{\psi}_1^\dagger\hat{\psi}_1 - \tfrac{\hbar}{2}\Delta(\mathbf{r}) \right) \hat{\psi}_1 + \tfrac{\hbar}{2}\Omega\hat{\psi}_2 \\ \imath\dot{\hat{\psi}}_2 &= -\tfrac{1}{\hbar}[\hat{H}, \hat{\psi}_2] = \frac{\delta\hat{H}}{\hbar\delta\hat{\psi}_2^\dagger} = \left(\frac{-\hbar^2\nabla^2}{2m} + u_{22}\hat{\psi}_2^\dagger\hat{\psi}_2 + \tfrac{\hbar}{2}\Delta(\mathbf{r}) \right) \hat{\psi}_2 + \tfrac{\hbar}{2}\Omega\hat{\psi}_1 \ . \end{aligned} \tag{52.120}$$

The adiabatic potentials follow from a point-wise diagonalization of the Hamiltonian, assuming that the atomic movement evolves in sufficiently small steps.

52.4.3.2 One-dimensional case

The reduction of the dimensionality of the Gross-Pitaevskii equation is shown in Sec. ??. Applying this to our case, we consider a one-dimensional potential $V(\mathbf{r}) = V(z)$ and assume condensates being radially homogeneous within the radial diameter r_h. In this case, we can neglect the radial kinetic energy. As normalization then requires,

$$\int_{-r_h}^{r_h}\int_{-r_h}^{r_h}\int_{-\infty}^{\infty} |\hat{\psi}(\mathbf{r})|^2 d^3r = (2r_h)^2 \int_{-\infty}^{\infty} |\hat{\psi}(z)|^2 dz = 1 \ , \tag{52.121}$$

replacing $\hat{\psi}(\mathbf{r}) = \frac{\hat{\phi}(z)}{2r_h}$ and $g_{kk} = \frac{u_{kk}}{(2r_h)^2}$, the Gross-Pitaevskii equation and the normalization condition adopt a particularly simple form,

$$\imath\hbar\frac{\partial}{\partial t}\hat{\phi}(z) = \left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + V_{trap}(z) + N g_{1D}|\hat{\phi}(z)|^2 \right) \hat{\phi}(z) \ . \tag{52.122}$$

[17] We are neglecting the possibility, that the coupling force may, in principle, be inhomogeneous, if the orientation of the magnetic field is not uniform.

The coupled equations are now,

$$\imath\dot{\hat{\phi}}_1 = \left(\frac{-\partial_z^2}{2m} + g_{11}\hat{\phi}_1^\dagger\hat{\phi}_1 - \frac{m}{4}\omega_z^2 z^2 - \tfrac{1}{2}\Delta_0\right)\hat{\phi}_1 + \tfrac{1}{2}\Omega\phi_2 \tag{52.123}$$
$$\imath\dot{\hat{\phi}}_2 = \left(\frac{-\partial_z^2}{2m} + g_{22}\hat{\phi}_2^\dagger\hat{\phi}_2 + \frac{m}{4}\omega_z^2 z^2 + \tfrac{1}{2}\Delta_0\right)\hat{\phi}_2 + \tfrac{1}{2}\Omega\hat{\phi}_1 \ .$$

with,

$$\int_{-\infty}^{\infty} |\hat{\phi}_1(z)|^2 + |\hat{\phi}_2(z)|^2 dz = 1 \ . \tag{52.124}$$

This set of equations can be solved numerically by first identifying the ground state using the 'steepest descent' method and then propagating it in real time while slowly varying $\Delta(\mathbf{r}, t)$ or $\Omega(t)$.

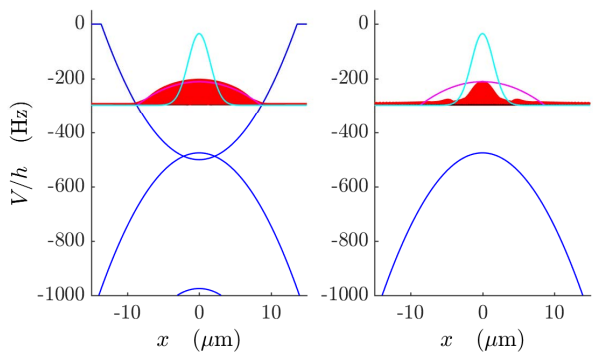

Figure 52.21: (code) Two coupled condensates.

52.4.3.3 Damping

A heuristic way of introducing damping could be as follows: We write down the condensate velocity field as,

$$m\mathbf{v}(\mathbf{r}, t) = \hbar\frac{\hat{\phi}^*(\mathbf{r}, t)\nabla\hat{\phi}(\mathbf{r}, t) - \nabla\hat{\phi}^*(\mathbf{r}, t)\hat{\phi}(\mathbf{r}, t)}{2\imath n(\mathbf{r}, t)} \ , \tag{52.125}$$

and subject it to a friction force,

$$E_{fr} = -\gamma r v \ . \tag{52.126}$$

The problem with the coupled GPE approach is that in the absence of damping any even small modification of the coupling triggers collective oscillations, so that the ground state is not found. A numerical method to minimize the total energy cannot be used, because the minimum is the untrapped state, so that all atoms are lost. It seems that a master equation approach is necessary to introduce damping. An alternative (but cheap) way is the following. The coupled GPEs were written in the dressed states basis. Thus, if the Rabi frequency is strong enough to completely

decouple the dressed states, the dressed states represent good quantum numbers, and the GPEs are appropriately written in a diagonal basis, i.e. the GPEs decouple on adiabatic potentials [18],

$$V_{ad,k}(z) = -(-1)^k \frac{1}{2}\sqrt{\hbar^2\Omega^2 + [\mu_B g_F B(z) - \hbar\omega]^2} \ , \tag{52.127}$$

and we obtain,

$$\imath\dot{\hat{\phi}}_k = \left(\frac{-\partial_z^2}{2m} + V_{ad,k}(z) + g_{kk}\hat{\phi}_k^\dagger\hat{\phi}_k\right)\hat{\phi}_k \ . \tag{52.128}$$

Programs on multiple BECs coupled by radiation via GPEs.

52.5 Interaction between condensates and optical cavities

In 52.4.1 we have set up the many-body Hamiltonian (52.103) describing the interaction of a matter wave (treated in mean-field approximation) with an incident light field. We emphasized the role of photonic recoil in (52.128). In the following sections we aim at applying this theory to the particular case of atoms interacting with two counterpropagating modes of an optical ring cavity. The system has already been studied in Chp. 48 in the context of CARL, where the atomic motion, as well as the light fields, have mostly been treated classically.

CARL is based on a coherent redistribution of photons between the two counterpropagating modes of a moving standing light wave mediated by atoms which are located in the mode volume. Cooperative Compton scattering induces a collective atomic recoil and a self-bunching of the atoms, which results in an exponential gain for the optical mode receiving the scattered photons. The recent observation of the MWSR [464] in a BEC raises the question about an ultra-cold version of CARL [665, 440]. In MWSR the long coherence time of a BEC establishes a strong correlation between subsequent elastic Rayleigh scattering events mediated by very stable quasi-particle excitations. The feedback of these excitations on the laser creates an *exponential* gain for the optical mode receiving the scattered photons [465, 204, 111, 557, 665, 664, 538, 466, 465].

We have discussed the classical CARL earlier in the superradiant as well as the good-cavity regime. We have also generalized the problem to the case of quantized atomic motion (see Sec. 48.4) and to quantized radiation fields (see Sec. 48.5). The internal states were always adiabatically eliminated. In the following, we will fully quantize the bosonic atomic particle field.

The advantages of this second quantization is that interatomic interactions, quantum fluctuations, and decoherence of the matter wave can be taken into account. Various proposals have been made focusing on either one of the above three aspects. Fundamental aspects of the BEC-in-a-cavity-system lead into two directions: 1. quantum synchronization and 2. quantum correlations.

[18] Gravitation can be included by $V_{ad,k}(z) \to V_{ad,k}(z) + mgz$.

The system under consideration is a BEC of two-level atoms with transition resonance frequency ω_0 trapped in an external magnetic trap, located inside the mode volume of a ring cavity and interacting with its light modes. The atomic field operators obey the commutation relations,

$$\begin{aligned}[\hat{\psi}_k(\mathbf{r}), \hat{\psi}_m^\dagger(\mathbf{r}')] &= \delta_{km}\delta^{(3)}(\mathbf{r}, \mathbf{r}') \\ [\hat{\psi}_k(\mathbf{r}), \hat{\psi}_m(\mathbf{r}')] &= 0 = [\hat{\psi}_k^\dagger(\mathbf{r}), \hat{\psi}_m^\dagger(\mathbf{r}')] \ ,\end{aligned} \tag{52.129}$$

where $k, m = 1, 2$ label the internal state of the atoms. In general, the light field consists of only *two* counterpropagating monochromatic modes with Rabi frequencies $2g\hat{a}_\pm^\dagger\hat{a}_\pm$. Choosing the coordinate system properly, we can set the wavevectors of the modes as $\mathbf{k}_+ \cdot \hat{\mathbf{e}}_r = k\hat{z} = -\mathbf{k}_- \cdot \hat{\mathbf{e}}_r$. The second-quantized Hamiltonian is a generalization of (48.4),

$$\mathcal{H} = \mathcal{H}_{atom} + \mathcal{H}_{atom-atom} + \mathcal{H}_{atom-cav} + \hat{H}_{cav} + \hat{H}_{laser-cav} \ , \tag{52.130}$$

where,

$$\boxed{\begin{aligned}
\mathcal{H}_{atom} &= \int d^3r\hat{\psi}_1^\dagger(\mathbf{r})\left(\frac{\hat{p}^2}{2m} + V_1(\mathbf{r})\right)\hat{\psi}_1(\mathbf{r}) \\
&\quad + \int d^3r\hat{\psi}_2^\dagger(\mathbf{r})\left(\frac{\hat{p}^2}{2m} + V_2(\mathbf{r}) - \Delta_a\right)\hat{\psi}_2(\mathbf{r}) \\
\mathcal{H}_{atom-atom} &= \textstyle\sum_{i=1,2}\displaystyle\int d^3r\hat{\psi}_i^\dagger(\mathbf{r})\hat{\psi}_i^\dagger(\mathbf{r})\tfrac{u_{ii}}{2}\hat{\psi}_i(\mathbf{r})\hat{\psi}_i(\mathbf{r}) \\
&\quad + \int d^3r\hat{\psi}_1^\dagger(\mathbf{r})\hat{\psi}_2^\dagger(\mathbf{r})\tfrac{u_{12}}{2}\hat{\psi}_2(\mathbf{r})\hat{\psi}_1(\mathbf{r}) \\
\mathcal{H}_{atom-cav} &= \textstyle\sum_\pm g\hat{a}_\pm\displaystyle\int d^3r\hat{\psi}_2^\dagger(\mathbf{r})e^{\pm\imath kz}\hat{\psi}_1(\mathbf{r}) + h.c. \\
\hat{H}_{cav} &= -\textstyle\sum_\pm \Delta_c\hat{a}_\pm^\dagger\hat{a}_\pm \\
\hat{H}_{laser-cav} &= -\textstyle\sum_\pm \imath\eta_\pm(\hat{a}_\pm - \hat{a}_\pm^\dagger)
\end{aligned}} \ , \tag{52.131}$$

with $u_{ij} \equiv 4\pi\hbar^2 a_{s,ij}/m$.

Various approximations can be made depending on the subject of interest. For example, if only one cavity mode, $\hat{a}_+$, is strongly pumped, such that the field becomes intense, we may remove the term $\hat{H}_{laser-cav}$ and describe the field mode classically by a Rabi frequency Ω. The interaction between the pump mode and the cavity is then, $\hat{H}_{atom-pump} = \frac{\hbar\Omega}{2}e^{-\imath\omega_2 t}\int d^3r\hat{\psi}_2^\dagger(\mathbf{r})e^{\imath k\hat{z}}\hat{\psi}_1(\mathbf{r}) + h.c.$.

A talk on this subject is available at (watch talk).

52.5.1 Ideal gas Hamiltonian after adiabatic elimination

Assuming the light fields to be tuned far from resonance we disregard spontaneous emission, as explained in Sec. 48.1.2, and adiabatically eliminate the internal states, as shown in Sec. 48.1.3 [748, 186]. On the other hand, we treat the light field and the atomic motion in second quantization. The canonical way to describe a BEC interacting with *two* optical modes $\hat{a}_\pm$ is to second-quantize the single-particle Hamiltonian

(48.26),

$$\boxed{\begin{aligned}\mathcal{H} &\simeq \int d^3r\hat{\psi}^\dagger(\mathbf{r})\left(\frac{\hat{\mathbf{p}}^2}{2m}+V_{trap}(\mathbf{r})+\frac{u}{2}\hat{N}(\mathbf{r})\right)\hat{\psi}(\mathbf{r})+(\hat{N}U_0-\Delta_c)\sum_{\pm}\hat{a}_\pm^\dagger\hat{a}_\pm \\ &+ U_0\hat{a}_+^\dagger\hat{a}_-\int d^3r\hat{\psi}^\dagger(\mathbf{r})e^{-2\imath kz}\hat{\psi}(\mathbf{r})+h.c.-\imath\sum_{\pm}\eta_\pm(\hat{a}_\pm-\hat{a}_\pm^\dagger)\end{aligned}} \ , \tag{52.132}$$

where $\hat{\psi}(\mathbf{r})$ is now the ground-state wave function of the matter wave, $u = 4\pi\hbar^2 a_s/m$ in the *mean-field approximation* and,

$$U_0 = \frac{g^2}{\Delta_a} \ , \tag{52.133}$$

when the mode to mode coupling strength. This adiabatically approximated Hamiltonian looks very similar to (48.26).

52.5.2 Expansion into momentum states

It is useful to convert the Hamiltonian to momentum space via a plane wave expansion of the BEC according to (50.70),

$$\hat{\psi}(\mathbf{r}) = \sqrt{\tfrac{V}{(2\pi)^3}}\int \hat{c}_{\mathbf{q}}e^{\imath\mathbf{q}\cdot\mathbf{r}}d^3q \qquad \text{with} \qquad [\hat{a}_{\mathbf{q}},\hat{a}_{\mathbf{q}'}] = \delta_{\mathbf{q},\mathbf{q}'} \ . \tag{52.134}$$

The conversion of that Hamiltonian part $\mathcal{H}_{bec}$ to momentum space has been demonstrated in (50.78),

$$\mathcal{H}_{bec} = \sum_{\mathbf{q}}\frac{\mathbf{q}}{2m}\hat{c}_{\mathbf{q}}^\dagger\hat{c}_{\mathbf{q}} + \sum_{\mathbf{q},\mathbf{q}'}\hat{c}_{\mathbf{q}}'^\dagger V_{\mathbf{q}',\mathbf{q}}\hat{c}_{\mathbf{q}} + \frac{u}{2}\sum_{\mathbf{q},\mathbf{q}',\mathbf{q}''}\hat{c}_{\mathbf{q}}^\dagger\hat{c}_{\mathbf{q}}'^\dagger\hat{c}_{\mathbf{q}}''\hat{c}_{\mathbf{q}} + \mathbf{q}' - \mathbf{q}'' \ . \tag{52.135}$$

The light field part $\hat{H}_{cav}$ remains unchanged and the atom-light interaction becomes using (52.3),

$$\begin{aligned}\mathcal{H}_{bec-cav} &= U_0\int \hat{\psi}^\dagger(\mathbf{r})\hat{a}_+^\dagger\hat{a}_-e^{-\imath(\mathbf{k}_+-\mathbf{k}_-)\cdot\mathbf{r}}\hat{\psi}(\mathbf{r})d^3r + h.c. \qquad (52.136)\\ &= \imath\hbar U_0\hat{a}_+^\dagger\hat{a}_-V\int\int\hat{c}^\dagger(\mathbf{q}')\hat{c}(\mathbf{q})\delta^3(\mathbf{q}-\mathbf{q}'-2k\hat{\mathbf{e}}_z)d^3qd^3q' = U_0\hat{a}_+^\dagger\hat{a}_-\sum_{\mathbf{q}}\hat{c}_{\mathbf{q}-2\mathbf{k}}^\dagger\hat{c}_{\mathbf{q}} \ .\end{aligned}$$

All in all,

$$\boxed{\begin{aligned}\mathcal{H} &= \sum_{\mathbf{q}}\frac{\mathbf{q}^2}{2m}\hat{c}_{\mathbf{q}}^\dagger\hat{c}_{\mathbf{q}} + \sum_{\mathbf{q},\mathbf{q}'}\hat{c}_{\mathbf{q}'}^\dagger V_{\mathbf{q}',\mathbf{q}}\hat{c}_{\mathbf{q}} + \frac{u}{2}\sum_{\mathbf{q},\mathbf{q}',\mathbf{q}''}\hat{c}_{\mathbf{q}}^\dagger\hat{c}_{\mathbf{q}'}^\dagger\hat{c}_{\mathbf{q}''}\hat{c}_{\mathbf{q}+\mathbf{q}'-\mathbf{q}''} \\ &+ (\hat{N}U_0-\Delta_c)\sum_{\pm}\hat{a}_\pm^\dagger\hat{a}_\pm + U_0\hat{a}_+^\dagger\hat{a}_-\sum_{\mathbf{q}}\hat{c}_{\mathbf{q}-2\mathbf{k}}^\dagger\hat{c}_{\mathbf{q}} - \imath\sum_{\pm}\eta_\pm(\hat{a}_\pm-\hat{a}_\pm^\dagger)\end{aligned}} \ . \tag{52.137}$$

The BEC-CARL equations of motion are readily obtained from the Heisenberg equations,

$$\imath\frac{d\hat{c}_{\mathbf{p}}}{dt} = [\hat{c}_{\mathbf{p}}, \mathcal{H}] = \frac{q^2}{2m}\hat{c}_{\mathbf{p}} + \sum_{\mathbf{q}} V_{\mathbf{p},\mathbf{q}}\hat{c}_{\mathbf{q}} + u\sum_{\mathbf{q},\mathbf{q}'}\hat{c}^\dagger_{\mathbf{q}}\hat{c}_{\mathbf{q}'}\hat{c}_{\mathbf{q}-\mathbf{q}'+\mathbf{p}} + U_0\hat{a}^\dagger_+\hat{a}_-\hat{c}_{\mathbf{p}+2\mathbf{k}} + h.c.$$

$$\imath\frac{d\hat{a}_\pm}{dt} = [\hat{a}_\pm, \mathcal{H}] = (\hat{N}U_0 - \Delta_c)\hat{a}_\pm + U_0\hat{a}_\mp\sum_{\mathbf{q}}\hat{c}^\dagger_{\mathbf{q}\mp 2\mathbf{k}}\hat{c}_{\mathbf{q}} + \imath\eta_\pm \ . \tag{52.138}$$

52.5.2.1 Discretization of the momentum space

Assuming the BEC to be initially at rest with 0 temperature, its momentum state can be written as $\hat{c}_{\mathbf{0}}$. And if the dynamics only involves the z-axis, then all momentum states are separated by multiples of $2\hbar k$, such that we may replace the labeling by integer numbers: $\hat{c}_{\mathbf{q}} \to \hat{c}_n$. We get,

$$\mathcal{H} = \sum_n \frac{n^2q^2}{2m}\hat{c}^\dagger_n\hat{c}_n + \sum_{n,n'}\hat{c}^\dagger_{n'}V_{n',n}\hat{c}_n + \frac{u}{2}\sum_{n,n',n''}\hat{c}^\dagger_n\hat{c}^\dagger_{n'}\hat{c}_{n''}\hat{c}_{n+n'-n''} \tag{52.139}$$
$$+\sum_\pm\left(\hat{N}U_0 - \Delta_c\right)\hat{a}^\dagger_\pm\hat{a}_\pm + U_0\hat{a}^\dagger_+\hat{a}_-\sum_n\hat{c}^\dagger_{n-1}\hat{c}_n + h.c. - \imath\eta_\pm(\hat{a}_\pm - \hat{a}^\dagger_\pm) \ .$$

Neglecting the external trapping potential and collisions the Heisenberg equations for the field and the atomic motion now read,

$$\frac{d\hat{c}_n}{dt} = -\imath[\hat{c}_n, \mathcal{H}] = -\imath\frac{n^2k^2}{2m}\hat{c}_n + U_0\hat{a}^\dagger_+\hat{a}_-\hat{c}_{n+1} + h.c. \tag{52.140}$$
$$\frac{d\hat{a}_\pm}{dt} = -\imath[\hat{a}_\pm, \mathcal{H}] = (\hat{N}U_0 - \Delta_c)\hat{a}_\pm + U_0\hat{a}_\mp\sum_n\hat{c}^\dagger_{n\mp 1}\hat{c}_n + \imath\eta_\pm \ .$$

These equations look identical to those found in (48.114).

52.5.3 BECs in two internal states coupled by a cavity

A lossy cavity can act as an effective *zero temperature reservoir*. One possible implementation [476] realizes a three-level cycling scheme, with two BECs in two ground states $|g_1\rangle$ and $|g_2\rangle$ coherently coupled by a two-photon transition (Raman-lasers or microwave-radiofrequency combination). The ground states are additionally coupled by an irreversible Raman transition via an intermediate spontaneously decaying level $|e\rangle$. One transition is not driven but stimulated by a ring cavity mode $\hat{a}$.

The Hamiltonian consists of three parts, the BEC energy $\mathcal{H}_{bec}$, the interaction energy with the coherent coupling assumed to be classical $\mathcal{H}_{cpl}$ and the interaction with the mode of a ring cavity $\mathcal{H}_{cav}$ treated quantum mechanically ($\hbar = 1$),

$$\mathcal{H} = \mathcal{H}_{bec} + \mathcal{H}_{cpl} + \mathcal{H}_{cav} \tag{52.141}$$
$$= \int d^3r\ \hat{\psi}^\dagger_1\left(\tfrac{-\nabla^2}{2m} + V + \tfrac{u_{11}}{2}\hat{\psi}^\dagger_1\hat{\psi}_1 + \tfrac{u_{12}}{2}\hat{\psi}^\dagger_2\hat{\psi}_2\right)\hat{\psi}_1 +$$
$$+\int d^3r\ \hat{\psi}^\dagger_2\left(\tfrac{-\nabla^2}{2m} + V + \tfrac{u_{12}}{2}\hat{\psi}^\dagger_1\hat{\psi}_1 + \tfrac{u_{22}}{2}\hat{\psi}^\dagger_2\hat{\psi}_2\right)\hat{\psi}_2 +$$
$$+\int d^3r\ \left(-\Delta_{mw}\hat{\psi}^\dagger_1\hat{\psi}_1 + \tfrac{\Omega_{mw}}{2}\hat{\psi}^\dagger_1\hat{\psi}_2 + h.c.\right) + \int d^3r\ \left(g_{cv}\hat{a}\hat{\psi}^\dagger_1\hat{\psi}_2 + h.c.\right) - \Delta_{cv}\hat{a}^\dagger\hat{a} \ .$$

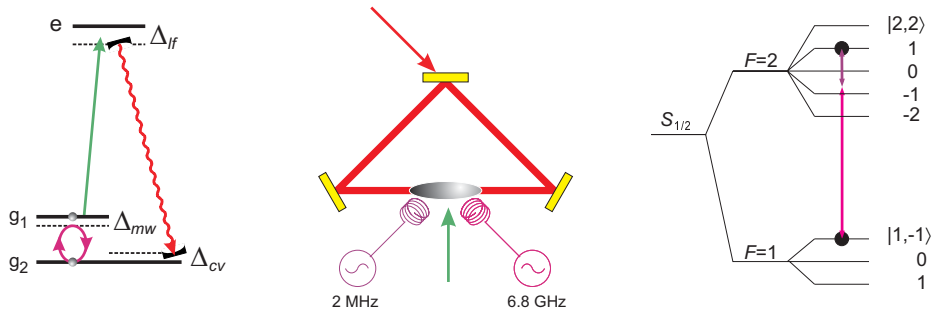

Figure 52.22: (code) (a) Level scheme with a microwave-driven hyperfine structure, a laser-driven optical transition, and a cavity-enhanced Raman deexcitation. (b) Ring cavity used for the experiment. (c) Scheme for coupling the Zeeman states $|2,1\rangle$ and $|1,-1\rangle$ with a two-photon transition in a magnetic trap.

The BEC energy consists of the two energies (kinetic, potential, self) of the individual BECs and the cross-species interaction proportional to $u_{kl} = 4\pi\hbar^2 a_{kl}/m$. The interaction energy with the classical microwave frequency (mostly we will assume $\Delta_{mw} = 0$) leads to Rabi flopping with frequency Ω_{mw}. Finally, the incident light field is treated classically with a Rabi frequency Ω_{lf} and a detuning Δ_{lf}, while the cavity field is treated quantum mechanically with a coupling constant Ω_{cv} and a detuning Δ_{cv}. The irreversible coupling leads to an energy contribution where $g_{cv} \equiv \Omega_{lf}\Omega_{cv}/2\Delta_{lf}$ is the two-photon Rabi-frequency if the auxiliary state is adiabatically eliminated. From the Heisenberg equations of motion for the matter wave and the optical field operators we obtain,

$$\begin{aligned}
\dot{\hat{\psi}}_1 &= \imath[H, \hat{\psi}_1] = -\imath\frac{\delta H}{\delta\hat{\psi}_1^\dagger} \qquad (52.142)\\
&= -\imath\left(\frac{-\nabla^2}{2m} + V + u_{11}|\hat{\psi}_1|^2 + u_{12}|\hat{\psi}_2|^2\right)\hat{\psi}_1 - \imath\left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a}\right)\hat{\psi}_2 - \imath\Delta_{mw}\hat{\psi}_1 \ ,\\
\dot{\hat{\psi}}_2 &= \imath[\hat{H}, \hat{\psi}_2] = -\imath\frac{\delta H}{\delta\hat{\psi}_2^\dagger}\\
&= -\imath\left(\frac{-\nabla^2}{2m} + V + u_{12}|\hat{\psi}_1|^2 + u_{22}|\hat{\psi}_2|^2\right)\hat{\psi}_2 - \imath\left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a}^\dagger\right)\hat{\psi}_1 \ ,\\
\dot{\hat{a}} &= \imath[\hat{H}, \hat{a}] - \tfrac{\kappa}{2}\hat{a} = -\imath\frac{\delta H}{\delta\hat{a}^\dagger} - \tfrac{\kappa}{2}\hat{a}\\
&= -\imath\int d^3r\ g_{cv}\hat{\psi}_1\hat{\psi}_2^\dagger - \left(\imath\Delta_{cv} + \tfrac{\kappa}{2}\right)\hat{a}\ .
\end{aligned}$$

Example 379 (*Single atoms in two states interacting with a cavity*): As a first example, we start from the matter wave Hamiltonian (52.141) for two coupled BECs and neglect the center-of-mass motion (and consequence the condensate part, i.e. self-interaction, kinetic energy and the external potential).

Furthermore, we assume $\hat{\psi}_i(\mathbf{r}) = \hat{c}_i \delta^3(\mathbf{r})$,

$$\begin{aligned} \mathcal{H} &= \mathcal{H}_{bec} + \mathcal{H}_{clp} + \mathcal{H}_{cav} \\ &= -\Delta_{mw}\hat{c}_1^\dagger \hat{c}_1 + \tfrac{\Omega_{mw}}{2}\hat{c}_1^\dagger \hat{c}_2 + g_{cv}\hat{a}\hat{c}_1^\dagger \hat{c}_2 + h.c. - \Delta_{cv}\hat{a}^\dagger \hat{a} \ . \end{aligned} \tag{52.143}$$

Consequently, the Heisenberg equations of motion are simply,

$$\begin{aligned} \dot{\hat{c}}_1 &= -\imath \left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a}\right)\hat{c}_2 - \imath\Delta_{mw}\hat{c}_1 \\ \dot{\hat{c}}_2 &= -\imath \left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a}^\dagger\right)\hat{c}_1 \\ \dot{\hat{a}} &= -\imath g_{cv}\hat{c}_1\hat{c}_2^\dagger - \left(\imath\Delta_{cv} + \tfrac{\kappa}{2}\right)\hat{a} \ . \end{aligned} \tag{52.144}$$

Obviously, since the matter wave degree of freedom is ignored, the dynamics only concerns the Bloch vector. Simulations of these equations are exhibited in Fig. 52.23 and in movies that can be watched under (watch movie) and (watch movie).

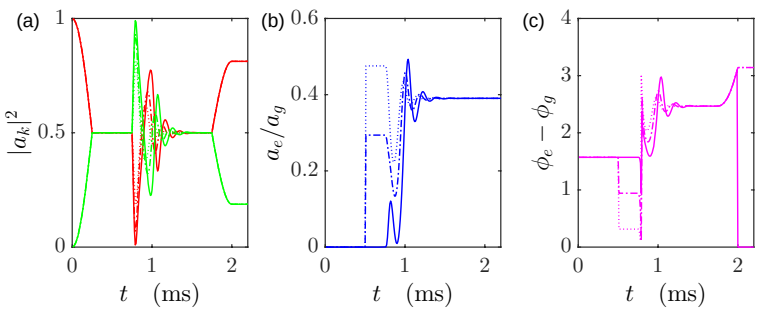

Figure 52.23: (code) Bloch vector phase stabilization in the cavity. (a) Populations and (b) coherences.

Example 380 (*Interpretation of the ultracold fusion via analogy with two-level system*): The chemical potential of the BECs in both states shifts the energy levels up depending on the inversion, $\mu_2 - \mu_1 \propto N_2 - N_1$. If the inversion oscillates the spontaneous Raman cycle periodically meets resonance, and takes place. Note that, since atomic motion is not considered, the energy gap due to the finite cavity detuning can only be bridged in resonance, $\mu_2 - \mu_1 = \kappa$. Oscillation simulates Doppler shift of thermal motion in Doppler cooling. Raman scattering takes the role of spontaneous emission in the cooling process. The only role of the cavity is to introduce irreversibility. Raman scattering is only supported in one direction: However, it is not relevant to have a ring cavity.

52.5.4 Exercises

52.5.4.1 Ex: BEC damping in cavities

Programs on BEC damping in cavities.

52.5.4.2 Ex: Second-quantized CARL equations

Calculate the commutators $[\hat{\psi}_j(\mathbf{r}), \mathcal{H}]$ and $[\hat{a}_\pm, \mathcal{H}]$, where $\mathcal{H}$ is the Hamiltonian (52.131) and $\hat{\psi}_1$ and $\hat{\psi}_2$ the ground and excited state wave functions, respectively.

52.5.4.3 Ex: Second-quantized adiabatically approximated CARL Hamiltonian

a. Derive the adiabatically approximated CARL Hamiltonian in second quantization.
b. Derive the CARL equations of motion from the adiabatically approximated Hamiltonian in second quantization.
c. Show that the derived Hamiltonian simplifies to (48.26) in the single atom limit.

52.5.4.4 Ex: BEC-CARL equations from the adiabatically approximated CARL Hamiltonian

Derive the BEC-CARL equations from the adiabatically approximated CARL Hamiltonian (52.134).

52.5.4.5 Ex: Origin of quantum correlations

The BEC-CARL Hamiltonian has been shown to generate quantum correlations between optical and matter wave modes [665, 738]. Discuss whether they are a many-body effect (bosonic stimulation) or just due to coherences between motional states of single atoms.

52.5.4.6 Ex: Ultracold fusion

Derive from Eqs. (52.144) using the definitions (**??**) and (**??**) the Eqs. (**??**).

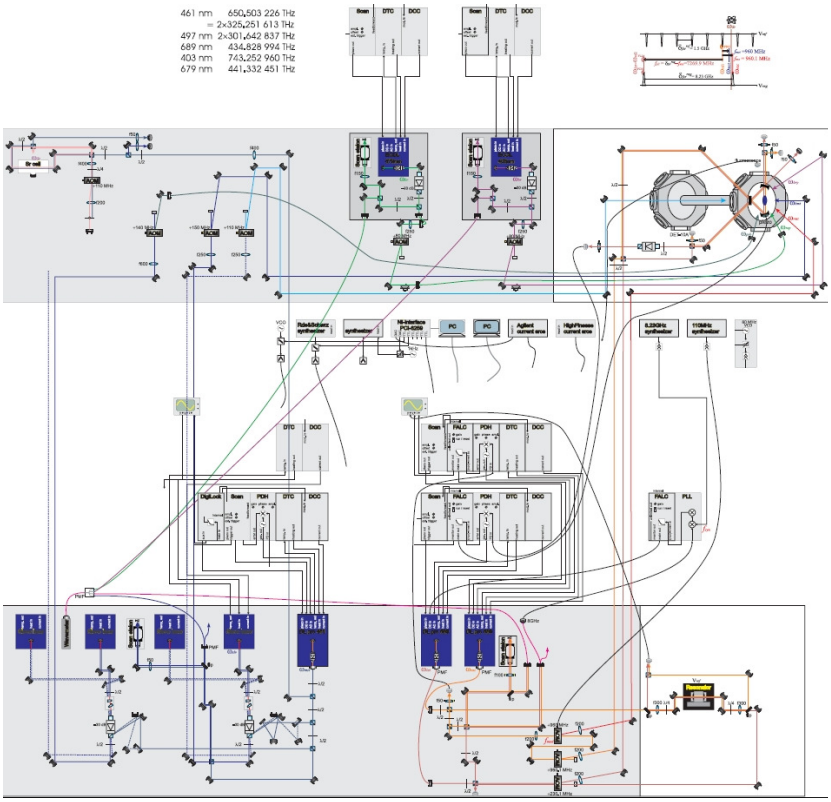
Part XI

Instrumentation of a Quantum Optics Lab

Preface to the part *Instrumentation of a Quantum Optics Lab*



This part of the script is issued from a practical lab course in *Quantum Optics* given at São Carlos Physics Institute of the University of São Paulo in the years between 2010 and 2025. It treats part of the knowledge that any student working in a modern quantum optics laboratory needs with emphasis in electronics and optics. The topics are certainly not exhaustive. For instance, many labs work with ultrahigh vacuum, cryogenics, or advanced instrumentation and experimental hardware control, which are beyond the scope of this course.

In chapter 53 we set the show how to work with Gaussian laser beams. In Chp. 54 we review some basic knowledge of applied electronics useful for the lab. In Secs. 55 and 56 we discuss some basic applications and finally in Sec. 57 we give a very brief introduction into control theory.

Chapter 53

Gaussian optics and the polarization of light

The objective of this part of the course is to introduce the student into the basics of *Gaussian optics* and *polarizations optics*. The student will learn how to transform the diameter and the divergence of a Gaussian beam using lenses and telescopes and to analyze and manipulate the polarization of a laser beam.

53.1 Some more basic notions

53.1.1 Definition of photometric quantities

The *radiant energy* W is the total energy emitted from a source. The *radiant power* P (or radiant flux) is the total energy emitted per second. The *radiance* $L(\Omega)$ is defined as the power radiated (emitted, reflected, transmitted or received) under an angle θ through a surface element $d\mathbf{A}$ into a solid angle element $d\Omega = \sin\theta d\theta d\phi$. It is a directional quantity indicating how much of the power will be received by an optical system looking at that surface from a specified angle of view,

$$\boxed{P = \int L(\Omega) dA_n d\Omega} \ . \tag{53.1}$$

Spectral densities are denoted by an index ν, e.g. $P = \int P_\nu(\nu) d\nu$. In (53.1), $dA_n \equiv \hat{\mathbf{n}} \cdot d\mathbf{A} = dA \cos\theta$ is the projection of the surface element onto the surface normal. The quantity,

$$I^* = \int L(\Omega) d\Omega \tag{53.2}$$

is called *radiant intensity*.

Example 381 (*Angular distribution of thermal radiation*): In a blackbody in thermal equilibrium with its surroundings (e.g the walls of a cavity) the radiation is isotropic with a spectral energy distribution given by Planck's law. This means that at any point of the volume of the blackbody radiator an imaginary volume element radiates energy in all directions of space, such that the radiance into a specific solid angle element is,

$$L(\Omega) = \bar{u} \frac{c}{4\pi} \ . \tag{53.3}$$

Radiation passing under an angle θ through a hole of size $dA = dA_n/\cos\theta$ into a specific solid angle element $d\Omega$ generates the radiance,

$$\frac{\partial^2 P}{\partial\Omega\partial A} = L(\Omega)\cos\theta \ . \tag{53.4}$$

In *any* direction we get,

$$\frac{\partial P_\nu}{\partial A} = \int_{\text{half sphere}} L_\nu(\Omega)\cos\theta d\Omega = \bar{u}\frac{c}{4\pi}\int_0^{2\pi} d\phi \int_0^{\pi/2} \cos\theta\sin\theta d\theta = \frac{c\bar{u}}{4} \ . \tag{53.5}$$

Summing up over all surface elements of a sphere of radius R,

$$P = \int \frac{\partial P}{\partial A} dA = \frac{c\bar{u}}{4} R^2 \int_0^{2\pi} d\phi \int_0^{\pi} \sin\theta d\theta = \pi R^2 c\bar{u} \ . \tag{53.6}$$

Accordingly, the spectral distribution is, using Planck's law,

$$P_\nu = P\frac{8\pi h\nu^3}{c^3}\frac{1}{e^{\beta\hbar\omega}-1} = \frac{8\pi^2 R^2 h\nu^3}{c^2}\frac{1}{e^{\beta\hbar\omega}-1} \ . \tag{53.7}$$

A detector covers itself a finite solid angle $d\Omega = \frac{dA'\cos\theta'}{r^2}$. The radiant flux for $r^2 \gg dA, dA'$ can then be expressed as,

$$d\Phi = L(\Omega)dA\cos\theta d\Omega = L(\Omega)dA\cos\theta\frac{dA'\cos\theta'}{r^2} \tag{53.8}$$

$$\text{that is} \qquad \Phi = \int_A\int_{A'} \frac{L(\Omega)}{r^2}\cos\theta\cos\theta' dA dA' \ .$$

Note that for isotropic sources (53.8) is symmetric upon interchanging emitter and detector with regard to θ and θ' or dA and dA'. Furthermore, the formula demonstrates that the radiant flux emitted into the unit solid angle is proportional to $\cos\theta$ (Lambert's law). An example for such a source is a hole with the area dA in a blackbody radiation cavity (see Fig. 53.1). Solve Excs. 53.1.2.1 and 53.1.2.2.

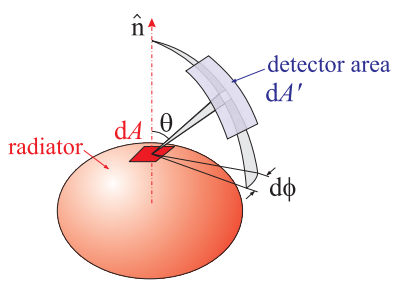


Figure 53.1: Illustration of the radiance.

Note that it is impossible to increase the radiance of a source by any sophisticated imaging optics [246]. This means that the image dA^* of a radiation source dA never has a larger radiance than the source itself. It is true that the flux density can be increased by focussing the radiation. The solid angle, however, into which radiation

from the image dA^* is emitted is also increased by the same factor. Therefore, the radiance does not increase. In fact, because of inevitable reflection, scattering, and absorption losses of the imaging optics, the radiance of the image dA^* is, in practice, always less than that of the source. A strictly parallel light beam would be emitted into the solid angle $d\Omega = 0$. With a finite radiant power this would imply an infinite radiance L, which is impossible. This illustrates that such a light beam cannot be realized. The radiation source for a strictly parallel beam anyway has to be a point source in the focal plane of a lens. Such a point source with zero surface cannot emit any power.

Example 382 (*Radiance of the sun*): An area $A = 1\,\mathrm{m}^2$ of the Earth's surface receives at normal incidence from the sun about $P/A = 1.35\,\mathrm{kW/m^2}$ of intensity. Since the sun covers an angle of $\theta = 0.53°$ seen from the Earth, we can estimate the sun's radiance as,

$$L = \frac{P}{A\Omega} = \frac{P}{A\int_0^{2\pi}\int_0^{\theta}\sin\theta d\theta d\phi} \simeq \frac{P}{A\pi\theta^2} \approx 2\cdot 10^4\,\mathrm{kW\,m^{-2}\,ster^{-1}} \ .$$

The total power received by the Earth is $\frac{P}{A}\pi R_{Earth}^2$. The total power emitted by the sun is $\frac{P}{A}4\pi d_{sun-Earth}^2$.

Example 383 (*Radiance of a HeNe laser*): We consider a HeNe laser emitting $P = 1\,\mathrm{mW}$ of power from a $w_0 = 1\,\mathrm{mm}$ beam waist into an angle of $2\theta = 0.067°$. With a typical emission bandwidth of $\Delta\nu = 1\,\mathrm{MHz}$ the spectral radiance is,

$$L_\nu = \frac{P_\nu}{A\Omega} \simeq \frac{P}{\pi w_0^2\,\pi\theta^2\,\Delta\nu} \approx 1\,\mathrm{kW\,s\,m^{-2}\,ster^{-1}} \ .$$

For comparison, the sun's radiance at it's surface ($T = 6000\,\mathrm{K}$) at the same wavelength as the HeNe laser is,

$$L_\nu = \frac{Lu_\nu}{\bar{u}} \approx 5\,\mathrm{nW\,s\,m^{-2}\,ster^{-1}} \ .$$

53.1.2 Exercises

53.1.2.1 Ex: Emission of an argon laser

The angular divergence of the output from a $P = 1\,\mathrm{W}$ argon laser is assumed to be $\alpha = 4\cdot 10^{-3}\,\mathrm{rad}$.
a. Calculate the radiance L and the radiant intensity I_1 of the laser beam and the irradiance I (intensity) at a surface 1 m away from the output mirror, when the laser beam diameter at the mirror is $2w_s = 2\,\mathrm{mm}$.
b. What is the spectral power density $u(\nu)$ if the laser bandwidth is 1 MHz?

53.1.2.2 Ex: Photosynthetically active radiation

The photon flux density and the photosynthetically active radiation (PAR) are defined as,

$$\eta_{photon} \equiv \frac{\int_{\lambda_1}^{\lambda_2} u(\lambda,T)\frac{\lambda}{\hbar c N_A}d\lambda}{\int_{\lambda_1}^{\lambda_2} u_{\mathrm{Pl}}(\lambda,T)d\lambda} \qquad \text{and} \qquad \eta_{\mathrm{PAR}} = \frac{\int_{\lambda_1}^{\lambda_2} u(\lambda,T)d\lambda}{\int_0^{\infty} u(\lambda,T)d\lambda} \ ,$$

where $\lambda_1 = 400\,\mathrm{nm}$ and $\lambda_2 = 700\,\mathrm{nm}$ delimit the range, where photosynthesis takes place. Calculate both quantities for a blackbody at $T = 5800\,\mathrm{K}$ temperature. Plot them as a function of temperature in the range $T = 300..6000\,\mathrm{K}$.

53.1.2.3 Ex: Power calibration of a Czerny-Turner spectrometer

Spectrometers are designed to measure power spectral densities $P_\lambda(\lambda)$, such that, integrated over a finite wavelength interval, one obtains the power, $P_{\mathrm{tot}} = \int_{\lambda_1}^{\lambda_2} P_\lambda(\lambda) d\lambda$. Figure out how to calibrate the power spectral density measured by a spectrometer with finite resolution $\Delta\lambda_{\mathrm{res}}$ using a HeNe laser with known power.

53.2 Introduction to Gaussian optics

53.2.1 Wave equation and beam parameters

At first sight, one might think that the propagation of laser light is well described by the laws of geometrical optics. On closer inspection it turns out, however, that laser beams behave in many respects more like plane waves with their energy is concentrated near an optical axis. The electro-magnetic fields satisfy the *wave equation*,

$$k^2 u + \nabla^2 u = 0 \ . \tag{53.9}$$

For waves propagating in z direction, $u = \psi(x, y, z) e^{-\imath k z}$, one obtains a Schrödinger-like equation [526],

$$2\imath k \frac{\partial \psi}{\partial z} - \frac{\partial^2 \psi}{\partial x^2} - \frac{\partial^2 \psi}{\partial y^2} = 0 \ , \tag{53.10}$$

where $\partial^2\psi/\partial z^2$ has been neglected.

To describe a *Gaussian beam*, we choose an exponential ansatz and introduce two parameters, which can vary along the propagation axis z: $P(z)$ is a complex phase shift and $q(z)$ a complex parameter, whose imaginary part describes the diameter of the beam. The ansatz,

$$\psi = e^{-\imath\left[P(z) + k(x^2+y^2)/2q(z)\right]} \tag{53.11}$$

leads to [1],

$$0 = (q' - 1)\frac{\imath k(x^2 + y^2)}{q^2} - 2\imath P' + \frac{2}{q} \ . \tag{53.12}$$

In order for Eq. (53.12) to hold for all x and y, we need $q' = 1$ and $P' = \frac{-\imath}{q}$. Integrating q', we find

$$q = q_0 + z \ . \tag{53.13}$$

It is useful to introduce real beam parameters,

$$\frac{1}{q} \equiv \frac{1}{R} - \imath \frac{\lambda}{\pi w^2} \ . \tag{53.14}$$

Inserting these into Eq. (53.10),

$$\psi = e^{-\imath P - \imath \frac{k(x^2+y^2)}{2R} - \frac{(x^2+y^2)}{w^2}} \ , \tag{53.15}$$

[1] See script on *Electrodynamics* (2023), Sec. 7.4.2..

it becomes clear that $R(z)$ is the radius of curvature and $w(z)$ the beam diameter. Evaluating q_0 at the position of the focus (waist of the beam), where $R = \infty$, we obtain from (53.13) and (53.14)

$$w^2(z) = w_0^2 \left[1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2\right] \qquad \text{and} \qquad R(z) = z\left[1 + \left(\frac{\pi w_0^2}{\lambda z}\right)^2\right] . \tag{53.16}$$

Normalizing the intensity to the total power, we may write the radial intensity distributions as,

$$I_z(x, y) = \frac{2P}{\pi w(z)^2} e^{-2(x^2+y^2)/w(z)^2} . \tag{53.17}$$

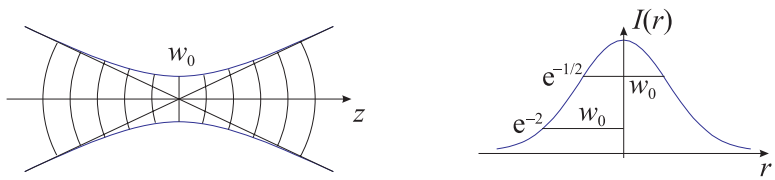

Figure 53.2: (Left) Propagation of the beam along the optical axis. (Right) Cross section of a Gaussian laser beam.

53.2.2 Transfer matrices

For the practical work with Gauss beams it is helpful to introduce transfer matrices, which describe the transformation of a Gauss beam through optical components along the optical axis. The matrix

$$\mathbf{M} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \tag{53.18}$$

transforms the beam parameter q in the following way:

$$q(z) = \frac{aq(0) + b}{cq(0) + d} . \tag{53.19}$$

Transfer matrices allow to calculate, how the parameters R and w transform along the optical axis across the optical elements or in free space. The most common optical elements are lenses, crystals, prisms, mirrors and cavities. For example, the matrix for propagation in free space of a beam over a distance d is,

$$\mathbf{M} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \tag{53.20}$$

and the matrix for transformation through a thin lens with focal distance f,

$$\mathbf{M} = \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix} . \tag{53.21}$$

It is interesting to note that the transfer matrices are the same as those, which in classical beam optics transform the vector, whose components are the distance of the beam from the optical axis y and its divergence $y'(z)$:

$$\begin{pmatrix} y(z) \\ y'(z) \end{pmatrix} = \mathbf{M} \begin{pmatrix} y(0) \\ y'(0) \end{pmatrix} \quad . \tag{53.22}$$

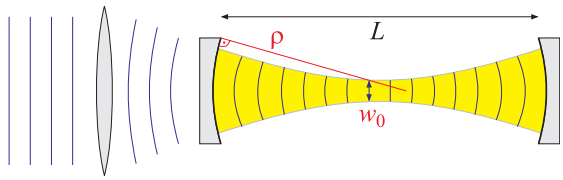

Figure 53.3: Coupling a Gaussian beam of light into cavity requires matching of the phase fronts.

Fig. 53.3 shows that coupling a Gaussian beam of light into a cavity requires matching of the phase fronts. Solve the Excs. 53.2.3.1 to 53.2.3.16 [246, 526, 963].

53.2.3 Exercises

53.2.3.1 Ex: Imaging through a thin lens

In classical ray optics the equations describing the focusing of a thin lens are given by,

$$\frac{1}{f} = \frac{1}{g} + \frac{1}{b} \qquad \text{and} \qquad \frac{b}{g} = \frac{B}{G} \ ,$$

where f is the focal distance of the lens, g the distance between the object and the lens, b the distance between the image and the lens, G the size of the object, and B the size of the image.
At what distance from an object of size $G = 1$ mm do you have to place a thin lens with focal distance $f = 100$ mm in order to obtain a ten times larger image? Test your result in practice.

53.2.3.2 Ex: Image of a convex lens

Show that with a convex lens of focal distance f the smallest distance between object and image should be $s = 4f$.

53.2.3.3 Ex: Telescope with ray optics

In classical optics the transfer matrix for the propagation of a beam through free space and through a thin lens are given, respectively, by

$$M_{\text{free}} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \qquad \text{and} \qquad M_{\text{lens}} = \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix} \ .$$

The transfer between a point z_0 of the optical axis and a point z_1 is described by

$$\begin{pmatrix} y(z_1) \\ y'(z_1) \end{pmatrix} = M_{\text{free}} \begin{pmatrix} y(z_0) \\ y'(z_0) \end{pmatrix} .$$

Here, y is the distance of a beam ray from the optical axis and $y' = \frac{dy}{dx}$ its divergence. Use this formalism to design a 3 times magnifying telescope with two lenses have, respectively, the focal lengths $f_1 = 100\,\text{mm}$ and $f_2 = 300\,\text{mm}$.

53.2.3.4 Ex: Ray tracing

Simulate the trajectory of a ray of light traversing under an angle a layer of a material with a refraction index characterized by a Gaussian profile.

53.2.3.5 Ex: The eye

The effective distance between the cornea and the lens of the eye is 2.5 cm, and the lens is in contact with the eye. To resolve two very close points, their images on the retina must be on two non-adjacent cone cells (i.e. there must be at least one non-activated cone cell between the images). The cone cells are about 1 µm apart.
a. What is the smallest angle ϵ under which two points are still separately perceptible? Assume that the direct beams P, P' are not refracted.
b. How close can the two points P_1 and P_2 be, at a distance of 20 m from the eye, so that they are still separately perceptible?

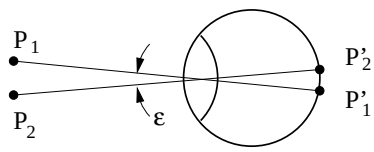

Figure 53.4: The eye.

53.2.3.6 Ex: Microscope

A simple homemade microscope consists of two convex lenses, each one with a diffractive power of 20 dpt, fixed at the extremities of a 30 cm long tube.
a. Wie groß ist die Tubuslänge dieses Mikroskops?
b. Wie groß ist der Abbildungsmaßstab des Mikroskops?
c. Welche Vergrößerung erreicht das Mikroskop? Gehen Sie davon aus, dass die deutliche Sehweite 25 cm beträgt.
d. Wie weit muss sich der Gegenstand vor dem Objektiv befinden, damit er im Auge des Betrachters scharf abgebildet wird?

53.2.3.7 Ex: Classical cloaking with four lenses

Can you design a system of four lenses (focal distances f_1, f_2, $f_3 = f_2$, and $f_4 = f_1$) separated by three distances $t_1 = f_1 + f_2$, t_2, and $t_3 = t_1$, such that the system appears to be invisible for an observer looking through the lenses [171]?

53.2.3.8 Ex: Diameter of a Gaussian beam

You are blocking part of a laser beam with a razor blade mounted on a translation stage allowing you to vary the horizontal position. At the same time, you observe the transmitted power P. You observe that, for varying the power between 16% and 84%, you need to vary the translation by 140 µm. What is the diameter of the Gaussian beam?

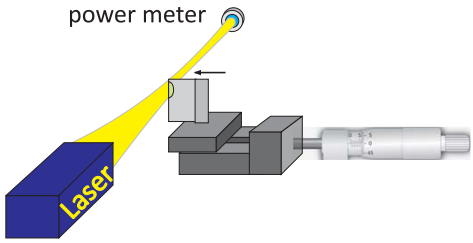

Figure 53.5: Diameter of a Gaussian beam.

53.2.3.9 Ex: Diffraction of a Gaussian beam at a slit

a. Determine the power loss suffered by a Gaussian beam passing through a one-dimensional slit, assuming that the beam hits the slit in its center.
b. Calculate the diffraction pattern produced by the slit.
c. A laser beam ($\lambda = 633\,\text{nm}$) looses 50% of its power after being passed through a slit. At a distance of $L = 1\,\text{m}$ behind the slit appear diffraction patterns exhibiting first minima at $\Delta x = 1\,\text{mm}$ to both sides of the central peak. Determine the diameter of the Gaussian beam.

53.2.3.10 Ex: Diffraction of a Gaussian beam at a pinhole

a. Determine the power loss suffered by a Gaussian beam passing through the center of a a pinhole of radius R.
b. A laser beam ($\lambda = 633\,\text{nm}$) looses 50% of its power after being passed through a slit. At a distance of $L = 1\,\text{m}$ behind the slit appear diffraction patterns exhibiting a first minimum at a distance $\Delta b = 1\,\text{mm}$ from the optical axis. Determine the diameter of the Gaussian beam. Help: The first ring of destructive interference occurs under an angle of $\sin\theta = 1.22\frac{\lambda}{2R}$.

53.2.3.11 Ex: Focusing a HeNe laser

The output beam from an HeNe laser with a confocal resonator ($\rho = L = 30\,\text{cm}$) is focused by a lens of $f = 30\,\text{cm}$, $50\,\text{cm}$ away from the output mirror. Calculate the location of the focus, the Rayleigh length, and the beam waist in the focal plane.

53.2.3.12 Ex: Spatial filtering

A nearly parallel Gaussian beam with $\lambda = 500\,\text{nm}$ is expanded by a telescope with two lenses of focal lengths $f_1 = 1\,\text{cm}$ and $f_2 = 10\,\text{cm}$, illustrated in the figure. The

spot size at the entrance lens is $w = 1\,\text{mm}$.
a. Why does an aperture in the focal plane improve the quality of the wave fronts in the expanded beam by eliminating perturbations due to diffraction effects by dust and other imperfections on the lens surfaces?
b. What is the diameter of this aperture, if 95% of the intensity is transmitted?

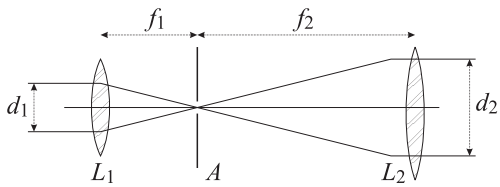

Figure 53.6: Beam-expanding telescope with an aperture in the focal plane.

53.2.3.13 Ex: Transverse mode selection in an Ar laser

An argon laser oscillating at $\lambda = 488\,\text{nm}$ with resonator length $d = 100\,\text{cm}$ and two mirrors with radius $R_1 = \infty$ and $R_2 = 400\,\text{cm}$ has an intracavity circular aperture close to the spherical mirror to prevent oscillation on transversal modes. Estimate the maximum diameter of the aperture that introduces losses $\gamma_{diffr} < 1\%$ for the TEM_{00} mode, but prevents oscillation of higher transverse modes, which without the aperture have a net gain of 10%.

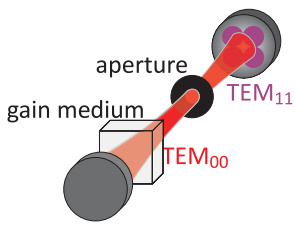

Figure 53.7: Transverse mode selection in an Ar laser.

53.2.3.14 Ex: Anamorphic prism

A prism can be used for expansion of a laser beam if the incident beam is nearly parallel to the prism surface. Calculate the angle of incidence α for which a laser beam transmitted through a rectangular glass prism with an $\varepsilon = 45°$ base angle is expanded tenfold.

53.2.3.15 Ex: Anamorphic prism pair

An *anamorphic prism* pair is a setup consisting of two prisms through which a laser beam is passed under specific angles. The angles can be chosen such as to change the beam diameter only in the p-plane.
a. Calculate, for a single prism with refractive index $n = 1.5$, the beam expansion for

an incidence angle of $\theta_1 = 57°$ and an exit angle of $0°$. How large must the base angle β of the prism be for this to be possible?
b. How must the second prism be aligned in order for the beam transmitted to this second prism to remain parallel to the incident beam? Note, that an anamorphic

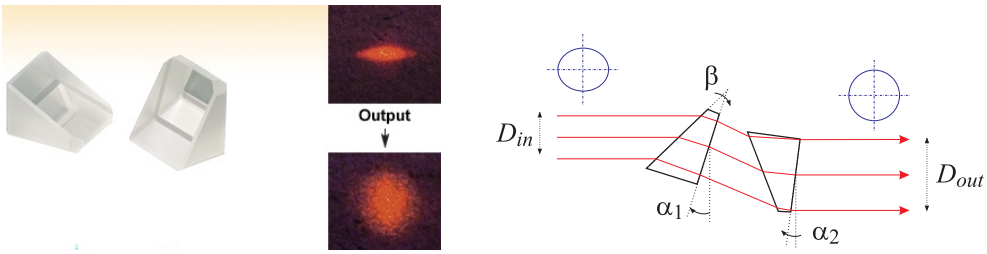

Figure 53.8: (Left) Anamorphic prisms (Thorlabs, PS870). (Right) Geometry of the beam transformation. The entrance side of a prism is often chosen close to the Brewster angle, while the exit side treated carries an anti-reflexion coating.

prism pair does not allow to correct for astigmatism. This requires cylindrical lenses.

53.2.3.16 Ex: Beam steering with two wedged substrates

The wavevector of a laser beam is generally aligned with one or more adjustable reflective mirrors. Alternatively, one may use a pair of rotatable transmissive wedged substrates. Calculate the wave vector of a laser beam after its transmission through two $\epsilon = 3°$ wedged, 2 mm thick, AR-coated substrates with the refraction index $n_{rfr} = 1.5134$ at 689 nm, each one rotated by $\theta_{1,2}$ from some normal position.

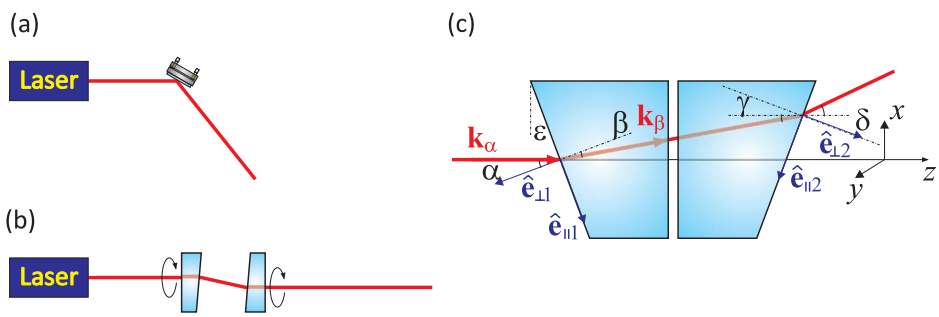

Figure 53.9: Beam steering with two rotatable wedged substrates (see Thorlabs, PS810).

53.2.4 *Experiment: Measuring the diameter of a Gaussian laser beam*

Most laser beams exhibit a Gaussian shape transverse intensity distribution, as we will study in this experiment.

1. Measure the phase profile of a helium-neon laser. To this end fix a razor blade on a translation stage and move it sideways into the beam. From the power of the partially blocked beam $\int_F I(x,y)dxdy$, where F is the cross section of the unblocked part of the beam, $w(z)$ can be determined (see Excs. 53.2.3.8 to 53.2.3.10).

53.2.5 *Experiment: Measuring the parameters of a Gaussian laser beam*

Once a Gaussian beam has been characterized at a given position z, the transfer matrix formalism allows us to calculate its shape at any position along the optical axis. In this experiment, we will study the propagation of a Gaussian beam through free space [see Eqs. (53.16)] and its transformation through a thin lens with focal distance f. For the latter one, we obtain directly after the lens,

$$\frac{1}{R(z \searrow 0)} = \frac{1}{R(z \nearrow 0)} - \frac{1}{f} \,. \tag{53.23}$$

1. Focus the beam with a lens. Measure the beam diameter at 3 different locations. Compare with the prediction of Gaussian optics.

2. Set up a 1:3 telescope and verify that the outgoing beam is collimated.

53.2.6 *Experiment: Spatial filtering with a pinhole*

Laser light emitted from diode lasers is often astigmatic and has an irregular beam profile. The beam profile can be purified by passing it through an optical fiber or a pinhole, however, at the price of losing power.

1. Focus the beam of a HeNe laser with a lens of $f = 100\,\mathrm{mm}$ focal distance onto a pinhole. Observe the interference fringes and, from their distance from the optical axis, infer the diameter of the pinhole.

2. Remove the higher-order diffraction rings with an iris and compare the beam profile with that of a Gaussian beam. What are the divergence and the waist of the spatially filtered beam (see Exc. 53.2.3.10)?

53.3 Introduction to polarization optics

A laser usually has a well-defined polarization, e.g. , linear or circular. The polarizations can be transformed into one another through a *quarter waveplate* ($\lambda/4$) or a *half waveplate* ($\lambda/2$) by a Fresnel rhomb or other birefringent elements. Superpositions of polarizations can be separated by a *polarizing beam splitter*.

Waveplates consist of thin sheets of *birefringents crystal*s, which are transparent material characterized by anisotropic refraction indices. Cut in a particular way, a birefringent crystal can exhibit a polarization-dependent refraction index, allowing to control the retardation of a light beam as a function of its polarization. The thickness

Figure 53.10: (Left) Transmission through a birefringent crystal. (Right) $\lambda/2$-waveplate mounted in a rotation stage.

of a waveplate determines the retardation of one polarization axis with respect to the other.

In practice, the degree of freedom of polarization is often used for separating counterpropagating light fields, e.g. in ring lasers, by means of elements called *optical diode* or *optical isolator*, which consist of a Faraday rotator and $\lambda/2$ waveplate. Another practical example is the use of $\lambda/4$ in double passage. An incoming beam can be separated from a returning beam by using a $\lambda/4$ waveplate and a polarizing beam splitter.

53.3.1 Jones matrices

The term *polarization* is defined in relation to a fixed coordinate system, while the term *helicity* denotes the direction of rotation of the polarization vector with respect to the direction of propagation of the light beam. The polarization of a beam propagating in z-direction can easily be expressed by a vector of complex amplitude,

$$\vec{\mathcal{E}}(\mathbf{r},t) = \begin{pmatrix} a \\ b \\ 0 \end{pmatrix} e^{\imath kz - \imath\omega t} = \begin{pmatrix} 1 \\ e^{-\imath\phi}|b|/|a| \\ 0 \end{pmatrix} |a| e^{\imath kz - \imath\omega t} \ . \tag{53.24}$$

The angle $\phi = \arctan \frac{\mathfrak{Im}\, ab^*}{\mathfrak{Re}\, ab^*}$ determines the polarization of the light beam. A polarization is linear when $\phi = 0$ and circular when $\phi = \pi/2$. $|b|/|a|$ is, hence, the degree of ellipticity. A polarization rotator for linearly polarized light (e.g., a sugar solution) is described by the following *Jones matrix* (we will restrict to the x-y-plane)

$$M_{\text{rotator}}(\phi) = \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \ , \tag{53.25}$$

where ϕ is the rotation angle. For the Faraday rotator the sign of the rotation angle depends on the propagation direction of the laser beam. A *polarizer* projects the polarization onto a specific axis. In the case of the x-axis Jones matrix is,

$$M_{\text{polarizer}} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \ . \tag{53.26}$$

If the rotation angle is ϕ,

$$M_{\text{polarizer}}(\phi) = \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix}^{-1} . \tag{53.27}$$

Other components, such as electro-optical modulators or phase plates are birefringent crystals, which act only on one of the two optical axes. If only the y axis is optically active, the Jones' matrix is,

$$M_{\theta\text{-waveplate}} = \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} . \tag{53.28}$$

For $\theta = 2\pi/n$ we obtain a λ/n-waveplate. When we rotate the waveplate and therefore the optically inactive axis to an angle ϕ, the Jones matrices are,

$$\begin{aligned} M_{\theta\text{-waveplate}}(\phi) &= \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix}^{-1} \\ &= \begin{pmatrix} \cos^2\phi + e^{\imath\theta}\sin^2\phi & -\sin\phi\cos\phi + e^{\imath\theta}\sin\phi\cos\phi \\ -\sin\phi\cos\phi + e^{\imath\theta}\sin\phi\cos\phi & \sin^2\phi + e^{\imath\theta}\cos^2\phi \end{pmatrix} . \end{aligned} \tag{53.29}$$

In most cases, we use quarter waveplates $\lambda/4$,

$$M_{\lambda/4}(\phi) = \begin{pmatrix} \cos^2\phi + \imath\sin^2\phi & (-1+\imath)\sin\phi\cos\phi \\ (-1+\imath)\sin\phi\cos\phi & \sin^2\phi + \imath\cos^2\phi \end{pmatrix} \tag{53.30}$$

and half waveplates $\lambda/2$,

$$M_{\lambda/2}(\phi) = \begin{pmatrix} \cos 2\phi & -\sin 2\phi \\ -\sin 2\phi & -\cos 2\phi \end{pmatrix} . \tag{53.31}$$

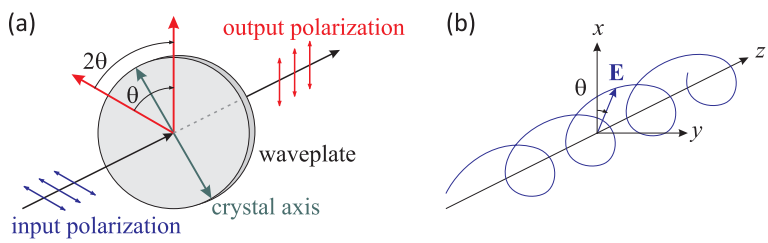

Figure 53.11: (a) Rotation of the polarization by a birefringent waveplate. (b) Illustration of a circularly polarized light wave.

Combinations of $\lambda/2$ waveplates and *Faraday rotator*s are used as *optical isolator*, also called *optical diode*.

53.3.2 Fresnel formulae

Reflection and transmission of a beam of light at a surface depend on the polarization of the light and the angle of incidence. They are described by the *Fresnel formula*:

$$\begin{aligned}
\left(\frac{I_{0t}}{I_{0i}}\right)_s &= T_s = \left(\frac{2\sin\theta_t\cos\theta_i}{\sin(\theta_i+\theta_t)}\right)^2 \\
\left(\frac{I_{0r}}{I_{0i}}\right)_s &= R_s = \left(-\frac{\sin(\theta_i-\theta_t)}{\sin(\theta_i+\theta_t)}\right)^2 \\
\left(\frac{I_{0t}}{I_{0i}}\right)_p &= T_p = \left(\frac{2\sin\theta_t\cos\theta_i}{\sin(\theta_i+\theta_t)\cos(\theta_i-\theta_t)}\right)^2 \\
\left(\frac{I_{0r}}{I_{0i}}\right)_p &= R_p = \left(\frac{\tan(\theta_i-\theta_t)}{\tan(\theta_i+\theta_t)}\right)^2 .
\end{aligned} \tag{53.32}$$

The angles of incidence and transmission are related by Snell's law: $n_1 \sin\theta_i = n_2 \sin\theta_t$.

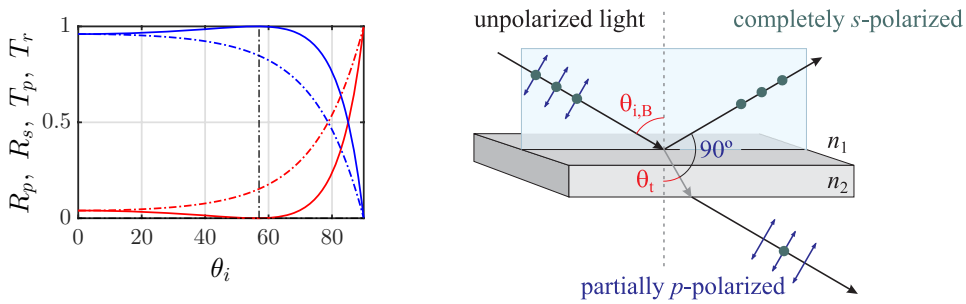

Figure 53.12: (code) (Left) Fresnel formulae showing the angular dependence of t_s (red solid), r_s (green dash-dotted), t_p (blue dashed), and r_p (cyan dotted) for reflection from and transmission through a piece of glass-air interface. (Right) Interfaces between optical media with different reflection indices can act like polarizers: Light reflected from a glas surface under the Brewster angle is completely s-polarized, while the transmitted light is partially p-polarized. The notation s comes from *senkrecht*, i.e. perpendicular to the plane spanned by the incident and reflected light beams, while p means *parallel* to this plane.

The *Brewster angle* $\theta_{i,B}$ is reached, when $\theta_{i,B} + \theta_t = 90°$, i.e., when following Snell's law,

$$n_1 \sin\theta_{i,B} = n_2 \sin(90° - \theta_{i,B}) = n_2 \cos\theta_{i,B} \ . \tag{53.33}$$

Hence, the Brewster angle is given by,

$$\tan\theta_{i,B} = \frac{n_2}{n_1} \ . \tag{53.34}$$

Resolve the exercises 53.3.4.1 to 53.3.4.5.

53.3.3 Stokes parameters

In quantum mechanics the *Stokes parameters* of a light beam with horizontal and vertical polarizations, $\hat{a}_h$ and $\hat{a}_v$, satisfying,

$$[\hat{a}_k, \hat{a}_m^\dagger] = \delta_{km} \ , \tag{53.35}$$

with $k, m = h, v$ are defined by,

$$\boxed{\begin{aligned} \hat{S}_0 &\equiv \hat{a}_h^\dagger \hat{a}_h + \hat{a}_v^\dagger \hat{a}_v \\ \hat{S}_1 &\equiv \hat{a}_h^\dagger \hat{a}_h - \hat{a}_v^\dagger \hat{a}_v \\ \hat{S}_2 &\equiv \hat{a}_h^\dagger \hat{a}_v e^{\imath\theta} + \hat{a}_v^\dagger \hat{a}_h e^{-\imath\theta} \\ \hat{S}_3 &\equiv -\imath(\hat{a}_h^\dagger \hat{a}_v e^{\imath\theta} - \hat{a}_v^\dagger \hat{a}_h e^{-\imath\theta}) \end{aligned}} \ . \tag{53.36}$$

The Stokes parameters exhaustively describe the polarization state of a light beam. It is interesting, that the vector $\hat{\mathbf{S}}$ with components S_j with $j = 1, 2, 3$ satisfies the SU(2) spin algebra,

$$[\hat{S}_k, \hat{S}_m] = 2\imath\epsilon_{kmn}\hat{S}_n \qquad \text{and} \qquad \hat{\mathbf{S}}^2 = \hat{S}_0^2 + 2\hat{S}_0 \ , \tag{53.37}$$

as will be shown in Exc. 53.3.4.6. It is conveniently pictured on a Poincaré sphere or as a polarization ellipse. In the classical limit we get,

$$\begin{aligned} \hat{S}_0 &= I \\ \hat{S}_1 &= Ip\cos 2\psi \cos 2\chi \\ \hat{S}_2 &= Ip\sin 2\psi \cos 2\chi \\ \hat{S}_3 &= Ip\sin 2\chi \ , \end{aligned} \tag{53.38}$$

with I the light intensity (eventually normalized to the single-photon light intensity), the degree of polarization p. Obviously,

$$\hat{S}_1^2 + \hat{S}_2^2 + \hat{S}_3^2 = p^2\hat{S}_0^2 \ . \tag{53.39}$$

53.3.4 Exercises

53.3.4.1 Ex: Light power control using polarization optics

The power of a laser beam can be regulated by a combination of a half-wave plate and a polarizing beam splitter. By how many degrees do you have to rotate the waveplate in order to reduce the light power by a factor of 2? Use the Jones matrices to justify your response. **Advice:** Look up the Jones matrices (53.31) and (53.26). Test your result in practice.

53.3.4.2 Ex: Jones matrices

Consider a linearly polarized laser beam passing twice through a $\lambda/4$, first in direction of the optical axis, the second time in opposite direction. Calculate the final polarization.

53.3.4.3 Ex: Intensity transmitted through a polarizer

Unpolarized light of intensity I_0 is transmitted through a polarizer with thickness $d = 1\,\mathrm{mm}$. Calculate the transmitted intensity when the absorption coefficients for the two polarizations are $\alpha_{\parallel} = 100\,\mathrm{cm}^{-1}$ and $\alpha_{\perp} = 5\,\mathrm{cm}^{-1}$.

53.3.4.4 Ex: Thickness of a half-waveplate

A birefringent quartz crystal is characterized by different refraction indices of the ordinary beam $n_o = 1.544$ and the extraordinary beam $n_e = 1.553$. Calculate the necessary thickness of a quartz waveplate to be used as a $\lambda/2$ retarder at 633 nm. Choose an appropriate waveplate from the Thorlabs catalogue. How thick would a calcite waveplate ($n_o = 1.658$, $n_e = 1.486$)?

53.3.4.5 Ex: Faraday isolator

A Faraday rotator is a device exploiting the Faraday effect to rotate the polarization of a light beam according to the Jones matrix,

$$M_{Faraday}(\phi) = \begin{pmatrix} \cos\phi & -\mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi \\ \mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi & \cos\phi \end{pmatrix} , \tag{53.40}$$

where $\mathbf{k}$ is the wavevector of the light beam. An optical diode is composed by a $\phi = 45°$ Faraday rotor sandwiched between two polarizers rotated by $\phi = 45°$ with respect to each other.
a. How is the polarization of a light beam changed after a double passage (back and forth) through a Faraday rotator?
b. Calculate what happens to a light beam upon a single passage through a Faraday rotator in either direction $\mathbf{k}$ and $-\mathbf{k}$?

53.3.4.6 Ex: Stokes parameters

For the Stokes parameters defined in (53.42) prove the following relationships,

$$[\hat{S}_k, \hat{S}_m] = 2\imath\epsilon_{kmn}\hat{S}_n \qquad \text{and} \qquad \hat{\mathbf{S}}^2 = \hat{S}_0^2 \ .$$

53.3.5 *Experiment: Polarization of a helium-neon laser*

We will now analyze and manipulate the polarization of a laser beam in practice.

1. Pass the beam of a helium-neon laser through a polarizer and a quarter- resp. half-waveplate. Analyze the polarization using a rotatable second polarizer for various rotation angles of the waveplate. Sketch the transmitted intensity as a function of the rotation angle of the beamsplitter in a polar diagram. How good can you achieve linear and circular polarization?

2. Characterize the polarization of a helium-neon laser by sketching the transmitted intensity through a polarizing beamsplitter as a function of the rotation

angle of the beamsplitter in a polar diagram. Now couple the laser beam to a Fabry-Pérot interferometer. What do you observe? Place a quarter-waveplate at the output of the helium-neon laser and characterize again the polarization. What do you observe at the Fabry-Pérot interferometer?

3. Use a quarter-waveplate to separate a beam of light from a counterpropagating beam according to Fig. 53.13.

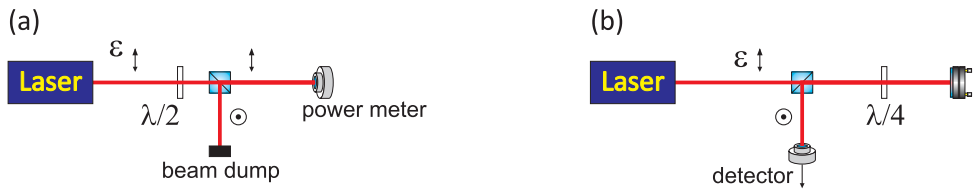

Figure 53.13: (a) Power control of a light beam and (b) separation of counterpropagating beams through polarization optics.

4. Characterize an optical insulator. Optimize its extinction.

53.3.6 *Experiment: Measuring the Brewster angle*

Any interface between two transparent materials with different refraction indices reflects a part of incident light depending on the polarization and the angle of incidence, as predicted by Fresnels formulae (53.32).

1. Measure the transmission by a glass plate as a function of the angle of incidence for two orthogonal polarizations and determine the Brewster angle.

2. Mirrors can change the polarization of a light beam and, for example, transform a linear polarization into elliptical. Determine the degree of ellipticity for a given mirror.

3. How does a mirror transform the polarization and the helicity of a reflected laser beam?

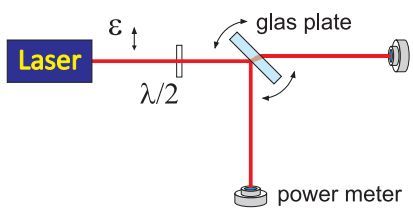

Figure 53.14: Measuring the Brewster angle by varying the tilt of a glas plate.

53.3.7 *Experiment: Pockels cell*

Pockels cells are birefringent crystals allowing to manipulate the polarization of a laser beam by application of a voltage.

1. Prepare a laser beam by passing it through a polarizer followed by a half-waveplate and a second polarizer. Observe the intensity transmitted and reflected through the last polarizer as a function of the rotation angle of the half-waveplate.

2. Use the EOM as a Pockels cell by placing it between the half-waveplate and the second polarizer. Supply a voltage between 0 V and 350 V to the EOM. Measures the intensity of reflected and transmitted light as a function of the supplied voltage and prepare a diagram. What do you observe when you rotate either the half-waveplate or the EOM?

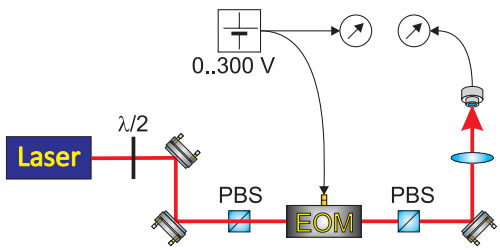

Figure 53.15: Scheme for using an EOM as a Pockels cell.

53.4 Laguerre-Gaussian light modes

Light beams not only possess polarization, but can also have orbital angular momentum. This property of light can impressively demonstrated at the so-called *Laguerre-Gaussian modes*.

These modes can be produced by means of masks resembling *Fresnel zone plate*. Fresnel zone plates are masks consisting of concentric sequences of bright (transmitting) and dark (absorbing) rings. The diameters of the rings are selected in such a way that the diameters of the rings defined by the bright rings interfere constructively at a certain distance f_1 on the optical axis and form a 'focus' there. For this purpose, the distance d_n of the nth ring must satisfy the condition,

$$d_n = \sqrt{(f_1 + n\lambda)^2 - f_1^2} \simeq \sqrt{2 f_1 n \lambda} \; . \tag{53.41}$$

For a given zone plate there are other focuses at smaller distances,

$$f_k = \frac{d_n^2 - k^2 n^2 \lambda^2}{2kn\lambda} \simeq \frac{d_n^2}{2kn\lambda} = \frac{f_1}{k} \; . \tag{53.42}$$

In order to separate the beams diffracted by the zone plate into a given focus from those diffracted into other focuses or not being diffracted at all, we pass the beam

through an iris diaphragm localized at the desired focus and recollimate the beam by means of a lens, as shown in Fig. 53.16.

The phase profile of the beam can be viewed interferometrically (see Fig. 53.16) by overlapping a plane wave laser beam. With a *neutral density filter* the intensities of the overlapping beams can be adjusted to maximize the contrast.

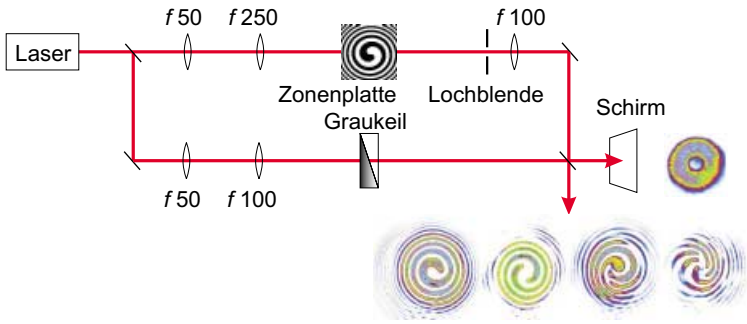

Figure 53.16: Creation of Laguerre-Gaussian modes.

Now, for realizing Laguerre-Gaussian light modes, we use Fresnel zone plates with spiral patterns, instead of concentric rings. In contrast to the Gaussian mode, the Laguerre-Gauß modes exhibit an intensity minimum on the optical axis (doonat mode). Their phase profiles can be viewed by interferometry [15].

53.4.1 *Experiment: Generating a Laguerre-Gaussian mode*

In this experiment, we will...

1. Construct the interferometer sketched in Fig. 53.16 using adequate Fresnel zone plates. What do you observe in the diffracted beam and in the interferogram, when instead of filtering the principal focus f_1 you filter a higher order focus?

2. Pass a Laguerre-Gauß laser beam through a $\lambda/2$ waveplate. How does the angular orbital momentum change when you change the rotation? What happens upon reflection from a mirror?

3. Slightly misalign the mode-matching between the Laguerre-Gauß beam and the Gaussian reference beam until you observe multiple fringes. What do you observe?

Chapter 54

Electronics and radiofrequency

For the control and regulation of important quantum optical devices, such as EOMs, AOMs, laser diodes, photodiodes, piezos etc., *electronic circuit*s are necessary. The aim of this chapter is to provide practical know-how in the basics of electronics.

54.1 Introduction to electronic circuits

54.1.1 Passive electronic components

Electronic components which are characterized by a fixed impedance are called *passive*. The most common devices are resistors, capacitors, and inductances. For their handling, it is useful to be able to identify their impedance from their labeling.

The values of the resistances of resistors are generally codified by colored rings. The first ring to be considered is the one closest to a terminal. In case of 4 rings, the first two rings are to be considered as digits, the third ring gives the exponent 10. With five rings, the first three are digits and the forth gives the exponent of 10. The last ring, in both cases specifies the tolerance of the value of the resistance.

There are various types of capacitors depending on the employed materials for the dielectric medium (paper, ceramics, polyester, electrolyte made of aluminum and electrolyte made of tantalum). Electrolyte capacitors have a defined polarity, and an reversion of their voltage supply can result in their explosion. The value of the capacitance is generally written on their body, as well as their maximum allowed operating voltage. Also the polarity of electrolyte capacitors is always indicated (although there can be some confusion with regard to the physical and technical direction of the current flow). Ceramic and polyester capacitors can have their values either written in letters or color coded. The color code sequence is similar to that of resistors, with the first two digits devoted to the digits, the third to the multiplier exponent, the forth to the tolerance, and the fifth for the maximum voltage. In case of printed numbers, the first two numbers represent the first two digits, and the third one represents the numbers of 0 before the decimal point. In all cases (colors or digits), the value is given in picoFarads. With more modern serigraphic techniques, some capacitors have their values printed directly in Farads (micro, nano and pico). In these cases, the letter denoting the unit also serves to mark the decimal point. For example, 2n2 means 2.2 nF.

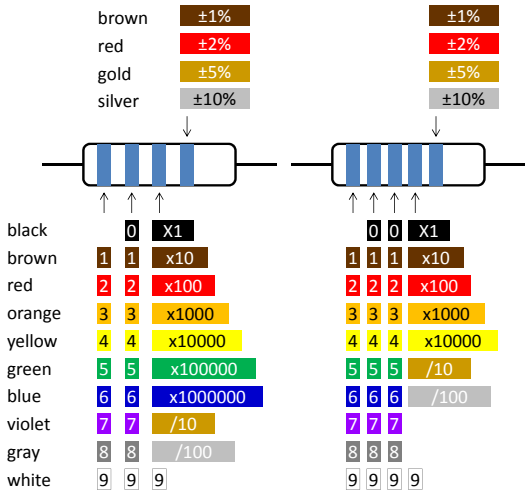

Figure 54.1: Color code for resistors with 4 and 5 rings.

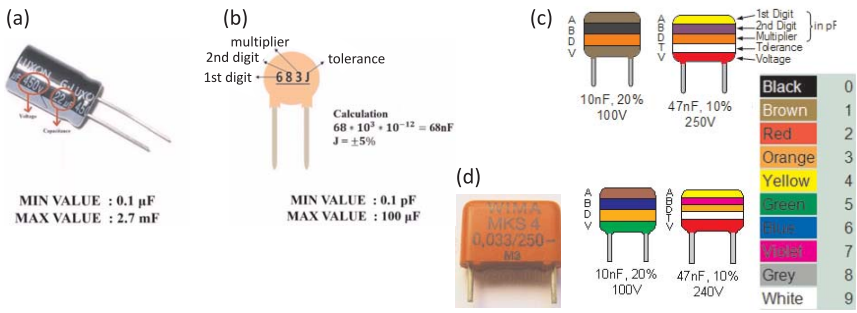

Figure 54.2: (Left) Electrolyte aluminum capacitors. (Center) Polyester capacitor and color code. (Right) Ceramic capacitor.

54.1.2 Active electronic components and the *pn*-junction

Diodes, transistors, photodiodes, operational amplifiers are called *active components*, because their current-to-voltage curve is non-linear, their response $I = I(U)$ cannot be described by a single constant value, but depends on the applied voltage.

During this course we will work a lot with *operational amplifiers* (OpAmp), which are integrated circuits designed to amplify input signals with characteristics that are entirely determined by external components. This feature makes them easy to use and extremely versatile.

OpAmps are generally found encapsulated in DIL type housings (dual in line), which means that they have two lines of 4 pins. The sequence of pins is numerated in counter-clockwise orientation, and they have a mark on the side of pin 1. It is always recommend to obtain the datasheet of the OpAmp since, despite a usual pin compatibility ensured by the various OpAmp manufacturers, deviations are frequent.

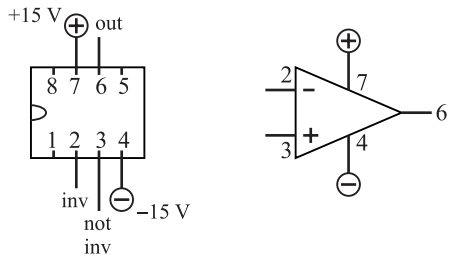

Figure 54.3: (Left) Schematic symbol of an OpAmp; (Right) Pin layout of a standard OpAmp.

54.1.3 Electronic circuits

Amplification or control circuits are nowadays mostly realized with *operational amplifiers* (*OpAmp*). The advantage of an OpAmp compared to circuits based on transistors is, that their properties are almost independent of their internal structure. Hence, their properties can be personalized via an external feedback realized with external components. The input of an OpAmp does not require current. OpAmps amplify the voltage difference between the non-inverting input (+) and the inverting (-). For most practical matters we can assume, that the OpAmp has infinite amplification and negligible input impedance.

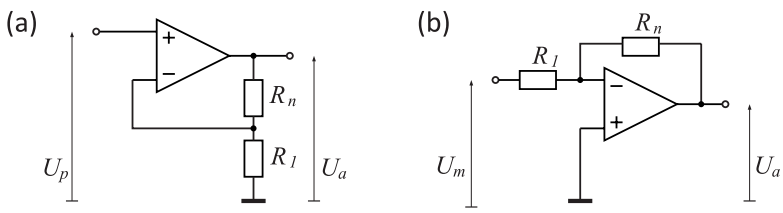

Figure 54.4: (Left) Principle scheme of a standard OpAmp. (Center) Non-inverting amplifier. (Right) Inverting amplifier.

OpAmps can be used as *inverting amplifiers* or *non-inverting amplifiers*. Using *Kirchhoff's rules* for the *loops* and *nodes* of the circuit, we find for a non-inverting amplifier,

$$\frac{U_e}{R_1} = -\frac{U_a}{R_1 + R_n} \quad , \quad G = 1 + \frac{R_n}{R_1} \ . \tag{54.1}$$

This becomes clear noting that, since no voltage is dropped between the inputs (+) and (-), the input voltage must be equal to the voltage drop at R_1. And since the non-inverting input does not deliver current, the currents traversing the resistances R_n and R_1 must be equal. For the inverting amplifier, we find,

$$\frac{U_a}{R_n} = -\frac{U_e}{R_1} \quad , \quad G = -\frac{R_n}{R_1} \ . \tag{54.2}$$

This becomes clear noting that, since the input (-) does not drag current, the currents traversing the resistances R_n and R_1 must cancel each other.

Changing the resistances R to inductances L or capacitances C, it becomes possible to influence the frequency response of the amplifying circuit. The impedance are,

$$Z_L = \imath L\omega \quad , \quad Z_C = \frac{1}{\imath C\omega} \ . \tag{54.3}$$

For the calculation of the amplification wit complex impedances, we just take the absolute value of the gain G.

54.1.4 The thermoelectric effect

54.1.4.1 Seebeck effect

The Seebeck effect is a classic example of an electromotive force (EMF) and leads to measurable currents or voltages in the same way as any other EMF. The local current density is given by,

$$\mathbf{J} = \sigma(-\nabla V + \mathbf{E}_{emf}) \ , \tag{54.4}$$

where V is the local voltage, and σ is the local conductivity. In general, the Seebeck effect is described locally by the creation of an electromotive field,

$$\mathbf{E}_{emf} = -S\nabla T \ , \tag{54.5}$$

where S is the Seebeck coefficient (also known as thermopower), a property of the local material, and ∇T is the temperature gradient.

The Seebeck coefficients generally vary as function of temperature and depend strongly on the composition of the conductor. For ordinary materials at room temperature, the Seebeck coefficient may range in value from $-100\,\mu\text{V/K}$ to $+1000\,\mu\text{V/K}$.

If the system reaches a steady state, where $\mathbf{J} = 0$, then the voltage gradient is given simply by the emf:

$$-V = S\Delta T \ . \tag{54.6}$$

This simple relationship, which does not depend on conductivity, is used in the thermocouple to measure a temperature difference; an absolute temperature may be found by performing the voltage measurement at a known reference temperature. A metal of unknown composition can be classified by its thermoelectric effect if a metallic probe of known composition is kept at a constant temperature and held in contact with the unknown sample that is locally heated to the probe temperature. It is used commercially to identify metal alloys. Thermocouples in series form a *thermopile*. Thermoelectric generators are used for creating power from heat differentials.

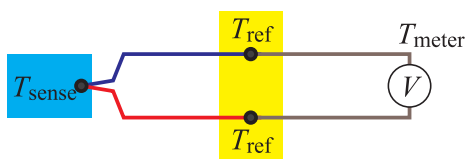

Figure 54.5:

54.1.4.2 Peltier effect

When an electric current is passed through a circuit of a thermocouple, heat is evolved at one junction and absorbed at the other junction. This is known as Peltier Effect and is named after a physicist. The Peltier effect is the presence of heating or cooling at an electrified junction of two different conductors. When a current is made to flow through a junction between two conductors, A and B, heat may be generated or removed at the junction. The Peltier heat generated at the junction per unit time is,

$$\dot{Q} = (\Pi_A - \Pi_B)I \ , \tag{54.7}$$

where Π_A and Π_B are the Peltier coefficients of conductors A and B, and I is the electric current (from A to B). The total heat generated is not determined by the Peltier effect alone, as it may also be influenced by Joule heating and thermal-gradient effects (see below).

The Peltier coefficients represent how much heat is carried per unit charge. Since charge current must be continuous across a junction, the associated heat flow will develop a discontinuity if Π_A and Π_B are different. The Peltier effect can be considered as the back-action counterpart to the Seebeck effect (analogous to the back-EMF in magnetic induction): if a simple thermoelectric circuit is closed, then the Seebeck effect will drive a current, which in turn (by the Peltier effect) will always transfer heat from the hot to the cold junction. The close relationship between Peltier and Seebeck effects can be seen in the direct connection between their coefficients [454, 919]:

$$\Pi = TS \ . \tag{54.8}$$

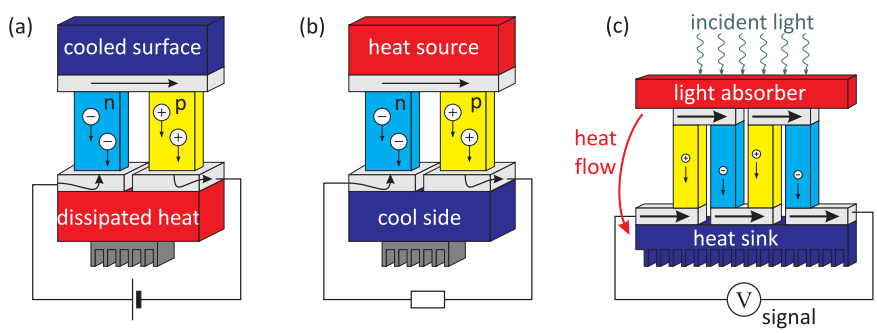

Figure 54.6: (a) Peltier cooler, (b) voltage generator or heat sensor, and (c) heat or radiation sensor with thermocouples connected in parallel.

54.1.5 Exercises

54.1.5.1 Ex: Integrator with operational amplifier

Based on the two golden rules for operational amplifiers, (1) $I_+ = I_- = 0$ A and (2) $U_+ = U_-$, show that the output voltage U_a at the integrated circuit shown in the figure is: $U_a = \frac{1}{RC}\int U_e dt$.

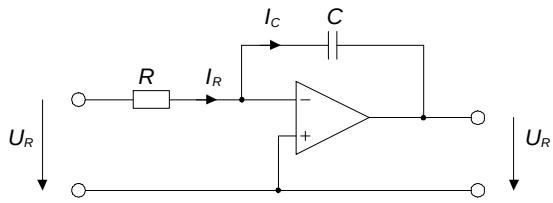

Figure 54.7: Integrator with operational amplifier.

54.1.5.2 Ex: Low-pass filter using an OpAmp

Using an inverting operational amplifier design a simple low-pass filter with a constant amplification of 10 at low frequencies and diminishing gain above 10 kHz. Calculate the Bode diagram (i.e. the frequency-dependent gain and phase-shift of your circuit. What is the gain reduction per octave?

54.1.6 *Experiment: Amplifiers and active filters*

Here, we will learn how to use OpAmps: We will start mounting a 10-fold inverting amplifier on a breadboard and then modify the external passive components, such as to build a low-pass filter.

1. Assemble on a breadboard a simple inverting amplifier using an OpAmp. Use 10 kΩ resistors at the input aim for an amplification factor of 10.

2. Test the circuit with a frequency generator and an oscilloscope.

3. Modify the circuit such as to obtain a low-pass filter with $f_g = 50\,\text{kHz}$ bandwidth and test the circuit again.

54.1.7 *Experiment: Peltier element and thermistor*

Here, we will learn how to use a Peltier element and a thermistor. A *thermistor* is nothing else than a well-calibrated resistor with temperature-dependent resistance (see Fig. 54.9).

1. Connect a Peltier element to a 1 A current source and bring one of the two surfaces of the Peltier element into thermal contact with a heat sink. What do you observe?

2. Bring a 10 kΩ thermistor in thermal contact with either of the two surfaces of the Peltier element and measure its resistance. What do you observe?

3. Can you imagine a feedback logic evaluating the measured resistance in order to control the current applied to the Peltier element such as to maintain constant the temperature of the surface not connected to the heat sink.

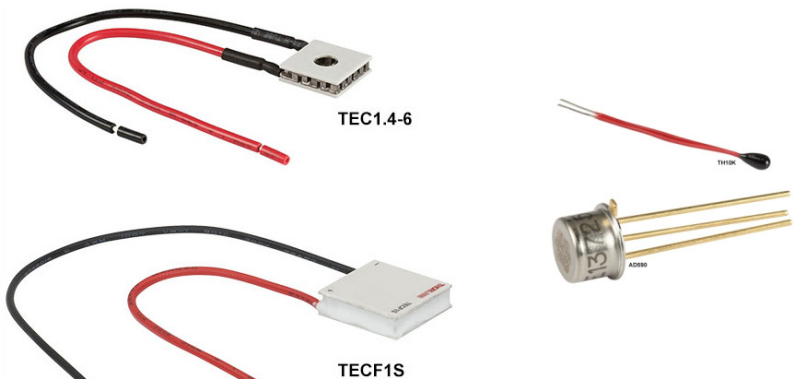

Figure 54.8: Pictures of Peltier elements, a thermistor, and an AD590 temperature transducer.

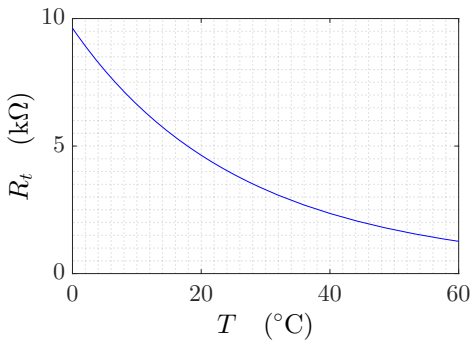

Figure 54.9: Calibration curve for a 10 kΩ thermistor from Thorlabs.

54.2 Detectors

54.2.1 Photodiodes

Most active components are many of *semiconductor* characterized by a relatively large band gap between the valence band and the conduction band. By appropriate doping of the material with donors (p-type) or acceptors (n-type) a semiconductor can be made conductive. The most basic semiconductor element, which is the *diode* consists of a junction of two types of semiconductors, as shown in Fig. 54.10.

Our first task will be to construct a *photo detector*. The central part of a photodetector is the photodiode. We have at our disposal silicium *pin*-photodiodes of the type C30822E of the company Perkin Elmer and of the type FFD100.

Photodiodes exploit an intrinsic photoeffect of semiconductor *pn*-junctions. In the transition region, free electrons of the n-type semiconductor and excess holes of the p-type semiconductor are drifting into the respective opposite semiconductor, where they recombine. The consequence is a transition zone with a charge carrier depletion, which acts as a barrier and has an intrinsic capacitance. The charge carrier imbalance

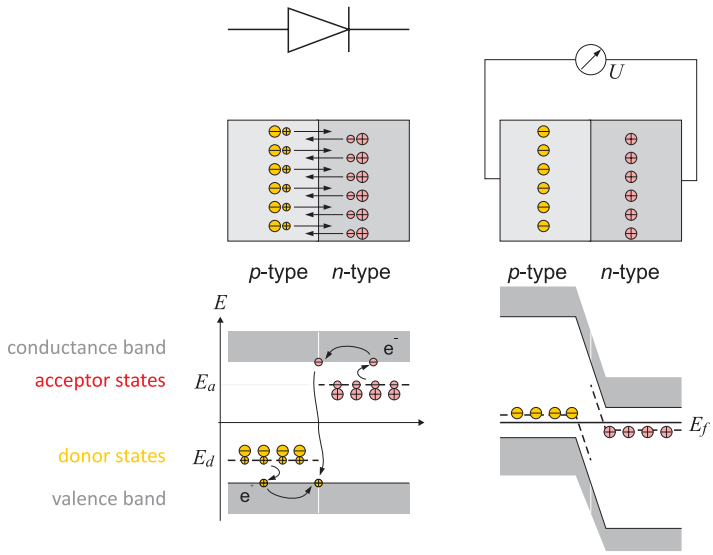

Figure 54.10: Joining a p-type and a n-type doped semiconductor (left) one observes a charge carrier redistribution across the pn transition (right).

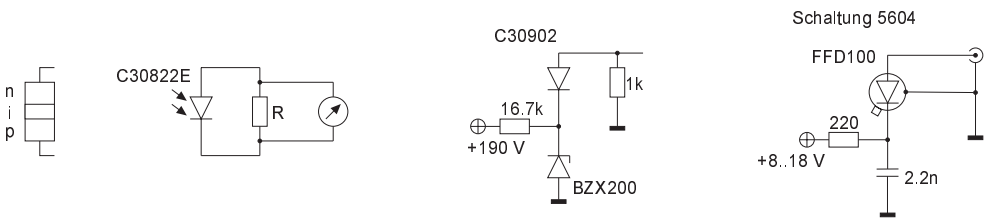

Figure 54.11: Circuit with photodiode.

gives rise to an electric field across the junction. The energy liberated during the recombination process can be dissipated via emission of light.

The reverse process is also possible: Via the intrinsic photoeffect, light irradiated into the pn-junction can lift electrons from the valence into the conduction band, thus generating pairs of charge carriers. Under the influence of the electric field across the junction, the holes flow to the edge of the p domain and the electrons flow to the n domain. This part of the current is called *drift current*. A smaller part, called the *diffusion current*, has its origin in the diffusion of the electron-hole pairs formed in the edge regions. Since these minority charge carriers have only a limited lifetime before they recombine, only the part of the current generated within a few units of the diffusion lengths near the charge carrier zone contributes. This results in an external photovoltaic voltage at the electrodes of the photodiode. If the photodiode is connected to a load, a photocurrent will flow, which is composed, as mentioned above, by the drift current of the charge carrier zone and the diffusion current from its edges.

The principal scheme of a pin diode is illustrated in Fig. 54.12(left): A weakly

doped intrinsic layer separates the p and the n conductor. This reduces the capacity of the barrier. The current at short circuit is proportional to the light power. A photodiode is always operated in blocking direction. A negative offset voltage reduces the capacity of the pn-junction.

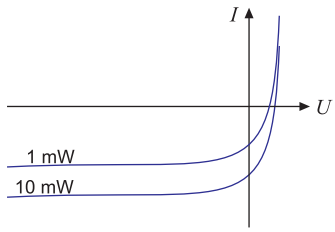

Figure 54.12: (code) U-I dependence of a photodiode.

Despite all measures the pn-junction capacity remains finite. One can model the impact of the pn-junction capacity via a replacement diagram. The voltage drop is

$$\frac{U(\omega)}{U_0} = \frac{R_L || \frac{1}{\imath\omega C}}{R_i + \left(R_L || \frac{1}{\imath\omega C}\right)} = \frac{\frac{R_i || R_L}{R_i}}{1 + \imath\omega C(R_i || R_L)} \ . \tag{54.9}$$

For high load resistances the frequency response obviously becomes load-independent. For small loads, $R_L < R_i$, the band width of the photodiode is dramatically increased to $\omega_g = 1/R_L C$. In the same time, however, the amplification drops to $V = R_L/R_i$.

54.2.2 Exercises

54.2.2.1 Ex: Photomultiplier

The anode of a photomultiplier tube is connected by a resistor of $R = 1\,\mathrm{k\Omega}$ to ground. The stray capacitance is 10 pF, the current amplification 10^6, and the anode rise time 1.5 ns. What is the peak amplitude and the halfwidth of the anode output pulse produced by a single photoelectron? What is the dc output current produced by 10^{-12} W cw radiation at $\lambda = 500\,\mathrm{nm}$, if the quantum efficiency of the cathode is $\eta = 0.2$ and the anode resistor $R = 10^6\,\Omega$? Estimate the necessary voltage amplification of a preamplifier (a) to produce 1 V pulses for single-photon counting; and (b) to read 1 V on a dc meter of the cw radiation?

54.2.2.2 Ex: Optical image intensifier

A manufacturer of a two-stage optical image intensifier states that incident intensities of 10^{-17} W at $\lambda = 500\,\mathrm{nm}$ can still be 'seen' on the phosphor screen of the output state. Estimate the minimum intensity amplification, if the quantum efficiency of the cathodes and the conversion efficiency of the phosphor screens are both 0.2 and the collection efficiency of light emitted by the phosphor screens is 0.1. The human eye needs at least 20 photons/s to observe a signal.

54.2.2.3 Ex: Photovoltaic detector

Estimate the maximum output voltage of an open photovoltaic detector at room temperature under 10 µW irradiation when the photocurrent of the shortened output is 50 µA and the dark current is 50 nA.

54.2.3 *Experiment: Taking the response function of a photodiode*

In this part of the lab course, we will learn to solder and set up simple electronic circuits. We will also learn how to identify the connections of a photodiode and mount into a case with BNC connectors. Finally, we will characterize the photodiode for use in future applications. Initially, we will work without offset voltage, later we will apply a voltage and identify its impact [1].

1. Connect an LED to a function generator and make it blink at low frequencies adjusting the offset and the amplitude of the output voltage. Shine the light onto your photodiode and monitor the signal on an oscilloscope. Explain your observations.

2. Reduce the amplitude and adjust the offset until you observe a sinusoidal signal. Increase the frequency and explain your observations. (Note that the response of LEDs is extremely fast (MHz).) Determine the bandwidth of your detector.

3. Measure the current at short circuit. Connect a $R = 10\,\mathrm{k\Omega}$ resistive load in parallel to the photodiode output and measure the voltage drop into this load.

4. Characterize the photodetector with respect to its sensitivity (in A/W) by varying the load.

5. How is the frequency response of the photodiode modified by the load? Measure bandwidth as a function of the load. Adjust the load until the detector (circuit including photodiode and resistor) has a bandwidth of 10 kHz (which is sufficient for many applications).

6. Apply a 10 V voltage in reverse direction and analyze again the sensitivity and the bandwidth of your photodetector. Note that the blinking LED can be replaced by a rotating chopper wheel.

Example of a measured characterization of a photodiode.

54.3 Introduction to radiofrequency components

54.3.1 VCOs and the generation of rf-sidebands

Voltage-controlled oscillators (*VCO*) serve to generate variable radiofrequencies. They are the basis for most function generators. A useful particularity of VCOs is the

[1] Datasheet for the Photodiode FFD100 see appendix Fig. 58.21,
data sheet for the Photodiode C30822E see appendix Fig. 58.22.

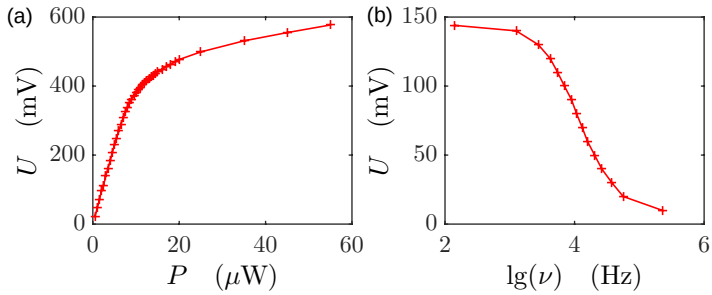

Figure 54.13: (a) Calibration of a photodiode, measured voltage as a function of the incident light power. (b) Low-pass behavior of a resistive charge of 90 kΩ.

possibility modulate the frequency and phase of an optical carrier wave by modulating the control voltage of a VCO at low frequency.

The modulation of the carrier wave generates sidebands. This can be seen by expanding the signal which carries the phase modulation into a Fourier series,

$$Ae^{\imath\omega t+\imath\beta\sin\Omega t} = Ae^{\imath\omega t}\sum_{k=-\infty}^{\infty} J_k(\beta)e^{\imath k\Omega t} \simeq Ae^{\imath\omega t} + J_1(\beta)Ae^{\imath\omega t+\imath\Omega t} + J_{-1}(\beta)Ae^{\imath\omega t-\imath\Omega t} \tag{54.10}$$

when the *modulation index* β is small. Here, $J_{-k}(\beta) = (-1)^k J_k(\beta)$ are the Bessel functions. This is in contrast to amplitude modulation, which is described by only two symmetric sidebands,

$$A(1+\beta\sin\Omega t)e^{\imath\omega t} = Ae^{\imath\omega t}\left(1+\frac{\beta}{2\imath}(e^{\imath\Omega t}-e^{-\imath\Omega t})\right) . \tag{54.11}$$

For *amplitude modulation* (*AM*) the beat signals between the carrier frequency and the two sidebands are in phase, i.e.,

$$\left|e^{\imath\omega t}+e^{\imath(\omega\pm\Omega)t}\right|^2 = 2+e^{\imath\Omega t}+e^{-\imath\Omega t} . \tag{54.12}$$

For *phase modulation* (*PM*) the beat signal are in counter-phase, i.e.,

$$\left|e^{\imath\omega t}+e^{\imath(\omega\pm\Omega)t+\imath\pi/2}\right|^2 = 2+\imath e^{\pm\imath\Omega t}-\imath e^{\mp\imath\Omega t} . \tag{54.13}$$

In the case of AM, the amplitude is blurred, but the phase at zero-crossing is well defined. In the case of PM, the amplitude in the antinode is sharp, but the phase of the zero-crossing is blurred.

It is not easy to transform AM into PM, and vice versa. In fact, the phase between carrier and sidebands can be varied, for example by adding an AC voltage, $\sqrt{2}e^{\imath\omega t+3\imath\pi/4}$ to the signal; however, it is not easy to transform synchronized phases into opposite phases.

As shown in Eq. (54.10), the spectrum of a signal with phase modulation (PM) consists of discrete lines, called sidebands, whose amplitudes are given by Bessel

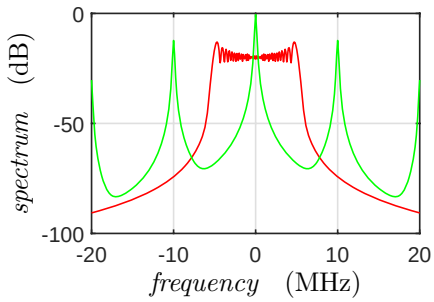

Figure 54.14: (code) Frequency spectra of a phase-modulated carrier frequency for $\Delta\omega = 5\,\text{MHz}$ modulation excursion and (red) $\omega = 100$ kHz modulation frequency ($\beta = \frac{\Delta\omega}{\Omega} = 50$) and (green) $\omega = 10\,\text{MHz}$ modulation frequency ($\beta = 0.5$). Furthermore, a $\gamma = 100\,\text{kHz}$ resolution linewidth is assumed.

functions,

$$S(\omega) = \sum_{k=-\infty}^{\infty} |A\mathcal{J}_k(\beta)|^2 \delta(\omega + k\Omega) \ . \tag{54.14}$$

In real systems, the sidebands have finite widths γ due to frequency noise or the finite resolution of the detectors. In the case of Lorentzian line profiles, we have,

$$S(\omega) = \sum_{k=-\infty}^{\infty} |A\mathcal{J}_k(\beta)|^2 \frac{\beta^2}{(\omega - k\Omega)^2 + \beta^2} \ . \tag{54.15}$$

54.3.2 Mixers

A *frequency mixer* is a nonlinear electrical circuit that creates new frequencies from two input signals, e.g. the sum and difference of the input frequencies. A device that has a non-linear (e.g. exponential) characteristic can act as a mixer. Passive mixers use one or more diodes and rely on their non-linear relation between voltage and current. Active mixers use an amplifying device (such as a transistor) to increase the strength of the product signal.

Mixers may be classified by their topology: An unbalanced mixer, in addition to producing a product signal, allows both input signals to pass through and appear as components in the output. A single-balanced mixer is arranged with one of its inputs applied to a balanced (differential) circuit so that either the local oscillator (LO) or signal input (RF) is suppressed at the output, but not both. A double-balanced mixer has both its inputs applied to differential circuits, so that neither of the input signals and only the product signal appears at the output. Double balanced mixers are more complex and require higher drive levels than unbalanced and single-balanced designs.

In practice, mixers are widely used to shift signals from one frequency range to another, a process known as *heterodyning*, in order to facilitate signal transmission or further signal processing. Frequency mixers are also used to modulate a carrier signal in radio transmitters, as product detectors, phase detectors, or frequency multipliers.

54.3.2.1 Diode

The non-linearity (or non-Ohmic behavior) of a diode can be used to create a simple unbalanced mixer producing the original frequencies as well as their sum and their difference. The current I through an ideal diode as a function of the voltage U across it is given by an exponential function,

$$I = I_0(e^{qU/k_BT} - 1) \ . \tag{54.16}$$

The exponential can be expanded as $e^x - 1 \simeq x + \frac{x^2}{2}$. Suppose that the sum of the two input signals $U_1 + U_2$ is applied to a diode, and that an output voltage is generated that is proportional to the current through the diode [e.g. by providing the voltage that is present across a resistor in series with the diode, as shown in Fig. 54.15(a)]. Then, disregarding the constants in the diode equation, the output voltage will have the form,

$$\begin{aligned} U_0 &= (U_1 + U_2) + \tfrac{1}{2}(U_1 + U_2)^2 + ... \\ &= (U_1 + U_2) + \tfrac{1}{2}(U_1^2 + 2U_1U_2 + U_2^2) + ... \ . \end{aligned} \tag{54.17}$$

The ellipsis represents all the higher powers of the sum which we assume to be negligible for small signals.

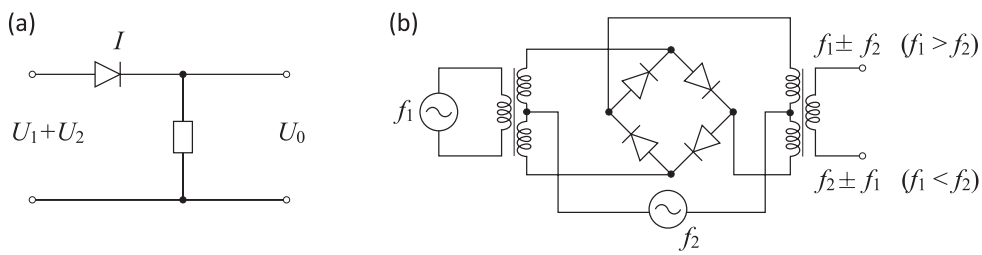

Figure 54.15: (a) Mixing two signal at a diode. (b) Schematic diagram of a double-balanced passive diode mixer (also known as a ring modulator). There is no output unless both f_1 and f_2 inputs are present, though f_2 (but not f_1) can be DC.

Suppose that two input sinusoids of different frequencies, $U_1 = \sin\omega_1 t$ and $U_2 = \sin\omega_2 t$ are fed into the diode. The signal U_0 becomes:

$$U_0 = (\sin\omega_1 t + \sin\omega_2 t) + \tfrac{1}{2}(\sin^2\omega_1 t + 2\sin\omega_1 t\sin\omega_2 t + \sin^2\omega_2 t) + ... \ . \tag{54.18}$$

Ignoring all terms except for the $\sin\omega_1 t\sin\omega_2 t$ term we get,

$$U_0 = 2\sin\omega_1 t\sin\omega_2 t + ... = \cos(\omega_1 t - \omega_2 t) - \cos(\omega_1 t + \omega_2 t) + ... \ , \tag{54.19}$$

demonstrating how new frequencies are created from the mixer.

54.3.2.2 Switching

Another form of mixer operates by switching, with the smaller input signal being passed inverted or non-inverted according to the phase of the local oscillator (LO).

This would be typical of the normal operating mode of a packaged double balanced mixer, with the local oscillator drive considerably higher than the signal amplitude.

The aim of a switching mixer is to achieve linear operation over the signal level by means of hard switching, driven by the local oscillator. Mathematically, the switching mixer is not much different from a multiplying mixer. Instead of the LO sine wave term, we would use the signum function. In the frequency domain, the switching mixer operation leads to the usual sum and difference frequencies, but also to further terms, e.g. $\pm 3f_{LO}$, $\pm 5f_{LO}$, etc.. The advantage of a switching mixer is that it can achieve (with the same effort) a lower noise figure and larger conversion gain. This is because the switching diodes or transistors act either like a small resistor (switch closed) or large resistor (switch open), and in both cases only a minimal noise is added. From the circuit perspective, many multiplying mixers can be used as switching mixers, just by increasing the LO amplitude.

54.3.2.3 Modulation and demodulation

Mixers are often used for modulation or demodulation purposes. Suppose we have on one hand a *carrier* signal, $U_{carrier} = \cos \omega t$, also called *local oscillator*. This may be a constant radiofrequency emitted by an antenna or a microwave. On the other hand, we have a reference signal which we want to transport somewhere else, $U_{ref} = \cos \Omega t$. Used as a modulator the mixer will simple multiply,

$$U_{mod} = U_{carrier} U_{ref} = \cos \omega t \cos \Omega t = \tfrac{1}{2} \cos[(\omega - \Omega)t] + \tfrac{1}{2} \cos[\omega + \Omega)t] \ . \tag{54.20}$$

Thus the mixer output contains two frequencies, the sum and the difference. Supposing that ω is a frequency in a range that can be radiated by antenna and Ω an acoustic frequency, both frequency components $\omega \pm \Omega \simeq \omega$ will be radiated.

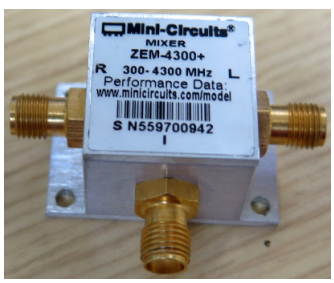

Figure 54.16: Picture of a radiofrequency mixer.

On the side of the receiver, who also has access to a synthesizer generating a signal $U_{carrier} = \cos \omega t$, we will use the mixer as a demodulator,

$$U_{demod} = U_{carrier} U_{mod} = \cos^2 \omega t \cos \Omega t = \tfrac{1}{2}(\cos 2\omega t + 1) \cos \Omega t \ . \tag{54.21}$$

If $\omega \gg \Omega$, the carrier oscillation can easily be removed by a low-pass filter,

$$U_{filtered} = \tfrac{1}{2} \cos \Omega t \propto U_{ref} \ . \tag{54.22}$$

That is, we recover the original information. And this holds even when the reference signal is (slowly) varying in amplitude or frequency, such as in the case of an acoustic signal [2]. Resolve Exc. 54.3.3.1.

54.3.2.4 Filtering with a mixer

Suppose we have a signal containing many frequency components (which may vary slowly in time), $U_{noisy}(t) = \sum_n A(\omega_n)e^{\imath\omega_n t}$ in complex notation, and that the signal we are interested in is an amplitude at a known particular frequency ω_0. By demodulating,

$$U_{sig}(t) = U_{noisy}(t)e^{-\imath\omega_0 t} = \sum_n A(\omega_n)e^{\imath\omega_n t}e^{-\imath\omega_0 t} = \sum_n A(\omega_n)e^{\imath(\omega_n-\omega_0)t} \ , \quad (54.23)$$

and low-pass filtering the lowest frequency component, i.e. $\omega_n - \omega_0 \simeq 0$,

$$U_{filtered} = A(\omega_0) \ . \quad (54.24)$$

This even holds for continuous noise spectra, $U_{noisy}(t) = \int A(\omega)e^{\imath\omega t}d\omega$, since,

$$U_{sig}(t) = U_{noisy}(t)e^{-\imath\omega_0 t} = \int_{-\infty}^{\infty} A(\omega)e^{\imath\omega t}e^{-\imath\omega_0 t}d\omega = \int_{-\infty}^{\infty} A(\omega+\omega_0)e^{\imath\omega t}d\omega \ , \quad (54.25)$$

and low-pass filtering with a filter bandwidth $\Delta\omega$,

$$U_{filtered} = \int_{-\Delta\omega}^{\Delta\omega} A(\omega+\omega_0)e^{\imath\omega t}d\omega \simeq A(\omega_0)2\Delta\omega \ . \quad (54.26)$$

Such techniques are widely used in lock-in amplifiers (see Sec. 54.4.3).

54.3.3 Exercises

54.3.3.1 Ex: Phase modulation

a. Show that it is not possible to construct a periodic phase modulation function such that the signal has only two sidebands.
b. Compare the spectra $\sum_{k=-\infty}^{\infty} J_k(M)e^{\imath k\Omega t} = e^{\imath M \sin\Omega t}$ and $\sum_{k=-\infty}^{\infty} |J_k(M)|e^{\imath k\Omega t}$. Can you detect phase modulation of a photodetector signal on a spectrum analyzer? How about amplitude modulation?

54.3.4 *Experiment: Creating sidebands on a radiofrequency*

In this exercise, we will understand the origin of sidebands as we'll see them emerge from a modulation spectrum when we gradually increase the modulation index [3].

1. Take a VCO, for example, ZOS-100+ from MiniCircuits. Study the datasheet and drive the VCO with an AC voltage. Vary the amplitude and the frequency of the voltage and observe the output signal of the VCO on a spectrum analyzer.

[2] In complex notation, $U_{in} = e^{\imath\omega t}$, $U_{mod} = U_{in}e^{\imath\Omega t} = e^{\imath(\omega+\Omega)t}$, $U_{demod} = U_{mod}e^{-\imath\omega t} = e^{\imath\Omega t}$.
[3] Datasheet for the VCO see appendix Fig. 58.16,
data sheet for the variable attenuator see appendix Fig. 58.17,
data sheet for the mixer see appendix data sheet Fig. 58.19.

2. Try to understand the spectrum observing the limiting cases $\Omega \gg \Delta\omega$ and $\Omega \ll \Delta\omega$. How can you read Ω and Δf from the spectra in both cases?

3. Write a MATLAB program to simulate the spectrum.

sample-and-hold circuit Solder on euroboard

54.4.2 Box-car integrator

box-car integrator Solder on euroboard

54.4.3 Lock-in amplifier

An *lock-in amplifier* (also called a phase-sensitive rectifier or *mixer*) is an amplifier that can measure a weak electrical signal by modulating the signal by a reference signal with a known frequency and phase. The device represents a bandpass filter with an extremely narrow bandwidth and, therefore, improves the signal-to-noise ratio (SNR). DC or AC noise components are efficiently filtered.

Download an illustration of the working principle of a *lock-in amplifier* here.

54.4.4 *Experiment: Building a lock-in amplifier*

Let's now build a lock-in amplifier. The principle is illustrated in Fig. 54.17(a). The sinusoidal signal discriminated at a non-linear line is switched on and off in the lock-in by a switch. At the same time, the inverted signal (i.e., phase shifted by 180°) is turned off and on. Both signals are combined and low-pass filtered. As Fig. 54.17(b) shows, the sign of the filtered signal depends on the phase between the discriminator and the TTL signal controlling the switch [4]

1. Create the circuit sketched in Fig. 54.17(a) on a circuit board and test it by varying the phase between the modulated output signal and the TTL signal provided by a function generator.

Chapter 55

Quantum optics and optical interferometry

The objective of this chapter is to introduce the basics of optical *interferometry*. We will see, how to match the light modes in optical cavities and fibers, and to phase-match the wavefronts of two laser beams in order to detect their frequency beating with a photodetector. Furthermore, he will learn how to handle essential tools of *quantum electronics*, such as a piezo-electric transducer, an electro-optic modulator, and an acousto-optic modulator, used in interferometry, as discussed in Secs. 55.4.1 to 55.4. Interferometers have versatile applications such as 1. for the detection of very small length variations (as for example caused by gravitational waves), 2. as vibration and inertial sensors, or in 3. the transmission of information (radio).

55.1 Introduction to interferometry

55.1.1 Beam splitter in $\mathcal{S}$-representation

The essential component of any interferometer is the (non-polarizing) *beam splitter*.

We consider a classical lossless beam splitter with electric fields incident at both its inputs. The two output fields E_c and E_d are linearly related to the inputs through

$$\begin{pmatrix} \mathcal{E}_c \\ \mathcal{E}_d \end{pmatrix} = \begin{pmatrix} t_{ac} & r_{bc} \\ r_{ad} & t_{bd} \end{pmatrix} \begin{pmatrix} \mathcal{E}_a \\ \mathcal{E}_b \end{pmatrix} , \tag{55.1}$$

where the 2×2 element is the beam splitter matrix. r and t are the reflectance and transmittance along a particular path through the beam splitter, that path being indicated by the subscripts.

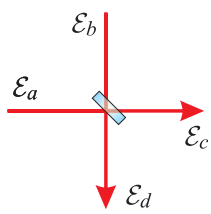

Figure 55.1: Beam splitter.

Assuming the beam splitter removes no energy from the light beams, the total output energy can be equated with the total input energy, reading

$$|\mathcal{E}_c|^2 + |\mathcal{E}_d|^2 = |t_{ac}\mathcal{E}_a + r_{bc}\mathcal{E}_b|^2 + |r_{ad}\mathcal{E}_a + t_{bd}\mathcal{E}_b|^2 = |\mathcal{E}_a|^2 + |\mathcal{E}_b|^2 \ . \tag{55.2}$$

Factorizing the expression in the center we obtain terms in $|\mathcal{E}_a|^2$, $|\mathcal{E}_b|^2$, $|\mathcal{E}_a\mathcal{E}_b^*|$, and $|\mathcal{E}_a^*\mathcal{E}_b|^2$. Comparing with the terms in the right-hand side expression we find that the equation can only be true for any field amplitudes, if the following relationships between reflectance and transmittance are satisfied,

$$\boxed{|t_{ac}|^2 + |r_{ad}|^2 = 1 = |t_{bd}|^2 + |r_{bc}|^2 \quad \text{and} \quad t_{ac}r_{bc}^* + r_{ad}t_{bd}^* = 0} \ . \tag{55.3}$$

We write each r and t as a complex number having an amplitude and phase factor accounting for possible phase shifts of a beam as it reflects or transmits at the beam splitting surface. From the second equation (55.3) we obtain,

$$t_{ac}r_{bc}^* + t_{bd}^*r_{ad} = |t_{ac}||r_{bc}|e^{\imath(\phi_{ac}-\phi_{bc})} + |t_{bd}||r_{ad}|e^{\imath(\phi_{ad}-\phi_{bd})} = 0 \ . \tag{55.4}$$

This expression can only be true if,

$$\phi_{ad} - \phi_{bd} + \phi_{bc} - \phi_{ac} = \pi \qquad \text{and} \qquad \frac{|r_{bc}|}{|t_{bd}|} = \frac{|r_{ad}|}{|t_{ac}|} \ . \tag{55.5}$$

Comparing the second equation (55.5) with the first two equations (55.3) we conclude,

$$|r_{ac}| = |r_{bd}| \equiv \sqrt{R} \qquad \text{and} \qquad |t_{ad}| = |t_{bc}| \equiv \sqrt{T} \ , \tag{55.6}$$

where we defined the reflection and the transmission of the beam splitter. It follows that

$$\boxed{R + T = 1} \ . \tag{55.7}$$

Without loss of generality, we may set $\phi_{bd} \equiv 0$, so that $\phi_{ac} = \phi_{ad} - \phi_{bc} - \pi$. Then,

$$\mathcal{S} = \begin{pmatrix} t_{ac} & r_{bc} \\ r_{ad} & t_{bd} \end{pmatrix} = \begin{pmatrix} -\sqrt{T}e^{\imath(\phi_{ad}-\phi_{bc})} & \sqrt{R}e^{\imath\phi_{bc}} \\ \sqrt{R}e^{\imath\phi_{ad}} & \sqrt{T} \end{pmatrix} \ . \tag{55.8}$$

Until, now the calculations were totally general, so that the above results hold for any type of beam splitting device. Let us now give a concrete example.

Example 384 (*Beam splitters*): For beam splitting at dielectric interfaces in particular we know that the electric field amplitude does not suffer phase shifts upon transmission, $\phi_{ac} \equiv 0$, implying $\phi_{ad} - \phi_{bc} = \pi$. Hence,

$$\mathcal{S} = \begin{pmatrix} \sqrt{T} & \sqrt{R}e^{\imath\phi_{bc}} \\ \sqrt{R}e^{\imath(\phi_{bc}+\pi)} & \sqrt{T} \end{pmatrix} \ . \tag{55.9}$$

Thus, the two off-diagonal elements are 180° out of phase. For the situation depicted in Fig. 55.1 one of the reflections occurs at an optical more dilute medium. For this reflection the phase shift is 0. But the other reflection occurs at an optical denser medium and therefore suffers a 180° phase shift. With this constraints the matrix describing a lossless beam splitter reads,

$$\boxed{\begin{pmatrix} \mathcal{E}_c \\ \mathcal{E}_d \end{pmatrix} = \begin{pmatrix} \sqrt{T} & \sqrt{R} \\ -\sqrt{R} & \sqrt{T} \end{pmatrix} \begin{pmatrix} \mathcal{E}_a \\ \mathcal{E}_b \end{pmatrix}} \ . \tag{55.10}$$

55.1.2 Piezo-electric actuator

The piezo-electricity effect describes the reciprocal action between mechanical pressure (from Greek: piézein - press) and electrical voltage in solids. It is based on the phenomenon that occurs in the regular deformation of certain piezoelectric materials: at the surface occur displacements of electric charges creating microscopic dipoles inside the unit cells. The sum over all the unit cells of the crystal leads to a macroscopically measurable electrical voltage. The deformation should be directed, which means, that the pressure is not applied from all sides on the crystal, but for example only on opposite sides.

On the other hand, by applying an electric voltage, a crystal (or piezo-ceramic element) may be deformed. Like any other solid body, piezo-electric crystals can execute mechanical vibrations. In a *piezo-electric actuator* (or piezo transducer PZT), these vibrations can be electrically excited. The frequency of the vibrations depend only on the speed of sound (which is a constant of the material) and the dimensions of the actuator. Therefore, actuators are also suitable for realizing oscillators (for example, quartz crystals). The piezo-electric effect can only occur in non-conductive materials (e.g., lead titanate zirconate).

When a voltage is applied to the piezo-ceramic in the direction of polarization, we observe an expansion in this direction and a perpendicular contraction. Depending on the employed material and the coefficient for piezo-electric strain d, stretches up to $\Delta l/l = 0.15\%$ can be obtained:

$$\Delta l = d\mathcal{E} l_0 \ , \tag{55.11}$$

where l_0 is the length of the actuator and $E = U/l_0$ the amplitude of the electric field. The elongation effect is therefore proportional to the field strength and the overall length of the actuator. To achieve large stretches with manageable electrical voltages, actuator discs are often stacked (mechanical circuit in series and electric circuit in parallel).

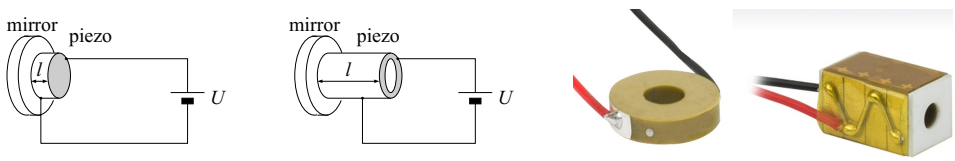

Figure 55.2: (Left) Scheme of mirrors mounted on a piezo actuator having the shape of a disc or a ring. (Right) Photos of a ring piezo and a piezo stack.

Negative voltages with respect to the orientation of the discs cause a contraction. However, negative voltages can also cause a change in the polarization state of the piezo and should therefore be avoided! In electrical circuits, piezoelectric actuators introduce a capacitance with a relative dielectric constant between 600 and 5000 and an internal resistance of about 10^8 Ω depending on the material. See Exc. 55.1.10.1.

55.1.3 Michelson and Mach-Zehnder interferometer

Interferometry is a technique exploiting the interference of waves coherently split and recombined by beam splitters. Sufficiently stable interferometers allow to visualize

variations of the path lengths of two or more partial waves following different pathways as an alteration of constructive and destructive interference.

The two most common types of interferometers are the *Michelson interferometer* and the *Mach-Zehnder interferometer* are depicted in Fig. 55.3. The advantages of the Michelson interferometer are an easy alignment and the need of only one beamsplitter. The advantage of the Mach-Zehnder interferometer is a direct optical access to both output ports of the interferometer. The following treatment applies to both types.

The field amplitude of a laser beam, $\mathcal{E}_i$, with frequency, $\omega = ck$, is divided by a beam splitter (reflectivity $\sqrt{R}$) into a transmitted $\mathcal{E}_t$ and a reflected beam $\mathcal{E}_r$,

$$\mathcal{E}_r = \sqrt{R_1}\mathcal{E}_i \qquad \text{and} \qquad \mathcal{E}_t = \sqrt{1-R_1}\mathcal{E}_i \ , \tag{55.12}$$

where we disregard possible phase-shifts upon reflection at optically dilute interface. The energy is obviously conserved, $|\mathcal{E}_r|^2 + |\mathcal{E}_t|^2 = \mathcal{E}_i^2$.

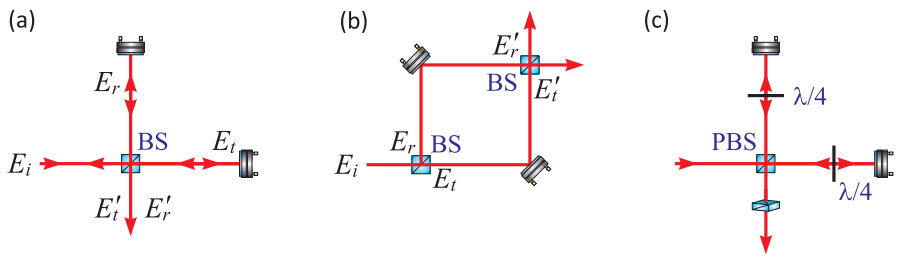

Figure 55.3: Principle of a two-beam interferometer: (a) Michelson interferometer and (b) Mach-Zehnder interferometer using non-polarizing beamsplitters. (c) Michelson interferometer using a polarizing beamsplitter.

We consider the Mach-Zehnder interferometer sketched in Fig. 55.3 with one arm of length L_r, which can be varied by a piezo, and the other arm of length L_t,

$$\mathcal{E}_r' = \mathcal{E}_r e^{\imath k L_r} \qquad \text{and} \qquad \mathcal{E}_t' = \mathcal{E}_t e^{\imath k L_t} \ . \tag{55.13}$$

The beams are recombined on a second beam splitter and sent to a photodetector, whose signal is,

$$\begin{aligned} I &\propto |\sqrt{R_2}\mathcal{E}_r' + \sqrt{1-R_2}\mathcal{E}_t'|^2 \\ &= |\sqrt{R_2}\sqrt{R_1}e^{\imath k L_r} + \sqrt{1-R_2}\sqrt{1-R_1}e^{\imath k L_t}|^2 \mathcal{E}_i^2 \ . \end{aligned} \tag{55.14}$$

Hence,

$$I \propto R_2 R_1 + (1-R_2)(1-R_1) + 2\sqrt{R_2}\sqrt{R_1}\sqrt{1-R_2}\sqrt{1-R_1}\cos[2k(L_t - L_r)] \ . \tag{55.15}$$

For reflectivities of $R_1 = R_2 = 50\%$, we get,

$$\boxed{I \propto \tfrac{1}{2} + \tfrac{1}{2}\cos[2k(L_t - L_r)]} \ . \tag{55.16}$$

It is important to realize that, while superpositions of light field amplitudes in the same mode interfere, *superpositions of light field amplitudes in different modes*

do not. For example, the superposition of two plane waves with equal frequency and polarization interferes,

$$\left|\begin{pmatrix}\mathcal{E}_1+\mathcal{E}_2\\0\end{pmatrix}\right|^2 = |\mathcal{E}_1+\mathcal{E}_2|^2 \ , \tag{55.17}$$

while the superposition of two plane waves with equal frequency but different polarizations does not,

$$\left|\begin{pmatrix}\mathcal{E}_1\\0\end{pmatrix}+\begin{pmatrix}0\\\mathcal{E}_2\end{pmatrix}\right|^2 = |\mathcal{E}_1|^2+|\mathcal{E}_2|^2 \ . \tag{55.18}$$

Solve the Excs. 55.1.10.2 to 55.1.10.4.

55.1.4 Coherence and spectrum of a light field

We have seen above that interferometers probe the electric field amplitude rather than the intensity. For this reason, they are suited to measure the first-order correlation function $g^{(1)}(\tau)$ and the emission spectrum, which are defined by,

$$g^{(1)}(\tau) \equiv \frac{\langle \mathcal{E}^-(t)\mathcal{E}^+(t+\tau)\rangle}{\langle \mathcal{E}^-(t)\mathcal{E}^+(t)\rangle} \qquad \text{and} \qquad S_{\mathcal{E}}(\omega) \equiv \mathcal{F}[g^{(1)}(\tau)] \ . \tag{55.19}$$

As an example, Fig. 55.4 shows the aurocorrelation function and spectrum of a simultaneously amplitude- and phase-modulated laser beam, $\mathcal{E}(t) = (1+n\cos\omega_n t)e^{\imath m \sin\omega_m t}$.

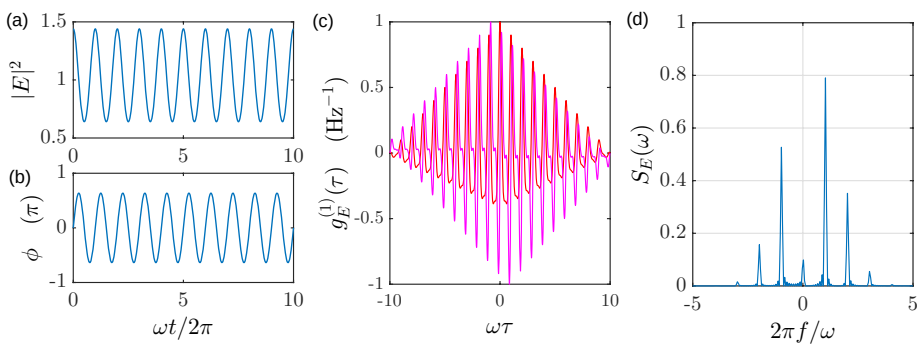

Figure 55.4: (code) (a) Amplitude and (b) phase of the electric field, with $n = 0.2$, $m = 1$, and $\omega_n = \omega_m = (2\pi)\ 1\,\mathrm{Hz}$. (c) Aurocorrelation function and (d) spectrum of the light field.

55.1.5 Birefringent interferometer

A *birefringent interferometer* or *Lyot filter* consists of one or more birefringent crystals mounted onto a rotation frame between two polarizers. Let n_o and $n_e = n_o + \Delta n$ be the refractive indices of the normal and the extraordinary axis, respectively. The corresponding Jones matrix is then,

$$\mathcal{M} = \begin{pmatrix}1&0\\0&0\end{pmatrix}\begin{pmatrix}\cos\phi&\sin\phi\\-\sin\phi&\cos\phi\end{pmatrix}\begin{pmatrix}e^{\imath k_0 L}&0\\0&e^{\imath k_e L}\end{pmatrix}\begin{pmatrix}\cos\phi&-\sin\phi\\\sin\phi&\cos\phi\end{pmatrix}\begin{pmatrix}1&0\\0&0\end{pmatrix} \ , \tag{55.20}$$

Such that,

$$\begin{pmatrix} \mathcal{E}_{out} \\ 0 \end{pmatrix} = \mathcal{M} \begin{pmatrix} \mathcal{E}_{in} \\ 0 \end{pmatrix} = \begin{pmatrix} \left(e^{\imath k_0 L} \cos^2 \phi + e^{\imath k_e L} \sin^2 \phi\right) \mathcal{E}_{in} \\ 0 \end{pmatrix} . \tag{55.21}$$

By trigonometric transformations it is possible to show, that the transmission $T \equiv |\mathcal{E}_{out}/\mathcal{E}_{in}|^2$ is,

$$\boxed{T(\lambda, \phi) = |e^{\imath k_0 L} \cos^2 \phi + e^{\imath k_e L} \sin^2 \phi|^2 = 1 - \sin^2 2\phi \sin^2 \tfrac{\pi L \Delta n}{\lambda}} . \tag{55.22}$$

For $\phi = 45°$ the transmission becomes simply,

$$T(\lambda, \tfrac{\pi}{4}) = \cos^2 \tfrac{\pi L \Delta n}{\lambda} . \tag{55.23}$$

In practice Lyot filters are often used, placed under the Brewster angle inside ring cavity lasers, as frequency selective elements. Frequently, birefringent plates of different thicknesses are stacked,

$$T(\lambda) = T_1(\lambda) T_2(\lambda) , \tag{55.24}$$

in order to increase the frequency selectivity. Furthermore, when the axis of the birefringent plates are rotated by fixed angles $\Delta\alpha$ with respect to each other,

$$T(\lambda, \alpha) = T_1(\lambda, \alpha) T_2(\lambda, \alpha + \Delta\alpha) , \tag{55.25}$$

the frequency of maximum transmission can be tuned by simply rotating the stack as a whole by an angle α. See 55.1.10.5.

A Lyot filter can be considered an interferometer, because it splits and recombines the polarization vector of a light beam in two parts following the ordinary and the extraordinary axis of the birefringent crystal. This is somewhat analogous to the Michelson interferometer depicted in Fig. 55.3(c).

55.1.6 Optical resonators

Optical cavities consist of an arrangement of mirrors reflecting the light beams in such a way, that they form a closed path. Since light that entered the cavity is performing there many round trips before it is transmitted again or absorbed, the light power is considerably enhanced, i.e. cavities can store light.

Light which is to resonate in the cavity must satisfy the boundary condition, that the mirror surfaces coincide with standing wave nodes. Therefore, in a cavity with length L only a discrete spectrum of wavelengths $N\frac{\lambda}{2} = L$ can be resonantly amplified, where N is a natural number. Because of this property, cavity are often used as frequency filters or optical spectrum analyzers: Only frequencies $\nu = N\delta_{fsr}$ are transmitted, where

$$\boxed{\delta_{fsr} = c/2L} \tag{55.26}$$

is the free spectral range of the cavity.

Cavities are characterized on one hand by their geometry, i.e. the curvature and the distance of their mirrors, and on the other hand by their finesse, which is given by the reflectivity of their mirrors. Let us first study the finesse. Regarding the cavity

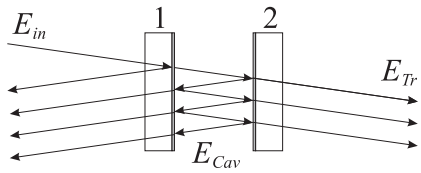

Figure 55.5: Multiple interference in an optical cavity.

as a multipass interferometer [245], we can derive expressions for the reflected and transmitted intensity as a function of frequency [1]. The so-called *Airy formula* for transmission and reflection are,

$$\frac{\mathcal{E}_{refl}}{\mathcal{E}_{in}} = r_1 - \frac{t_1^2 r_2 e^{2\imath kL}}{1 - r_1 r_2 e^{2\imath kL}} \quad \text{and} \quad \frac{\mathcal{E}_{trns}}{\mathcal{E}_{in}} = \frac{t_1 t_2 e^{\imath kL}}{1 - r_1 r_2 e^{2\imath kL}} \ . \tag{55.27}$$

In terms of intensity, assuming identical mirrors, $r_1 = r_2 = \sqrt{R}$ and $t_1 = t_2 = \sqrt{T}$, and neglecting possible absorptive losses, $A = 1 - R - T = 0$,

$$\boxed{\frac{I_{refl}}{I_{in}} = \frac{(\frac{2F}{\pi})^2 \sin^2 \frac{\Delta}{2\delta_{fsr}}}{1 + (\frac{2F}{\pi})^2 \sin^2 \frac{\Delta}{2\delta_{fsr}}} \quad \text{and} \quad \frac{I_{trns}}{I_{in}} = \frac{1}{1 + (\frac{2F}{\pi})^2 \sin^2 \frac{\Delta}{2\delta_{fsr}}}} \ , \tag{55.28}$$

where R is the reflectivity of a mirror and $\delta = 4\pi L/\lambda = 2\pi\nu/\delta_{fsr}$. The transmission curve of a cavity has a finite transmission bandwidth $\Delta\nu$, which depends on the reflectivity of the mirrors. The finesse of a cavity is defined by

$$\boxed{F \equiv \frac{2\pi\delta_{fsr}}{\kappa} = \frac{\pi\sqrt{R}}{1 - R}} \ . \tag{55.29}$$

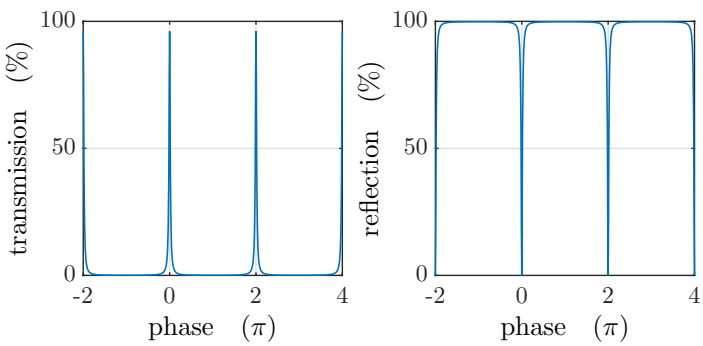

Figure 55.6: (code) Transmission and reflection through a resonator.

Note that factors others than the finite reflectivity may degrade the finesse of a cavity. For example, an imperfect mirror flatness (commonly specified as λ/F_{surf})

[1] See script on *Electrodynamics* (2023), Exc. 7.3.6.16.

reduces the finesse to [245],

$$F_{tot} = \left(\frac{1}{F} + \frac{1}{F_{surf}}\right)^{-1} . \tag{55.30}$$

.

The geometry of a cavity must satisfy certain conditions, in order to be stable [526]. Besides the main longitudinal modes a cavity possesses transverse modes of the order TEM_{mn}, whose frequencies are given by [2],

$$\nu/\delta_{fsr} = (q+1) + \frac{m+n+1}{\pi} \arccos \sqrt{\left(1 - \frac{L}{\rho_1}\right)\left(1 - \frac{L}{\rho_2}\right)} . \tag{55.31}$$

A *confocal cavity* with degenerate transverse modes, $\rho_1 = \rho_2 = L$, is particularly suited as optical spectrum analyzer.

The diameter of the beam waist in the cavity is,

$$w_0 = \sqrt[4]{\left(\frac{\lambda}{\pi}\right)^2 \frac{L(\rho_1 - L)(\rho_2 - L)(\rho_1 + \rho_2 - L)}{(\rho_1 + \rho_2 - 2L)^2}} . \tag{55.32}$$

For an optimal coupling of the light into the cavity the Gaussian laser beam must be matched to the cavity's geometry of the cavity, i.e. diameter and divergence of the laser beam must be adapted to the cavity mode with a suitable arrangement of lenses [246, 526]. See Excs. 55.1.10.6 to 55.1.10.11.

55.1.7 Dielectric mirrors and filters

Dielectric mirrors and filters are multiple beam interferometers in a similar sense as Fabry-Pérot cavities. They consist of stacks of thin dielectric layers with alternating refraction indices [3].

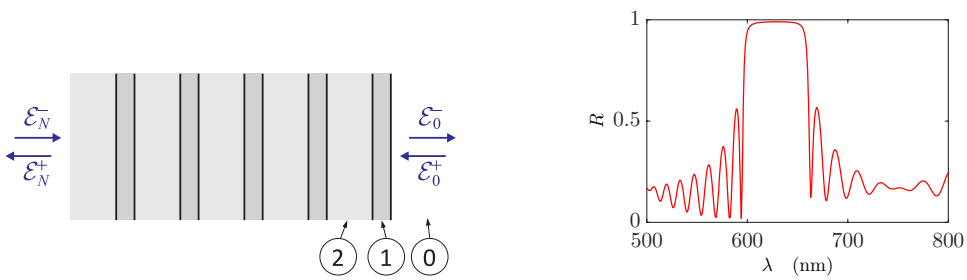

Figure 55.7: (code) Reflection by a high reflecting mirror made of 10 layers with $n_1 = 2.4$ and $\Delta z_1 = 80\,\mathrm{nm}$ alternating with 10 layers with $n_2 = 1.5$ and $\Delta z_2 = 500\,\mathrm{nm}$. The absorption coefficient for each layer is supposed to be $\alpha = 0.2\%$. The beam impinges from vacuum, $n_0 = 1$.

Reflections of $R = 99.999\%$ can be reached which, applied of superpolished mirrors, allow for the construction of cavities with finesse $F > 300000$. On the other

[2] See script on *Electrodynamics* (2023), Sec. 7.4.2.2.
[3] See script on *Electrodynamics* (2023), Sec. 7.1.7.

anti-reflection coatings can be applied to surfaces reducing their reflections to below $R = 0.1\%$. See Excs. 55.1.10.12 and 55.1.10.13 [246, 576].

55.1.8 Optical fibers

An *optical fiber* is a waveguide in which light is guided by internal total reflection. The total reflection occurs between layers with different refractive indices called *fiber core* and *fiber cladding*. The core is the central region of the optical fiber where the light is guided. In order to create guiding conditions, the refractive index of the core must be higher than the one of the cladding. The cladding diameter is typically 8 to 10 times the *mode field diameter* (MFD) of the fundamental mode. In general, MFD is greater than the physical diameter of the fiber core, which means that some optical power is always guided by the fiber cladding as an evanescent wave.

The *cut-off wavelength* λ_{co} of an optical fiber is the wavelength above which a guided mode of a waveguide ceases to exist. For wavelength longer than λ_{co} an optical fiber becomes single-mode. At wavelengths shorter than λ_{co} several optical modes may propagate and the fiber becomes multi-mode. The cut-off wavelength is directly related to the core diameter of the fiber $\lambda_{co} \propto \emptyset$. For

$$\tfrac{\lambda}{2} < \emptyset < \lambda \qquad \text{or equivalently} \qquad \emptyset < \lambda < 2\emptyset \tag{55.33}$$

the fiber is single-mode. For $\lambda > 2\emptyset$ no guided mode exists and for $\emptyset > \lambda$ the fiber becomes multimode.

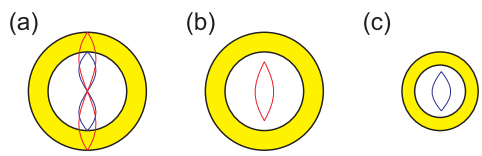

Figure 55.8: Mono-mode waveguiding by optical fibers.

The *numerical aperture* is a measure of the acceptance angle of the fiber. It is very important because it determines how strongly a fiber guides light, and so how resistant it is to bend-induced losses. The numerical aperture can be defined by the acceptance angle of the fiber, though as this is highly diverging in space it is rather complicated to reach a simple definition. It is most convenient to define the NA in terms of the relative indices of core and cladding glass forming the fiber waveguide:

$$NA = \sin\tfrac{\theta_a}{2} = \sqrt{n_{core}^2 - n_{clad}^2} \simeq \sqrt{2n_{core}^2 \delta n}\ , \tag{55.34}$$

where δn is the index difference between the core and cladding. An optical fiber with 'high' numerical aperture will confine light more strongly in the core, and so support guidance further above cut-off. This attribute has two important effects: (a) it will be single-mode over a greater range of wavelengths than is possible with a fiber with a 'low' numerical aperture fiber and (b) it will still guide a single-mode when coiled or bent to a smaller diameter.

55.1.8.1 Multi-mode, mono-mode, and polarization maintaining fibers

Many types of fibers are currently available for a large variety of applications.

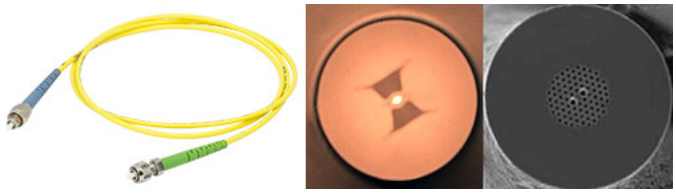

Figure 55.9: (Left) Fiber patch cord, (center) cross section of a bow-tie polarization maintaining fiber, and (right) cross section of a photonic crystal fiber.

55.1.9 Laser gyroscope and the Sagnac effect

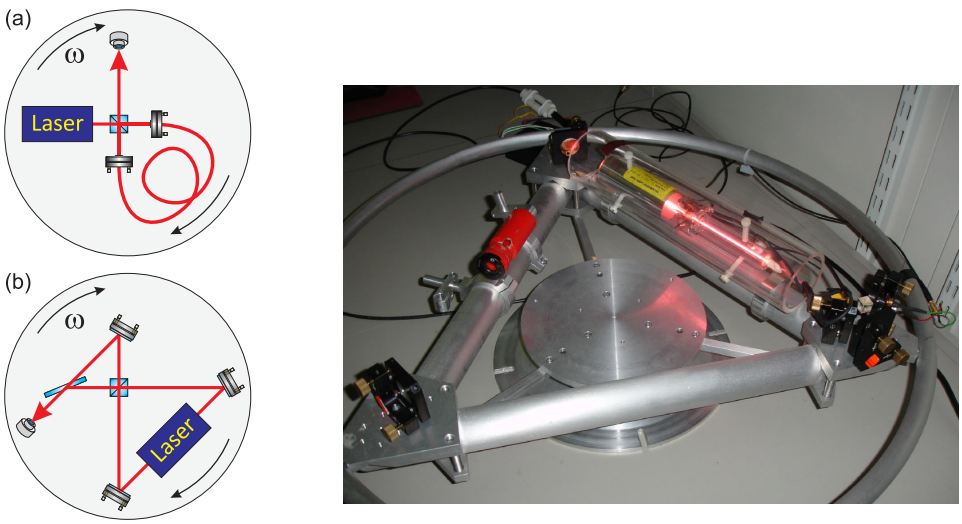

Figure 55.10: (a) Principle scheme of a fiber-based Sagnac interferometer. (b,c) Laser gyroscope realized with a HeNe gain tube.

Gyroscopes are based on the *Sagnac effect*. They are based on a ring cavity mounted on a rotating stage, as shown in Fig. 55.10(a). Let us, for simplicity first consider a circular path for the light beam (e.g. a fiber-based ring cavity) rotating at an angular velocity Ω. Then the time needed for the light beam to travel in either one of the two directions is,

$$t_\pm = \frac{(2\pi \pm \Omega t_\pm)r}{c} = \frac{2\pi r}{c \mp \Omega r} \ , \tag{55.35}$$

that is,

$$\Delta t \equiv t_+ - t_- = \frac{4\pi r^2 \Omega}{c^2 - \Omega^2 r^2} \simeq \frac{4\pi r^2 \Omega}{c^2} \equiv \frac{4A\Omega}{c^2} \ , \tag{55.36}$$

where A is the area enclosed by the path. This formula can be generalized to arbitrary paths.

For example, assuming an interferometer with $A = 1\,\mathrm{m}^2$ at rest in an Earth-based system, $\Omega \simeq 2\pi/24\,\mathrm{h}$, the time difference for light propagating along the two directions

is $\Delta t \approx 3 \cdot 10^{-21}$ s and the path difference $\Delta L = c\Delta t \approx 100$ fm. The frequency shift is,

$$\boxed{\Delta v = k(v_+ - v_-) = k(2\Omega r) = \frac{\sqrt{4\pi A}\Omega}{\lambda}}\,, \tag{55.37}$$

yielding for the given example of an Earth-based interferometer $\Delta\nu \approx 400$ Hz.

55.1.10 Exercises

55.1.10.1 Ex: Characterizing a piezo actuator

In order to characterize a recently purchased piezo actuator (Thorlabs, TA0505D024W) a Scientific Initiation student sets up a Michelson interferometer driven by a HeNe laser beam. Scanning the voltage applied to the piezo through the entire permitted range, he observes 8.8 oscillations of the interference fringes. What is the piezo displacement per volt?

55.1.10.2 Ex: Michelson interferometer

The figure 55.11 shows a Michelson interferometer containing in one arm an airtight 5 cm long cell with glass windows. Light with wavelength $\lambda = 500$ nm is used. After the cell has been evacuated, the interference pattern shifts by 60 fringes. Use this information to calculate the refractive index of air at atmospheric pressure. With what accuracy can you determine the refractive index with this method?

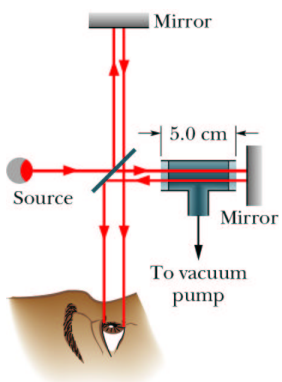

Figure 55.11:

55.1.10.3 Ex: Michelson interferometer

Assume that a signal-to-noise ratio of 50 has been achieved in measuring the fringe pattern of a Michelson interferometer with one continuously moving mirror. Estimate the minimum path length ΔL that the mirror has to travel in order to reach an accuracy of $\Delta\lambda = 10^{-4}$ nm in the measurement of a laser wavelength at $\lambda = 600$ nm.

55.1.10.4 Ex: Rotating the polarization with a Mach-Zehnder interferometer

Using the Jones matrix formalism demonstrate how to use the Mach-Zehnder interferometer setup sketched in the figure to rotate the polarization of a linearly polarized laser beam in an electronically controlled way using a piezo actuator mounted in ones of the interferometer arms.

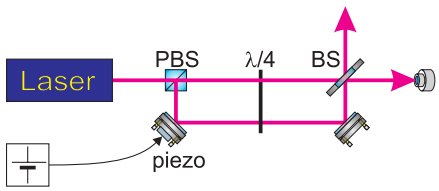

Figure 55.12:

55.1.10.5 Ex: Lyot filter

Consider a Lyot filter with two plates ($L_1 = 1\,\text{mm}$ and $L_2 = 4\,\text{mm}$) with the refraction indices $n_o = 1.40$ in the fast axis and $n_e = 1.45$ in the slow axis.
a. Calculate the transmission peaks of the Lyot filter as a function of λ for the rotation angle $\phi = 45°$.
b. Determine the transmitted intensity $I(\phi)$ as a function of the rotation angle ϕ for a fixed wavelength λ. What is the contrast of the transmitted intensity for arbitrary values of λ if the absorption losses are 2%?

55.1.10.6 Ex: Wedge-shaped etalon

A beam of light of wavelength $\lambda = 683\,\text{nm}$ with large diameter is incident perpendicularly on the first of two quadratic plates. Each plate has the edge length 120 mm; at the left edge the plates touch each other, at the right edge they are separated by a wire of $d_w = 0.048\,\text{mm}$ in diameter. The air between the plates acts as a thin layer.
a. How many interference fringes does an observer see from above this arrangement?
b. Now suppose that the incident light be white. Will the interference pattern at the far left be bright or dark?
c. Starting from the left edge there will be a series of interference minima, whose position depend on the wavelength of the light. For what light color (blue or red) will the minimum be closer to the edge?

55.1.10.7 Ex: Fabry-Perot interferometer

The dielectric coatings of each plate of a Fabry-Perot interferometer have the following specifications: $R = 98\%$, $A = 0.3\%$. The flatness of the surfaces is $\lambda/100$ at $\lambda = 500\,\text{nm}$.
a. Estimate the finesse from (55.27) and (55.30), the maximum transmission, and the spectral resolution of the FPI for a plate separation of 5 mm.

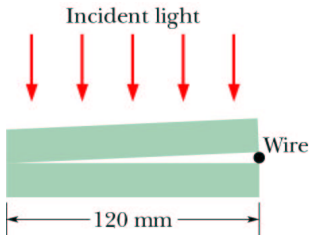

Figure 55.13:

b. Show that, for a given absorption, the transmitted intensity decreases with increasing reflectivity. Explain why. **Note:** A trade-off between high finesse and high transmission at a given absorption $A > 0$, called *impedance matching*, is reached by maximizing the intracavity intensity. For a symmetric cavity, it can be shown that impedance matching is reached for $A = T$.

55.1.10.8 Ex: Confocal and concentric cavities

a. Calculate the spectrum of longitudinal and transverse modes for (i) a confocal cavity ($\rho_a = \rho_b = L$) and (ii) a concentric cavity ($\rho_a = \rho_v = L/2$). Interpret the results.
b. Assuming radii of curvature $\rho_a = \rho_b = 5$ cm and a finesse of $F = 500$ for the cavity, how precise must the length of the cavity be adjusted in order to observe only longitudinal modes in the transmission spectrum?

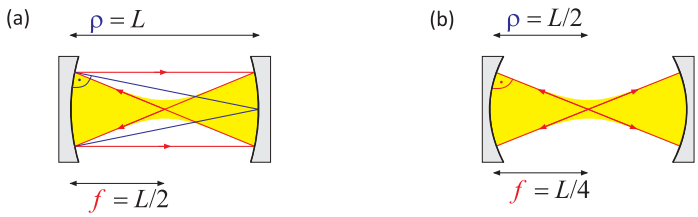

Figure 55.14: (a) Confocal cavity and (b) concentric cavity.

55.1.10.9 Ex: Thermal drift of a laser cavity

Estimate the frequency drift of a laser oscillating at $\lambda = 500\,\text{nm}$ because of thermal expansion of the resonator at a temperature drift of $1°\,\text{C/h}$, when the resonator mirrors are mounted on distance-holder rods a. made of invar and b. made of fused quartz.

55.1.10.10 Ex: Stability of a supercavity

Consider a non-confocal optical cavity of 10 cm length whose spacer is made of (i) aluminum, (ii) stainless steel, (iii) invar steel, (iv) fused quartz, (v) Zerodur, and (vi) ULE. The cavity is maintained at constant temperature with a precision of

0.001 C. What maximum drift do you estimate for its resonance frequency at 633 nm?

55.1.10.11 Ex: Fabry-Perot interferometer as optical spectrum analyzer

A confocal FPI shall be used as optical spectrum analyzer, with a free spectral range of $\delta_{fsr} = 3\,\text{GHz}$. Calculate the mirror separation L and the finesse that is necessary to resolve spectral features in the laser output within $\Delta\nu = 10\,\text{MHz}$. What is the minimum reflectivity R of the mirrors, if the surface finesse is $F_S = 500$?

55.1.10.12 Ex: Interference and colors filters

Strontium atoms resonantly driven by two lasers at 461 nm and 689 nm emit fluorescence light at both wavelengths. Because the red transition is 5000 times narrower than the blue one, the red fluorescence is much weaker and difficult to detect. Find a suitable low-pass filter in the Thorlabs® catalogue suppressing the blue light sufficiently to be sure that any fluorescence recorded after the filter must be resulting from the red transition. What signal ratios can you achieve with a single filter? Consider interference filters as well as color filters.

55.1.10.13 Ex: Interference filter

An interference filter shall be designed with peak transmission at $\lambda = 550\,\text{nm}$ and a bandwidth of 5 nm. Estimate the reflectivity R of the dielectric coatings and the thickness of the etalon, if no further transmission maximum is allowed between 350 and 750 nm.

55.1.10.14 Ex: Cut-off wavelength of a single-mode fiber

You want to transport 461 nm light via a polarization maintaining single-mode fiber. How do you need to choose the cut-off wavelength of the fiber? Assuming a 50% coupling efficiency, how much power can you get through the 5 nm long fiber? Choose a model from the Thorlabs catalog and justify your choice.

55.1.10.15 Ex: Exc Numerical aperture of a fiber

Calculate the numerical aperture of a step-index fiber with core refraction index n_{core} and cladding refraction index $n_{cladding}$ considering the scheme 55.15.

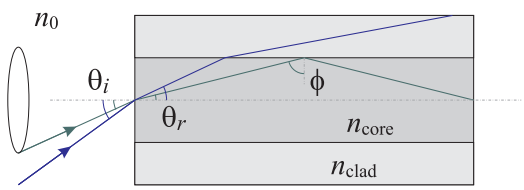

Figure 55.15:

55.1.10.16 Ex: Tuning by tilting an etalon

a. It is a common method to tune an etalon (or dielectric mirror or waveplate) to a certain transmission wavelength by tilting it as a whole with respect to the optical axis (without changing its intrinsic alignment. Does the tilt increase or decrease the wavelengths of the transmission peaks? Justify your answer. What is the implication for a dielectric mirror to be used under a non-normal angle of incidence?
b. A narrow band interference filter consisting of a glas plate coated on both surfaces has the following characteristics: thickness $L = 0.5\,\text{mm}$, refractive index $n_{rfr} = 1.45$, central wavelength $\lambda_{eff} = 706\,\text{nm}$, and bandwidth $\Delta\lambda = 0.3\,\text{nm}$. Considering the filter as Fabry-Pérot etalon, calculate its free spectral range, its finesse, and the reflectivity of its surfaces.
c. Assuming that the filter of part (b) can be tilted from normal incidence up to an angle $\theta_{max} = 35°$, how far will the center frequency shift. Prepare a graph showing λ_{eff} as a function of θ.

55.1.10.17 Ex: Double MZI as a model for Coherent Back-Scattering

Consider the setup shown in Fig. 55.16 and calculate the signal observed on the photodetector for arbitrary phase shifts ϕ and arbitrary rotation angles α by the $\lambda/2$-waveplate.

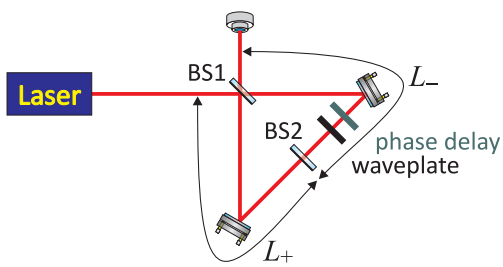

Figure 55.16: Double Mach-Zehnder interferometer.

55.1.11 *Experiment: Mach-Zehnder interferometer*

The Mach-Zehnder interferometer and the Michelson interferometer are the two most common two-beam interferometers. For the realization of the following project prior knowledge of 1. Gaussian beams (see Sec. 53.2), 2. photodetectors (see Sec. 54.2.1), and 3. piezo-electric transducers (see Sec. 55.1.2) is required.

1. Set up a Mach-Zehnder interferometer with a piezo in one of the arms according to Fig. 55.3(a). Optimize the phase matching of the two beams onto a photodetector and the rotation of the $\lambda/2$-waveplates until you obtain visible interference patterns.

2. Vary the length of one arm of the interferometer using the piezo. Measure the contrast of the interference fringes and discuss from which parameters it depends and how it can be maximized.

3. Rotate the first $\lambda/2$-waveplate (behind the laser). What do you observe? Explain the observation!

4. Remove the PBS in front of the photodetector. What do you observe? Explain the observation!

5. If a piezo is used, vary the voltage applied to the piezo-electric actuator and measure the voltage expansion coefficient d.

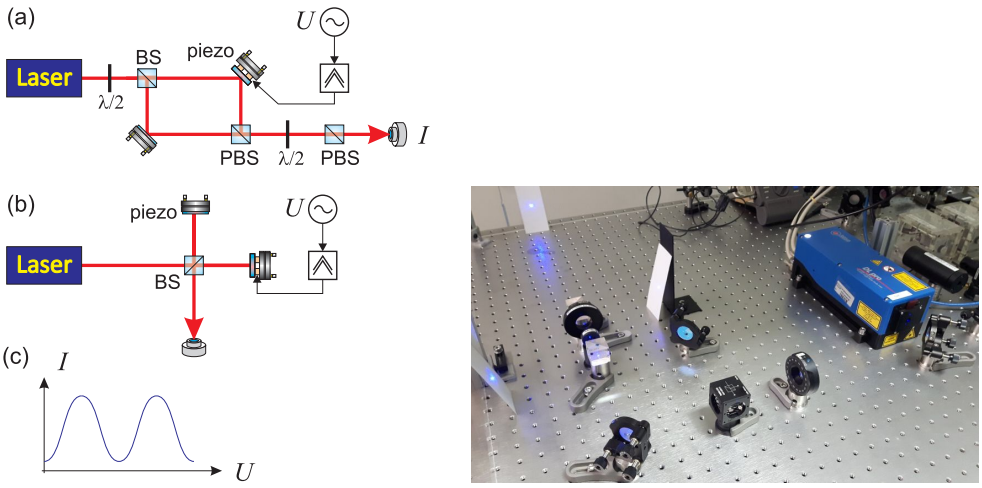

Figure 55.17: Setup for (a) a Mach-Zehnder interferometer or (b) a Michelson interferometer. (BS) non-polarizing beamsplitter, (PBS) polarizing beamsplitter. (c) Signal on the photodetector as a function of the length variation of an arm of the interferometer.

55.1.12 *Experiment: Fabry-Pérot cavity*

A Fabry-Pérot cavity is a typical multi-beam interferometer.

1. Set up a Fabry-Pérot cavity according to Fig. 55.18 and mode-match a laser beam into the cavity. Scan the cavity length using a piezo and observe the transmitted spectrum on an oscilloscope. What do you observe?

2. If an ECDL is used, vary the current and the temperature of the laser diode. What do you observe? Vary the frequency of the diode laser by scanning the piezo transducer of the laser cavity. Observe the mode spectrum of the laser in the transmission signal of the cavity. Measure its free spectral range, the transmission linewidth, and the finesse of the cavity.

Optical cavities are frequently used as *optical spectrum analyzers*. For this application, it is helpful to simplify the intrinsic mode spectrum of the cavity by using a confocal design, where all transerse modes are degenerated. We will now set up an optical cavity and characterize it by its free spectral range and its finesse. Then we will analyze its mode spectrum and modify its geometry to make it confocal.

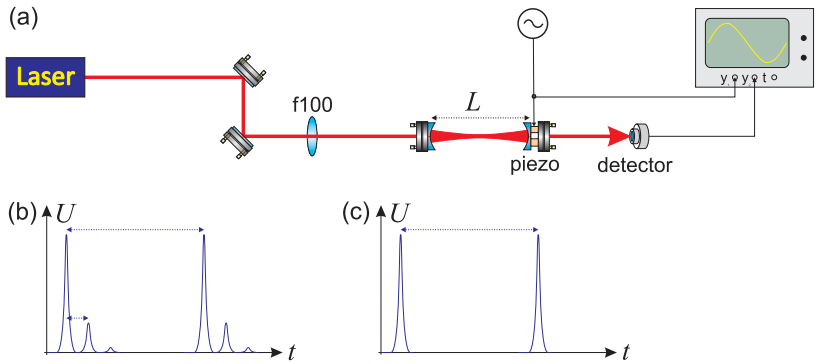

Figure 55.18: (a) Setup for aligning a confocal resonator. (b) Transmission spectrum of the cavity for non-confocal alignment. (c) Same as (b) but for the case of confocal alignment.

1. Couple a laser beam into a cavity as shown in Fig. 55.18. The cavity provided by this tinker course consists of a plane incoupler ($\rho_1 = \infty$, $R_1 = 98\%$) and a high reflector ($\rho_2 = 25\,\mathrm{mm}$, $R_2 = 99.8\%$). Position the mirror at a distance L, where the cavity is stable. Calculate the free spectral range, the finesse, the diameter of the beam waist.

2. Optimize the phase-matching of the laser beam to the cavity. In order to do this, (a) measure the diameter of the diode laser beam, (b) determine the lens which can be used to focus down to the beam waist of the cavity. How does the transmission spectrum change upon the beam matching?

55.1.13 *Experiment: Fizeau interferometer*

A *Fizeau interferometer* is a device allowing to analyze the rugosity of surfaces.

1. Set up a Fizeau interferometer according to Fig. 55.18.

55.1.14 *Experiment: Coupling light into an optical fiber*

Coupling a laser beam into an optical fiber is a delicate task, requiring a good collimation optics and full control over the 6 degrees of freedom defining a laser beam: horizontal and vertical position, horizontal and vertical tilt, beam diameter and divergence.

1. Redirect the light of a HeNe laser via two adjustable mirrors into a fiber collimator in such a way that the beam is not deviated from the optical axis by the collimator.

2. Now connect (a) a multimode fiber and (b) a single mode fiber to the collimator. Optimize the coupling by walking the laser beam and by adjusting the focus of the fiber collimator. What differences do you observe for multi- and single mode fibers?

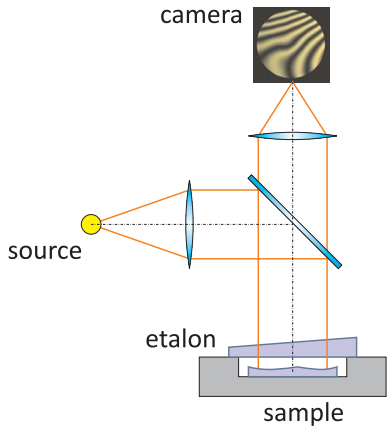

Figure 55.19: Principle of operation of a Fizeau interferometer.

55.2 Conventional light sources and lasers

For the first half of the 20-th century these assumptions matched the available light sources, usually incandescent, arc or plasma discharge lamps. After the invention of the laser in 1958, single mode and pulsed lasers quickly replaced the lamps as a source for optical excitation. These new light sources initiated a revolution in optical science, the consequence of which continue to reverberate through modern sciences and applied technologies. The characteristics of laser sources are far superior to the old lamps in all respects. They are intense, collimated, spectrally narrow and phase coherent. The laser gave rise to a multitude of new spectroscopic techniques and new disciplines, such as quantum electronics, the study of statistical properties of light in quantum optics, optical cooling and trapping of microscopic particles, the control of chemical reactivity, and new technologies for imaging and high resolution microscopy. The impact the laser had on technology is only comparable to that of to the invention of the transistor. See also (watch talk).

The laser produces light through an optical quantum amplification process based on the stimulated emission of electromagnetic radiation. The term 'laser' is an acronym for 'Light Amplification by Stimulated Emission of Radiation'. A laser differs from other light sources in that it emits *coherent* light. Its spatial coherence allows the light to be focused on a very tiny spot, where the concentration of energy is sufficient for applications such as laser cutting and lithography. The spatial coherence also allows it to collimate a laser beam over large distances, that is, the light forms a concentrated beam propagating in a straight line. Lasers can also have a very high temporal coherence, which corresponds to a very narrow spectrum, that is, lasers usually emit a single very well defined color of light. The extreme temporal coherence can be used to produce pulses of light as short as a femtosecond. In addition, laser light is polarized.

In 1917, Albert Einstein established the theoretical foundations of the laser in an article 'Zur Quantentheorie der Strahlung' through a rederivation of Max Planck's radiation law. He proposed a mechanism explaining how light is absorbed and emitted from atoms. The fundamental ingredient is that the photon can be emitted in two

different ways, by spontaneous emission, an indeterministic process that occurs without physical reason, or by stimulated emission. This latter emission process occurs because of stimulation by light, which is already present in the system and represents the fundamental mechanism of the laser. In the following decade German and American researchers experimentally confirmed the phenomena of stimulated emission and negative absorption, that is, gain. In 1950, Alfred Kastler (French physicist and Nobel Prize in Physics of 1966) proposed the method of optical pumping, confirmed experimentally two years later by other French physicists.

In 1953, Charles Townes produced the first microwave amplifier called *maser*, a device that operates similarly to the laser but amplifies microwave radiation instead of visible or infrared radiation. However, Townes' maser was unable to emit light continuously. In 1955, in the Soviet Union, Nikolay Basov and Aleksandr Prokhorov solved the problem of continuous operation using atoms with more than two energy levels. These level systems were able to sustain a permanent population inversion of an energetic level decaying to a less energetic system by releasing light via stimulated emission. Despite the fact that several prominent physicists, including Niels Bohr, John von Neumann, and Isidor Rabi, argued that the maser violates Heisenberg's uncertainty principle and therefore could not work, in 1964, Charles Townes, Nikolay Basov and Aleksandr Prokhorov shared the Nobel Prize in Physics for fundamental work in the field of quantum electronics that led to the realization of oscillators and amplifiers based on the maser principle.

In 1957, Charles Townes and Arthur Schawlow, from the Bell labs, began to seriously study feasibility of an 'optical maser'. In 1958, the Bell labs submitted a patent proposing a scheme for optical radiation, and Schawlow and Townes presented a scientific paper. Simultaneously, at the Columbia University, the PhD student Gordon Gould was working on the energy levels of excited thallium. In 1957-8, Gould and independently Prokhorov, Schawlow and Townes proposed the use of an open resonator, which later became an essential component of the laser. Gould also proposed several possible applications for a laser, such as spectrometry, interferometry, the radar, and nuclear fusion. He continued to develop the idea, and filed a patent application in April 1959. The United States Patent Office dismissed his application, and granted a patent to the Bell Labs in 1960. Gould won his first minor patent in 1977 after a 28-year fight, and it took him until 1987 to win his first significant process in the struggle, when a federal judge ordered the United States Patent Office to issue to Gould patents for optical pumping and the invention of a laser based on the principle of electrical gas discharge.

It was Theodore Maiman, who on May 16, 1960, operated the first working laser at the Hughes Research Laboratories, Malibu, California, evincing several other research teams, including the ones of Townes at Columbia University, of Schawlow at Bell Labs, and Gould at the company TRG (Technical Research Group). Maiman's laser used a synthetic solid-state ruby crystal pumped by a flash lamp to produce red laser light at 694 nm wavelength; however, the device was only capable of pulsed operation due to its three-level pumping scheme. Later in 1960, the first gas laser was built, using a helium-neon mixture, which was capable of continuous operation in the infrared spectrum. Basov and Javan proposed the concept of a semiconductor laser diode. In 1962, the first laser diode device, made of gallium arsenide, was realized emitting near-infrared light. Nowadays, laser diodes are available in various spectral regimes

up to the UV.

Figure 55.20: First suggested application in 1964 of a (left) HeNe laser and (right) a diode laser.

Interestingly, despite many attempts, it has not yet been possible to manufacture yellow or green laser diodes.

55.2.1 Features and operation of lasers

To understand how a laser operates, we consider the process of absorption and emission of light by an atom. Following Bohr's model an absorbed photon raises an electron from a lower orbit to a higher orbit, and when the electron returns back to the ground state, it re-emits a photon in an arbitrary direction.

When we illuminate a sample of N atoms, N_1 atoms of which are in the ground state, by a radiation field, the absorption rate depends on the field intensity $I(\nu)$ and a constant B_{12}, which is characteristic for the transition,

$$R_{abs} \propto B_{12} I(\nu) N_1 \ . \tag{55.38}$$

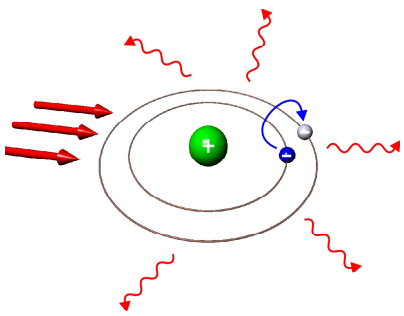

Figure 55.21: Bohr's model of photon absorption.

The emission rate depends on the number of atoms N_2 in the excited state, such that,

$$R_{sp} \propto A_{21} N_2 \ . \tag{55.39}$$

As the excited state has more energy, it can decay by itself (i.e. spontaneously) to a lower energy state. Einstein's brilliant idea now was to postulate a third process, which he called stimulated emission,

$$R_{st} \propto B_{21} I(\nu) N_2 \ . \tag{55.40}$$

In this process, an incident photon stimulates an excited atom to transfer the electron to a lower orbit. The released energy is then used to form a second photon, which is in all respects identical to the first. This process is necessary to ensure that, in thermal equilibrium, the population of the states follows Boltzmann's law.

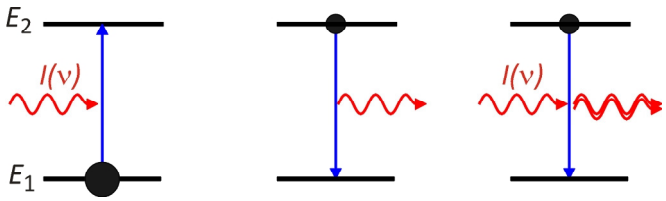

Figure 55.22: Einstein's model of absorption and spontaneous and stimulated emission.

Obviously, absorption decreases the intensity of a light beam crossing the atomic sample, while stimulated emission amplifies it. In order to amplify incident light, the gain in intensity must overcome the losses. Therefore, we need the absorption processes to be less frequent than the stimulated emission processes, i.e. the number of atoms in the excited state N_2 must exceed the number of atoms in the ground state $N_1 < N_2$.

We can easily write the rate equation,

$$\frac{dN_2}{dt} = -A_{21} N_2 - B_{21} I(\nu) N_2 + B_{21} I(\nu) N_1 = -\frac{dN_1}{dt} \ , \tag{55.41}$$

with $N = N_1 + N_2$. It is easy to solve this equation. The result is,

$$N_2 = \frac{I(\nu) B_{21} N}{A + 2B_{21} I(\nu)} [1 - e^{-(A_{21} + 2B_{21} I(\nu))t}] < N_1 \ . \tag{55.42}$$

The graphical representation 55.23 shows the temporal behavior of the populations N_1 (in green in the figure) and N_2 (in blue), reaching a state of equilibrium after a certain time. By increasing the intensity of the incident light, we observe that the curves approach each other but never cross. That is, in a two-level system, we always get $N_1 > N_2$ and the populations are never inverted. Therefore, amplification of light as in the laser does not happen.

Fortunately, we can resort to a trick by inserting a third level. Ensuring that the decay rate of the (metastable) state E_3 is much slower than the optical pumping to this state via the driven transition $E_1 \to E_2$ followed by a rapid decay $E_2 \to E_3$, we can reach the situation $N_3 > N_1$. Now it is possible to amplify light, which is resonant with the transition $E_2 \to E_3$.

What are the minimum requirements for the realization of a laser? The first condition is that the *pumping cycle is irreversible* to ensure that the processes of

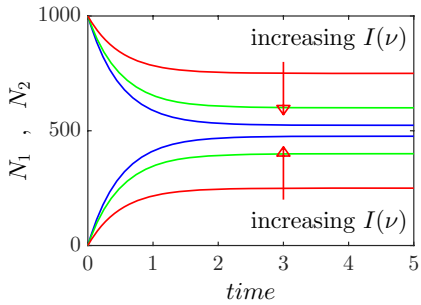

Figure 55.23: (code) Impossibility of achieving inversion in a two-level system.

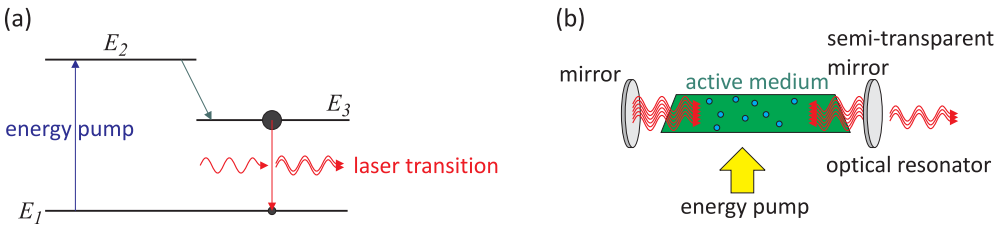

Figure 55.24: Basics of a laser: (a) Level system and (b) principle scheme.

stimulated emission and absorption do not compensate. Spontaneous emission is irreversible and can be incorporated into a three-level system.

The second condition is the existence of a *stimulated emission process*, because we want the amplified photon to be an exact copy of the incident photon.

The third requirement is a *feedback mechanism* that synchronizes the amplification processes by different atoms in a disordered environment, such as a gas. Mirrors are ideal because they increase the effective gain path, i.e. the distance within which inverted atoms can amplify light. Also, the mirrors define the phase of the light wave, since the standing wave formed by the counterpropagating light fields must have nodes on the surfaces of the mirrors.

55.2.1.1 Threshold condition

According to the *Lambert-Beer law* the intensity of a monochromatic laser beam evolves, on its way through a gas of two-level atoms with energies $E_2 - E_1 = \hbar\omega_0$ like,

$$I(z,\nu) = I(0,\nu)e^{-\alpha(\nu)z} \ , \tag{55.43}$$

where the frequency-dependent absorption coefficient,

$$\boxed{\alpha(\nu) = [N_1 - \tfrac{g_1}{g_2}N_2]\sigma(\nu)} \ , \tag{55.44}$$

is determined by the absorption cross section $\sigma(\nu)$ for the transition and by the inversion,

$$\Delta N \equiv \tfrac{g_1}{g_2}N_2 - N_1 \ , \tag{55.45}$$

which determines whether stimulated emission prevails or absorption: For $\Delta N > 0$, the absorption coefficient $\alpha(\nu)$ becomes negative and the incident wave is amplified instead of attenuated [245].

If the active medium is placed between two mirrors [Fig. 55.24(b)], the wave is reflected back and forth, and traverses the amplifying medium many times, which increases the total amplification. With the length L of the active medium the total gain factor per single round-trip without losses is,

$$G(\nu) = \frac{I(\nu, 2L)}{I(\nu, 0)} = e^{-2\alpha(\nu)L} \ . \tag{55.46}$$

A mirror with reflectivity R reflects only the fraction R of the incident intensity. The wave therefore suffers at each reflection a fractional reflection loss of $(1 - R)$. Furthermore, absorption in the windows of the cell containing the active medium, diffraction by apertures, and scattering due to dust particles in the beam path or due to imperfect surfaces introduce additional losses. When we summarize all these losses by a loss coefficient γ, which gives the fractional energy loss $\Delta W/W$ per round-trip time T, the intensity I decreases without an active medium per round-trip as,

$$I(2d, \nu) = I(0, \nu)e^{-\gamma} \ . \tag{55.47}$$

Including the amplification by the active medium with length L, we obtain for the intensity after a single round-trip through the resonator with length d, which may be larger than L:

$$I(2d, \nu) = I(0, \nu)e^{-2\alpha(\nu)L-\gamma} \ . \tag{55.48}$$

The wave is amplified if the gain overcomes the losses per round-trip. This implies that,

$$-2L\alpha(\nu) = 2L\Delta N\sigma(\nu) > \gamma \ , \tag{55.49}$$

which yields the threshold condition for the population difference,

$$\Delta N > \Delta N_{thr} = \frac{\gamma}{2L\sigma(\nu)} \ . \tag{55.50}$$

If the inverted population difference ΔN of the active medium is larger than ΔN_{thr}, a wave that is reflected back and forth between the mirrors will be amplified in spite of losses, therefore its intensity will increase.

The wave is initiated by spontaneous emission from the excited atoms in the active medium. Those spontaneously emitted photons that travel into the right direction (namely, parallel to the resonator axis) have the longest path through the active medium and therefore the greater chance of creating new photons by induced emission. Above the threshold they induce a photon avalanche, which grows until the depletion of the population inversion by stimulated emission just compensates the repopulation by the pump. Under steady-state conditions the inversion decreases to the threshold value ΔN_{thr}, the saturated net gain is zero, and the laser intensity limits itself to a finite value I_L. This laser intensity is determined by the pump power, the losses γ, and the gain coefficient $\alpha(\nu)$.

The frequency dependence of the gain coefficient $\alpha(\nu)$ is related to the line profile $g(\nu - \nu_0)$ of the amplifying transition. Without saturation effects (i.e. for small

intensities), $\alpha(\nu)$ directly reflects this line shape, for homogeneous as well as for inhomogeneous profiles. According to (55.44) and (23.87) we obtain with the Einstein coefficient B_{ik},

$$\alpha(\nu) = \Delta N \sigma(\nu) = -\Delta N (h\nu/c) B_{12}(\nu - \nu_0) \ , \tag{55.51}$$

which shows that the amplification is largest at the line center ν_0. For high intensities, saturation of the inversion occurs, which is different for homogeneous and for inhomogeneous line profiles.

The loss factor γ also depends on the frequency ν because the resonator losses are strongly dependent on ν. The frequency spectrum of the laser therefore depends on a number of parameters.

55.2.1.2 Applications of lasers in industry and fundamental research

Among their many applications, lasers are nowadays used in compact disc players, laser printers, and bar code scanners, optical fibers and optical communication, laser surgery and skin treatments, welding, cutting and machining, military devices, distance and velocity measurements, projectors, laser pointers, etc..

In fundamental research (in particular on atomic gases, metamaterials, etc.), the laser plays elementary roles in the areas of photonics, quantum computers, metrology, frequency combs, and atomic clocks (laser-based clocks are up to 1000 times more stable than the best state-of-the-art microwave clocks).

We all know that light is a wave. With the invention of the laser we found a process and a device to make this light coherent. On the other hand, since de Broglie's assertion we know that *matter is a wave, as well.* Is it conceivable to construct a matter laser? Yes, it is! The first coherent matter wave was in fact observed in 1995. This state of matter, also called Bose-Einstein condensate, was predicted by Bose and Einstein in 1924. To create a Bose-Einstein condensate, we need, similarly to the laser, that the matter waves interfere constructively in a way that they amplify each other. For this, the Broglie wavelength of the particles, which constitute the matter, must be longer than the distance between them. Assuming a typical average distance on the order of µm, this corresponds to an average velocity of the particles of mm/s or a temperature of some 100 nK.

55.2.2 HeNe laser

HeNe lasers are gas lasers, whose gain medium consists of a mixture of 90% helium and 10% neon at a total pressure of about 1 Torr excited by a small electrical discharge. The most widely used transition wavelength is at 632.8 nm.

Fig. 55.25(a) shows the principle scheme of a commercial HeNe laser. The distance between the high-reflecting mirror (R_{hr}) and the output coupler (R_{oc}) determines the free spectral range δ_{fsr}. Typically, a HeNe laser operates on two or three longitudinal modes separated by δ_{fsr}. As illustrated in Fig. 55.25(b), the numbers of lasing modes above threshold depends on the ratio of gain-to-loss. Fig. 55.25(c) shows the optical pumping scheme to reach inversion on three of the lasing transitions at 632.8 nm, 1.15 µm, and 3.39 µm.

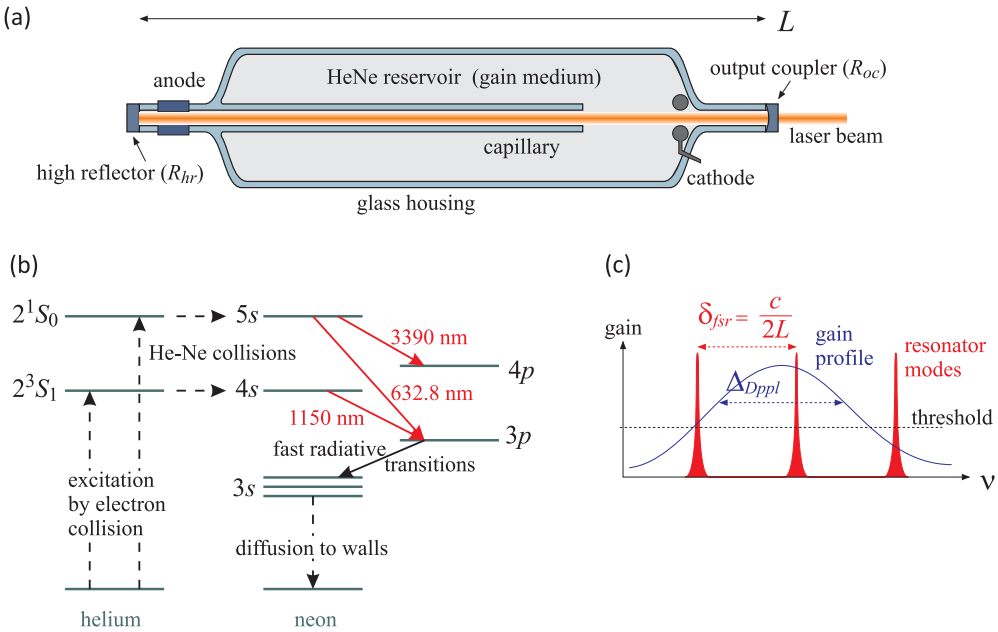

Figure 55.25: (a) Construction scheme of a HeNe laser. (b) Gain and emission profile. (c) Optical pumping scheme.

55.2.3 Diode laser

A laser diode is electrically a *pin*-diode. The active region of the laser diode is in the intrinsic (i) region, and the carriers (electrons and holes) are pumped into that depletion region from the n- and p-doped regions respectively. The depletion region, devoid of any charge carriers, forms as a result of the difference in electrical potential between n- and p-type semiconductors wherever they are in physical contact. Unlike a regular diode, the goal for a laser diode is to recombine all carriers in the i region, and produce light.

Figure 55.26: (Left) Laser diode with protective housing removed, e.g. using a can opener. (Right) Laser diode collimator.

55.2.3.1 Generation of light

Electrons and holes present in the same region may recombine or 'annihilate' by spontaneous emission of photons with energy equal to the difference between the electron's original state and hole's state (see Fig. 54.10). This is in contrast to a conventional semiconductor junction diode, where the energy released from the recombination is carried away as phonons, i.e. lattice vibrations. Spontaneous emission below the lasing threshold is the operating mode of an LED. While spontaneous emission is necessary to initiate laser oscillation, it contributes to reduce the efficiency of a laser operating above threshold.

One condition for lasing is that, in the absence of stimulated emission, electrons and holes may coexist in proximity to one another without recombining immediately. For typical diode laser materials the 'upper-state lifetime' or 'recombination time' is on the order of a nanosecond. A nearby photon with energy equal to the recombination energy can cause recombination by stimulated emission. This generates another photon of the same frequency, polarization, and phase, traveling in the same direction as the first photon. In this way stimulated emission will cause gain for an optical wave in the injection region, and the gain increases as the number of electrons and holes injected across the junction increases.

55.2.3.2 Optical cavity and laser modes

As in other lasers, the gain region needs to be surrounded by an optical cavity providing optical feedback. In its simplest form, a laser diode is made in the shape of a narrow optical waveguide on a the surface of a crystal. The two ends of the crystal are cleaved to form perfectly smooth, parallel edges, forming a Fabry-Pérot resonator. Emitted photons will travel along the waveguide, be amplified by stimulated emission and reflected several times from each end face before exiting. If the losses due to absorption and incomplete reflection from the end facets are smaller than the gain, the diode begins to 'lase'.

Important properties of laser diodes are determined by the geometry of the optical cavity. If the waveguide is thick compared to the wavelength of the light, it can support higher-order transverse optical modes. The laser is then called 'multi-mode'. These transversely multi-mode lasers are adequate for application where high power is needed, for example, in printing, activating chemicals, or pumping other types of lasers.

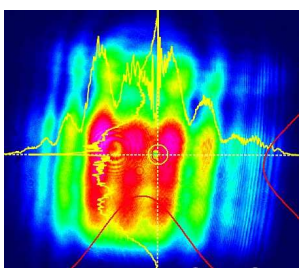

Figure 55.27: Typical beam profile of a multimode laser diode (Thorlabs, L450P1600MM.

For applications requesting small focused beams the waveguide must be made narrow, on the order of the optical wavelength, such that only a single transverse mode is supported, and one ends up with a diffraction-limited beam. Such single spatial mode devices are used for optical storage, laser pointers, and fiber optics. Note that these lasers may still support multiple longitudinal modes, and thus can lase simultaneously at multiple wavelengths. The wavelength emitted is a function of the band-gap of the semiconductor material and the modes of the optical cavity. In general, the maximum gain will occur for photons with energy slightly above the band-gap energy, and the modes nearest the peak of the gain curve will lase most strongly. The width of the gain curve will determine the number of additional 'side modes' that may also lase, depending on the operating conditions. Single spatial mode lasers that can support multiple longitudinal modes are called Fabry-Pérot (FP) lasers. A FP laser will lase at multiple cavity modes within the gain bandwidth of the lasing medium. The number of lasing modes in an FP laser is usually unstable, and can fluctuate due to changes in current or temperature.

Single spatial mode diode lasers can be designed so as to operate on a single longitudinal mode. These single frequency diode lasers exhibit a high degree of stability, and are used in spectroscopy and metrology, and as frequency references. Single frequency diode lasers are classed as either distributed feedback (DFB) lasers or distributed Bragg reflector (DBR) lasers.

Due to diffraction, the beam diverges (expands) rapidly after leaving the chip, typically at 30 degrees vertically by 10 degrees laterally. A lens must be used in order to form a collimated beam like that produced by a laser pointer. If a circular beam is required, cylindrical lenses and other optics are used. For single spatial mode lasers, using symmetrical lenses, the collimated beam ends up being elliptical in shape, due to the difference in the vertical and lateral divergences.

55.2.3.3 Distributed Bragg reflector lasers and distributed feedback lasers

The simple diode described above has been heavily modified in recent years to accommodate modern technology, resulting in a variety of types of laser diodes. One example is the distributed Bragg reflector laser (DBR). It consists of a monolithic single frequency laser diode, characterized by an optical cavity consisting of an electrically or optically pumped gain region between two mirrors to provide feedback. One of the mirrors is a broadband reflector and the other mirror is wavelength selective so that gain is favored on a single longitudinal mode, resulting in lasing at a single resonant frequency. The broadband mirror is usually coated with a low reflectivity coating to allow emission. The wavelength selective mirror is a periodically structured diffraction grating with high reflectivity. The diffraction grating is etched into the semiconductor within a non-pumped, or passive region of the cavity.

A distributed feedback laser (DFB) is a monolithic single frequency laser diode with a diffraction grating etched close to the *pn*-junction of the diode aiming at stabilizing the lasing wavelength. This grating acts like an optical filter, causing a single wavelength to be fed back to the gain region and lase. Since the grating provides the feedback that is required for lasing, reflection from the facets is not required. Thus, at least one facet of a DFB is anti-reflection coated. The DFB laser has a stable wavelength that is set during manufacturing by the pitch of the grating,

and can only be tuned slightly with temperature. DFB lasers are widely used in optical communication applications, where a precise and stable wavelength is critical.

55.2.3.4 ECDL

An *extended-cavity diode laser* (*ECDL*) is an optical setup based on a laser diode chip, which typically has one end anti-reflection (AR) coated, and the laser resonator is completed with a collimating lens and a mirror, as shown in Fig. 55.28(a). The extended external laser resonator introduces various new features and options: Compared to a standard laser diode, the longer resonator increases the damping time of the intracavity light according to Eq. (55.29), and thus allows for lower phase noise and a smaller emission linewidth (in single-frequency operation). Furthermore, it opens the way for inserting frequency-selective optical components into the extended laser resonator, such as narrow-band Fabry-Pérot etalons or diffraction gratings, which can further *reduce the linewidth* and even allow to *tune and control the frequency* of the laser.

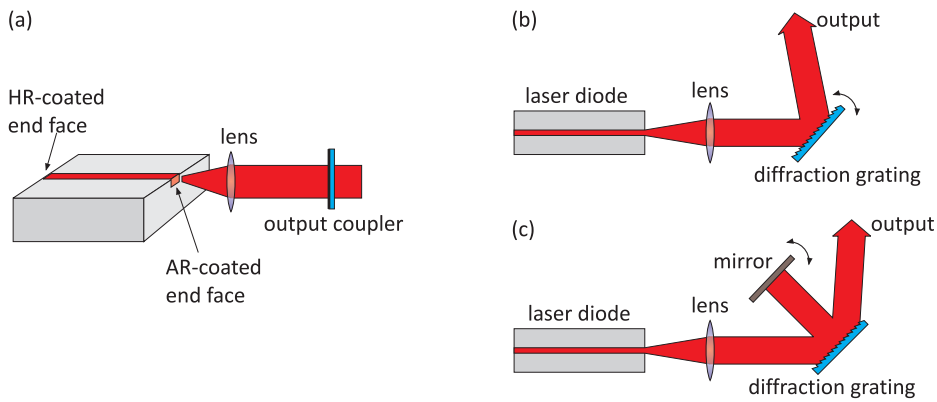

Figure 55.28: (a) ECDL with an AR-coated laser diode and an external mirror. (b) Littrow configuration. (c) Littmann configuration.

Tunable ECDLs based on diffraction grating as the wavelength-selective element are also called grating-stabilized diode lasers. The common Littrow configuration Fig. 55.28(b) generates optical feedback to the laser diode chip by retro-reflecting the first-order diffracted beam from the grating. The emission wavelength can be tuned by slightly tilting the diffraction grating. A disadvantage of this configuration is, that the tilt also changes the direction of the output beam, which is inconvenient for many applications.

In the Littman-Metcalf configuration Fig. 55.28(c), the grating angle is held fixed, and an additional mirror is used to reflect the first-order beam back into the laser diode. The wavelength can be tuned by rotating that mirror. This configuration offers a fixed direction of the output beam, and also tends to exhibit a smaller linewidth, as the wavelength selectivity is stronger, because the wavelength-dependent diffraction occurs twice per resonator round trip. A disadvantage is that the zero-order reflection of the beam reflected by the tuning mirror is lost, so that the output power is lower than that of a Littrow laser.

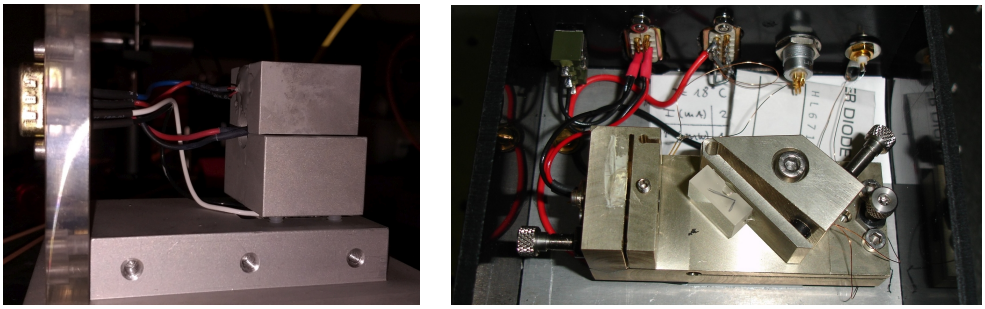

Figure 55.29: (Left) Side view of a 'free-running' laser diode mounted in a collimator (Thorlabs, LT110P-B) clamped in an aluminum block cooled by a Peltier element (Thorlabs, TEC3-6) and whose temperature is measured by a thermistor (Thorlabs, TH10K). (Right) Top view of a home-built ECDL laser in Littrow configuration. The diode collimator is clamped into the left mount. a holographic grating (Newport, 10HG2000-475-1) is glued to the right mount, whose angle can be adjusted mechanically and via a piezo. The whole setup is cooled by a Peltier element mounted on the bottom of the base plate.

New concepts have recently become popular, such as the so-called *cat-eye laser* [54, 357, 80], where the frequency-selective element is an extremely narrow-band (0.3 nm) optical filter [4].

By adjusting the tilt angle of a grating or a narrow-band filter by means of a piezo an extremely fine tuning of the emission frequency is possible, while coarse tuning of the frequency over a range of several nanometers is typically achieved by changing the temperature and the laser current. Typical linewidths of free-running ECDLs are well below 5 MHz. Controlling the laser temperature, current, and piezo voltage by active feedback circuits (e.g. within a Pound-Drever-Hall servo electronics) emission bandwidths in the milliHertz range have been achieved, which corresponds to quality factors of the laser oscillator of up to 10^{18}.

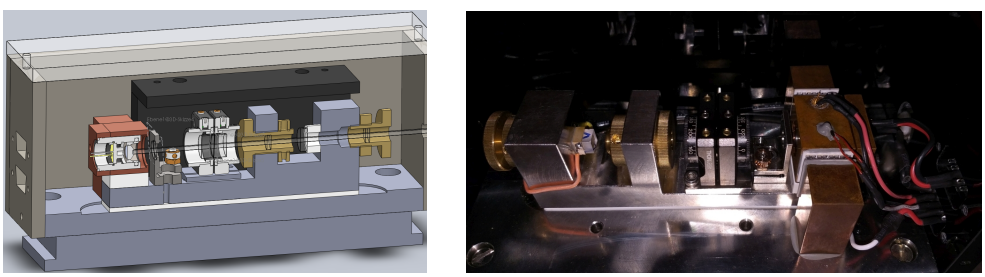

Figure 55.30: (Left) Construction plan of a home-built ECDL lasers in cat-eye configuration. (Right) Side view of the cat-eye laser.

In comparison to other laser types, a *diode laser* exhibits, the advantage of a very small size and a compact design. They are, in general, easy to handle and can be

[4] Available from Semrock or Laseroptik.

controlled conveniently via current and temperature. However, they also have the disadvantage of a large beam divergence and a broad emission spectrum. The beam divergence can be compensated by a collimation optics in front of the laser diode.

The temperature has an impact on the band structure of the *pn*-transition of the laser diode and hence on the frequency. Therefore, it is stabilized via a Peltier element, which is mounted underneath the laser diode holder. The degree of freedom is used for tuning the laser frequency in wide steps.

55.2.3.5 Pulsed diode lasers

Diode lasers can be used for generating ultrashort pulses either with various techniques of mode locking or with gain switching. Typically, pulses with durations between 0.5 and 5 ps and pulse repetition rates between 1 GHz and hundreds of giga-Hertz are generated with mode locking. In extreme cases, the repetition rate can even be above 1 THz. The main application of ultrafast diode lasers is in optical fiber communications systems, where such lasers function as pulse sources of fast data transmitters or for all-optical signal processing.

Common techniques for mode locking of diode lasers are active ore passive mode locking. Active mode locking can be accomplished with an optical modulator in the laser resonator. This is usually either an electro-absorption modulator in the form of an unpumped region with some modulated voltage, or an amplifying section where the drive current is modulated. Passive mode locking relies on a saturable absorber in the resonator. This can simply be an unpumped section of the device. It is common to apply an electrical bias for adjusting the absorber properties. However, the recovery time of that kind of absorber is fairly long. Shorter recovery times are achieved e.g. by implanting nitrogen (N^+ or N_2^+) ions from one facet. This introduces crystal defects, where carriers can recombine. The absorber is often placed at a resonator end, but it can also be placed somewhere within the resonator so that different pulses can meet in the absorber (colliding pulse mode locking).

For pulse repetition rates roughly below 10 GHz, an external cavity setup is usually required, as a monolithic device would become too long. The extended cavity may be an ECDL setup. Another technical approach is to incorporate the semiconductor chip into a ring laser resonator made of optical single-mode fiber. In the latter case, the resonator is typically much longer, and allows the use of fiber-optic components. The semiconductor device may then be a fiber-coupled semiconductor optical amplifier (SOA).

External-cavity lasers have various advantages: The pulse repetition rate can be chosen in a wide range, and can easily be tuned e.g. by moving the end mirror, or with a fiber resonator by stretching a piece of fiber with a piezo transducer. It is possible to insert an optical filter for fixing the emission wavelength, or use a diffraction grating as the end mirror (Littrow configuration; see the article on external-cavity diode lasers). Even for higher pulse repetition rates, where harmonic mode locking is required, external-cavity devices can be advantageous, because they have a potential for lower laser noise, e.g. in the form of timing jitter. Therefore, mode-locked external-cavity diode lasers sometimes compete with mode-locked fiber lasers in areas where monolithic laser diodes would not be suitable. On the other hand, a monolithic setup with fundamental mode locking can be very compact, much cheaper to manufacture,

and can exhibit very robust pulse emission.

On the other hand, mode-locked diode lasers are subject to various limitations, which do not allow them to reach the full performance potential of, e.g., mode-locked fiber lasers: The pulse energy is fairly limited often far below 1 pJ. Average output powers are often below 1 mW. Due to the short upper-state lifetime, ultrafast semiconductor lasers are generally not suitable for lower repetition rates of e.g. well below 1 GHz, except with synchronous pumping. Although the gain bandwidth of semiconductors would be compatible with pulse durations of a few tens of femtoseconds, the pulse durations achieved are usually much longer at least hundreds of femtoseconds, and often picoseconds. The pulse formation dynamics are relatively complicated, e.g. due to nonlinear phase changes associated with gain saturation, and difficult to optimize. The pulse quality is normally not as good as e.g. for mode-locked fiber lasers. In particular, there are often additional satellite pulses, caused e.g. by imperfections of the anti-reflection coating. Also, the pulses are often chirped, i.e. they are not bandwidth-limited. The timing jitter and the noise of other pulse parameters are higher than for other mode-locked lasers. This is partly a consequence of the low power level.

55.2.3.6 Tapered amplifiers and injection locking

Other ways to amplify a the power of a laser without altering its coherence properties are using a *tapered amplifier* or via *injection locking* also called *master-slave locking* [134, 586] (see Fig. 55.31).

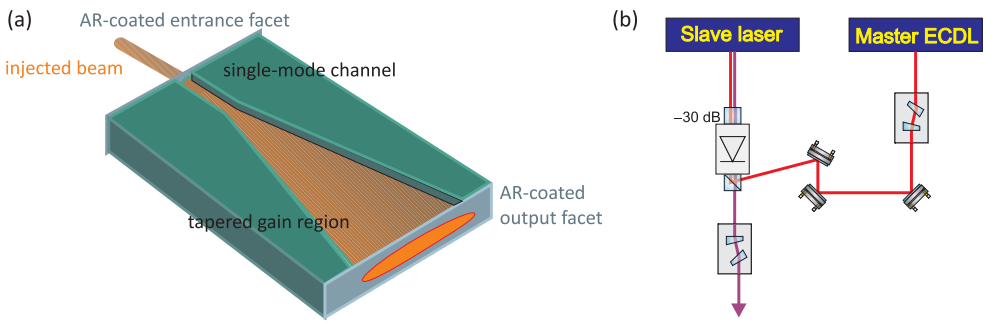

Figure 55.31: (a) Tapered amplifiers are available e.g. from Eagleyard. (b) Principle of injection locking.

The description presented here uses semi-classical laser rate equations [585]. Assuming that the master and the slave laser field are given by, respectively,

$$E_{\text{inj}} = A_{\text{inj}} e^{-\imath\omega_{\text{inj}} t} e^{\imath\phi_{\text{inj}}(t)} \qquad \text{and} \qquad E = A e^{-\imath\omega_s t} e^{\imath\phi_s(t)} \ , \tag{55.52}$$

The phase difference between the both fields is denoted by $\phi(t) = \phi_s(t) - \phi_m(t)$. Now, Considering the semi-classical laser rate equations we can describe the impact of the

master laser field in the slave laser,

$$\begin{aligned}\frac{dA(t)}{dt} &= \frac{1}{2}g[N(t)-N_{\text{th}}]A(t)+\kappa A_{\text{inj}}\cos\phi(t) \\ \frac{d\phi(t)}{dt} &= \frac{\alpha}{2}[N(t)-N_{\text{th}}]-\kappa\frac{A_{\text{inj}}}{A(t)}\sin\phi(t)-\Delta\omega \\ \frac{dN(t)}{dt} &= J-\gamma_N N(t)-[\gamma_p+g[N(t)-N_{\text{th}}]A(t)^2\ ,\end{aligned} \tag{55.53}$$

where $A(t)$ is the field amplitude normalized as $A^2(t)=S(t)$, and $S(t)$ is the photon number. $N(t)$ is the number of carriers in the slave laser, and the other parameters are g laser gain coefficient, N_{th} threshold carrier number, κ coupling coefficient, α linewidth enhancement factor, γ_p photon decay rate, N carrier recombination rate, J pump current normalized by electron charge, $\Delta\omega$ frequency difference between the master and the free running slave $\omega_m-\omega_s$. The parameter κ describes the rate at which the photons of the master laser enter into the slave laser cavity and is given in terms of the cavity quality factor,

$$\kappa=\frac{\omega_s}{2Q}\ . \tag{55.54}$$

From the steady state solutions of above equations, we can obtain the frequency locking range,

$$-\kappa\sqrt{(}1+\alpha^2)\sqrt{\frac{P_{\text{inj}}}{P_s}}<\Delta\omega<\kappa\sqrt{\frac{P_{\text{inj}}}{P_s}}\ , \tag{55.55}$$

where P_{inj}/P_s is the master laser fraction power used for the injection locking and P_s is the power of slave laser. From equation 4.25 we can see that the locking range is determined by the amplitude ratio between the fields and by the cavity quality factor since $\kappa\propto Q^{-1}$. Therefore, lasers with low Q are easier to lock. On the other hand, this leads to increased laser linewidth that reduces the phase noise performance of the injection locking systems. For higher injection ratio P_{inj}/P_s also results in a large locking range, which also makes the lock easier to achieve.

55.2.4 Exercises

55.2.4.1 Ex: Conventional light sources and lasers

Compare the properties of an incandescent light and a laser.

55.2.4.2 Ex: Threshold inversion for lasing 1

Calculate the necessary threshold inversion of a gas laser transition at $\lambda=500\,\text{nm}$ with the transition probability $A_{ik}=5\cdot10^7\,\text{s}^{-1}$ and a homogeneous linewidth $\Delta\nu_{hom}=20\,\text{MHz}$. The active length is $L=20\,\text{cm}$ and the resonator losses per round-trip are $\gamma=5\%$.

55.2.4.3 Ex: Threshold inversion for lasing 2

A laser medium has a Doppler-broadened gain profile of halfwidth $\delta\nu=2\,\text{GHz}$ and central wavelength $\lambda=633\,\text{nm}$. The homogeneous width is 50 MHz, and the transition

probability $A_{ik} = 10^8\,\mathrm{s}^{-1}$. Assume that one of the resonator modes ($L = 40\,\mathrm{cm}$) coincides with the center frequency ν_0 of the gain profile. What is the threshold inversion for the central mode, and at which inversion does oscillation start on the two adjacent longitudinal modes if the resonator losses are 10%?

55.2.4.4 Ex: Mode pulling in an active resonator

The frequency of a passive resonator mode ($L = 15\,\mathrm{cm}$) lies $0.5\Delta\nu_D$ away from the center of the Gaussian gain profile of a gas laser at $\lambda = 632.8\,\mathrm{nm}$. Estimate the mode pulling if the cavity resonance width is 2 MHz and $\Delta\nu_D = 1\,\mathrm{GHz}$.

55.2.4.5 Ex: Spatial hole-burning

Assume a laser transition with a homogeneous width of 100 MHz, while the inhomogeneous width of the gain profile is 1 GHz. The resonator length is $d = 200\,\mathrm{cm}$ and the active medium with length $L \ll d$ is placed $a = 20\,\mathrm{cm}$ from one end mirror. Estimate the spacing of the spatial hole-burning modes. How many modes can oscillate simultaneously if the unsaturated gain at the line center exceeds the losses by 10%?

55.2.4.6 Ex: Optimizing the transmission of laser output mirrors

Estimate the optimum transmission of the laser output mirror if the unsaturated gain per round trip is 2 and the internal resonator losses are 10%.

55.2.4.7 Ex: Mode selection in a HeNe laser

A HeNe laser with an unsaturated gain of $G(\nu_0) = 1.3$ per round trip at the center of the Gaussian gain profile with halfwidth $\Delta\nu_D = 1.5\,\mathrm{GHz}$ has a resonator length of $d = 50\,\mathrm{cm}$ and total losses of 4%. Single-mode operation at ν_0 is achieved with a coated tilted etalon inside the resonator. Design the optimum combination of etalon thickness and finesse.

55.2.4.8 Ex: Mode hopping in a HeNe laser

A single-mode HeNe laser with resonator length $L = 15\,\mathrm{cm}$ is tuned by moving a resonator mirror mounted on a piezo. Estimate the maximum tuning range before a mode hop will occur, assuming an unsaturated gain of 10% at the line center and resonator losses of 3%. What voltage has to be applied to the piezo (expansion 1 nm/V) for this tuning range?

55.2.4.9 Ex: Mode selection with an intracavity etalon

Mode selection in an argon laser is often accomplished with an intracavity etalon. What is the frequency drift of the transmission maximum
a. for a solid fused quartz etalon with thickness $d = 1\,\mathrm{cm}$ due to a temperature change of 2° C?
b. For an air-space etalon with $d = 1\,\mathrm{cm}$ due to an air pressure change of 4 mbar?
c. Estimate the average time between two mode hopes (cavity length $L = 100\,\mathrm{cm}$) for a temperature drift of 1° C/h or a pressure drift of 2 mbar/h.

55.2.4.10 Ex: Frequency and intensity noise of a laser

A single-mode laser is frequency stabilized onto the slope of the transmission maximum of an external reference Fabry-Perot interferometer made of invar with a free spectral range of 8 GHz. Estimate the frequency stability of the laser
a. against temperature drifts, if the FPI is temperature stabilized within 0.01°C,
b. against acoustic vibrations of the mirror distance L in the FPI with amplitudes of 100 nm.
c. Assume that the intensity fluctuations are compensated to 1% by a difference amplifier. Which frequency fluctuations are still caused by the residual intensity fluctuations, if a FPI with a free spectral range of 10 GHz and a finesse of 50 is used for frequency stabilization at the slope of the FPI transmission peak?

55.2.5 *Experiment: Analyzing the mode structure of a HeNe laser*

Here we will analyze the mode structure of a HeNe laser via (i) an optical spectrum analyzer and (ii) a radiofrequency spectrum analyzer. We will also try to unravel the polarization of the laser light.

1. Couple the light of a HeNe laser simultaneously into an optical spectrum analyzer and a radiofrequency spectrum analyzer. What do you observe when you slightly heat the laser housing? Calculate from your observations the length of the laser cavity.

2. Pass the light through a $\lambda/4$-plate and then through a polarizing beam splitter. What do you observe in the two output ports of the PBS?

55.2.6 *Experiment: Adjusting the threshold of an ECDL laser*

Here we will construct a diode laser in Littmann configuration.

1. Take a laser diode, a Peltier cooler, a thermistor, a piezo transducer, and a diffraction grating. Put everything together.

2. Optimize the threshold. Analyze the emission spectrum with an optical spectrum analyzer.

55.3 Introduction to optical phase and frequency modulation

55.3.1 Acousto-optic modulator

The *acousto-optic modulator AOM* permits fast frequency and amplitude variations of a laser beam. Because it does not incorporate mechanical parts, it works without fatigue. AOMs are used, for instance, in laser printers, where the gray tone of a pixel can be adjusted via the intensity of the laser beam, while its position (rows and

columns) is varied by a rotating mirror and the drum propagating the paper sheet. In quantum optics labs they are frequently used for fast (down to μs) switching on and off, intensity control, and super-fine frequency-tuning of laser beams. The angular deflection of the first-order diffracted beam upon frequency tuning, which is often perceived as an inconvenience, can be circumvented by double-passage through the AOM.

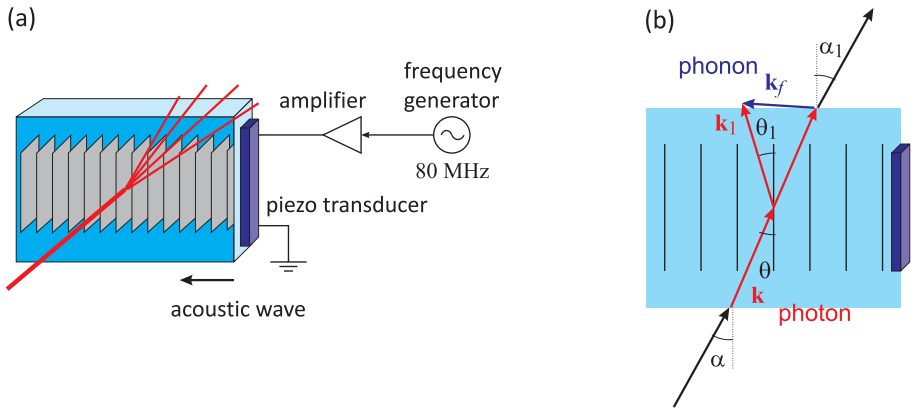

Figure 55.32: (a) Principle of the acousto-optic modulator. (b) Scheme of the diffraction in an acousto-optic modulator: A photon with wavevector k is scattered by a phonon with wavevector k_1 resulting in a photon with wavevector k_f.

The acousto-optic modulator consists of a piece of crystal (or glass) excited by an acoustic wave with frequency f produced by a piezo-electric transducer (see Sec. 55.3.1) mounted perpendicularly to propagation direction of the laser beam. The sound waves propagate through the crystal as density fluctuations periodically changing the refraction index n. The incident light is diffracted through Brillouin scattering at the spatial modulation of the refraction index. In a wave picture, the process can be interpreted as Bragg scattering of a light wave (with its wavelength inside the crystal $\lambda_n = 2\pi/k_n = c/n\nu$) from a density grating. c/n is the propagation velocity of light inside the crystal. Since phonons (with their wavelength $\lambda_f = 2\pi/k_f = c_f/f$, where c_f is the sound velocity in the crystal) are quantized and can only be emitted and absorbed entirely, the frequency of the first-order diffraction is $\nu_1 = \nu + f$. In case of an ideal adjustment of the Bragg angle, the *Bragg condition* results in $\theta_1 = \theta$ (see Fig. 55.32),

$$\sin\theta = \frac{k_f}{2k} = \frac{f\lambda_n}{2c_f} \ . \tag{55.56}$$

Since the laser beam is refracted when it enters the crystal, the relation between the incidence and exit angle is given by *Snell's law*, $\sin\alpha = n\sin\theta$. With this, the Bragg condition can be written,

$$\boxed{\sin\alpha = \frac{f\lambda}{2c_f}} \ . \tag{55.57}$$

The angle between the 0th and the 1st order is, hence, 2α.

In a corpuscular picture, the process can be understood as a *four-wave mixing* (*4WM*) between photons and phonons. The deflection of the laser beam is a consequence of momentum, $\mathbf{k}_1 = \mathbf{k} + \mathbf{k}_f$. The frequency shift corresponds exactly to the Doppler shift induced by the Brillouin scattering (absorption and reemission of a phonon in reverse direction), and we obtain a relationship that is equivalent to the Bragg condition,

$$f = \nu_1 - \nu = 2\nu \frac{c_f \sin\theta}{c/n} \ . \tag{55.58}$$

From the Bragg condition, knowing the deflection angle and the (fixed) frequency shift, we can calculate the sound velocity. A typical value is $c_f \simeq 4200$ m/s [5]

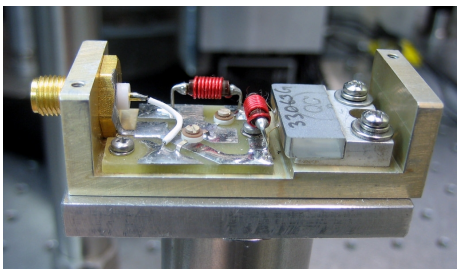

Figure 55.33: Image of an AOM without cover.

An AOM works best (highest diffraction efficiency in to the first Bragg order, which may reach more than 90%) at a specific radiofrequency, which typically is located somewhere in the range $f = 40...800$ MHz, the most common one being 80 MHz. Deviations from this 'center frequency' are possible within a range of typical $\pm 10\%$ of the center frequency.

55.3.2 Electro-optic modulator

An *electro-optic modulator* is an optical device with which, by an applied voltage, the phase, frequency, amplitude or direction of a light beam can be modulated. Modulation bandwidths in the GHz regime are possible. In the simplest case, the EOM consists of a crystal (e.g., lithium niobate), whose refractive index depends on the amplitude of the local electric field. That is, when a lithium niobate crystal is exposed to an electric field the speed of light propagation is reduced. One can thus control the phase of a light beam at the output of a crystal by inserting it into a plate capacitor and applying a voltage. The phase shift of the light depends linearly on the applied voltage.

EOMs are often used to generate sidebands in a monochromatic laser beam. They are also used as *Pockels cell*, i.e., as a voltage-controlled phase-plate. The Pockels

[5] The result (55.58) can be derived from conservations laws for energy $\omega_1 = \omega + \omega_f$ and momentum $\mathbf{k}_1 = \mathbf{k} + \mathbf{k}_f$. Defining $\omega \equiv 2\pi\nu$, $\omega_1 \equiv 2\pi\nu_1$ and $\omega_f \equiv 2\pi f$ we find,

$$\frac{\omega_f^2}{c_f} = \mathbf{k}_f^2 = (\mathbf{k}_1 - \mathbf{k})^2 = k_1^2 + k^2 - 2\mathbf{k}_1 \cdot \mathbf{k} = \frac{\omega_1^2}{c_n^2} + \frac{\omega^2}{c_n^2} - \frac{2\omega\omega_1}{c_n^2}\cos(2\theta) \simeq \frac{4\omega\omega_1}{c_n^2}\sin^2\theta \ .$$

With $\omega_1 \simeq \omega$ we reproduce the result [997, 998].

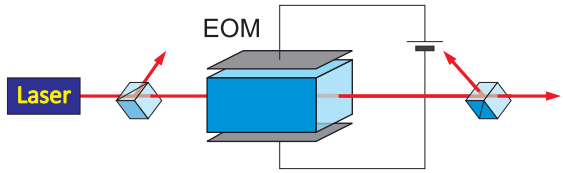

Figure 55.34: Electro optic modulator.

effect produces in a medium a *birefringence*, which depends linearly on the applied electric field. This is in contrast to the *Kerr effect*, in which the birefringence depends in a quadratic form of the electric field.

Suppose the optically inactive axis is x. In this case, the influence of EOM on the polarization of a laser beam is described by

$$\mathcal{M}_{EOM}(\theta) = \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} . \tag{55.59}$$

For operation as a Pockels cell, the EOM is inserted between two crossed polarizers oriented, e.g., along the x and y axis. The EOM itself is rotated by an angle ϕ,

$$\begin{aligned} \mathcal{M}_{Pockels}(\theta,\phi) &= \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \\ &= 2\imath e^{\imath\theta/2} \sin\tfrac{\theta}{2} \sin\phi\cos\phi \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} , \end{aligned} \tag{55.60}$$

For $\phi = \pi/4$ we get,

$$\mathcal{M}_{Pockels}(\theta, \tfrac{\pi}{4}) = \imath e^{\imath\theta/2} \sin\tfrac{\theta}{2} \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} . \tag{55.61}$$

That is, an incident beam of light, $\mathbf{E} = E\hat{\mathbf{e}}_x$, linearly polarized in x-direction is rotated into the y-direction and, depending on the phase shift θ, it is completely blocked or transmitted through the Pockels cell [see Fig. 55.35(a)],

$$I_{tr} = I_0 \sin^2 \tfrac{\theta}{2} . \tag{55.62}$$

55.3.3 Optical phase modulation

The frequency and the phase of a laser beam can be influenced and modulated similarly to radiofrequency signals. We can therefore use the calculation of Sec. 54.3.1 completely, only changing the carrier frequency to be the frequency of the light: The Fourier expansion of a complex-valued periodic function $s(x)$ into a series is defined as,

$$s_N(x) = \sum_{k=-N}^{N} c_k e^{\imath kx} \qquad \text{where} \qquad c_k = \frac{1}{2\pi} \int_{2\pi} s(x) e^{-\imath kx} dx . \tag{55.63}$$

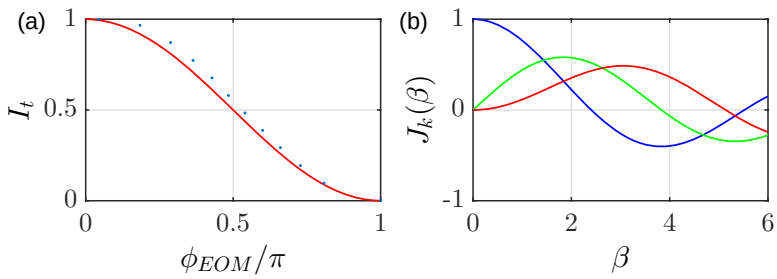

Figure 55.35: (code) (a) Effect of a Pockels cell. The solid line was calculated with the Eq. (55.60), the dotted was measured experimentally. (b) Lowest-order Bessel functions.

Applying this to the modulated phase shift factor $s(\Omega t) = e^{\imath\theta(t)}$ with $\theta(t) \equiv \beta \sin \Omega t$, we get,

$$s_N(\Omega t) = \sum_{k=-\infty}^{\infty} c_k e^{\imath k\Omega t} \qquad \text{where} \qquad c_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{\imath\beta \sin \Omega t} e^{-\imath k\Omega t} d\Omega t \ , \tag{55.64}$$

but the Fourier coefficients are nothing else than the integral definition of the k-th order Bessel function,

$$J_k(\beta) \equiv \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{\imath(\beta \sin \tau - k\tau)} d\tau \ , \tag{55.65}$$

where $J_{-k}(\beta) = -J_k(\beta)$. Hence, we may write the electric field,

$$\boxed{\begin{aligned} E(t) &= e^{\imath[kz-\omega t+\imath\theta(t)]} = e^{\imath(kz-\omega t)} \sum_{k=-\infty}^{\infty} J_k(\beta) e^{\imath k\Omega t} \\ &\simeq J_0(\beta)e^{\imath\omega t} + J_1(\beta)e^{\imath\omega t+\imath\Omega t} + J_{-1}(\beta)e^{\imath\omega t-\imath\Omega t} \end{aligned}} \ . \tag{55.66}$$

For small modulation indices β only the lowest-order Bessel function contribute noticeable amplitudes, as illustrated in Fig. 55.35(b).

The interpretation of this is, that *phase modulation* imprints sidebands onto a monochromatic laser beam. These sidebands are independent modes which can be resolved, e.g. with an optical spectrum analyzer, as illustrated in Fig. 55.36.

Technically the phase can be modulated by means of an electro-optical modulator, as shown in Fig. 55.37(b). Alternatively, one may apply a periodic modulation of the current which controls a diode laser, as shown in Fig. 55.37(a), which can be done e.g. by inductive coupling using a *bias-T*.

From (55.66) we immediately see that phase modulation remains invisible for a photodetector measuring $|E(t)|^2$. Imagine, however, that the light passes through a frequency-selective absorber, as illustrated in Fig. 55.37(b), such that the sidebands suffer unequal losses. Then the photodetector will record (apart from a constant offset) a signal oscillating at the frequency Ω,

$$\begin{aligned} |E(t)|^2 &= \left|J_0(\beta)e^{\imath\omega t} + aJ_1(\beta)e^{\imath\omega t+\imath\Omega t} + bJ_{-1}(\beta)e^{\imath\omega t-\imath\Omega t}\right|^2 \\ &= J_0(\beta)^2 + (a+b)J_1(\beta)^2 + (a-b)J_0(\beta)J_1(\beta)2\cos\Omega t + \dots \ . \end{aligned} \tag{55.67}$$

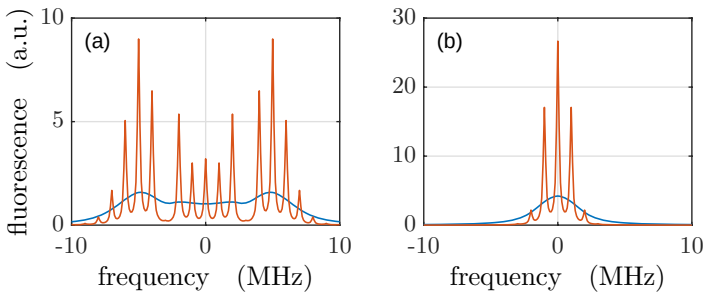

Figure 55.36: (code) Phase modulation sidebands with high (left) and low (right) modulation index resolved by a narrow (red) or broad (blue) filter.

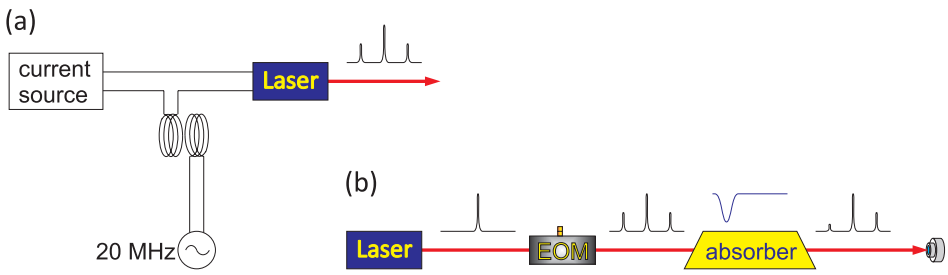

Figure 55.37: (a) Scheme for phase modulation of a diode laser by modulating the drive current. (b) Phase modulation with an external EOM followed by frequency-selective absorption of the lower sideband.

This idea is at the heart of powerful spectroscopic techniques, such as *frequency modulation spectroscopy*, *modulation transfer spectroscopy*, and the *Pound-Drever-Hall* frequency stabilization technique.

55.3.4 Exercises

55.3.4.1 Ex: Response time of an AOM

A beam of light at 689 nm focused to a waist of 100 µm passes through the crystal of an 80 MHz AOM, characterized by a sound velocity of $c_s = 4200\,\mathrm{m/s}$.
a. By how much the first diffraction order is deflected by the AOM? Regarding the beam divergence of the Gaussian beam, will it be possible to spatially separate the diffraction orders?
b. An experimentalist ramps the driving frequency between 70 and 90 MHz by means of a voltage-controlled oscillator. What is the range of diffraction angles covered?
c. Estimating the response time of the AOM by the time that the traveling sound wave needs to cover a distance corresponding to the focus of the light beam, how fast can the experimentalist switch off the light beam by suddenly interrupting the driving signal? What is the modulation bandwidth of the AOM?
d. The light beam passes through the AOM at a distance of $d = 2\,\mathrm{mm}$ from the piezo transducer generating the sound wave. How will this fact limit response time?

55.3.4.2 Ex: Intensity stabilization with a Pockels cell

Assume that the output power of a laser shows random fluctuations of about 5%. Intensity stabilization is accomplished by a Pockels cell with a halfwave voltage of 600 V. Estimate the ac output voltage of the amplifier driving the Pockels cell that is necessary to stabilize the transmitted intensity if the Pockels cell is operated around the maximum slope of the transmission curve.

55.3.4.3 Ex: Generating sidebands with an EOM

An EOM (e.g. Thorlabs, EO-PM-NR-C1) characterized by a half-wave voltage of $U_{hwv} = 230\,\mathrm{V}$ at 689 nm is to be used to generate optical sidebands at 20 MHz.
a. Estimate numerically, how much voltage amplitude at what frequency a frequency generator must provide in order to generate optical sidebands having half the light power as the carrier?
b. How high must the finesse of a 5 cm confocal Fabry-Pérot spectrum analyzer be in order to resolve the sidebands.

55.3.4.4 Ex: Reflection of a phase-modulated signal from an optical cavity

A phase-modulated light beam (modulation frequency $f = 20\,\mathrm{MHz}$) is reflected from an optical cavity and recorded by a fast photodetector, whose bandwidth is larger than f. Using the Airy formulae for the electric field of a light beam reflected from a cavity (55.27) calculate the reflection spectrum, that is, the intensity of reflected light as a function of detuning $\Delta = \omega - \omega_c$, where ω is the frequency of the light and ω_c a resonant frequency of the cavity. What frequency components does the photodetector signal contain.

55.3.4.5 Ex: Switching time for an EOM

a. Describe what happens to a laser beam passing through an EOM when its refraction index n is suddenly changed.
b. Estimate the transient time for the phase shift to take place.
c. For a length of the EOM crystal of $L = 1\,\mathrm{cm}$ and a laser wavelength of $\lambda = 689\,\mathrm{nm}$ estimate the change Δn required to achieve a phase shift of 180°.

55.3.5 *Experiment: Characterizing an AOM*

Fig. 55.38 illustrates the setup, use, and test of an AOM. It is recommended familiarizing with the operation principle of a *voltage-controlled oscillator* (*VCO*) (see Sec. 54.3.1) and a voltage-controlled *variable attenuator*. We will also learn how to use a spectrum analyzer [6].

1. Optimize a diffraction efficiency of the AOM. What are the impacts of the Bragg angle, the radiofrequency power, and the laser beam diameter.

[6] Data sheet for the VCO see appendix Fig. 58.16,
data sheet for the AOM see appendix Fig. 58.20

2. Measure the deflection angle as a function of the applied radiofrequency. Based on this result, calculate the sound velocity in the crystal.

3. Measure the diffraction efficiency as a function of the applied radiofrequency power at a fixed Bragg angle. Repeat the measurement optimizing the Bragg angle for every value of the radiofrequency.

4. Reduce the radiofrequency power using the variable voltage-controlled attenuator. Determine the diffraction efficiency as a function of radiofrequency power.

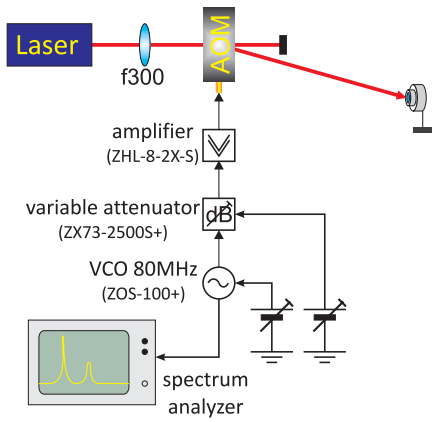

Figure 55.38: Setup for testing an acousto-optic modulator.

See Fig. 55.39.

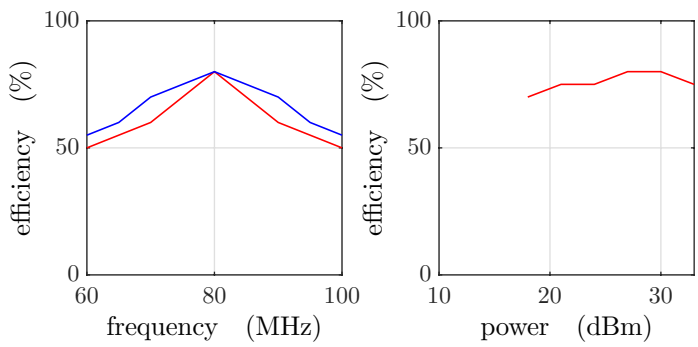

Figure 55.39: Example of measured efficiency curves.

55.3.6 *Experiment: EOM in a Mach-Zehnder interferometer*

Here we will learn to operate an EOM as Pockels cell and as phase modulator.

1. Align a laser beam through an electro-optic modulator. Supply a voltage between 0 V and 500 V to the EOM. Test its operation by beating the ordinary with the extraordinary beam. Modulate the supply voltage at a low frequency.

2. Set up a Mach-Zehnder interferometer by phase-matching the exit beam of the EOM with a part of the input beam.

3. The interferometer provides a mean to convert a phase modulation into an amplitude modulation. Describe this feature theoretically using the Eqs. (54.12) and (54.13).

4. Use the EOM as a Pockels cell. Rotate the EOM by 45° around the optical axis. Probe the polarization of the outgoing beam with a polarization filter.

5. Modulate the EOM and show that the light acquires sidebands.

55.3.7 *Experiment: Creating sidebands with an EOM*

EOMs can be used to generate optical sidebands [7].

1. Apply the required voltages to a VCO (MiniCircuits, ZOS100), until it generates a variable frequency between 40 and 60 MHz. Attenuate the power with a variable attenuator up to −20 dBm. Check the amplitude and frequency with a spectrum analyzer.

2. Add a bias-T to the power supply of a laser diode. Observe the transmission spectrum of a Fabry-Pérot cavity for various frequencies and modulation amplitudes. Determine the modulation index. Use the known distance of the sidebands to estimate the finesse of the Fabry-Pérot cavity.

55.4 Radiofrequency techniques and the transfer of information

It often happens that information is coded within a frequency band corresponding to wavelengths which are not easily transported to other locations. For example, audio frequencies (speech or music), ones they are converted to electromagnetic vibrations, correspond to wavelengths of hundreds of kilometers. Such waves are very difficult to radiate and are subject to diffraction.

For this reason, audio frequencies are often used to *modulate* so-called carriers, which in turn are chosen in frequency ranges which are easy to radiate by antennas. This is the basic idea of the radio, where the carrier frequencies are typically chosen in the MHz regime. But information can as well be encoded into laser beams, as illustrated in Fig. 55.40.

[7] Datasheet for the VCO see appendix Fig. 58.16,
data sheet for the power divider see appendix Fig. 58.18,
data sheet for the mixer see appendix Fig. 58.19

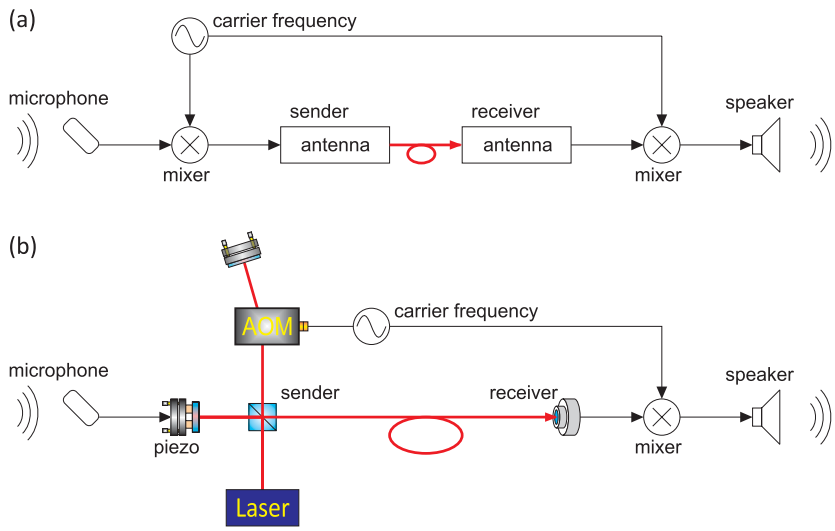

Figure 55.40: Analogy between radio transmission (a) and heterodyne techniques with a laser (b).

55.4.1 Measurement of a frequency beat

Interferometry is always based on the splitting and recombination of a wave, e.g., a laser beam or a matter wave. The recombination of laser beams is always a little technical challenge, as it requires a perfect phase matching of the Gaussian laser modes. Let us consider two plane waves $\mathcal{E}_1 = Ae^{\imath\omega_1 t}$ and $\mathcal{E}_2 = Ae^{\imath\omega_2 t}$ impinging on a photodiode. We suppose that they are phase-matched, such that their wavevectors are parallel. The photodiode then generates a *beat signal*,

$$\boxed{I = |\mathcal{E}_1 + \mathcal{E}_2|^2 = AB[2 + 2\cos(\omega_1 - \omega_2)t]} \ . \tag{55.68}$$

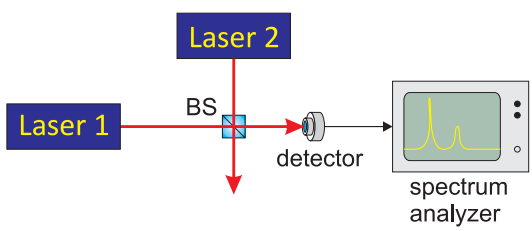

Figure 55.41: Principle of a beat frequency measurement.

In practice, laser beams are usually not plane waves, but have a finite diameter and radius of curvature. In order to get a high contrast signal, a good phase-matching of the beams is important in order to obtain a strong photodiode signal.

55.4.2 Homodyne method

For the *homodyne method* the field amplitude of a laser beam, E_i, with frequency, $\omega = ck$, is divided by a beam splitter (reflectivity $R = |\eta|^2 \simeq 50\%$) into a reference beam (reflection at an optically dilute medium) and a probe beam, exactly as we have done for the Michelson interferometer in Sec. 55.1.3, when we obtained the formula (55.16) [8],

$$I \propto 1 + \cos[k(L_t - L_r)] \ . \tag{55.69}$$

However, we will now modulate the path length of one interferometer arm, e.g. using an EOM, $L_r = L_r(t)$. The modulation can, but does not need to be sinusoidal. In fact it may be an arbitrary radiofrequency signal, e.g. generated by acoustic sound. Restricting to small modulation amplitudes, $kL_r \ll \pi$, and choosing the length of the interferometer arms such that,

$$\boxed{I(t) \propto \sin kL_r \simeq kL_r(t)} \ , \tag{55.70}$$

we see, that the photodetector signal will reproduce the modulation signal. In other words, we encoded information on a laser beam, which carries it (e.g. through an optical fiber) to another place.

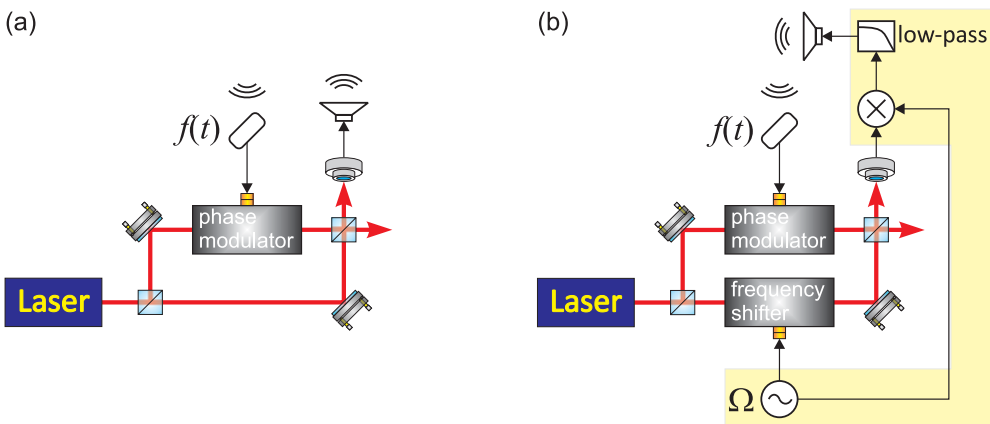

Figure 55.42: Principle scheme of the (a) homodyning and (b) heterodyning technique at the example of a Mach-Zehnder interferometer. The components in the yellow area of (b) constitute a Lock-In amplifier.

55.4.3 Heterodyne method

The *heterodyne method* is similar to the homodyne one, except that the probe beam is frequency-shifted (e.g., by the passage through an AOM operated at frequency Ω),

$$\mathcal{E}'_t = \mathcal{E}_t e^{\imath kL_t + \imath\Omega t} \ . \tag{55.71}$$

[8] Here, we call $L_{t,r}$ the total length of the interferometer arm (back and forth for Michelson, one-way for Mach-Zehnder).

The photodetector signal generated by the beams after their recombination at the beam splitter is,

$$\begin{aligned} I &\propto \left|(1-\eta)\mathcal{E}_r e^{\imath k L_r} + \eta \mathcal{E}_t e^{\imath k L_t + \imath \Omega t}\right|^2 \\ &= \left|-(1-\eta)\eta \mathcal{E}_i e^{\imath k L_r} + \eta(1-\eta)\mathcal{E}_i e^{\imath k L_t + \imath \Omega t}\right|^2 \\ &= \left|(1-\eta)\eta\mathcal{E}_i\right|^2 \left|-e^{2\imath k L_r} + e^{\imath k L_t + \imath \Omega t}\right|^2 \ . \end{aligned} \tag{55.72}$$

This signal is now demodulated with the AOM frequency,

$$I e^{\imath \Omega t} \propto \left|-e^{\imath k L_r} + e^{\imath k L_t + \imath \Omega t}\right|^2 e^{i\Omega t} = e^{2\imath \Omega t} - e^{\imath k (L_t - L_r) + 2\imath \Omega t} - e^{-\imath k (L_t - L_r)} \ . \tag{55.73}$$

A low-pass filter cuts all ac-components of the signal,

$$\boxed{I_{\text{filtered}}(t) \propto -e^{-\imath k (L_t - L_r)} \simeq -1 + \imath k [L_t - L_r(t)]} \ , \tag{55.74}$$

for small signal amplitudes $L_r(t)$.

55.4.4 Measuring the quadrature components of an electric field

Photodetectors measure intensities $I \propto |\vec{\mathcal{E}}|^2$. Sometimes, however, we are interested in the electric field itself, for example, when we want to get the correlation function $g^{(1)}(\tau)$ and the spectrum $S_{\mathcal{E}}(\omega)$ of a signal. A frequently used procedure consists in beating the signal of interest with a frequency-shifted local oscillator and demodulating the *quadrature components* of the beat signal.

Let us consider a signal of interest $\mathcal{E}_{\text{sig}}(t) = |\mathcal{E}_{\text{sig}}| e^{\imath \phi(t)}$ with information encoded in the temporal behavior of the phase $\phi(t)$. The first step consists in beating this signal on a photodetector with a frequency-shifted local oscillator $\mathcal{E}_{\text{lo}}(t) = |\mathcal{E}_{\text{lo}}| e^{\imath \omega_{\text{lo}} t}$, yielding a photocurrent,

$$S \propto |\mathcal{E}_{\text{sig}} + \mathcal{E}_{\text{lo}}|^2 = |\mathcal{E}_{\text{sig}}|^2 + |\mathcal{E}_{\text{lo}}|^2 + 2|\mathcal{E}_{\text{lo}}||\mathcal{E}_{\text{sig}}| \cos[\omega_{\text{lo}} t - \phi(t)] \ . \tag{55.75}$$

Now, demodulating this signal simultaneously with the local oscillator frequencies $\cos \omega_{\text{lo}} t$ and $\sin \omega_{\text{lo}} t$, we get,

$$\begin{aligned} U_c &= S \cos \omega_{\text{lo}} t = |\mathcal{E}_{\text{lo}}||\mathcal{E}_{\text{sig}}| \cos \phi(t) + \text{oscillating terms} \\ U_s &= S \sin \omega_{\text{lo}} t = |\mathcal{E}_{\text{lo}}||\mathcal{E}_{\text{sig}}| \sin \phi(t) + \text{oscillating terms} \ , \end{aligned} \tag{55.76}$$

where the oscillating terms can be removed by a low-pass filtering. Finally, we calculate,

$$|\mathcal{E}_{\text{sig}}| = \frac{\sqrt{U_c^2 + U_s^2}}{|E_{\text{lo}}|} \qquad \text{and} \qquad \tan \phi(t) = \frac{U_s}{U_c} \ , \tag{55.77}$$

and obtain the electric field via,

$$\boxed{\mathcal{E}_{\text{sig}} = |\mathcal{E}_{\text{sig}}| e^{\imath \phi(t)} = \frac{\sqrt{U_c^2 + U_s^2}}{|\mathcal{E}_{\text{lo}}|} e^{\imath \arctan \frac{U_s}{U_c}}} \ . \tag{55.78}$$

55.4.5 Exercises

55.4.5.1 Ex: Pound-Drever-Hall signal

Consider the photodetector signal of Exc. 55.3.4.4. What signal do you observe when demodulating the signal with an oscillation of frequency f? Calculate the derivative of the signal close to resonance; from which parameters does the slope depend, and how must you choose the modulation index to maximize it?

55.4.6 *Experiment: Beating two lasers*

In this exercise, we will ...

1. Take two independent lasers operating at nearly the same frequency (within $\sim 1\,\mathrm{GHz}$) and overlap them at a (non-polarizing) beam splitter.
2. Focus one of the ports of the beam splitter on a photodetector with large band width ($\sim 1\,\mathrm{GHz}$).
3. Analyze the beat signal on a spectrum analyzer.
4. Focus a helium-neon laser onto a fast photodetector and determine the free spectral range of the laser resonator.

55.4.7 *Experiment: Homo- and heterodyning with a Michelson interferometer*

In this exercise, we will ...

1. Set up a Michelson interferometer.

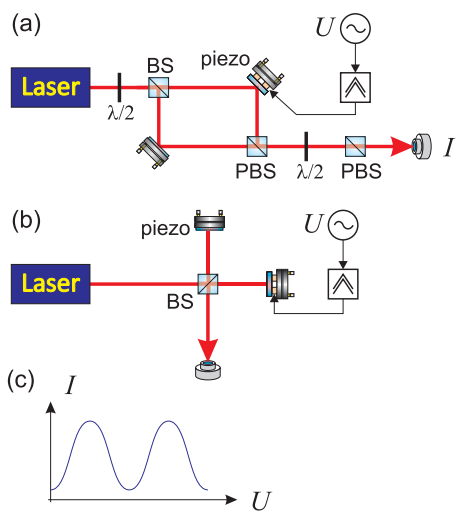

Figure 55.43: Homo- and heterodyning with a Michelson interferometer.

Chapter 56

Optical spectroscopy

Modern 'optics' is to be understood as 'physics of light-matter interaction' in the optical energy regime. In this sense, this area of physics comprises quantum optics, photonics, atomic physics, and atom optics. Since the invention of the laser the field of optics has seen a huge technological progress leading to the development of extremely powerful and precise tool for investigating and manipulating matter. The femtosecond laser, the frequency comb, atomic interferometers and clocks, and Bose-Einstein condensation are just a few examples.

Spectroscopy is the art of taking and interpreting spectra, i.e. frequency-dependent response functions. The variety of spectroscopic techniques is so overwhelming that a survey is hopeless. As the course also aims at familiarizing the student with applications, a major part of this course will concentrate on techniques employed and available in quantum optics labs. These techniques are mostly oriented toward ultra-high resolution spectroscopy and techniques of manipulating the motion of atoms.

In Sec. 56.1 to 56.4.3, we will try various spectroscopic techniques applied to atomic or cavity resonances.

56.1 Spectrometer and monochromator

Typical dispersive devices are *prisms* and *gratings*.

- lateral displacement as a function of λ
- spectral resolving power $R = |\lambda/\Delta\lambda| = |\nu/\Delta\nu|$
- Rayleigh criterion

56.1.1 Prism spectrometer

For a symmetrical arrangement ($\alpha_1 = \alpha_2 = \alpha$) it is easy to see from Fig. 56.1 that, $\beta = \frac{1}{2}\epsilon$ and $\theta = 2(\alpha - \beta)$. Snell's law the yields,

$$n = \frac{\sin\alpha}{\sin\beta} = \frac{\sin\frac{1}{2}(\theta+\epsilon)}{\sin\frac{1}{2}\epsilon} \ . \tag{56.1}$$

Hence,

$$\frac{dn}{d\theta} = \frac{1}{2}\frac{\cos\frac{1}{2}(\theta+\epsilon)}{\sin\frac{1}{2}\epsilon} \ , \tag{56.2}$$

or

$$\frac{d\theta}{dn} = \frac{\sin\frac{1}{2}\epsilon}{1 - n^2\sin\frac{1}{2}\epsilon} \ . \tag{56.3}$$

The angular dispersion is therefore,

$$\frac{d\theta}{d\lambda} = \frac{\sin\frac{1}{2}\epsilon}{1 - n^2\sin\frac{1}{2}\epsilon}\frac{dn}{d\lambda} \ . \tag{56.4}$$

The spectral dispersion of typical transparent materials is on the order of $-dn/d\lambda \approx 10^{-4}$.

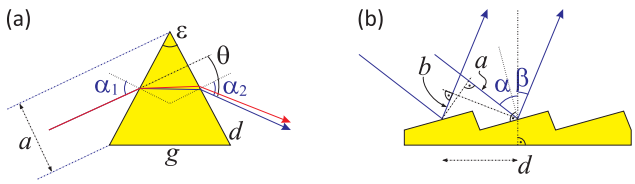

Figure 56.1: Illustration of (a) the prism spectrometer and (b) the grating spectrometer.

Example 385 (*Prism spectrometer*): We calculate the angular dispersion for an equilateral prism ($\sin\frac{1}{2}\epsilon = 0.5$) made of BK7 for two superposed wavelength $\lambda_1 = 461\,\text{nm}$ ($n_{\lambda_1} = 1.5243$) and $\lambda_2 = 633\,\text{nm}$ (with $n_{\lambda_2} = 1.5151$) to be,

$$d\theta = \frac{1}{\sqrt{1-(n/2)^2}}dn \approx 0.8^\circ \ .$$

The resolving power can be calculated, once we have expressed the limiting aperture $a = d\cos\alpha$ where $d = g/(2\sin\frac{\epsilon}{2})$,

$$\left|\frac{\lambda}{\Delta\lambda}\right| = a\frac{d\theta}{d\lambda} = \frac{g\cos\alpha}{1 - n^2\sin\frac{1}{2}\epsilon}\frac{dn}{d\lambda} = g\frac{dn}{d\lambda} \ . \tag{56.5}$$

Solve Exc. 53.2.3.14.

56.1.2 Grating spectrometer

Destructive interference occurs for,

$$\Delta s = m\lambda = a - b = d\sin\alpha - d\sin\beta \ . \tag{56.6}$$

Frequently used is the so-called *Littrow configuration* for which $\alpha = -\beta$.

The grating represents a multiple beam interferometer, because the beams reflected from every groove of the grating are phase-shifted by amounts (setting $\alpha = 0$,

$$\delta = \tfrac{2\pi}{\lambda}\Delta s = -2\pi\frac{d}{\lambda}\sin\beta \ . \tag{56.7}$$

The sum of the reflections from N grooves of an incident plane wave $E_{in} = E_0 e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t}$ is therefore,

$$\mathcal{E}_r = \sqrt{R}\mathcal{E}_0 \sum_{m=0}^{N} e^{\imath \mathbf{k}_r\cdot\mathbf{r}-\omega t} e^{im\delta} = \sqrt{R} E_0 e^{\imath \mathbf{k}_r\cdot\mathbf{r}-\omega t} \frac{1-e^{\imath N\delta}}{1-e^{\imath\delta}} \ . \tag{56.8}$$

Consequently, the intensity is,

$$I_r = R I_0 \frac{\sin^2 \frac{N}{2}\delta}{\sin^2 \frac{1}{2}\delta} \ . \tag{56.9}$$

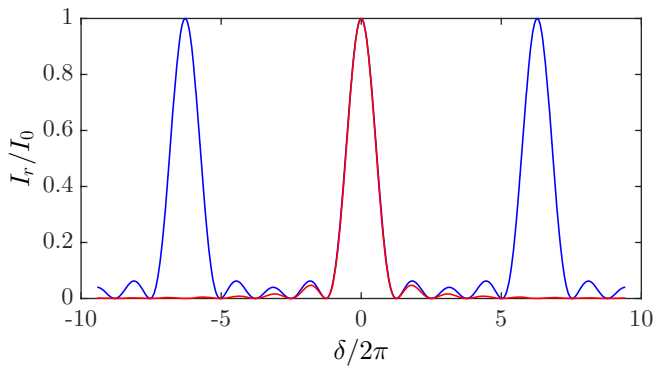

Figure 56.2: (code) Reflection curve of a diffraction grating.

The angular dispersion is, using Eqs. (56.7) and (56.6),

$$\frac{d\beta}{d\lambda} = \left(\frac{d\lambda}{d\beta}\right)^{-1} = -\frac{m}{d\cos\beta} = -\frac{\sin\alpha - \sin\beta}{\lambda\cos\beta} \ . \tag{56.10}$$

The resolving power is,

$$\left|\frac{\lambda}{\Delta\lambda}\right| = \frac{Nd(\sin\alpha - \sin\beta)}{\lambda} = mN \ . \tag{56.11}$$

Solve Exc. 56.1.3.1, 56.1.3.2, and 56.1.3.3.

56.1.3 Exercises

56.1.3.1 Ex: Resolution of a grating spectrometer

Calculate the spectral resolution of a grating spectrometer with an entrance slit width of 10 µm, focal lengths $f_1 = f_2 = 2\,\mathrm{m}$ of the mirrors M1 and M2, a grating with 1800 grooves/mm and an angle of incidence $\alpha = 45°$. What is the useful minimum slit width if the size of grating is $100 \times 100\,\mathrm{mm}^2$?

56.1.3.2 Ex: Grating spectrometer

The spectrometer in Exc. 56.1.3.1 shall be used in first order for a wavelength range around 500 nm. What is the optimum blaze angle, if the geometry of the spectrometer allows an angle of incidence α about 20°?

56.1.3.3 Ex: Littrow grating

Calculate the number of grooves/mm for a Littrow grating for a 25° incidence at $\lambda = 488\,\text{nm}$ (i.e., the first diffraction order is being reflected back into the incident beam at an angle $\alpha = 25°$ to the grating normal).

56.1.3.4 Ex: Combining spectrometers

A fluorescence spectrum shall be measured with a spectral resolution of 10^{-2} nm. The experimenter decides to use a crossed arrangement of grating spectrometer (linear dispersion: 0.5 nm/mm) and FPI of Exc. 55.1.10.7. Estimate the optimum combination of spectrometer slit width and FPI plate separation.

56.1.4 *Experiment: Separating bichromatic light by prisms and gratings*

In this experiment we will study the dispersive power of a prism and a grating.

1. Combine the beams of a helium-neon laser and a laser at 461 nm via a beam-splitter. Pass this combination through a prism and quantify the dispersion.
2. Calculate the minimum angle between the two beams.
3. Shine the combination onto a reflection grating and quantify the dispersion.

56.1.5 *Experiment: Thorlabs optical spectrum analyzer*

CCS175, characterization, Thorlabs ® tour.

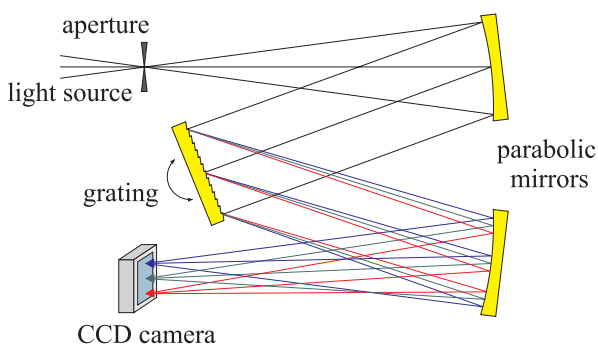

Figure 56.3: Principle of operation of a Czerny-Turner monochromator.

Czerny-Turner CCD spectrometer

1. Irradiate light on OSA and observe the spectrum.

56.1.6 *Experiment: HighFinesse wavemeter*

Wavemeters measure the wavelength of monochromatic light sources by interference. One type of wavemeter is based on a Michelson interferometer, where the length of one interferometer arm is uniformly increased while the interference fringes are counted. Counting the fringes of a known reference laser simultaneously and comparing the counts of the unknown and the reference laser, the wavelength of the unknown laser can be determined with high precision (down to 2 MHz resolution).

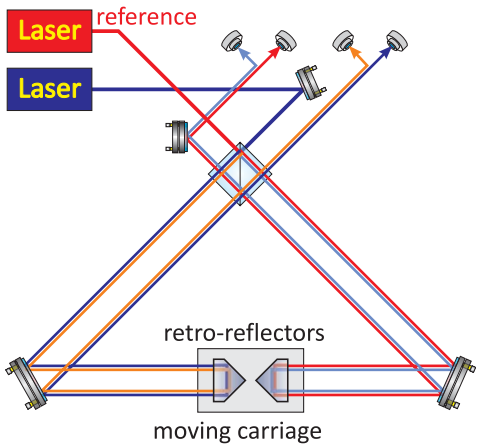

Figure 56.4: Principle of operation of a Michelson-type wavemeter.

1. HighFinesse WSU30, characterization.

56.2 Fluorescence, excitation, and absorption spectroscopy

Depending on the information we want to extract from a sample and on the available instrumentation various types of spectroscopic techniques are possible, which will be discussed on the following sections.

56.2.1 Classification of spectroscopic methods

It is important to distinguish *fluorescence spectra* from *excitation spectra*: Fluorescence spectra are taken by processing the light emitted from a radiator in a monochromator. That is, the light is shone onto a spectral band filter, which only transmits a narrow fraction of the fluorescence spectrum. The power of the transmitted light is measured with a detector. Upon changing the center frequency of the band filter,

different components of the fluorescence spectrum are measured, thus yielding a curve $u(\nu)$, which represents the spectral energy density of the radiator [see Fig. 56.5(a,d)].

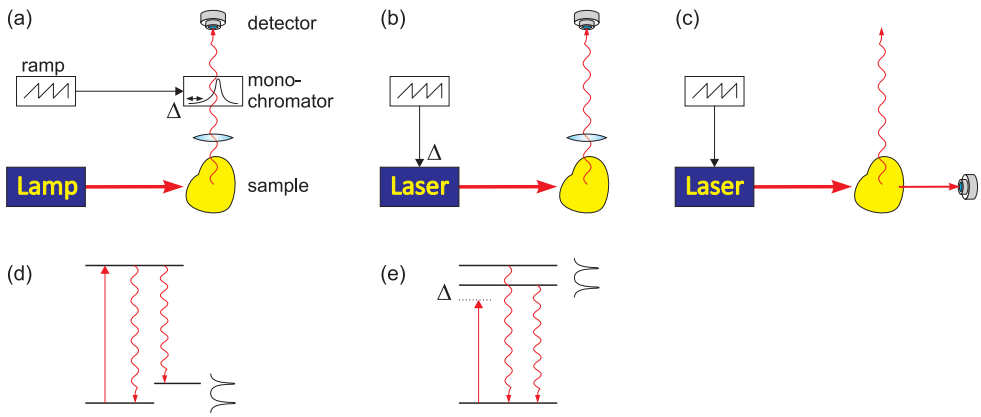

Figure 56.5: (a) Taking a fluorescence spectrum, (b) an excitation spectrum, and (c) an absorption spectrum. Typical level schemes for (d) fluorescence spectroscopy and (e) excitation or absorption spectroscopy.

In contrast to fluorescence spectroscopy, excitation or absorption spectra are taken by varying the frequency of the light exciting a sample. The reemitted light is then measured by a detector without discriminating its frequency components. Obviously, both method yield very different information about the scatterer [see Fig. 56.5(b,c,e)]. Depending on whether the scattered of the transmitted light is detected, we speak of excitation and absorption spectroscopy.

56.2.2 Saturated absorption spectroscopy

One of the most popular spectroscopic technique is *saturation spectroscopy*, as it is simple, robust, and allows to avoid Doppler-broadening. There are, however, many

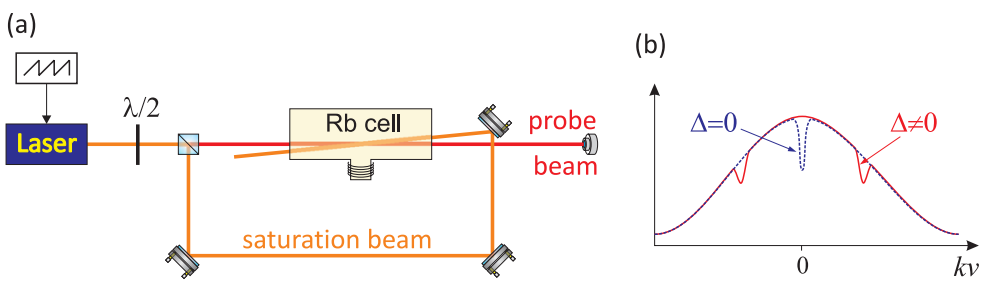

Figure 56.6: (a) Experimental scheme for saturated absorption spectroscopy. (b) Spectral hole burning by the counter-propagating saturation and probe beams for (red) detuned and (blue) resonant light.

possible implementations of saturation spectroscopy, f.ex. *frequency modulation spec-*

troscopy or *modulation transfer spectroscopy*, which we will present in the following.

56.2.2.1 Calculation of the Lamb-dip

The scheme known as *Lamb-dip spectroscopy* and which is illustrated in Fig. 56.6(a), consists in a cell filled with a gas [for example, atomic rubidium whose resonance frequency is $\omega_0 = ck = 2\pi c/780\,\text{nm}$ and decay rate is $\Gamma = (2\pi)\ 6\,\text{MHz}$] and two laser beams with the same frequency ω, but propagating in opposite directions. One is called the saturating beam, the other probe beam.

The basic idea is that, if the laser frequency is detuned from resonance, $\omega \neq \omega_0$, the counter-propagating beams will interact with different velocity classes (i.e. atomic velocities projected on the optical axis, $v = \mathbf{v}\cdot\hat{\mathbf{e}}_{\mathbf{k}}$), which results in two distinct 'holes' in the excitation profile [red curve in Fig. 56.6(b)]. Only for resonant light, $\omega = \omega_0$, will the counter-propagating beams interact with the same velocity class (i.e. atomic velocities with $v = 0$). The 'holes' in the excitation profile then overlap thus leading to a deeper depression called Lamb-dip [blue curve in Fig. 56.6(b)].

For a quantitative description of the Lamb-dip we consider Maxwell's one-dimensional and normalized velocity distribution,

$$\rho(v)dv = \sqrt{\frac{m}{2\pi k_B T}} e^{-mv^2/2k_B T} dv \ . \tag{56.12}$$

As an example, we consider a gas at $T = 300\,\text{K}$ temperature, where the partial pressure of rubidium is about $P = 10^{-1}$ mbar, such that the particle density is,

$$n(T) = \frac{P}{k_B T} \ . \tag{56.13}$$

We also assume a cell length of $L = 10\,\text{cm}$.

The probe laser intensity is below saturation, such that the optical cross section for an atom moving with velocity v, is,

$$\sigma(v) = \frac{6\pi}{k^2} \frac{\Gamma^2}{4(\omega - \omega_0 - kv)^2 + \Gamma^2} \ , \tag{56.14}$$

where we considered the fact that the atoms moving with the velocity v along the optical axis perceive the probe laser beam as Doppler-shifted by an amount kv.

The saturating laser now has high intensity. Let us suppose here, $\Omega \equiv 10\Gamma$, where Ω is the Rabi frequency caused by the saturating laser. In this way, it creates a population of N_e atoms in the excited state. Since this population is missing in the ground state, $N_g = N - N_e$, the absorption is reduced for the probe beam by a factor,

$$\frac{N_e}{N} = \frac{\Omega^2}{4(\omega - \omega_0 + kv)^2 + 2\Omega^2 + \Gamma^2} \ . \tag{56.15}$$

In contrast to (56.14), we now have to consider saturation broadening.

We will now calculate the spectrum of the optical density for the probe laser, $O_D(\omega)$, and the light intensity transmitted through the cell, $\frac{I}{I_0} = e^{-O_D}$, according to the Lambert-Beer law.

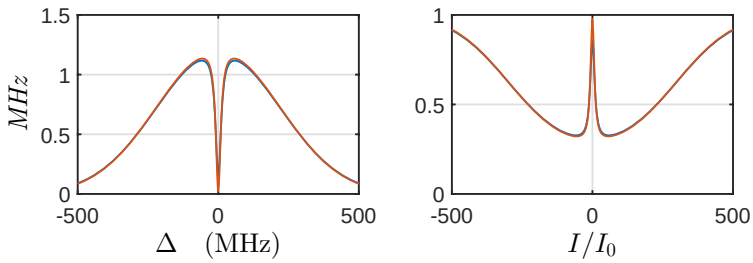

Figure 56.7: (code) (a) Optical density and (b) absorption. (Blue) Integral formula and (green) approximation for high temperature and high saturation.

The optical density with Doppler broadening is,

$$O_D(T,\omega) = Ln(T)\int_{-\infty}^{\infty} \tfrac{N_g-N_e}{N}\sigma(v)\rho(v)dv \tag{56.16}$$
$$= L\frac{P}{k_BT}\sqrt{\frac{m}{2\pi k_BT}}\frac{6\pi}{k^2}\int_{-\infty}^{\infty}\left(1-\frac{2\Omega^2}{4(\Delta+kv)^2+2\Omega^2+\Gamma^2}\right)\frac{\Gamma^2}{4(\Delta-kv)^2+\Gamma^2}e^{-mv^2/2k_BT}dv\ ,$$

with $\Delta \equiv \omega-\omega_0$ and substituting $N_g - N_e = N - 2N_e$. The widths of the three distribution functions are, respectively,

$$\begin{aligned}
\delta\nu_{sat} &= \sqrt{\tfrac{1}{2}\Omega^2+\tfrac{1}{4}\Gamma^2} \approx (2\pi)\ 68\,\text{MHz} && \text{for the saturating beam}\\
\delta\nu_{Dpp} &= k\sqrt{\tfrac{k_BT}{m}} \approx (2\pi)\ 217\,\text{MHz} && \text{for the Doppler broadening}\\
\delta\nu_{prb} &= \tfrac{1}{2}\Gamma \approx (2\pi)\ 3\,\text{MHz} && \text{for the probe beam}
\end{aligned} \tag{56.17}$$

where $\bar{v} = \sqrt{k_BT/m}$ is the mean atomic velocity (or the *rms* width) of Maxwell's distribution. Since the spectral width of the probe laser spectrum is much smaller, we can replace it by a δ-function,

$$\frac{\Gamma^2}{4(\Delta-kv)^2+\Gamma^2} \longrightarrow \frac{\pi\Gamma}{2}\delta(\Delta-kv)\ , \tag{56.18}$$

which gives,

$$\begin{aligned}
O_D(T,\omega) &\simeq L\frac{P}{k_BT}\sqrt{\frac{m}{2\pi k_BT}}\frac{6\pi}{k^3}\int_{-\infty}^{\infty}\left(1-\frac{2\Omega^2}{4(\Delta+kv)^2+2\Omega^2+\Gamma^2}\right)\times \\
&\qquad\times\frac{\pi\Gamma}{2}\delta(\Delta-kv)e^{-mv^2/2k_BT}dkv \\
&= L\frac{P}{k_BT}\sqrt{\frac{m}{2\pi k_BT}}\frac{6\pi}{k^3}\frac{\pi\Gamma}{2}\left(1-\frac{2\Omega^2}{8\Delta^2+2\Omega^2+\Gamma^2}\right)e^{-m(\Delta/k)^2/2k_BT}\ .
\end{aligned} \tag{56.19}$$

The *Lamb dip* is the narrow (Doppler-free) feature in the center of the the spectrum exhibited in Fig. 56.7. Lamb-dip spectra are commonly serve as frequency references for laser frequency stabilization schemes.

56.2.3 Frequency modulation and modulation transfer spectroscopy

Variations of the saturation spectroscopic idea are the *frequency modulation spectroscopy* (FMS) and the *modulation transfer spectroscopy* (MTS). The basic scheme of those techniques is shown in Fig. 56.8. As in saturation spectroscopy, two counterpropagating beams interact with the same atoms of a molecular gas, but now one of the beams is frequency-modulated (e.g. using an electro-optic modulator). In the FMS configuration, the probe beam is modulated, and the sidebands are discriminated at the spectral feature generated by the saturation beam in a very similar way as for the Pound-Drever-Hall technique. The profile of the FMS signal is calculated in Exc. 56.2.4.3 [571, 93, 410, 863, 498, 154, 278, 845, 818, 450, 606].

In the MTS configuration, the saturation beam is modulated, and the sidebands are transferred to the probe beam via nonlinear four-wave mixing processes. In both cases, the sidebands are demodulated with the local oscillator frequency driving the EOM.

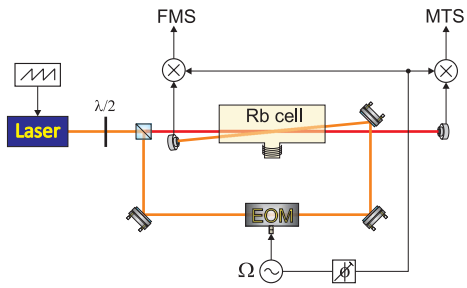

Figure 56.8: Schemes of frequency-modulation and modulation transfer spectroscopy.

The advantages of both techniques is, that they generate dispersive Doppler-free lineshapes. The FMS signal appears as a sharp feature on top of a large Doppler background (similarly to the Lamb-dip). In contrast, the MTS signal is free from Doppler background. The MTS signal recorded by the photodetector is given by,

$$I(\Delta) = \sum_{a,b} \frac{\mu_{ab}^2}{\gamma_j + \imath\delta} \left(\frac{1}{\gamma_{ab} + \imath(\Delta + \delta/2)} - \frac{1}{\gamma_{ab} + \imath(\Delta + \delta)} + \frac{1}{\gamma_{ab} - \imath(\Delta - \delta)} - \frac{1}{\gamma_{ab} - \imath(\Delta - \delta/2)} \right) , \tag{56.20}$$

where a and b denote the lower and upper levels, μ_{ab}^2 is the electric dipole moment, γ_{ab} is the optical relaxation rate, γ_j is the decay of the energy level j of the molecule, and δ is the modulation frequency. Behind the mixer we see the electric signal,

$$S(\Delta, \vartheta) = \mathrm{Re}\left[I(\Delta) e^{-\imath\varphi} \right] , \tag{56.21}$$

where ϑ is the demodulation phase [605]. The curves are shown in Fig. 56.8.

Example 386 (*Modulation transfer spectroscopy*): Modulation transfer spectroscopy is caused by four-wave mixing (4WM) processes, which have the

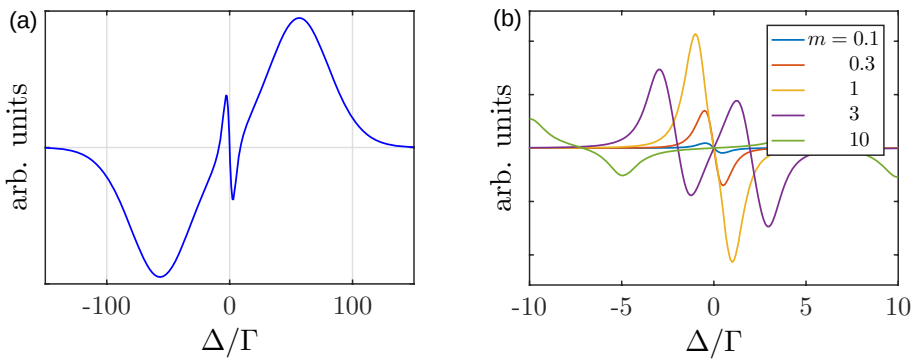

Figure 56.9: (code) (a) Calculated FMS signals and (b) MTS signals as a function of detuning for various modulation indices.

general form $P(\omega+\Omega) = \chi^{(3)}(\omega+\Omega)E_s(\omega_s)E_p(\omega_s)E_s^*(\omega_s-\Omega)$, or similar. When the beams ω and ω_s are counter-propagating, and the atoms are moving, their resonances shift toward $\omega\mp\mathbf{k}\cdot\mathbf{v}$, respectively in the atomic rest system. Resonant enhancement of 4WM occurs, when one of the intermediate levels coincides with ω_0:

$$
\begin{aligned}
&\omega - \mathbf{k}\cdot\mathbf{v} = \omega_0 \\
&(\omega - \mathbf{k}\cdot\mathbf{v}) - (\omega + \mathbf{k}\cdot\mathbf{v} - \Omega) = 0 \\
&(\omega - \mathbf{k}\cdot\mathbf{v}) - (\omega + \mathbf{k}\cdot\mathbf{v} - \Omega) + (\omega + \mathbf{k}\cdot\mathbf{v}) = \omega_0 \\
&(\omega - \mathbf{k}\cdot\mathbf{v}) - (\omega + \mathbf{k}\cdot\mathbf{v} - \Omega) + (\omega + \mathbf{k}\cdot\mathbf{v}) - (\omega - \mathbf{k}\cdot\mathbf{v} + \Omega) = 0\ .
\end{aligned}
$$

Assuming $\omega = \omega_s = \omega - 0$, these resonances reduced to,

$$\mathbf{k}\cdot\mathbf{v} = 0, \pm\Omega\ ,$$

and similarly for the other 4WM processes. This means, that the saturation beam burns holes in the velocity distribution at $\mathbf{k}\cdot\mathbf{v} = 0, \pm\frac{1}{2}\Omega, \pm\Omega$, which modulate the probe beam.

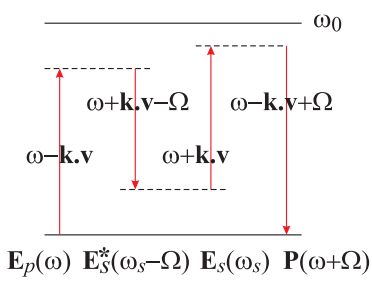

Figure 56.10: Levels involved in 4WM upon MTS.

56.2.4 Exercises

56.2.4.1 Ex: Width of the absorption band

The resonator of a dye laser with a large emission bandwidth additionally contains an absorbing (dense) gas. The absorption spectrum of the gas is Lorentzian with a width of 3 GHz, and the absorption coefficient has, in the middle of the absorption line (at 600 nm), the value of 0.2. What are the maximum and minimum relative spectral distances $\Delta f/\Delta f_0$ of the axial modes within the spectral range of the absorption, compared to the distances Δf_0 of the empty resonator?

56.2.4.2 Ex: Lorentz and Gaussian profiles

At which detuning is a Doppler-broadened line dominated by Lorentzian profile of the transition?

56.2.4.3 Ex: Frequency-modulation spectroscopy

Calculate the FMS spectrum for a rubidium gas (describing the atoms as a two-level system) under the conditions specified in Sec. 56.2.2 and assuming a modulation frequency of $f = 10\,\mathrm{MHz}$ and a modulation index of $\beta = 1$.

56.2.5 *Experiment: Rubidium Lamb-dips*

In this exercise, we will spectroscopically identify the various lines of the rubidium D_2-transition of the isotopes ^{87}Rb and ^{85}Rb. The hyperfine splittings of the ground and excited states are reproduced in Fig. 56.11.

1. Set up the optics for a Lamb-dip spectroscopy as shown in Fig. 56.11.

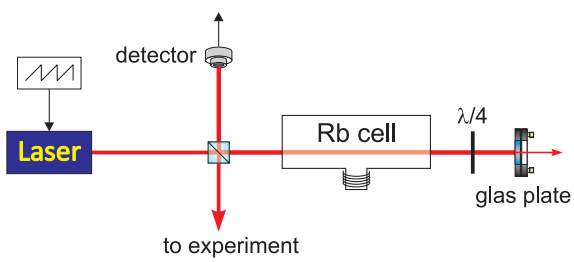

Figure 56.11: Saturation spectroscopy.

2. Fig. 56.12 shows a typical spectrum recorded with a rubidium gas cell. Find an interpretation for the various lines of the spectrum.

56.3 Polarization spectroscopy

The *Hänsch-Couillaud technique* uses the *birefringence* of certain materials, devices, or gases.

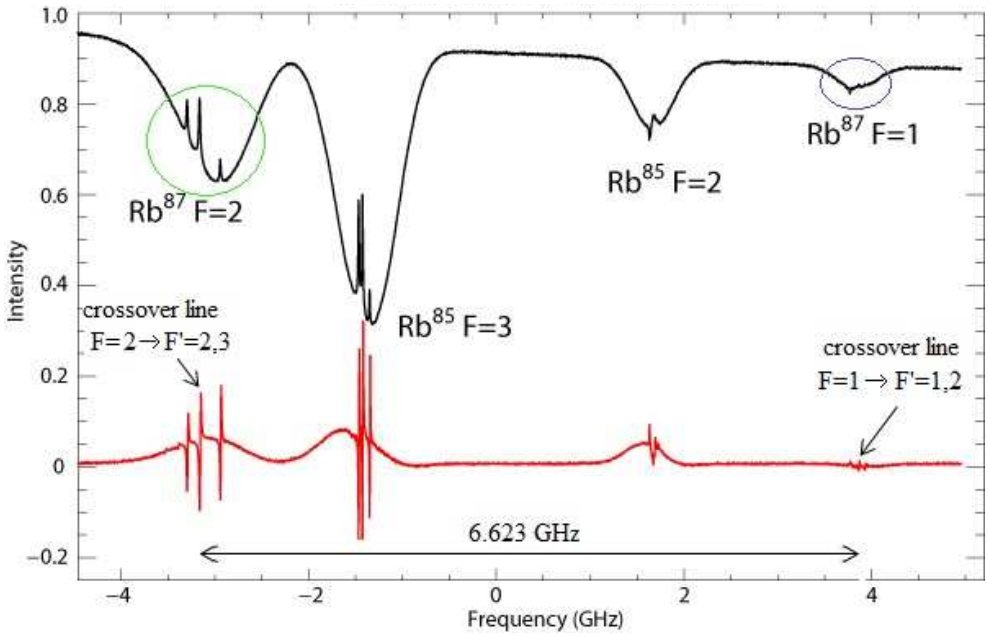

Figure 56.12: (Black) Lamb-dip spectroscopy of a rubidium gas (natural isotope mixture of ^{85}Rb and ^{87}Rb) showing the hyperfine structure transitions of the D2-line. (Red) Derivative of the spectrum in (a).

56.3.1 Birefringent cavity

We consider a birefringent cavity exhibiting slightly different path lengths for two axis that we will call, respectively, *ordinary* and*extraordinary*. Fig. 56.13(a) shows the optical setup. The detector signals may be calculated via a concatenation of the Jones matrices for a $\lambda/2$-plate, the transmissive response of the cavity, another $\lambda/2$-plate, and finally a polarizing beam splitter,

$$\begin{pmatrix} E_o \\ E_e \end{pmatrix} = M \begin{pmatrix} 1 \\ 0 \end{pmatrix} \qquad with \tag{56.22}$$

$$M \equiv \begin{pmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} \frac{T}{1-Re^{2\imath k_o L}} & 0 \\ 0 & \frac{T}{1-Re^{2\imath k_e L}} \end{pmatrix} \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} . \tag{56.23}$$

For the particular polarization angles $\alpha = \frac{\pi}{4}$ and $\beta = 0$, we derive the difference of the photodetector signals,

$$\Delta I = |E_o|^2 - |E_e|^2 = \frac{T^2}{2} \left[\frac{1}{1 - R^2 - 2R\cos 2k_o L} - \frac{1}{1 - R^2 - 2R\cos 2k_e L} \right] . \tag{56.24}$$

As Fig. 56.13(b) demonstrates, the spectra corresponding to the axis, obtained by ramping the laser frequency are slightly shifted with respect to each other. Their subtraction leads to a dispersive lineshape that suits for laser locking purposes in the so-called *Hänsch-Couillaud* stabilization.

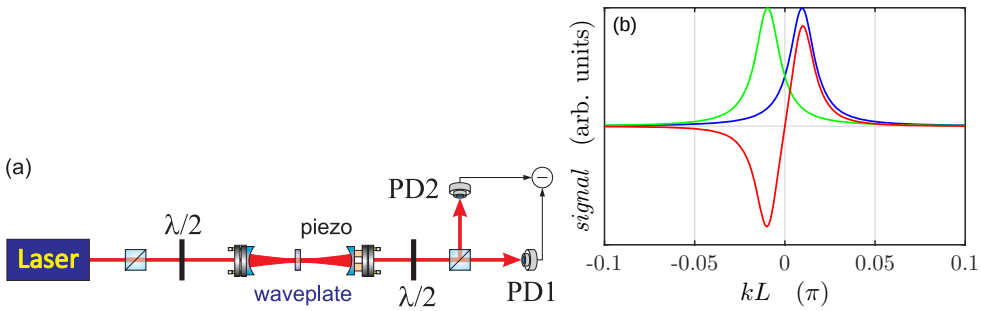

Figure 56.13: (code) (a) Generating a Hänsch-Couillaud error signal by transmission of a birefringent linear cavity. (b) Signals recorded by the two photodetectors (blue and green) and their difference (red).

56.3.2 *Experiment: Birefringence of a ring cavity*

Birefringence automatically occurs in a ring cavities. In this exercise, we will analyze the birefringence observed in reflection of a such a ring cavity. In a *ring cavity*, the resonance frequencies of the s-polarized and the p-polarized modes are slightly shifted from one another due to the different penetration depth of the s- and p-polarized light modes into the layers of the dielectric mirrors. For a moderate finesse of the cavity (say $\mathcal{F} = 2000$), the modes actually overlap. This leads to a birefringence used in the

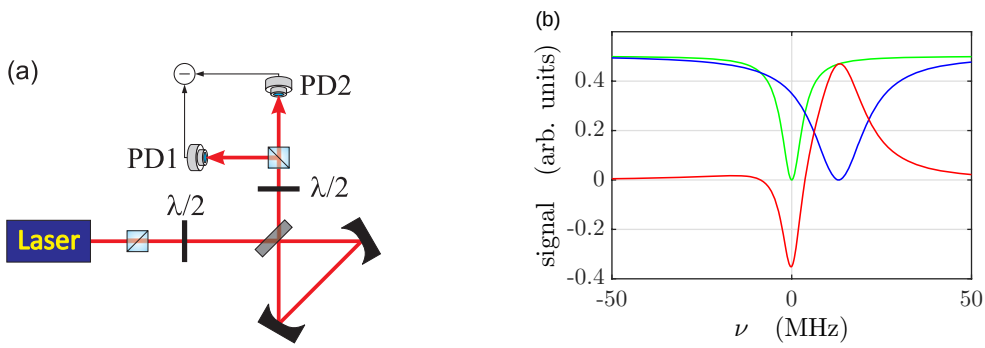

Figure 56.14: (code) (a) Generating a Hänsch-Couillaud error signal by (a) reflection from a ring cavity and (b) transmission of a linear cavity containing a Brewster plate. (b) Signals recorded by the two photodetectors (blue and green) and their difference (red). (a) Reflection signals $|E_s|^2$ and $|E_p|^2$ from a birefringent cavity with $\delta_{fsr} = 8.2\,\text{GHz}$, $\varphi_s = 0$, $R_{hr,s} = 99.97\%$, $R_{ic,s} = 99.74\%$, $F_s = \pi(R_{hr,s}^2 R_{ic,s})^{1/6}/[1-(R_{hr,s}^2 R_{ic,s})^{1/3}]$, $\varphi_p = 0.01$, $R_{hr,p} = 99.92\%$, $R_{ic,p} = 99.34\%$, and $F_p = \pi(R_{hr,p}^2 R_{ic,p})^{1/6}/[1-(R_{hr,p}^2 R_{ic,p})^{1/3}]$. (b) Difference $|E_s|^2 - |E_p|^2$.

famous Hänsch-Couillaud locking scheme. The detector signal in the scheme shown in the figure may calculated via a concatenation of the Jones matrices for a $\lambda/2$-plate, the reflective response of the ring cavity, another $\lambda/2$-plate, and finally a polarizing

beam splitter,

$$\begin{pmatrix} E_s \\ E_p \end{pmatrix} = M \begin{pmatrix} 1 \\ 0 \end{pmatrix} \qquad with \tag{56.25}$$

$$M \equiv \begin{pmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} \frac{1-e^{-2\pi\imath\omega/\delta_{fsr}+\imath\phi_s}}{1-R_s e^{-2\pi\imath\omega/\delta+\imath\phi_s}} & 0 \\ 0 & \frac{1-e^{-2\pi\imath\omega/\delta_{fsr}+\imath\phi_p}}{1-R_p e^{-2\pi\imath\omega/\delta+\imath\phi_p}} \end{pmatrix} \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} .$$

Calculating $|E_s|^2$ and $|E_p|^2$ as a function of the laser frequency ω reproduces the curves plotted in Fig. 56.14(a).

1. x

56.4 Other spectroscopic techniques

56.4.1 Mode-locked femtosecond laser

Mode-locking is a technique in optics by which a laser can be made to produce pulses of light of extremely short duration, down to the order of femtoseconds. The basis of the technique is to induce a fixed-phase relationship between the longitudinal modes of the laser's resonant cavity. Constructive interference between these modes can cause the laser light to be produced as a train of pulses.

In a simple laser, each of these cavity modes amplified within the bandwidth of the gain medium oscillates independently, with no fixed relationship between each other. The individual phase of the light waves in each mode is not fixed, and may vary randomly due to such things as thermal changes in materials of the laser. In lasers with only a few oscillating modes, interference between the modes can cause beating effects in the laser output, leading to fluctuations in intensity; in lasers with many thousands of modes, these interference effects tend to average to a near-constant output intensity.

If instead of oscillating independently, each mode operates with a fixed phase relation to the other modes. Instead of a random or constant output intensity, the modes of the laser will periodically constructively interfere with one another, producing an intense burst or pulse of light. Such a laser is said to be *mode-locked* or *phase-locked*. These pulses occur separated in time by $\tau = 2L/c$, where τ is the laser cavity round trip time and corresponds to the cavity's inverse free spectral range.

56.4.1.1 Active mode-locking

The most common active mode-locking technique places a standing wave electro-optic modulator (EOM) into the laser cavity. When driven with a sinusoidal electrical signal, this produces an amplitude modulation of the light in the cavity. Considering this in the frequency domain, if a mode has optical frequency ν, and is amplitude-modulated at a frequency f, the resulting signal has sidebands at optical frequencies $\nu \pm f$. The modulation frequency is now chosen to coincide with the cavity's free spectral range, $f = \delta_{fsr}$, and since the sidebands are driven in-phase, the central mode and the adjacent modes will be phase-locked together. Further operation of the

modulator on the sidebands produces phase-locking of the $\nu \pm 2f$ modes, and so on until all modes in the gain bandwidth are locked.

This process can also be considered in the time domain. The amplitude modulator acts as a weak 'shutter' to the light bouncing between the mirrors of the cavity, attenuating the light when it is 'closed', and letting it through when it is 'open'. If the modulation rate f is synchronized to the cavity round-trip time τ, then a single pulse of light will bounce back and forth in the cavity. The actual strength of the modulation does not have to be large; a modulator that attenuates 1% of the light when 'closed' will mode-lock a laser, since the same part of the light is repeatedly attenuated as it traverses the cavity.

Related to this amplitude modulation (AM), active mode-locking is frequency modulation (FM) mode-locking, which uses a modulator device based on the acousto-optic effect. This device, when placed in a laser cavity and driven with an electrical signal, induces a small, sinusoidally varying frequency shift in the light passing through it. If the frequency of modulation is matched to the round-trip time of the cavity, then some light in the cavity sees repeated upshifts in frequency, and some repeated downshifts. After many repetitions, the upshifted and downshifted light is swept out of the gain bandwidth of the laser. The only light which is unaffected is that which passes through the modulator when the induced frequency shift is zero, which forms a narrow pulse of light.

The third method of active mode-locking is synchronous mode-locking, or synchronous pumping. In this, the pump source (energy source) for the laser is itself modulated, effectively turning the laser on and off to produce pulses.

56.4.1.2 Passive mode-locking

Passive mode-locking techniques are those that do not require a signal external to the laser to produce pulses. Rather, they use the light in the cavity to cause a change in some intracavity element, which will then itself produce a change in the intracavity light. A commonly used device to achieve this is a saturable absorber.

A saturable absorber is an optical device that exhibits an intensity-dependent transmission. For passive mode-locking, ideally a saturable absorber will selectively absorb low-intensity light, and transmit light which is of sufficiently high intensity. When placed in a laser cavity, a saturable absorber will attenuate low-intensity constant wave light (pulse wings). However, because of the somewhat random intensity fluctuations experienced by an un-mode-locked laser, any random, intense spike will be transmitted preferentially by the saturable absorber. As the light in the cavity oscillates, this process repeats, leading to the selective amplification of the high-intensity spikes, and the absorption of the low-intensity light. After many round trips, this leads to a train of pulses and mode-locking of the laser.

Considering this in the frequency domain, if a mode has optical frequency ν, and is amplitude-modulated at a frequency nf, the resulting signal has sidebands at optical frequencies $\nu \pm nf$ and enables much stronger mode-locking for shorter pulses and more stability than active mode-locking, but has startup problems.

Saturable absorbers are commonly liquid organic dyes, but they can also be made from doped crystals and semiconductors. Semiconductor absorbers tend to exhibit very fast response times ($\sim$100 fs), which is one of the factors that determines the

final duration of the pulses in a passively mode-locked laser. In a colliding-pulse mode-locked laser the absorber steepens the leading edge while the lasing medium steepens the trailing edge of the pulse.

There are also passive mode-locking schemes that do not rely on materials that directly display an intensity dependent absorption. In these methods, nonlinear optical effects in intracavity components are used to provide a method of selectively amplifying high-intensity light in the cavity, and attenuation of low-intensity light. One of the most successful schemes is called Kerr-lens mode-locking (KLM), also sometimes called 'self mode-locking'. This uses a nonlinear optical process, the optical Kerr effect, which results in high-intensity light being focussed differently from low-intensity light. By careful arrangement of an aperture in the laser cavity, this effect can be exploited to produce the equivalent of an ultra-fast response time saturable absorber.

56.4.2 Frequency comb

In optics, a frequency comb is a laser source whose spectrum consists of a series of discrete, equally spaced frequency lines. Frequency combs can be generated by a number of mechanisms, including periodic modulation (in amplitude and/or phase) of a continuous-wave laser, four-wave mixing in nonlinear media, or stabilization of the pulse train generated by a mode-locked laser. The invention of the *frequency comb* represents a breakthrough in ultrahigh resolution spectroscopy, which was honored with the Nobel price attributed to Theodor Hänsch in 2005 [1002, 489, 451, 452, 677, 8, 909].

The frequency domain representation of a perfect frequency comb is a series of delta functions spaced according to,

$$f_n = f_{ceo} + n f_{rep} \ , \tag{56.26}$$

where n is an integer, f_{rep} is the comb tooth spacing (equal to the mode-locked laser's repetition rate or, alternatively, the modulation frequency), and f_{ceo} is the carrier offset frequency, which is less than f_{rep}. Combs spanning an octave in frequency (i.e., a factor of two) can be used to directly measure (and correct for drifts in) f_{ceo}. Thus, octave-spanning combs can be used to steer a piezoelectric mirror within a carrier-envelope phase-correcting feedback loop. Any mechanism by which the combs' two degrees of freedom (f_{rep} and f_{ceo}) are stabilized generates a comb that is useful for mapping optical frequencies into the radio frequency for the direct measurement of optical frequency.

56.4.2.1 Spectrum of a frequency comb

The field emitted by a pulsed laser characterized by its pump laser frequency ν, the *repetition rate* f_{rep}, and the pulse width T, can be given as a temporal sequence of Gaussian shaped pulses. The repetition is mathematically described as a convolution of the Gaussian profile with a sum of temporal δ-functions displaced in time,

$$\boxed{E(t) = \cos 2\pi\nu t \left(\sum_n \delta(t - \tfrac{n}{f_{rep}}) \star e^{-t^2/T^2} \right) = \cos 2\pi\nu t \sum_n e^{-(t-\frac{n}{f_{rep}})^2/T^2}} \ . \tag{56.27}$$

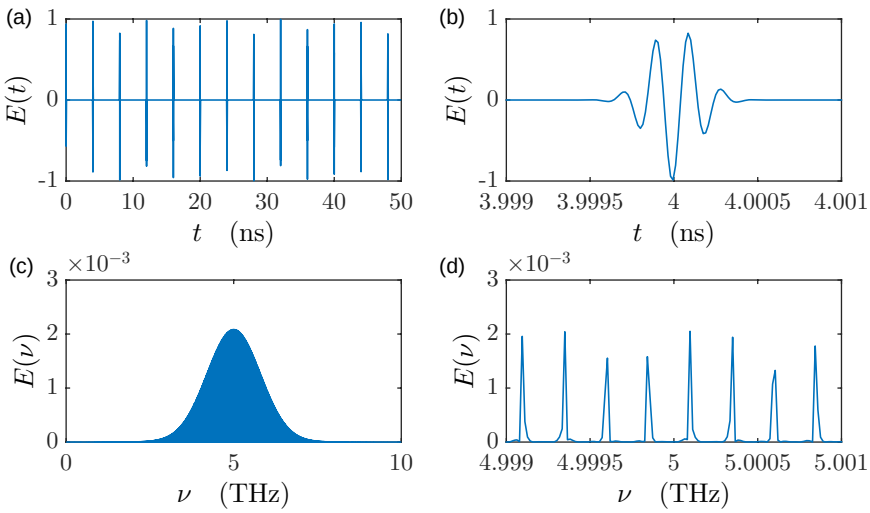

Figure 56.15: (code) Pulse train (a,b) and spectrum (b,c).

The carrier under each pulse is phase-shifted with respect to the adjacent pulse, except when the laser is mode-locked, that is, when,

$$\cos 2\pi\nu t = \cos 2\pi\nu(t + \tfrac{1}{f_{rep}}) \ . \tag{56.28}$$

The Fourier transform of the laser field (56.27) is,

$$\begin{aligned}\mathcal{F}[E(t)] &= \int_{-\infty}^{\infty} e^{-\imath\omega t} \cos 2\pi\nu t \sum_n e^{-(t-n/f_{rep})^2/T^2} dt \\ &= \tfrac{1}{2}\sum_n \int_{-\infty}^{\infty} e^{-\imath(\omega-2\pi\nu)t} e^{-(t-n/f_{rep})^2/T^2} dt \ ,\end{aligned} \tag{56.29}$$

where neglect negative frequency components. Using the rules,

$$\begin{aligned}\mathcal{F}[f(t)e^{\imath\Omega t}] &= \int_{-\infty}^{\infty} e^{-\imath\omega t} f(t) e^{\imath\Omega t} dt = (\mathcal{F}f)(\omega - \Omega) \\ \text{and} \qquad \mathcal{F}[f(t-T)] &= \int_{-\infty}^{\infty} e^{-\imath\omega t} f(t-T) dt = e^{-\imath\omega T}(\mathcal{F}f)(\omega) \\ \text{and} \qquad \mathcal{F}[e^{-t^2/T^2}] &= \int_{-\infty}^{\infty} e^{-\imath\omega t} e^{-t^2/T^2} dt = T\sqrt{\pi} e^{-T^2\omega^2/4}\end{aligned} \tag{56.30}$$

we get,

$$E(\omega) = \mathcal{F}[E(t)] = \tfrac{1}{2} T\sqrt{\pi} e^{-T^2(\omega-2\pi\nu)^2/4} \sum_n e^{-\imath(\omega-2\pi\nu)n/f_{rep}} \ . \tag{56.31}$$

We now write the pump laser frequency as,

$$\nu \equiv m f_{rep} + f_{ceo} \ , \tag{56.32}$$

where we set $m \in \mathbb{N}$ and call $|f_{ceo}| < f_{rep}$ the *carrier envelope offset*. We also express the Fourier frequency by,

$$\omega \equiv 2\pi(\eta f_{rep} + f_{ceo}) \ , \tag{56.33}$$

firstly *without* specifying that η be an integer number. The spectrum is,

$$|E(\omega)|^2 = \tfrac{1}{4}\pi T e^{-T^2(\omega-2\pi\nu)^2/2} \left| \sum_n e^{-2\pi i n(\eta-m)} \right|^2 \ , \tag{56.34}$$

which only gives contributions for,

$$\eta = \frac{\omega - 2\pi f_{ceo}}{2\pi f_{rep}} \in \mathbb{N} \ . \tag{56.35}$$

I.e. the spectrum of comb frequencies is,

$$\boxed{|E(\omega)|^2 = \tfrac{1}{4}\pi T e^{-T^2(\omega-2\pi\nu)^2/2} \sum_n \delta[\omega - (n f_{rep} + f_{ceo})]} \ . \tag{56.36}$$

The δ-function comes from the fact that the sum of (56.35) over many oscillations $e^{-2\pi i n(\eta-m)}$ vanishes by destructive interference, except when they are *in phase*, which is just the case when $\omega = n f_{rep} + f_{ceo}$.

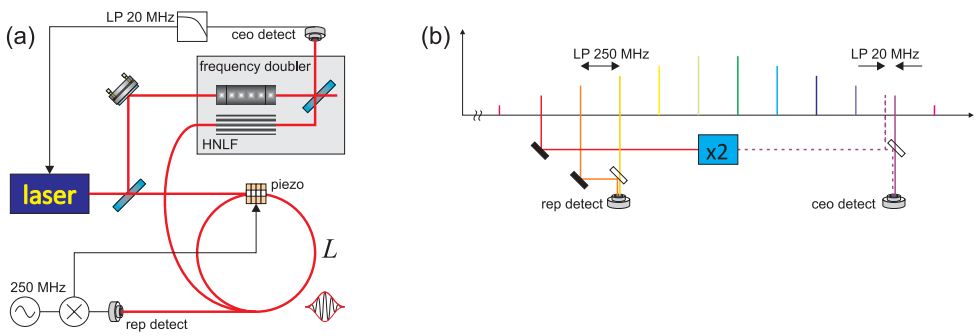

Figure 56.16: (a) Scheme and (b) operation principle of a frequency comb with control of the repetition rate and the carrier envelope offset.

56.4.2.2 Mode-locking of a frequency comb

From Eq. (56.28) we see that *mode-locking* is achieved when,

$$\frac{\nu}{f_{rep}} = m + \frac{f_{ceo}}{f_{rep}} \in \mathbb{N} \ , \tag{56.37}$$

which implies $f_{ceo} = 0$. Eq. (56.36) then becomes,

$$|E(\omega)|^2 = \frac{\pi T}{4} e^{-T^2(\omega-2\pi\nu)^2/2} \sum_n \delta(\omega - n f_{rep}) \ , \tag{56.38}$$

which means that all comb frequencies are locked.

56.4.2.3 Referencing radio and optical frequencies

In a frequency comb f_{rep} is easy to measure, as one just has to filter the beat of the comb light with a low pass filter cutting off frequency components higher than f_{rep}, as illustrated in Fig. 56.16. In contrast, measuring f_{ceo} is more complicated. Unless we have an octave spanning frequency comb, i.e. there are two frequencies in the comb,

$$\nu_1 = m_1 f_{rep} + f_{ceo} \qquad \text{and} \qquad \nu_2 = m_2 f_{rep} + f_{ceo} \ , \tag{56.39}$$

such that $\nu_2 = 2\nu_1 + \Delta\nu$ with $|\Delta\nu| < |f_{ceo}|$, i.e. $m_2 = 2m_1$. We get,

$$m_2 f_{rep} + f_{ceo} = 2m_1 f_{rep} + 2f_{ceo} + \Delta\nu \ , \tag{56.40}$$

or,

$$f_{ceo} = -\Delta\nu \ . \tag{56.41}$$

56.4.2.4 Dual comb spectroscopy

Optical sensors are based on the interaction of light with matter and are often implemented like some kind of spectrometer. The ideal sensor should detect a given substance with great sensitivity, identify it (especially in the presence of many other substances or a noisy background) and quantify it. Add to these features the ability to perform measurements in real time, if possible remotely, in a compact and easy-to-use assembly at affordable price, and we have an absolutely non-trivial problem. Broadband sources allow to detect multiple substances, but have limitations in resolution, calibration or acquisition time. Monochromatic sources allow good resolution, but in general have limitations on tunability and spectral coverage. The sensitivity can be increased by increasing the optical path of interaction, requiring multi-pass cells or resonant optical cavities, which augment the complexity of the setup. Finally, the detection method places limits on the acquisition rate and also on the sensitivity. Particularly the Fourier transform spectroscopy uses broadband incoherent light sources and the time of acquisition and resolution are limited by the speed of translation of a mechanical stage, as well as the range of its displacement. Here, the use of optical frequency combs replacing the incoherent sources, combined with *dual comb spectroscopy*, brings important advantages [938, 436].

56.4.3 Multi-photon spectroscopy

56.4.4 Raman spectroscopy

Raman spectroscopy is a spectroscopic technique typically used to determine vibrational modes of molecules, although rotational and other low-frequency modes of systems may also be observed. Raman spectroscopy is commonly used in chemistry to provide a structural fingerprint by which molecules can be identified. Raman spectroscopy relies upon inelastic scattering of photons, known as Raman scattering. A source of monochromatic light, usually from a laser in the visible, near infrared, or near ultraviolet range is used, although X-rays can also be used. The laser light interacts with molecular vibrations, phonons or other excitations in the system, resulting in the energy of the laser photons being shifted up or down. The shift in energy

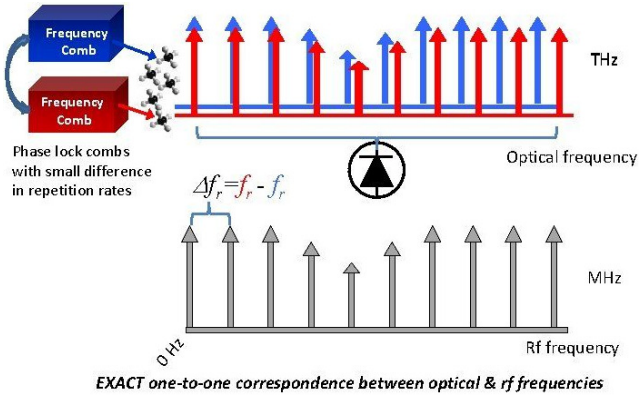

Figure 56.17: Principle of dual comb spectroscopy.

gives information about the vibrational modes in the system. Infrared spectroscopy typically yields similar, complementary, information.

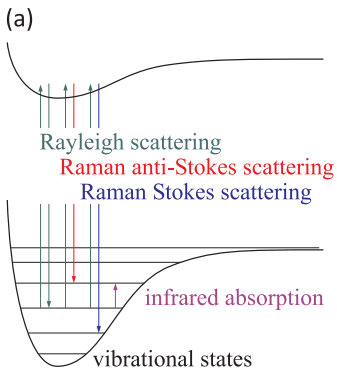

Figure 56.18: Energy-level diagram showing the states involved in Raman spectra.

Typically, a sample is illuminated with a laser beam. Electromagnetic radiation from the illuminated spot is collected with a lens and sent through a monochromator. Elastic scattered radiation at the wavelength corresponding to the laser line (Rayleigh scattering) is filtered out by either a notch filter, edge pass filter, or a band pass filter, while the rest of the collected light is dispersed onto a detector.

Spontaneous Raman scattering is typically very weak; as a result, for many years the main difficulty in collecting Raman spectra was separating the weak inelastically scattered light from the intense Rayleigh scattered laser light (referred to as 'laser rejection'). Historically, Raman spectrometers used holographic gratings and multiple dispersion stages to achieve a high degree of laser rejection. In the past, photomultipliers were the detectors of choice for dispersive Raman setups, which resulted in long acquisition times. However, modern instrumentation almost universally employs notch or edge filters for laser rejection. Dispersive single-stage spectrographs, for example Czerny-Turner (CT) monochromators (see Sec. 56.1.5), paired with CCD

detectors are common.

The name 'Raman spectroscopy' typically refers to vibrational Raman using laser wavelengths which are not absorbed by the sample. Raman spectroscopy is used in chemistry to identify molecules and study chemical bonding and intramolecular bonds. Because vibrational frequencies are specific to a molecule's chemical bonds and symmetry (the fingerprint region of organic molecules is in the wavenumber range $500 - 1500\,\mathrm{cm}^{-1}$, Raman provides a fingerprint to identify molecules.

In solid-state physics, Raman spectroscopy is used to characterize materials, measure temperature, and find the crystallographic orientation of a sample. As with single molecules, a solid material can be identified by characteristic phonon modes. Information on the population of a phonon mode is given by the ratio of the Stokes and anti-Stokes intensity of the spontaneous Raman signal. Raman spectroscopy can also be used to observe other low frequency excitations of a solid, such as plasmons, magnons, and superconducting gap excitations. Distributed temperature sensing (DTS) uses the Raman-shifted backscatter from laser pulses to determine the temperature along optical fibers.

Chapter 57

Locking circuits

In a laboratory we are often confronted with the need to control the value of a physical parameter, f.ex., room temperature, currents and voltages, or the frequency and intensity of laser beams. The physical discipline dealing with the fundamental concepts of this field is called *control theory* and its application to development of automatic control systems is called *control engineering*.

In this chapter, after a brief introduction into *control theory*, we will design and construct a few automatic control systems, which are common in quantum optics labs.

57.1 Introduction to control theory

The minimum ingredients of a control system are 1. a *sensor* measuring the actual value of the parameter to be controlled (e.g., a thermometer), 2. an *actuator* capable of correcting the value (e.g., a heater or cooler), and 3. a suitable *controller* (*servo system*) linking sensor and actuator thus providing a feedback.

The controller comprises a *comparator* comparing the measured value with a reference and delivers the difference to a controller, which may be implemented electronically by proportional control, *PID control*, bistable hysteretic control, or programmable logic control. Older controller units have been mechanical, as in a carburetor. Finally, the value computed by the controller is delivered to an actuator, which manipulates and changes a variable in the controlled system (or *plant*).

57.1.1 Open- and closed-loop control

Fundamentally, there are two types of control loop: *open loop* control, and *closed loop* (feedback) control.

In open loop control, the control action from the controller is independent of the 'process output' (or 'controlled process variable'). An example of this is a central heating boiler controlled only by a timer, so that heat is applied for a constant time, regardless of the temperature of the building. The control action is the switching on/off of the boiler. The process output is the building temperature.

In closed loop control, the control action from the controller is dependent on the process output. In the case of the boiler analogy, this would include a thermostat to monitor the building temperature, and thereby feed back a signal to ensure the controller maintains the building at the temperature set on the thermostat. A closed loop controller therefore has a feedback loop which ensures the controller exerts a

control action to give a process output the same as the 'reference input' or 'set point'. For this reason, closed loop controllers are also called feedback controllers.

The definition of a closed loop control system is *a control system capable of canceling the deviation of a system variable from a reference value by means of a feedback signal computed from a measured value of the variable and used to act on the system in a controlled way* [880]. Automatic feedback control has revolutionized all areas of human activities.

To overcome the limitations of the open-loop controller, control theory introduces *feedback*. A closed-loop controller uses feedback to control states or outputs of a dynamical system. Its name comes from the information path in the system: process inputs (e.g. voltage applied to an electric motor) have an effect on the process outputs (e.g. speed or torque of the motor), which is measured with sensors and processed by the controller; the result (the control signal) is 'fed back' as input to the process, closing the loop.

Closed-loop controllers have the following advantages over open-loop controllers:

- disturbance rejection (such as hills in the cruise control example above)
- guaranteed performance even with model uncertainties, when the model structure does not match perfectly the real process and the model parameters are not exact
- unstable processes can be stabilized
- reduced sensitivity to parameter variations
- improved reference tracking performance

In some systems, closed-loop and open-loop control are used simultaneously. In such systems, the open-loop control is termed feedforward and serves to further improve reference tracking performance.

57.1.1.1 Closed-loop transfer function

Due to noise the variables of the system become time-dependent. The output of the system $y(t)$ is fed back through a sensor measurement F to a comparison with the reference value $r(t)$. The controller C then takes the error $e(t)$ (difference) between the reference and the output to change the inputs $u(t)$ to the system under control P. This is shown in the figure. This kind of controller is a closed-loop controller or feedback controller. We will restrain here to *single-input-single-output control* systems (SISO) disregarding the possibility of having multiple and interdependent inputs and outputs.

If we assume the controller C, the plant P, and the sensor F are linear and time-invariant (i.e. elements of their transfer function $C(s)$, $P(s)$, and $F(s)$ do not depend on time), the systems above can be analyzed using the Laplace transform on the variables, $U(s) = \mathcal{L}u(t)$, $Y(s) = \mathcal{L}y(t)$, and $R(s) = \mathcal{L}r(t)$. Here,

$$s \equiv \imath f \tag{57.1}$$

is an abbreviation for the imaginary Fourier frequency component f of the noise. In the following sections we will, however, characterize the transfer functions in terms

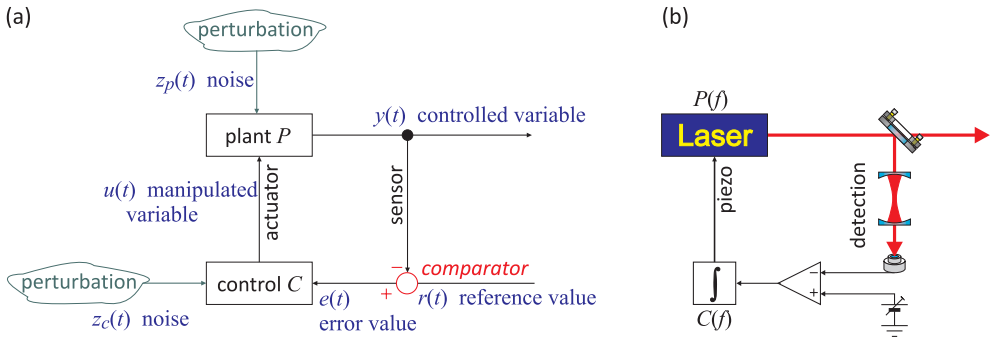

Figure 57.1: (a) General schematic diagram of a feedback loop. (b) Possible implementation for the frequency stabilization of a laser to a cavity resonance,

of real Fourier frequencies. The theoretical foundation of Linear Time-Independent (LTI) systems is outsourced to Sec. 58.2.

For a control to work, it needs to know in which direction to act and when the control point is reached. Therefore, each control needs a slope (*discriminator*) crossing zero. This can be implemented by comparing the signal $Y(f)$ delivered by the detector (for simplicity assumed to be frequency-independent) with a reference signal R. The error signal $E(f) = R(f) - Y(f)$ is then processed by a controller C, and the control signal $U(f)$ is passed, via an actuator (for simplicity assumed to be frequency-independent), to the controlled device P. The controlled device (and obviously all other components of the circuit) are subject to perturbations Z. The transfer functions form a closed control circuit described by the following relations:

$$Y(f) = P(f)U(f) \quad \text{and} \quad U(f) = C(f)E(f) \quad \text{and} \quad E(f) = R(f) - Y(f) \,. \tag{57.2}$$

Solving the system of equations (57.2) for $Y(f)$ in terms of $R(f)$ gives,

$$\boxed{Y(f) = \frac{P(f)C(f)}{1 + P(f)C(f)}\, R(f) \equiv H(f)R(f)} \,. \tag{57.3}$$

$H(s)$ is referred to as the closed-loop transfer function of the system. The numerator $V(f) \equiv P(f)C(f)$ is called the *forward gain* (*open-loop gain*) from R to Y, and the denominator is one plus the gain in going around the feedback loop, the so-called *loop gain*. If $|P(f)C(f)| \gg 1$, i.e. it has a large norm with each value of f, and then $Y(f) \simeq R(f)$ and the output closely tracks the reference input.

57.1.1.2 Noise reduction via feedback circuits

We have seen that the idea of *locking*, whether mechanical or electronic, is to bring a given physical signal Y to a predetermined value R and lock it there, which is the role of the control circuit or *regulator*. Now, considering a possible perturbation of the plant (see Fig. 57.1) by noise Z_p and also of the regulator by noise Z_c, the result (57.3) must be generalized,

$$Y(f) = \frac{P(f)C(f)}{1 + P(f)C(f)} R(f) + \frac{P(f)C(f)}{1 + P(f)C(f)} Z_c(f) + \frac{1}{1 + P(f)C(f)} Z_p(f) \,, \tag{57.4}$$

or,

$$\boxed{Y(f) = \frac{1}{1+V(f)^{-1}}[R(f)+Z_c(f)] + \frac{1}{1+V(f)}Z_p(f)} \,. \tag{57.5}$$

This shows that, provided the open loop gain is high enough, perturbations affecting the plant can be efficiently be neutralized. In contrast, noise entering via the control cannot be suppressed, and this fact is independent on the chosen controller transfer function: *Perturbations entering between the measurement point and the input of the regulator are not eliminated*! Consequently, the detector (which generally works with very low signals) should not introduce or let penetrate noise, because this affects the variable to be controlled: Any variation of the steering variable at the regulator will be transmitted 1 to 1.

In the following, we will discuss the most common controller called PID-servo.

57.1.2 PID feedback control

A *PID controller* continuously calculates an error value $e(t)$ as the difference between a desired setpoint and a measured process variable and applies a correction based on proportional, integral, and derivative terms. PID is an acronym for Proportional-Integral-Derivative, referring to the three terms operating on the error signal to produce a control signal.

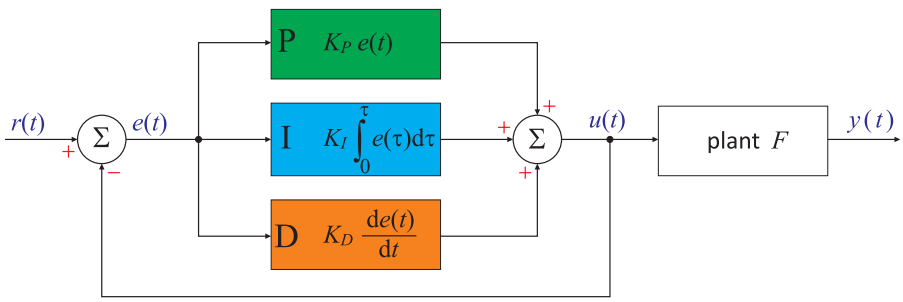

Figure 57.2: A block diagram of a PID controller in a feedback loop, $r(t)$ is the desired process value or 'set point', and $y(t)$ is the measured process value. A proportional-integral-derivative controller (PID controller) is a control loop feedback mechanism control technique widely used in control systems.

The theoretical understanding and application dates from the 1920s, and they are implemented in nearly all analogue control systems; originally in mechanical controllers, and then using discrete electronics and latterly in industrial process computers. The PID controller is probably the most-used feedback control design.

If $u(t)$ is the control signal sent to the system, $y(t)$ is the measured output and $r(t)$ is the desired output, and tracking error $e(t) = r(t) - y(t)$, a PID controller has the general form,

$$\boxed{u(t) = K_P e(t) + K_I \int e(\tau)d\tau + K_D \frac{de(t)}{dt}} \,. \tag{57.6}$$

The desired closed loop dynamics is obtained by adjusting the three parameters K_P, K_P, and K_I, often iteratively by 'tuning' and without specific knowledge of a plant model. Stability can often be ensured using only the proportional term. The integral term permits the rejection of a step disturbance (often a striking specification in process control). The derivative term is used to provide damping or shaping of the response [1].

Applying Laplace transformation results in the transformed PID controller equation,

$$\boxed{U(f) = \left(K_P + K_I \frac{1}{\imath f} + K_D \imath f\right) E(f) \equiv C(f)E(f)} \,, \tag{57.7}$$

defining the PID controller transfer function $C(f)$.

From equations (57.6) or (57.7) we immediately see that the PID transfer functions can readily be implement in electronic circuits using resistors (P), capacitors (I), and inductances (D).

Example 387 (*Comparing servo controllers*): We now assume a low-pass behavior for the plant,

$$P(f) = \frac{1}{1 + \imath f/f_c} \,,$$

and analyze the feedback circuit for four cases.

- The first one is that of a proportional servo, $C(f) = K_P$. Then, Eq. (57.5) reads,

$$Y = \frac{K_P}{1 + \imath f/f_c + K_P}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + \imath f/f_c + K_P} Z_p$$
$$\begin{cases} \xrightarrow{s\to 0} \frac{K_P}{1+K_P}(R + Z_c) + \frac{1}{1+K_P} Z_p \\ \xrightarrow{s\to\infty} \frac{K_P f_c}{\imath f}(R + Z_c) + Z_p \end{cases} .$$

  We see that, for limited open-loop gain, noise affecting the plant Z_p is not eliminated at low frequencies. Additionally, at high frequencies, the gain for the error signal R drops like -6dB/oct.

- The second case is that of an integral servo $C(f) = K_I/\imath f$. Then Eq. (57.5) reads,

$$Y = \frac{K_I/\imath f}{1 + \imath f/f_c + K_I/\imath f}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + \imath f/f_c + K_I/\imath f} Z_p$$
$$\begin{cases} \xrightarrow{f\to 0} R + Z_c + \frac{\imath f}{K_I} Z_p \\ \xrightarrow{\to\infty} \frac{K_I f_c}{(\imath f)^2}(R + Z_c) + Z_p \end{cases} .$$

  Apparently, the noise Z_p is now eliminated at low frequencies. However, the gain for R drops even faster at high frequencies.

[1] PID controllers are the most well established class of control systems: however, they cannot be used in several more complicated cases, especially if MIMO systems are considered.

- The third case is that of a PI-servo, $C(f) = K_P + K_I/\imath f$. Then Eq. (57.5) reads,

$$Y = \frac{K_P + K_I/\imath f}{1 + \imath f/f_c + K_P + K_I/\imath f}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + \imath f/f_c + K_P + K_I/\imath f} Z_p$$
$$\begin{cases} \xrightarrow{f\to 0} R + Z_c + \frac{\imath f}{K_I} Z_p \\ \xrightarrow{f\to\infty} \frac{f_c K_P}{\imath f}(R + Z_c) + Z_p \end{cases},$$

  which represents a viable compromise, since it has the same low-frequency behavior as the I-servo, but at high frequencies the gain for R drops only like -6dB/oct.

- Finally, the forth case is that of a PID-servo, $C(f) = K_D \imath f + K_P + K_I/\imath f$. Then Eq. (57.5) reads,

$$Y = \frac{K_D \imath f + K_P + K_I/\imath f}{1 + \imath f/f_c + K_D \imath f + K_P + K_I/\imath f}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + K_D \imath f + K_P + K_I/\imath f} Z_p$$
$$\begin{cases} \xrightarrow{f\to 0} R + Z_c + \frac{\imath f}{K_I} Z_p \\ \xrightarrow{f\to\infty} \frac{1}{1+1/f_c K_d}(R + Z_c) + \frac{1}{f_c K_D} Z_p \end{cases}.$$

  The low-frequency behavior remains still the same, but at high frequencies the gain for R stays constant.

A time domain analysis shows that P regulators have little phase lag, but the controlled variable can not be zeroed. On the other hand, I regulators have finite control bandwidth, but the controlled variable can be zeroed. PI regulators (parallel circuit of P and I regulators) have a reaction time $T_n = K_P/K_I$; that is, the jump response is advanced by T_n in comparison to the regulator I.

In the time domain we can summarize that regulators

- D are characterized by the absence of memory, but they are very fast,
- P have no idea of the strength of their impact,
- I increase their impact in time until the error disappears.

For practical PID controllers, a pure differentiator is neither physically realizable nor desirable due to amplification of noise and resonant modes in the system. Therefore, a phase-lead compensator type approach is used instead, or a differentiator with low-pass roll-off [454, 322, 323, 919]. See Excs. 57.2.3.1 and 57.2.3.2.

Like any real system, the controlled device behaves as a low-pass for manipulations or perturbations at high frequency. In other words, the device can only respond to external perturbations with finite speed. This delay of the response leads to a phase shift that can reverse the sign of the error signal $E(f)$ and transform a negative feedback into a positive feedback. Now, in the case that there are high frequency perturbations, for which the amplification of the closed control circuit is > 1, these perturbations can be amplified to form oscillations. These oscillations, which occur at the bandwidth of the closed loop gain are called *servo oscillations*.

Fig. 57.3 illustrates the necessity of optimizing the gain and the frequency response of the servo circuit: A proportional servo simply providing a frequency-independent gain $C(f) = K_P$ will lead to a forward gain $R(f) \propto P(f)$ exhibiting a low-pass behavior, i.e. a phase-shift $\phi = -\pi/2$ transforming negative to positive feedback. The gain at the frequency where this happens need to be lower than 1, otherwise the feedback servo will generate servo-oscillations, i.e. it will oscillate at the lowest Fourier frequencies where noise is amplified. A PI-servo alleviates this problem by a phase shift in opposite direction.

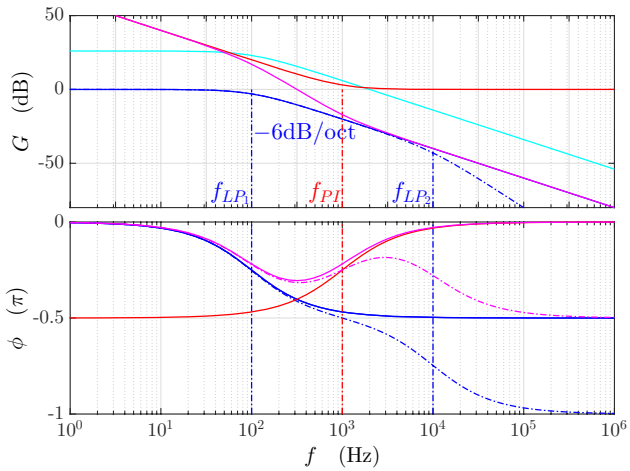

Figure 57.3: (code) Bode diagram for a plant subject to low-pass behavior and for a PI-servo. (blue solid) Low-pass filter with 100 Hz bandwidth; (blue dash-dotted) another low-pass filter at 100 kHz; (cyan) same as blue, but amplified by 20 dB; (red) PI-servo; (magenta) open-loop amplification.

57.1.3 Noise transfer in feedback loops

In order to develop a model for noise transfer we must understand what noise is and how it can be measured. This is not a simple task and we therefore outsourced a proper discussion to Sec. 58.3. Here, we will only use the information that noise affecting a signal $y(t)$ is quantified by a *spectral noise density* defined as the Fourier transform of the signal's autocorrelation function (58.59),

$$S_y(f) \equiv \mathcal{F}[\overline{y^*(t)y(t+\tau)}] \ . \tag{57.8}$$

Now, we can see how noise is transmitted through an LTI device $P(f)$:

$$\boxed{Y(f) = P(f)X(f) \quad \Rightarrow \quad S_y(f) = |P(f)|^2 S_x(f)} \ . \tag{57.9}$$

This result can be applied to our formula (57.5) describing a feedback loop,

$$\boxed{S_y(f) = \left|\frac{1}{1+V(f)^{-1}}\right|^2 S_c(f) + \left|\frac{1}{1+V(f)}\right|^2 S_p(f)} \ . \tag{57.10}$$

This formula describes how a servo control shapes the noise spectrum of a feedback-controlled variable $y(t)$.

Example 388 (*Noise reduction by feedback*): As an example, let us study the control circuit for stabilizing a laser to a cavity mode depicted in Fig. 57.1(b) using the following additional background information: The laser frequency ω be perturbed by $1/f$ noise described by the power spectral density,

$$S_p(f) \equiv 2 \cdot 10^{-24}/f \ .$$

This noise enters the feedback loop via the fluctuations $z_p(t)$ depicted in

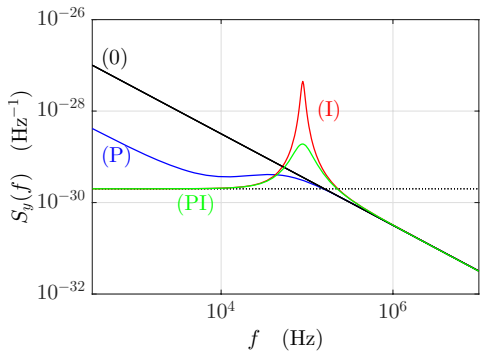

Figure 57.4: (code) Spectral density of frequency fluctuations of the servo system exhibited in Fig. 57.2. Shown is the spectral noise density $S_y(f)$ of the laser light for 4 different feedback gain curves: (black solid) no feedback control $C(f) = 0$, (blue) P-regulator with $C(f) = 4$, (red) I-regulator with $C(f) = 5 \cdot 10^6/\imath f$, and (green) PI-regulator $C(f) = 4 + 5 \cdot 10^6/\imath f$.

Fig. 57.1(a). The black solid line in Fig. 57.4 traces the noise spectrum $S_p(f)$, which is also the noise expected for the laser without feedback loop. Furthermore the optical cavity, which constitutes the essential part of the regulator, is itself afflicted by acoustic noise and thermal drifts which, for simplicity, we describe by a white Fourier frequency spectrum given by,

$$S_c(f) \equiv 2 \cdot 10^{-30}\,\mathrm{Hz}^{-1} \ ,$$

and represented by the black dotted line in Fig. 57.4. As we have seen, servos systems always have a finite bandwidth beyond which noise is fully coupled to the system. For example in laser frequency locks, the weakest point of a servo chain is often the small bandwidth of a piezo transducer used to correct the length of the laser cavity. We describe this behavior by a low-pass filter for the transfer function of the laser,

$$P(f) = \frac{1}{1 + \imath f/f_c}$$

with a bandwidth of $f_c = 10\,\mathrm{kHz}$.
Fig. 57.4 demonstrates how the $1/f$ noise $S_p(f)$ can be efficiently suppressed at frequencies below the low-pass filter cut-off f_c to a value limited by the white noise $S_c(f)$ entering through the regulator. As predicted by the formula (57.10), the suppression of the noise $S_p(f)$becomes all the better, as the open-loop gain

$V(f)$ gets higher. However, with the amplification of the controller, also the gain of the closed control circuit increases, and this necessarily causes phase shifts, which lead to (servo-)oscillations in the circuit appearing as a strong peak of strong noise around a certain Fourier frequency f_{bw} characterizing the bandwidth of the closed loop servo system. Note that high-frequency noise, to which the cavity might be subject, is not coupled to the laser, because it is filtered by the low-pass filter $P(f)$ to the same extend as the error signal itself.

The next example, exhibited in Fig. 57.5, shows the experimental characterization of a dye laser locked via the Pound-Drever-Hall technique (see Sec. 57.3.3) to an optical cavity.

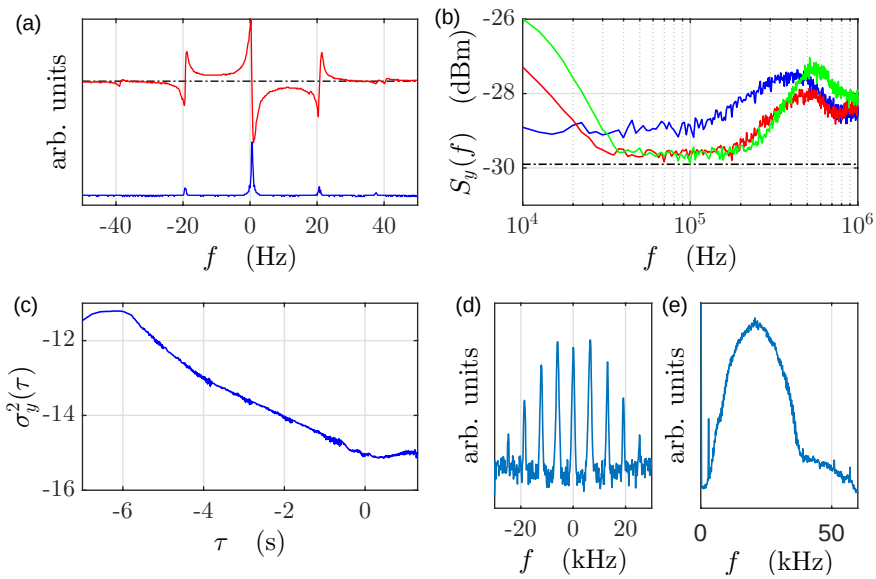

Figure 57.5: Characterization of a Pound-Drever-Hall stabilization of a dye laser. (a) PDH error signal (red) and cavity transmission signal (blue), (b) spectral density of frequency fluctuations, (c) Allan variance. (d-e) Beat signals of Mach-Zehnder interferometers. In (d) one interferometer arm is passed through an optical fiber attached to a piezo transducer to which a sinusoidal 5 kHz modulation of is applied. This demonstrates the sensitivity of optical fibers to acoustic noise. In (e) one interferometer arm is send to another optical table and back. This demonstrates how mechanical vibrations of optical components in the beam path can broaden the spectrum of a laser field.

57.2 Amplitude stabilization circuits

57.2.1 Laser intensity stabilization with an AOM

The light emitted from lasers is generally subject to *frequency fluctuations* and *intensity fluctuations*, which are unacceptable for many applications. In this section we will construct an *intensity stabilization* for a laser beam.

One way of stabilizing the light intensity of a laser beam consists in using the an acousto-optic modulator, as shown in Fig. 57.6. The first Bragg diffraction order (see Sec. 55.3.1) is focused onto a photodiode. Intensity fluctuations of the light recorded by the photodiode are converted into voltage fluctuations, processed by an electronic circuit fed back to the AOM. The intensity of light diffracted into the first order can be controlled via the power of the radiofrequency alimenting the AOM. The control circuit can now be conceived such as to neutralize the intensity fluctuations recorded by the photodiode.

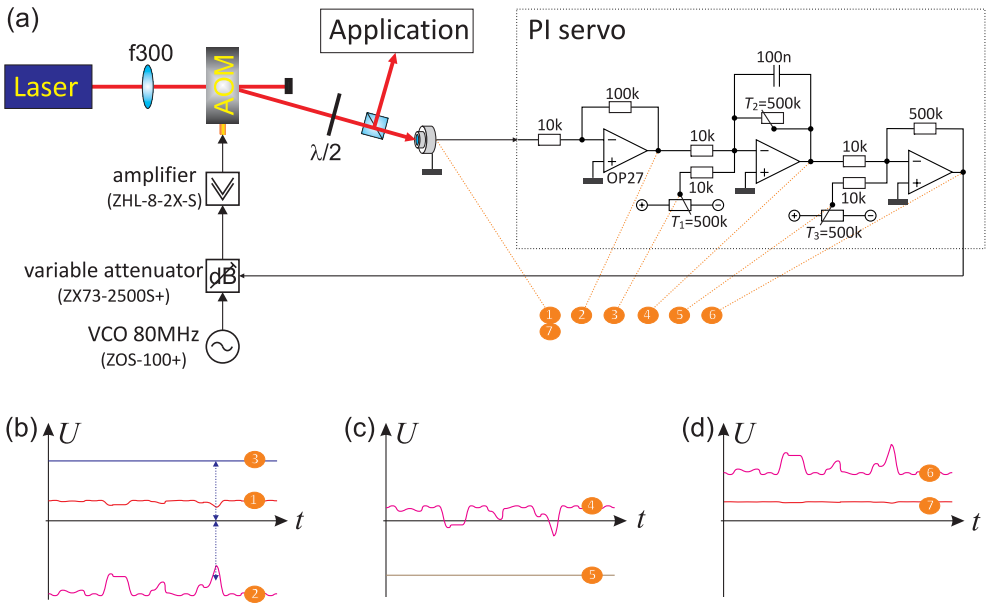

Figure 57.6: (a) Layout of the intensity control. The variable attenuator controls the amplitude of the radiofrequency driving the AOM: low voltage (0 V) increases the attenuation, high voltage (+16 V) reduces it. The sketched control circuit realizes a negative feedback, when the photodetector produces a positive signal. (b-d) Signals recorded at the test points of the circuits shown in (a). See text for explanations.

57.2.1.1 Operation principle and adjustment procedure

The idea of the intensity stabilization is illustrated in Fig. 57.6(b-d): The laser intensity scattered into the first diffraction order is recorded by a photodiode (test point 1 in the figure). The signal is then amplified (and inverted) by a first OpAmp (test point 2). The trimmer T_1 (test point 3) is now adjusted to a positive voltage compensating the DC part of the signal (2), i.e., the sum (2+3) after being inverted and amplified by the second OpAmp (test point 4), should be around zero DC. The signal (2+3) is called *error signal*, since it is this signal which tells us in which direction the control circuits has to work to counteract the power fluctuation. In the present design, the second OpAmp also incorporates the PI servo (see Sec. 57.1), which can be adjusted via the amplification of the trimmer T_2 and the capacity C.

It is now important to realize, that the variable attenuator works best around a given control voltage, which is provided by adding via the trimmer T_3 (test point 5) and a third OpAmp an appropriate offset. Furthermore, we note that variable attenuator reduces its attenuation with increasing control voltage. Thus, the control signal (test point 6) works to enhance the efficiency of the AOM, when the photodiode signals a power drop, and vice versa. As a result, the light power in the first diffraction order is stabilized, however, at a level inferior to the unstabilized power [919, 323].

The trimmers of the servo circuits can be adjusted using the following procedure:

1. Observe the light intensity and its fluctuations at test point (1), set test point (4) to ground (e.g. short-circuiting the trimmer T_2), and adjust trimmer T_3 until the light intensity level is at bit lower than the lowest fluctuations.
2. Reconnect test point (4) to the circuit and adjust trimmer T_1 until the voltage at test point (4) cancels to zero.

57.2.2 PI servo for a current stabilization

Many applications in quantum optics require very stable high currents, for instance, in coils generating magnetic field for atomic trapping potentials. Here, we will construct a *PI servo* to para realize a *current stabilization*.

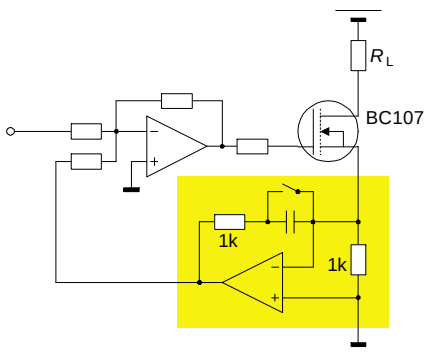

Figure 57.7: Current stabilization.

57.2.3 Exercises

57.2.3.1 Ex: Integrator

Determine the transfer function of the circuit depicted in Fig. 57.8. What kind of control circuit is it?

57.2.3.2 Ex: PID controller

Consider the PID controller transfer function in series,

$$C(f) = K\left(1 + \frac{1}{\imath f T_I}\right)(1 + \imath f T_D) \ ,$$

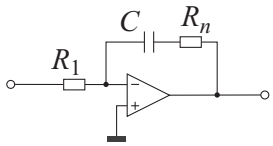

Figure 57.8:

a first-order low-pass filter in the feedback loop,

$$F(f) = \frac{1}{1 + \imath f T_F} \ ,$$

and a linear actuator with low-pass behavior,

$$P(f) = \frac{A}{1 + \imath f T_P} \ .$$

How do you have to choose the various time constants in order to let the closed-loop transfer function be $H(f) = 1$.

57.2.4 *Experiment: Development of an intensity stabilization*

We will now set up up an intensity stabilization. For the realization of the project prior knowledge of 1. photodetectors (see Sec. 54.2.1), 2. acousto-optic modulators (AOM) (see Sec. 55.3.1), 3. electronic circuits (see Sec. 54.1.3), and 4. control circuits (see Sec. 57.1) is required.

1. Realize the optical setup illustrated in Fig. 57.6. Optimize the alignment of the AOM (in particular, the focus and the Bragg angle) in order to maximize the efficiency of the AOM. Take care not to saturate the photodiode, if necessary adapt the load resistance (see Sec. 54.1.). Study the data sheet of the variable attenuator.

2. Derive and plot the transfer function for ac-signals of the electronic circuit. What kind of control circuit is it?

3. Set up the electronic circuit exhibited in Fig. 57.6. Test it by observing the signals at the six test points marked in the circuit diagram. Understand and interprete the roles of the three adjustable parameters: input offset, amplification, and output offset.

4. Incorporate the servo circuit into the optical setup as shown in Fig. 57.6. How to make sure the circuit is operating properly? [2].

[2] Datasheet for the VCO see appendix Fig. 58.16,
data sheet for the variable attenuator see appendix Fig. 58.17,
data sheet for the amplifier see appendix Fig. 58.15.

57.2.5 *Experiment: PI servo for a current stabilization*

How to control high currents? How to dramatically increase the switching speed despite inductive loads and eddy currents?

1. Connect a resistive charge to a voltage source. Insert a *MOSFET* into the circuit and a small resistor. Control the gate of the MOSFET with a voltage and measure the current of the circuit via the voltage drop at the small resistor as a function of the gate voltage.

2. Now control the gate voltage via the voltage measured at the small resistor and measure again the dependency voltage-to-current.

57.3 Frequency stabilization circuits

Although lasers are often monochromatic, they generally have a poor intrinsic frequency stability, that is, the frequency of the light field $E(t) = \sin \omega t$ drifts in time, $\omega = \omega(t)$ on a time scale, which is slow in comparison to the oscillation period $1/\omega$. The reasons for these drifts are typically acoustic noise or thermal drifts to which the laser device is subject and which are difficult to avoid.

Often it is much easier to guarantee the mechanical and thermal stability of a passive device exhibiting resonances, such as an optical cavity. Furthermore, nature provides intrinsically stable resonances, such as narrow atomic transitions. These resonances can be used to actively stabilize the frequency of lasers via feedback servo circuits. In the following sections we will present a few common techniques.

57.3.1 Side-of-fringe stabilization to/of a Fabry-Pérot cavity

Resonances are generally characterized by peaked profiles symmetrically centered about a resonance frequency ω_0. Excited by a laser field of frequency ω, they respond by an oscillation whose amplitude depends on the detuning $\omega - \omega_0$. Unfortunately, the amplitude of the response signal does not tell us, whether the detuning is positive or negative. We have to invent techniques allowing us to extract this information from the response signal and to generate a true error signal.

One of these techniques is the *side-of-fringe stabilization* technique illustrated in Fig. 57.9. Here, the laser tuned to one side of the optical resonance such that, when the laser frequency drifts, the response signal increases or decreases correspondingly. Technically, this is achieved by comparing (i.e. subtracting) the response signal with a stable reference signal.

57.3.2 Lock-in method for frequency stabilizing to/of a cavity

One method of stabilizing a laser on a resonator consists in modulating the frequency slightly and then demodulating the transmission signal of the resonator at the same frequency. This is the so-called *lock-in method*. Frequency modulation of the laser beam can be done by modulating the laser diode feed current, the piezo of the extended laser cavity or using an AOM. Fig. 57.10 shows the layout of the optical assembly.

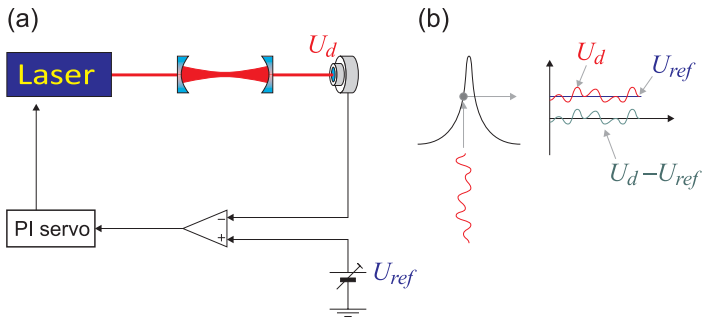

Figure 57.9: (a) Frequency stabilization to a cavity using the side-of-fringe method. (b) The laser is tuned to rising (or falling) slope of a transmission curve of a Fabry-Pérot cavity. The error signal is compared with reference voltage.

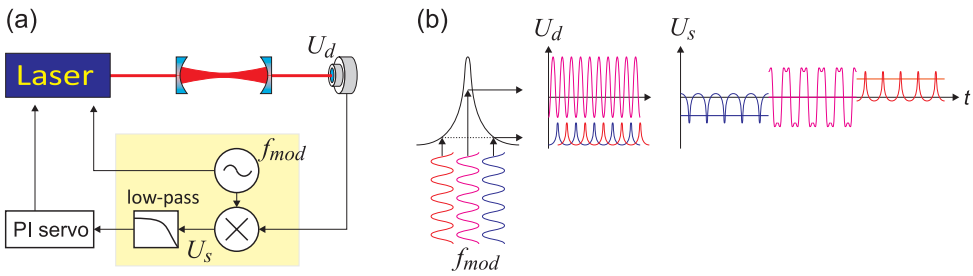

Figure 57.10: (a) Frequency stabilization to a cavity using the lock-in method. (b) Frequency-modulated signals applied to a resonance suffer a period doubling, when the signal frequency is close to resonance. By demodulating the signals discriminated at the resonance profile, we obtain, after averaging over a period, a DC voltage that is proportional to the frequency detuning. The yellow area denotes the components constituting the lock-in amplifier.

The principle of control through modulation is explained in Fig. 57.10(a). A laser beam passes twice (round-trip) through an *acousto-optic modulator* fed by a radiofrequency voltage with modulated frequency, $\omega(t) = \omega_c + M \cos ft$. Here, the modulation frequency is much lower than its amplitude (or frequency excursion), $f \ll M$. The laser beam is now injected into an optical cavity and the frequency of the laser tuned near a resonance of the cavity. The dependence of the transmission on the frequency is described in good approximation of the *Airy formula* by a Lorentzian,

$$I(\omega) = \frac{\gamma^2}{4(\omega - \omega_0)^2 + \gamma^2} \ . \tag{57.11}$$

The signal transmitted through the cavity [see Fig. 57.10(b)],

$$U_d(t) = I(\omega(t)) = \frac{\gamma^2}{4\left(\omega_c + M \cos ft - \omega_0\right)^2 + \gamma^2} \ , \tag{57.12}$$

is demodulated by a lock-in amplifier [see Fig. 57.10(c)],

$$U_s(t) = U_d(t) \cos(ft + \phi) \ , \tag{57.13}$$

integrated with a locking electronics [see Fig. 57.10(d)]

$$\bar{U}_s(t) = \frac{1}{T}\int_0^T U_s(t)dt \ . \tag{57.14}$$

and used to control the piezo of the laser's extended cavity.

57.3.3 Pound-Drever-Hall stabilization

When the frequency of a carrier wave ω is modulated by a frequency Ω [3], the spectrum consists of sidebands the frequencies and phases of which can be calculated from an expansion of the wave in Bessel functions. Let N be the modulation excursion and $J_k(x)$ the Bessel function of the order k. Higher-order sidebands $k > 1$ are usually dropped in the calculation,

$$e^{\imath(\omega t + N\sin\Omega t)} = e^{\imath\omega t}[-J_1(N)e^{\imath\Omega t} + J_0(N) + J_1(N)e^{-\imath\Omega t}] \ . \tag{57.15}$$

From the latter expression, it can be seen that the spectrum of sidebands is formed

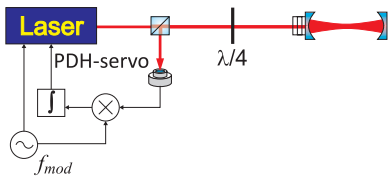

Figure 57.11: Frequency stabilization to a cavity using the Pound-Drever-Hall method.

by the frequencies ω and $\omega \pm \Omega$. A resonator responds to a field of incident light $E_0(\omega)$ oscillating with frequency ω by reflecting the field (R: reflectivity of mirrors, δ_{fsr}: free spectral range)

$$E_r(\omega) = E_0(\omega)\sqrt{R}\frac{1 - e^{-\imath\omega/\delta_{fsr}}}{1 - R\ e^{-\imath\omega/\delta_{fsr}}} \ , \tag{57.16}$$

where the amplitude and the phase of the reflected light field follow from the relation $E_r(\omega) = |E_r(\omega)|e^{\imath\phi(\omega)}$. Obviously the field of the reflected light is strong only, when the laser frequency is close to one mode of the resonator (when ω/δ is an integer number). By inserting Eq. (57.16) into Eq. (57.15), we obtain the response of the resonator to a field containing sidebands as a function of the frequency of light ω, of the modulation frequency Ω, and of the cavity finesse,

$$\begin{aligned} |E_{tot}|^2 &= |e^{\imath\omega t}[J_1(N)E_r(\omega+\Omega)e^{\imath\Omega t} + J_0(N)E_r(\omega) - J_1(N)E_r(\omega-\Omega)e^{-\imath\Omega t}]|^2 \\ &= J_0(N)J_1(N)E_r(\omega+\Omega)e^{\imath\Omega t} + J_0(N)J_1(N)E_r^*(\omega-\Omega)e^{\imath\Omega t} + ... + c.c. \ . \end{aligned} \tag{57.17}$$

The contributions of the reflected field to the current in the photodetector, $|E_r|^2$, oscillating with frequency Ω and extracted by the alternating current $e^{-i\Omega t + i\theta}$ (θ is

[3] Remember that we specify all frequencies except the free spectral range δ_{fsr} in radians.

an arbitrarily chosen phase angle), are

$$\begin{aligned} S_{PDH} &= |E_{tot}|^2 e^{-i\Omega t + i\theta} \\ &= J_0(N) J_1(N) \mathfrak{Re}\left\{ e^{\imath\theta} [E_r^*(\omega) E_r(\omega+\Omega) - E_r(\omega) E_r^*(\omega-\Omega)] \right\} + \dots \,. \end{aligned} \tag{57.18}$$

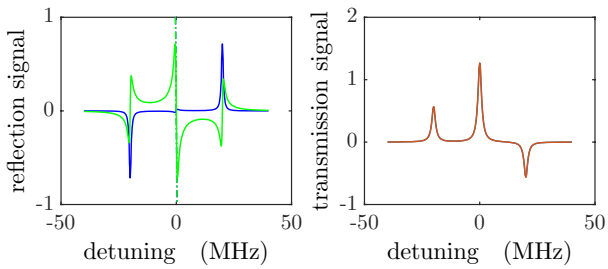

Figure 57.12: (code) (Left) Pound-Drever-Hall reflection signal for $\theta = 0, \pi/2$. (Right) Transmission signal.

By a suitable choice of the modulation index, the pre-factor containing Bessel functions (and therefore the signal amplitude) can be maximized. That is the case, for $M \simeq 1.1$ (see Exc. 55.4.5.1). Each of the two parts of the summation in the above equation is the result of a beating of the carrier $E_r(\omega)$ with one of the sidebands $E_r(\omega \pm \Omega)$. Only those optical sidebands being close to a mode of the resonator provide, along with the radiofrequency sidebands, contributions to the reflection signal

The dependence of the reflection signal S_{PDH} on the frequency ω is shown in Fig. 57.12(a). The antisymmetric shape and the zero-crossing slope are ideal for use as a discriminator generating an *error signal* for a frequency stabilization. This method is called *Pound-Drever-Hall method*.

57.3.4 Phase stabilization of standing waves

For the stabilization of the phase of a standing wave one can use the following scheme. It is similar to the homodyne method used with the Michelson interferometer with the difference that laser beam separation and recombination are done at different beam splitters.

57.3.5 Frequency-offset locking with phase-locked loops

Many application in spectroscopy require two stable lasers emitting at different but well-defined and tunable frequencies. Examples are stimulated Raman transitions, or the spectroscopy of atoms interacting with optical cavities [147]. In the following we will discuss and compare different approaches to locking one laser to another laser using a phase-locked loop (PLL). See also (watch talk).

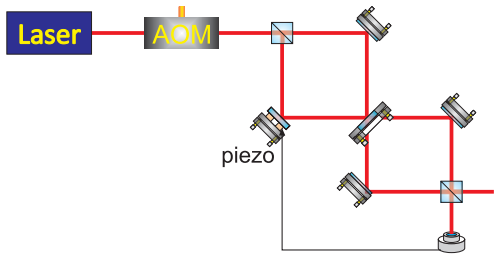

Figure 57.13: Phase stabilization.

57.3.5.1 VCO and mixing

In a *phase-locked loop* one tries to synchronize a self-sustained oscillator, in general realized by a VCO, with a local oscillator. The VCO generates an ac-voltage U_{rf}, whose frequency is tuned via a dc-control-voltage U_{ct} around a center frequency ω_0, as shown in Fig. 57.14(a). It can be modeled by,

$$\boxed{U_{rf}(t) = 2B\cos\phi(t) \qquad \text{with} \qquad \frac{d\phi}{dt} = \omega_0 + KU_{ct}(t)} \ . \tag{57.19}$$

The local oscillator produces an ac-voltage, $U_{lo}(t) = A\sin\phi_{lo}(t)$. A mixer multiplies both signals,

$$U_d(t) = AB\left(\sin[\phi_{lo}(t) - \phi(t)] + \sin[\phi_{lo}(t) + \phi(t)]\right) \ . \tag{57.20}$$

See also Exc. 57.3.7.1.

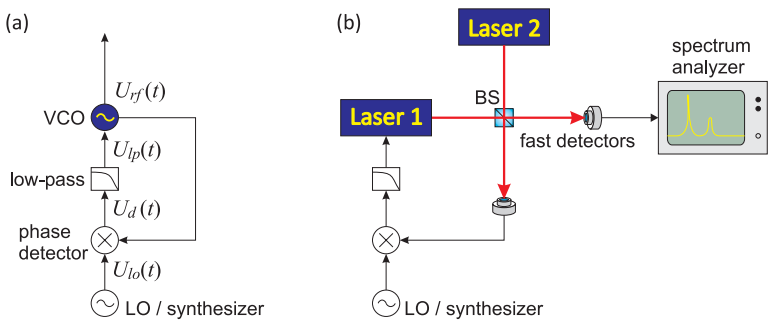

Figure 57.14: (a) PLL to lock a VCO to a reference oscillator LO. (b) PLL to lock the difference frequency of two lasers to a LO.

57.3.5.2 Low-pass filtering

The multiplied signal U_d contains all information about frequency deviations of the VCO from the LO. To extract them, we *low-pass filter* this signal, cutting off all high frequency components, i.e. apply the filter transfer function,

$$F(f) = (1 + sRC)^{-1} \ . \tag{57.21}$$

The signal of the filter is $U_{lp}(f) \equiv F(f)U_d(f)$. In time domain, which is obtained by a Laplace transform, $F(t) = (RC)^{-1}\theta(t)e^{-t/RC}$, such that

$$U_{lp}(t) = F \star U_d(t) = \int_{-\infty}^{\infty} F(t-\tau)U_d(\tau)d\tau = \frac{e^{-t/RC}}{RC}\int_{-\infty}^{t} e^{\tau/RC}U_d(\tau)d\tau \ . \quad (57.22)$$

The derivative is obviously,

$$\frac{dU_{lp}}{dt} + \frac{U_{lp}}{RC} = \frac{U_d(t)}{RC} = \frac{AB}{RC}\sin\left[\phi_{lo}(t) - \phi(t)\right] \ , \quad (57.23)$$

inserting the above expression for U_d. Note, that we would have obtained the same result using control theory (see Sec. 57.1).

57.3.5.3 Phase synchronization

The phase synchronization servo is closed by setting $U_{ct} = U_{lp}$. Thus we may substitute $U_{lp}(t)$ and define $\psi \equiv \phi - \phi_{lo}$,

$$\frac{d^2\psi}{dt^2} + \frac{1}{RC}\frac{d\psi}{dt} + \frac{KAB}{RC}\sin\psi = -\frac{d^2\phi_{lo}}{dt^2} - \frac{1}{RC}\left(\frac{d\phi_{lo}}{dt} - \omega_0\right) \ . \quad (57.24)$$

In most cases the LO frequency varies slowly, so that we may assume $\dot{\phi}_{lo} = \omega_{lo}$,

$$\frac{d^2\psi}{dt^2} + \frac{1}{RC}\frac{d\psi}{dt} + \frac{KAB}{RC}\sin\psi = -\frac{1}{RC}\left(\omega_{lo} - \omega_0\right) \ . \quad (57.25)$$

Hence, a PLL generates a signal $U_{rf}(t)$ having approximately the same (time-dependent) frequency as the local oscillator $U_{lo}(t)$. The equation is identical to that of an overdamped rotator or a resistively shunted Josephson junction [734].

We observe that the PLL is locking to servo oscillations. The spectrum of signal produced by the VCO exhibits sidebands as soon as the loop is closed. Their amplitude depends on the gain, their frequency varies with the offset voltage controlling the VCO.

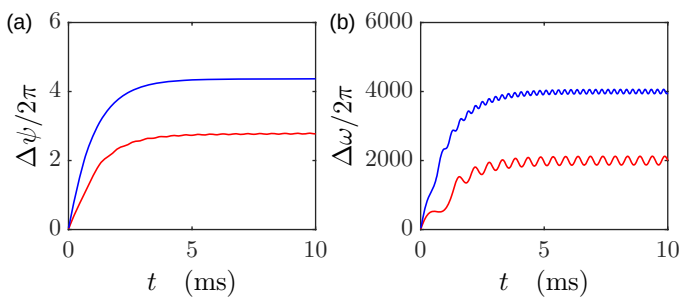

Figure 57.15: (code) Simulation of (a) the phase and (b) frequency difference in a PLL for (red) $\omega_{lo} - \omega_0 = (2\pi)$ 2 kHz and (blue) 4 kHz.

57.3.6 Frequency-offset locking using transfer cavities

Sometimes we want to take a ultra-high resolution spectrum in a frequency region, where there is no reference frequency available nearby. By nearby we mean frequency regimes which can be reached by PLLs based on frequency beats on fast photodetectors, as studied in Sec. 57.3.5. A possible method consists in the use of an optical *transfer cavity*.

Here, a reference laser stabilized to a known frequency ω_{ref}, e.g. via a saturation spectroscopy to an atomic transition, is used to lock a piezo-tunable optical cavity (called transfer cavity), as shown in Fig. 57.16. The cavity in turn is used to lock the spectroscopy laser $\omega_{blu-las}$, e.g. via the Pound-Drever-Hall method.

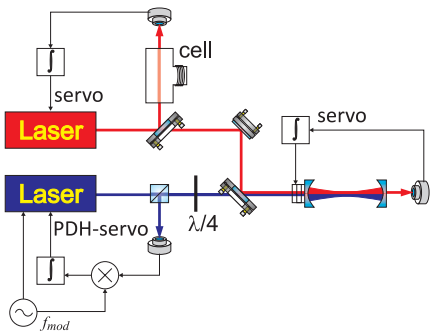

Figure 57.16: Schematic view of a transfer cavity locking system involving three cascaded servo systems for (i) the stabilization of the reference laser to a known frequency; (ii) of the transfer cavity to the reference laser, and (iii) of the spectroscopy laser to the transfer cavity.

Two issues need to be considered when using the transfer cavity scheme:

- The scheme does not permit tuning of the spectroscopy laser; this feature must be included using, e.g. AOMs (see Sec. 55.3.1) of PLL offset locks (see Sec. 57.3.5).
- The use of piezo in the transfer cavity is incompatible with its high-level thermal and mechanical stabilization. This means that special care must be taken in the design of the reference laser in order to avoid degradation of the stability of the transfer cavity via the servo lock.

The whole locking scheme consists of three cascaded servo loops (see Fig. 57.16). To model the transfer of stability from the reference to the spectroscopy laser, we write down the following relations,

$$\begin{aligned} \omega_{red-las} &= H_{sat}(f)\omega_{ref} \\ N_{red-trns}\delta_{fsr} &= H_{trns}(f)\omega_{red-las} \\ \omega_{blu-las} &= H_{pdh}(f)N_{blu-trans}\delta_{fsr} \ . \end{aligned} \tag{57.26}$$

In the absence of noise or for perfect servos, $H_x \to 1$, we get,

$$\omega_{blu-las} = \frac{N_{blu-trans}}{N_{red-trans}}\omega_{red-las} \ . \tag{57.27}$$

We assume specific transfer functions for the closed-loop gains of the three servos and describe the impact of noise by adding frequency deviations $\Delta\omega$ entering at various points.

57.3.7 Exercises

57.3.7.1 Ex: Schemes for laser tuning

Discuss the two PLL-setups shown in Fig. 57.17.

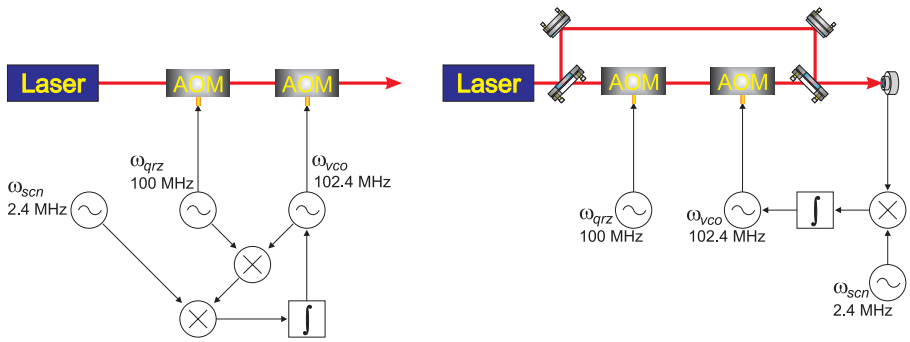

Figure 57.17: Two schemes for laser tuning.

57.3.8 *Experiment: Stabilizing a laser to a cavity*

Here is, how we are going to stabilize a laser to a cavity:

1. Stabilize a helium-neon laser to a Fabry-Pérot cavity, generating a frequency modulation by modulating the laser diode current or the piezo of the extended cavity. Choose a modulation frequency in the range of $f \simeq 1\,\text{kHz}$ and a modulation amplitude in the range of $M \simeq 5$ MHz. Adjust the reference voltage of the control electronics until the error signal is symmetrical.

2. If you do not have a lock-in amplifier available, construct one following the project Sec. 54.4.3.

3. Now, do the opposite, stabilizing the optical cavity to the laser frequency using the resonator piezo as control element.

4. Vary the optical setup now modulating the frequency using an AOM (see Fig. 57.18).

57.3.9 *Experiment: Pound-Drever-Hall locking*

Now we will stabilize a laser to a cavity using the Pound-Drever-Hall technique [116, 274]:

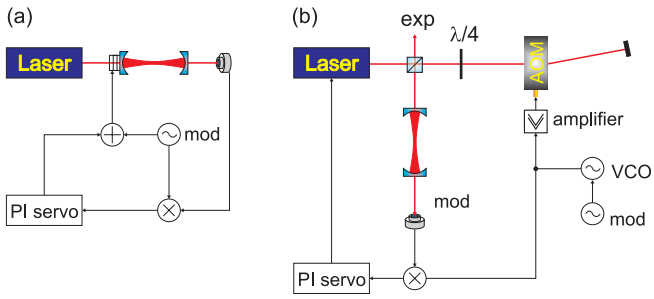

Figure 57.18: Variations on the same theme: (a) Frequency stabilization of a cavity to a laser frequency using the lock-in method. This method is often used for spectral filtering of a laser beam by a transmission etalon. (b) Frequency stabilization of a laser to a cavity using an AOM. The advantage of using an AOM compared to the scheme shown in Fig. 57.10 is, that only the beam injected into the cavity is modulated, but not the beam used for the main experiment.

1. Consider the reflected signal. To do this, separate the beam injected into the resonator from the reflected beam by means of a $\lambda/4$ waveplate and a polarizing beam splitter.

2. Now analyze the reflected signal with a fast photodetector at a spectrum analyzer.

3. Demodulate the signal with the modulation frequency. Vary the length of the cables. Optimize the slope of the error signal by a suitable choice of frequency and modulation excursion [4].

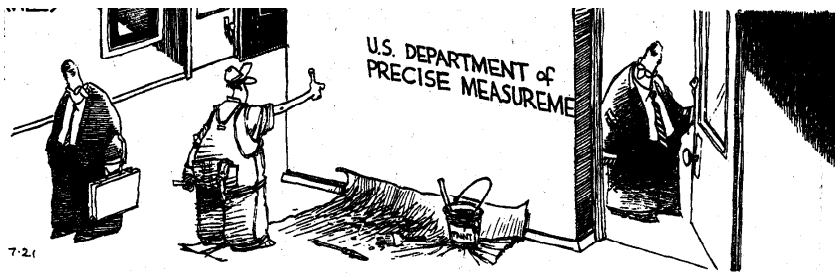

Figure 58.1: At the National Institute for Standards and Technology (NIST).

58.1 Calculating the uncertainty of measured quantities

58.1.1 Mean value and standard deviation

Mean value and *standard deviation* are defined by,

$$\bar{x} \equiv \frac{1}{N}\sum_k x_k \qquad \text{and} \qquad \sigma_{\bar{x}} \equiv \sqrt{\frac{1}{N-1}\sum_k (x_k - \bar{x})^2}\ . \tag{58.1}$$

The standard deviation can be weighed by a confidence parameter,

$$\bar{x} \equiv \frac{\sum_k w_k x_k}{\sum_k w_k} \qquad \text{and} \qquad \sigma_{\bar{x}} \equiv \frac{1}{\sqrt{\sum_k w_k}} \tag{58.2}$$

Weighing by individual standard deviation,

$$w_k \equiv \frac{1}{\sigma_k^2} \qquad \text{for} \qquad \sigma_k = \sigma_0 \tag{58.3}$$

gives,

$$\bar{x} \equiv \frac{\sum_k \frac{x_k}{\sigma_k^2}}{\sum_k \frac{1}{\sigma_k^2}} = \sigma_{\bar{x}}^2 \sum_k \frac{x_k}{\sigma_k^2} \overset{\sigma_k=\sigma_0}{\longrightarrow} \frac{1}{N}\sum_k x_k \quad \text{with} \quad \sigma_{\bar{x}} \equiv \frac{1}{\sqrt{\sum_k \frac{1}{\sigma_k^2}}} \overset{\sigma_k=\sigma_0}{\longrightarrow} \frac{\sigma_0}{\sqrt{N}} \tag{58.4}$$

or,

$$\hat{\sigma}_{\bar{x}} \equiv \sigma_{\bar{x}}\chi_v \overset{\sigma_k=\sigma_0}{\longrightarrow} \sqrt{\frac{1}{N-1}\sum_k (x_k-\bar{x})^2} \tag{58.5}$$

$$\chi_v = \sqrt{\frac{1}{N-1}\sum_k \frac{(x_k-\bar{x})^2}{\sigma_i^2}} \ .$$

From error propagation

$$\Delta\bar{x} \equiv \sqrt{\frac{1}{N}\sum_k \Delta x_k^2} \ . \tag{58.6}$$

58.1.1.1 χ^2-fit

The χ^2-fit of a constant of a function $y = f(x)$ to a measured data set (x_k, y_k) is,

$$\chi^2 = \frac{1}{N(N-1)}\sum_k [f(x_k) - y_k]^2 \ . \tag{58.7}$$

The above formula suggest that, increasing the number of measurements $N \to \infty$ we could pull the error to zero. This, however, is NOT TRUE. If the standard deviation is smaller than the precision Δ of the measurement tool, the error will be limited by Δ,

$$\bar{y} \pm \max(\sigma, \Delta) \ . \tag{58.8}$$

58.1.2 Error propagation

The *error propagation* for a function $f(x_1, x_2, ..)$ is given by,

$$\Delta f = \sqrt{\left(\frac{\partial f}{\partial x_1}\right)^2 \Delta x_1^2 + \left(\frac{\partial f}{\partial x_2}\right)^2 \Delta x_2^2 + ...} < \left|\frac{\partial f}{\partial x_1}\right| \Delta x_1 + \left|\frac{\partial f}{\partial x_2}\right| \Delta x_2 + ... \ . \tag{58.9}$$

Calculations can often be simplified by noting that the four fundamental operations, $f = x_1 \pm x_2$, $f = x_1 x_2$, and $f = \frac{x_1}{x_2}$ allow us to simply add the relative errors,

$$\frac{\Delta f}{f} = \frac{\Delta x_1}{x_1} + \frac{\Delta x_2}{x_2} \ . \tag{58.10}$$

Alternatively, we may use the following quick rules,

$$\begin{array}{rlcll}
sum: & f \pm \Delta f = & (x \pm \Delta x) + (y \pm \Delta y) & = & (x+y) \quad \pm (\Delta x + \Delta y) \\
subtraction: & f \pm \Delta f = & (x \pm \Delta x) - (y \pm \Delta y) & = & (x-y) \quad \pm (\Delta x + \Delta y) \\
multiplication: & f \pm \Delta f = & (x \pm \Delta x)\cdot(y \pm \Delta y) & = & (x\cdot y) \quad \pm (x\Delta y + y\Delta x) \\
division: & f \pm \Delta f = & \frac{x\pm\Delta x}{y\pm\Delta y} & = & \frac{x}{y} \quad \pm \frac{1}{y^2}(x\Delta y + y\Delta x) \\
power: & f \pm \Delta f = & (x \pm \Delta x)^n & = & x^n \quad \pm n x^{n-1}\Delta x
\end{array} \ . \tag{58.11}$$

Example 389 (*Error propagation*): Let us study the following example,

$$f = \frac{x_1}{x_2 + a}$$
$$\Longrightarrow \Delta f = f\frac{\Delta x_1}{x_1} + f\frac{\Delta(x_2 + a)}{x_2 + a} = f\frac{\Delta x_1}{x_1} + f\frac{\Delta x_2}{x_2 + a} \ .$$

58.1.3 Fitting a curve

We start defining the following prescription to calculate mean values,

$$\bar{x} \equiv \frac{1}{N}\sum_{k=1}^{N} x_k \quad , \quad \overline{xy} \equiv \frac{1}{N}\sum_{k=1}^{N} x_k y_k \ . \tag{58.12}$$

For a *fit* of a *linear curve* $f(x) = ax + b$ to a data set $\{x_k, y_k\}_{k\in[1,N]}$, we calculate (see also Exc. 27.2.3.3),

$$\boxed{f(x) = ax + b \quad , \quad a = \frac{\overline{xy} - \bar{x}\,\bar{y}}{\overline{x^2} - \bar{x}^2} = \frac{\overline{(x - \bar{x})y}}{\overline{(x - \bar{x})^2}} \quad , \quad b = \frac{\bar{y}\,\overline{x^2} - \overline{xy}\,\bar{x}}{\overline{x^2} - \bar{x}^2} = \bar{y} - a\bar{x}} \ . \tag{58.13}$$

The uncertainties are obtained via,

$$\Delta y = \sqrt{\frac{N}{N-2}\overline{(ax + b - y)^2}} \quad , \quad \Delta a = \Delta y\sqrt{\frac{1}{N\,(\overline{x^2} - \bar{x}^2)}} = \frac{\Delta y}{\sqrt{N\,\overline{x - \bar{x}}}} \tag{58.14}$$
$$, \quad \Delta b = \Delta y\sqrt{\frac{\overline{x^2}}{N\,\overline{x^2} - \bar{x}^2}} = \Delta y\sqrt{\frac{\overline{x^2}}{N\,\overline{x - \bar{x}}}} \ .$$

To fit an *exponential curve* $f(x) = \beta e^{\alpha x}$, we simply convert the data set $\{x_k, v_k\} \equiv \{x_k, \lg y_k\}$, calculate the mean values of the decadal logarithm using the recipe (58.12), and fit a linear curve $\tilde{f}(x) = \lg f(x) = \frac{\alpha}{\ln 10}x + \lg\beta \equiv ax + b$ in a semi-logarithmic scale to the data set $\{x_k, v_k\}$. This gives,

$$\boxed{f(x) = \beta e^{\alpha x} \quad , \quad \frac{\alpha}{\ln 10} = a = \frac{\overline{x\lg y} - \bar{x}\,\overline{\lg y}}{\overline{x^2} - \bar{x}^2} \quad , \quad \lg\beta = b = \frac{\overline{\lg y}\,\overline{x^2} - \overline{x\lg y}\,\bar{x}}{\overline{x^2} - \bar{x}^2}} \ . \tag{58.15}$$

To fit a *power law curve* $f(x) = \beta x^{\alpha}$, we simply convert the data set $\{u_k, v_k\} \equiv \{\lg x_k, \lg y_k\}$, calculate the mean values of the decadal logarithm using the recipe (58.12), and fit the linear curve $\tilde{f}(x) = \lg f(x) = \alpha\lg x + \lg\beta \equiv ax + b$ in a double-logarithmic scale to the data set $\{u_k, v_k\}$. This gives,

$$\boxed{f(x) = \beta x^{\alpha} \quad , \quad \alpha = a = \frac{\overline{\lg x\lg y} - \overline{\lg x}\,\overline{\lg y}}{\overline{\lg x^2} - \overline{\lg x}^2} \quad , \quad \lg\beta = b = \frac{\overline{\lg y}\,\overline{\lg x^2} - \overline{\lg x\lg y}\,\overline{\lg x}}{\overline{\lg x^2} - \overline{\lg x}^2}} \ . \tag{58.16}$$

58.1.4 Probability density

Consider a function $P(x)$ having the meaning of a *probability* depending on a variable $x \in [-\infty, \infty]$. The *probability density* $\rho(x)$ is defined as its derivative, $\rho(x) = P'(x)$, such that,

$$P(x) = \int_{-\infty}^{\infty} \rho(t)dt \qquad \text{with} \qquad P(-\infty) = 0 \qquad \text{and} \qquad P(\infty) = 1 \ . \tag{58.17}$$

Every probability must have the same likeliness, i.e.,

$$P(x) = \zeta_n \ , \tag{58.18}$$

where $\zeta_n \in [0, 1]$ is a uniformly distributed *random variable*. In order to numerically generate a *stochastic distribution*, we have to invert the distribution function, i.e. when ζ_n is generated by a computer, then

$$\boxed{x_n = P^{-1}(\zeta_n)} \tag{58.19}$$

is the distribution of the random variable x_n. In other words, a histogram of x_n reproduces the probability density $\rho(x)$.

Let us, for example, consider the Boltzmann distribution,

$$P(x) \equiv 1 - e^{-\beta x} \ . \tag{58.20}$$

Probing the probability with a random number, as in (58.18), we obtain the random variable via (58.19),

$$x_n = P^{-1}(\zeta_n) = -\frac{1}{\beta} \ln(1 - \zeta_n) \ . \tag{58.21}$$

The histogram of this random variable x_n can directly be compared with the probability density $\rho(x)$ given by,

$$\rho(x) = P'(x) = \beta e^{-\beta x} \ . \tag{58.22}$$

This is illustrated in Fig. 58.2(a).

Example 390 (*Probability density of a Gaussian distribution*): Another example is the *error function* given by,

$$\text{erf}(x) \equiv \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \ .$$

By define the probability function,

$$P(x) \equiv \frac{1}{2}[\text{erf}(x) - \text{erf}(-\infty)] = \frac{1}{\sqrt{\pi}} \int_{-\infty}^x e^{-t^2} dt \ .$$

Probing the probability with a random number, as in (58.18), we obtain the random variable via (58.19),

$$x_n = P^{-1}(\zeta_n) = \text{erf}^{-1}(2\zeta_n - 1) \ .$$

The histogram of this random variable x_n can directly be compared with the probability density $\rho(x)$, which is nothing else than the Gauss function,

$$\rho(x) = P'(x) = \frac{1}{\sqrt{\pi}} e^{-x^2} = 2\text{erf}'(x) \ .$$

This is illustrated in Fig. 58.2(b).

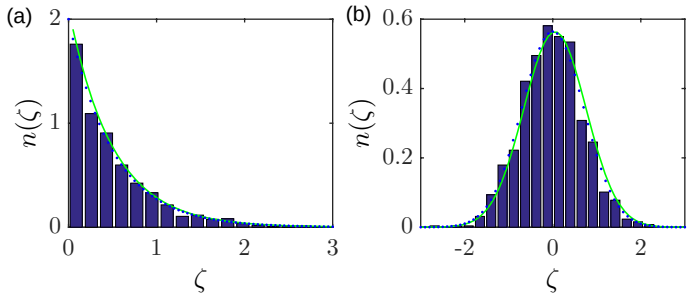

Figure 58.2: (code) (a) Boltzmann distribution simulated by random numbers (histogram). The numerical derivative of this distribution is shown as a blue dotted line, and the probability density as a green solid line. (b) Error function probability distribution simulated by random numbers (histogram). The numerical derivative of the error function is shown as a blue dotted line, and the Gauss function as a green solid line.

58.2 Deepening control theory

The variation of a physical quantity (e.g., a voltage or a temperature) in time is called *signal*. In a specific environment or technical device, such a variation may cause other physical quantities to change as well. For example, the rise in temperature of an optical cavity may modify its length and its resonance frequency, while the inverse is not true. This feature is illustrated by a block diagram as shown in Fig. 58.3, where $x(t)$ denotes the variation of a physical quantity (called *input*) that causes the variation of another quantity $y(t)$ (called *output*). The precise way how $y(t)$ depends on $x(t)$ depends on the particularities of the device, which is labeled by a symbol $\mathcal{T}$ called transfer function. $\mathcal{T}$ is in fact an operator acting on functions and transforming input signals into output signals.

Figure 58.3: Transfer and modification of a time-dependent signal.

While we have described above the transfer of (time-varying) signals, the same feature can be treated in frequency domain via Fourier or Laplace-transforms. This script is not the right place to recapitulate the mathematics of these transforms, and we will restrict ourselves to reproducing some on the most fundamental results, as we may need them in the following.

58.2.1 Analysis techniques - frequency domain and time domain

Mathematical techniques for analyzing and designing control systems fall into two different categories:

Frequency domain: In this type the values of the state variables, the mathematical variables representing the system's input, output and feedback are represented

as functions of frequency. The input signal and the system's transfer function are converted from time functions to functions of frequency by a transform such as the Fourier transform, Laplace transform, or Z transform. The advantage of this technique is that it results in a simplification of the mathematics; the differential equations that represent the system are replaced by algebraic equations in the frequency domain which are much simpler to solve. However, frequency domain techniques can only be used with linear systems, as mentioned above.

Time-domain state space representation: In this type the values of the state variables are represented as functions of time. With this model the system being analyzed is represented by one or more differential equations. Since frequency domain techniques are limited to linear systems, time domain is widely used to analyze real-world nonlinear systems. Although these are more difficult to solve, modern computer simulation techniques such as simulation languages have made their analysis routine.

In contrast to the frequency domain analysis of the classical control theory, modern control theory utilizes the time-domain state space representation, a mathematical model of a physical system as a set of input, output and state variables related by first-order differential equations. To abstract from the number of inputs, outputs and states, the variables are expressed as vectors and the differential and algebraic equations are written in matrix form (the latter only being possible when the dynamical system is linear). The state space representation (also known as the 'time-domain approach') provides a convenient and compact way to model and analyze systems with multiple inputs and outputs. With inputs and outputs, we would otherwise have to write down Laplace transforms to encode all the information about a system. Unlike the frequency domain approach, the use of the state-space representation is not limited to systems with linear components and zero initial conditions. 'State space' refers to the space whose axes are the state variables. The state of the system can be represented as a point within that space.

58.2.1.1 Signal transfer through LTI systems without delay

For an operator $\mathcal{T}$ transforming a temporal signal $x(t)$ into a signal $y(t)$,

$$y(t) = \mathcal{T}x(t) \ , \tag{58.23}$$

to be *linear* and time-independent, we require,

$$\begin{aligned} \mathcal{T}[\alpha x_1(t) + \beta x_2(t)] &= \alpha\mathcal{T}[x_1(t)] + \beta\mathcal{T}[x_2(t)] \\ \mathcal{T}[x(t-\tau)] &= \mathcal{T}[x(t)] \star \delta(t-\tau) \ , \end{aligned} \tag{58.24}$$

where the $\star$ denotes a convolution,

$$(f \star g)(t) = \int_{-\infty}^{\infty} f(\tau)g(t-\tau)d\tau \ . \tag{58.25}$$

Such system are called *Linear Time-Independent LTI* systems [1].

[1] To be more general, also the derivative and integral of the output signal must be included (see later sections).

58.2.1.2 Laplace transform

We define the *Laplace transform* $\mathcal{L}$ as a linear operator acting on a signal $x(t)$ defined through,

$$\mathcal{L}... \equiv \int_{-\infty}^{0} ...e^{st} d\tau \ . \tag{58.26}$$

The frequency variable is denoted by the imaginary quantity $s = \imath f$. The question is now, what is the meaning of the Laplace operator?

To answer this question, we start introducing the pulse response $h(t)$ via

$$h(t) = \mathcal{T}[\delta(t)] \tag{58.27}$$

as the reaction of a system $\mathcal{T}$ to a pulse $\delta(t)$. Now, it is easy to see, that the operator $\mathcal{P}$ defined as,

$$\mathcal{P}... \equiv h(t) \star ... \ , \tag{58.28}$$

and which describes the convolution of an arbitrary input signal with the pulse response, satisfies the above linearity condition. Now calculating,

$$\mathcal{P}e^{st} = h(t) \star e^{st} = \int_{-\infty}^{0} h(\tau) e^{s(t-\tau)} d\tau = \mathcal{L}[h(t)] \cdot e^{st} = (\mathcal{L}h)(s) \cdot e^{st} \ , \tag{58.29}$$

we find that the functions e^{st} are eigenfunctions of the operator $\mathcal{P}$ with the eigenvalues $\mathcal{L}[h(t)]$, which are just the Laplace transforms of the pulse response.

We can now expand arbitrary functions $x(t)\theta(t)$ in a Laplace series and obtain,

$$\mathcal{L}[h(t) \star x(t)] = \int_{-\infty}^{0} h(t) \star e^{st} \ x(t) dt = (\mathcal{L}h)(s) \int_{-\infty}^{0} e^{st} x(t) dt = (\mathcal{L}h)(s) \cdot (\mathcal{L}x)(s) \ . \tag{58.30}$$

The convolution on the left-hand side is in time domain, while the product on the right-hand side is in frequency domain.

58.2.1.3 Pulse and jump response from a transfer function

The transmission of a signal by an element of a control loop can be described in the temporal or spectral domain [323, 344, 611], and we can switch from one representation to another via Laplace transformation. Operators of LTI systems $\mathcal{T}$ are represented by products with spectral functions in frequency-domain, $\tilde{F}(s) \cdot ... = (\mathcal{L}F)(s) \cdot ...$ or convolutions with time-varying functions in time-domain, $F(t) \star ...$,

$$\begin{aligned} y(t) &= \mathcal{T}x(t) \\ \xrightarrow{Laplace} \tilde{y}(s) &= \tilde{F}(s) \cdot \tilde{x}(s) \\ \xrightarrow{inverse\ Laplace} y(t) &= F(t) \star x(t) \ . \end{aligned} \tag{58.31}$$

In practice, the function $\tilde{F}(f)$ can be determined by feeding a sinusoidal signal with amplitude $x(s)$ into the system, measuring $y(s)$ (which is a complex number) [2],

[2] From now on, we will drop the tilde $\sim$ on transfer functions and amplitudes, when it is clear that we are in frequency-domain.

and calculating

$$F(s) = \frac{y(s)}{x(s)} \ . \tag{58.32}$$

The transitory behavior $F(t)$ can in practice be extracted via an adequate choice of the test function, f.ex., the response to a pulse:

$$\begin{aligned} x(t) &= \delta(t) \\ \xrightarrow{Laplace} y(s) &= F(s) \\ \xrightarrow{inverse\ Laplace} y(t) &= F(t) \ , \end{aligned} \tag{58.33}$$

or to a sudden jump:

$$\begin{aligned} x(t) &= \theta(t) \\ \xrightarrow{Laplace} y(s) &= F(s)/s \\ \xrightarrow{inverse\ Laplace} y(t) &= \int_0^t F(\tau) d\tau \ . \end{aligned} \tag{58.34}$$

Here, $\theta(t)$ denotes the Heavyside function, which is 1 for $t > 0$ and 0 else. The time-dependent function, which describes the pulse response is often used as a symbol for a specific control loop element.

The pulse response works in a similar way as the Green's function procedure: Wanting to know how a loop control element F transforms a given input signal $x(t)$ into an output signal $y(t)$, i.e., $y(t) = F(t) \star x(t)$, we produce a rapid pulse leading to the output,

$$y_\delta(t) = F(t) \star \delta(t) = F(t) \ . \tag{58.35}$$

Now, once we know $F(t)$, the response to arbitrary input signals can be computed via,

$$y(t) = y_\delta(t) \star x(t) \ . \tag{58.36}$$

58.2.1.4 Bode diagram and polar diagram

The *Bode diagram* illustrates the transfer function in the spectral domain on a bilogarithmic scale separating the amplitude spectrum from the phase spectrum [see Fig. 58.4(a-b)]. Frequency regions, where $|F(s)|$ or $\varphi(s)$ vary particularly strongly are nicely emphasized in the polar representation [see Fig. 58.4(c-d)].

For LTI systems $F(s)$ is always a rational function and can, hence, be represented by its poles and zeros in the complex plane,

$$F(s) = A \frac{(s-a_1)(s-a_2)...(s-a_n)}{(s-b_1)(s-b_2)...(s-b_n)} \ . \tag{58.37}$$

With this, $F(s)$ is analytical and conform, i.e., multiple curves in the s-plane are represented in an isogonal way in the $F(s)$-plane. In order to avoid that the eigenfunctions e^{st} oscillate and diverge, it is necessary that all the poles and zeros are in the left halfplane.

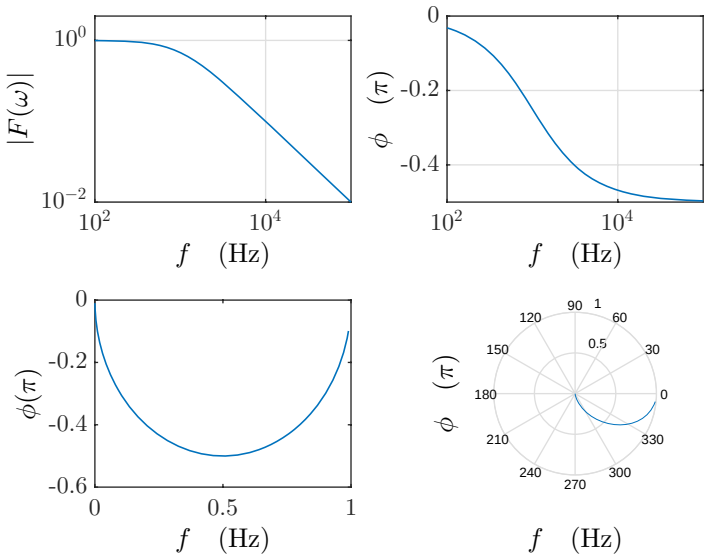

Figure 58.4: (code) Bode diagram.

58.2.2 Algebra of transfer circuits

A technical realization of a signal transfer circuit is illustrated by a signal flux diagram, which itself corresponds to the formalism of linear operators. As shown in Fig. 58.5, signals can be

- (a) added $(f_1 + f_2)(t) \equiv f_1(t) + f_2(t)$,
- (b) multiplied $(f_1 \cdot f_2)(t) \equiv f_1(t) \cdot f_2(t)$,
- (c) combined $f_1(t) = f_2(t)$,
- (d) transformed $f_2(t) = F[f_1](t) \equiv F(f_1(t))$,
- (e) connected in parallel $(F_1 + F_2)[f(t)] \equiv F_1[f(t)] + F_2[f(t)]$,
- (f) connected in series $(F_1 \circ F_2)[f(t)] \equiv F_1[F_2[f(t)]]$,

Mathematically, the functions $f(t)$ form a *vector space* and the operators $F[f]$ a *ring*. The linear operators generally are defined implicitly by a system of differential equations. The particular case of linear systems is considerably simpler. The general circuit shown in Fig. 58.5(g) corresponds to the differential equation,

$$0 = F[x_1, .., x_k, \partial_t x_1, .., \partial_t x_k, y_1, .., y_j] \ . \tag{58.38}$$

The linearity $F[\lambda f_1 + \mu f_2] = \lambda F[f_1] + \mu F[f_2]$ warrants that this equation becomes,

$$0 = [1 + \partial_t + ... + \int dt + ...]y_k = [1 + \partial_t + ... + \int dt + ...]x_j \ . \tag{58.39}$$

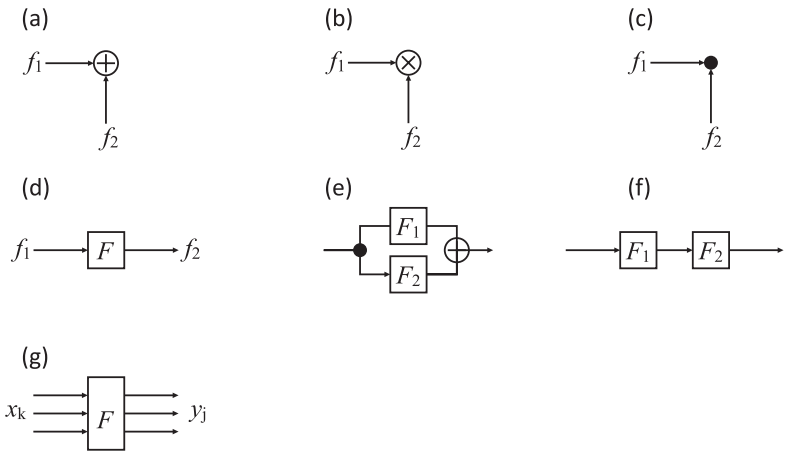

Figure 58.5: LTI circuits.

Note that the multiplication, the derivation, and the integration are linear operators in the same sense as the Fourier and the Laplace transformation.

Linear differential equations can be Laplace transformed. The corresponding transfer function is,

$$F(s) = F(-\delta + \imath\omega) \equiv \frac{\mathcal{L}y(t)}{\mathcal{L}x(t)} \ . \tag{58.40}$$

In the Laplace-transformed space the operations multiplication, derivation, and integration are all replaced by multiplications:

$$\mathcal{L}[\lambda + \partial_t + ... + \int dt + ...] = \lambda + s + ... + \frac{1}{s} \ . \tag{58.41}$$

With this, the control loop elements and the additive nodes can be used to completely represent a control circuit.

The characteristic responses of components are frequently non-linear (e.g. transistor). For small signal amplitudes, these response functions, and also multiplication points (e.g. mixers) can be linearized by Taylor expansion up to first order,

$$\begin{aligned} y_0 + \Delta y &= F[x_{01} + \Delta x_1, ..., x_{0k} + \Delta x_k] \\ &= F[x_{01}, ..., x_{0k}] + \left(\frac{\partial F}{\partial x_1}\right)_0 \Delta x_1 + ... + \left(\frac{\partial F}{\partial x_k}\right)_0 \Delta x_k \ , \end{aligned} \tag{58.42}$$

with $y_0 = 0 = F[x_{01}, ..., x_{0k}]$ giving,

$$\Delta y = \left(\frac{\partial F}{\partial x_1}\right)_0 \Delta x_1 + ... + \left(\frac{\partial F}{\partial x_k}\right)_0 \Delta x_k \ . \tag{58.43}$$

For example for a multiplication point,

$$\Delta y = K_1 \Delta x_1 + K_2 \Delta x_2 \ . \tag{58.44}$$

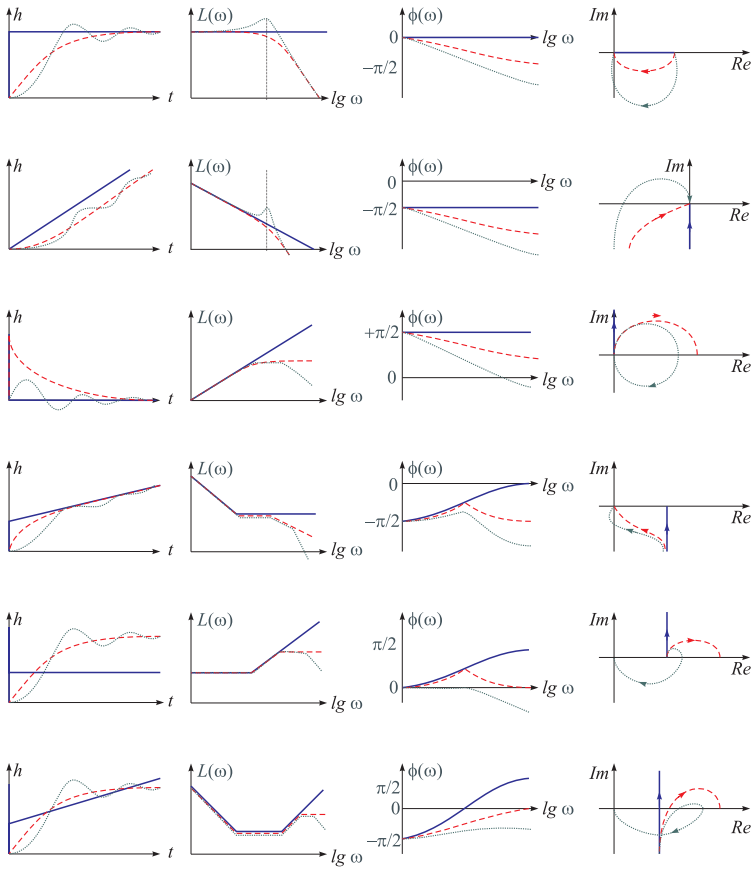

Figure 58.6: Transfer function $h(t) = \frac{y(t)}{x_w}$, Bode diagram amplitude $L(\omega) = 20 \lg |F_R|$ and phase $\varphi = \arctan \frac{\mathfrak{Im}\ F_R}{\mathfrak{Re}\ F_R}$, and polar representation $F(i\omega) = \mathfrak{Re}\, F_R + \imath \mathfrak{Im}\, F_R$ of the most common regulators. With delay time (—), $T_2 = T_1 = 0$, first order with delay time (- - -), $T_2 = 0 \neq T_1$, and second order $(\cdots)$, $T_2 \neq 0 \neq T_1$. From top to bottom, the diagrams show the regulators P, I, D, PI, PD, and PID, described by the equations (58.45) and (58.46).

58.2.2.1 Regulators

For many circuits, it is sufficient to restrict to combinations of resistive (proportional), capacitive (integral), and inductive (differential) circuits. Then, the general case of a control regulator is that of a $PID - T_1 ... T_n$-element, meaning that:

$$T_2^2 \ddot{y} + T_1 \dot{y} + y = K_D \dot{x} + K_P x + K_I \int dt x = K_P \left(x + T_v \dot{x} + \frac{1}{T_n} \int dt x \right) \ , \quad (58.45)$$

corresponding to the transfer function,

$$F(s) = \frac{K_D s + K_P + K_I/s}{1 + T_1 s + T_2^2 s^2} = \frac{(1 + T_v s + 1/T_n s)}{1 + T_1 s + T_2^2 s^2} \ . \quad (58.46)$$

In literature, two notations are used for the constants. They are linked via: $K_D \equiv K_P T_v$ and $K_I \equiv K_P / T_n$. The stationary behavior is obtained setting the delays to

zero: $T_n \equiv 0$.

Example 391 (*PID regulators*): For example, for a *proportional regulator*, we have,

$$y = K_P x_w \qquad \text{and} \qquad F_R = K_P \ , \tag{58.47}$$

for an *integral regulator* with time delay T_1, we have,

$$T_1 \dot{y} + y = K_I \int x_w dt \qquad \text{and} \qquad F_R = \frac{K_I}{s(1+sT_1)} \ , \tag{58.48}$$

or for a *PID regulator* without delay, we have,

$$y = K_P x_w + K_D \dot{x}_w + K_I \int x_w dt \qquad \text{and} \qquad F_R = K_P + \frac{K_I}{s} + K_D s \ . \tag{58.49}$$

Since there are three basic operations (multiplication with 1, s and $1/s$), in the end, all rational circuit elements can be reduced to an addition and concatenation of proportional $F(s) = K_P$, integral $F(s) = K_I/s$, and differentials elements, $F(s) = K_D s$. In particular, $PID{-}T_1...T_n$ circuits can be constructed by putting in parallel P, I, and D regulators concatenated with delay elements T_1. The possibility of feedback opens other possibilities [see Fig. 58.7(a)].

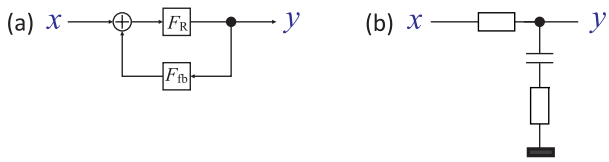

Figure 58.7: (a) Circuit with feedback, (b) low-pass filter circuit.

Example 392 (*Low-pass filter and time delays*): We consider the example of a low-pass filter exhibited in Fig. 58.7(b) and described by the equation,

$$F(\imath\omega) = \frac{R + \imath\omega L + 1/\imath\omega C}{R_i + R + \imath\omega L + 1/\imath\omega C} \ . \tag{58.50}$$

I.e., we have a $PID - T_1 T_2$ circuit.
Another example, is the dead time circuit,

$$y(t) = x(t - T_t) \quad \text{and} \quad F(s) = e^{-sT_t} \ . \tag{58.51}$$

We have,

$$F(\imath\omega) = e^{-\imath\omega T_t} F_0 \quad \text{and} \quad |F(\imath\omega)| = F_0 \quad \text{and} \quad \varphi(\imath\omega) = -\omega T_t \ . \tag{58.52}$$

Hence, dead time circuits produce phase shifts, which are proportional to the dead time interval T_t.

58.2.2.2 Heuristic rules for the Bode diagram

Any deviation of the amplitude spectrum from $n \cdot 6$dB/octave to $(n+1) \cdot 6$dB/octave causes a retardation in the phase spectrum of 90°. At the cut-off frequency, where the inclination changes its behavior, the phase shift is just 45°. A deviation to higher/lower inclinations shifts the phase by ±90°. (This does not hold for some phase-shifting circuits).

58.2.2.3 Transfer function of feedback circuits

Fig. 58.7 shows the idea underlying the feedback,

$$F(s) = \frac{1}{1/F_R - F_{fb}} \ . \tag{58.53}$$

For example, for $F_R = 1/T_1 s$ and $F_{fb} = -1$ we have,

$$F(s) = \frac{1}{1 + T_1 s} \ , \tag{58.54}$$

which corresponds to a delay element (or high-pass filter).

For F_r being a proportional element, we say that the feedback rigid, for F_r being differential, the feedback is anticipating, and for F_r being integral, the feedback is delaying.

58.2.3 Stability of feedback circuits

As discussed above, the transfer function of the feedback circuit is,

$$H(s) = \frac{F(s)}{1 + F(s)F_{fb}(s)} \ . \tag{58.55}$$

The *open loop gain* is $V(s) = F(s)F_{fb}(s)$. The circuit is stable, when for all the eigenfunctions e^{st}, that do not decay with $Re\ s \geq 0$, the transfer function of the feedback circuit is finite, $H(s) < \infty$.

An equivalent criterion is the *Nyquist criterion*: *The curve $V(\imath\omega)$ to $\omega \in [0; \infty[$ must always bypass the point of instability at $Re\ s = -1$ leaving it on the left side. That is, considering negative frequencies, the curve should not circle this point.* Fig. 58.9 shows an example.

58.2.4 Further topics in control theory

58.2.4.1 Nonlinear control theory

Linear control theory applies to systems made of devices which obey the superposition principle, which means roughly that the output is proportional to the input. They are governed by linear differential equations. A major subclass is systems which in addition have parameters which do not change with time, called linear time invariant (LTI) systems. These systems are amenable to powerful frequency domain mathematical techniques of great generality, such as the Laplace transform, Fourier transform, Z transform, Bode plot, root locus, and Nyquist stability criterion. These lead to a description of the system using terms like bandwidth, frequency response, eigenvalues, gain, resonant frequencies, poles, and zeros, which give solutions for system response and design techniques for most systems of interest.

Nonlinear control theory covers a wider class of systems that do not obey the superposition principle, and applies to more real-world systems, because all real control systems are nonlinear. These systems are often governed by nonlinear differential equations. If only solutions near a stable point are of interest, nonlinear systems can often be linearized by approximating them by a linear system using perturbation theory, and linear techniques can be used.

P-servo with rigid feedback		*P*	$K_P = \frac{K_R}{1+K_rK_R} \xrightarrow{K_P\to\infty} \frac{1}{K_r}$
P-servo with yielding feedback		*P-T*$_1$ *I*	$K_P = K_R$, $T_1 = K_RK_r$ for $K_R \ll \infty$ $K_I = K_r^{-1}$ for $K_R \to \infty$
P-servo with yielding feedback		*PD-T*$_1$ *PI*	$K_P = K_R$, $T_v = T_r$, $T_1 = T_r + K_rK_R$ for $K_R \ll \infty$ $K_P = T_r/K_r$, $T_n = T_r$ for $K_R \to \infty$
P-servo with delayed feedback		*PD-T*$_1$ *PD*	$K_P = \frac{K_R}{1+K_rK_R}$, $T_v = T_r$, $T_1 = \frac{T_r}{1+K_rK_R}$ for $K_R \ll \infty$ $K_P = 1/K_r$, $T_v = T_r$ for $K_R \to \infty$
P-servo with delayed yielding feedback		*PID*	$K_P = \frac{T_{r1}+T_{r2}}{K_{r1}K_{r2}}$, $T_v = \frac{T_{r1}T_{r2}}{T_{r1}+T_{r2}}$, $T_n = T_{r1}+T_{r2}$ for $K_R \to \infty$
P-servo with two delay circuits in the feedback		*PID*	$K_P = \frac{T_{r1}+T_{r2}}{K_{r1}(T_{r1}-T_{r2})}$, $T_v = \frac{T_{r1}T_{r2}}{T_{r1}+T_{r2}}$, $T_n = T_{r1}+T_{r2}$ for $K_R \to \infty$ and $T_{r1} > T_{r2}$
I-servo with rigid feedback		*P-T*$_1$	$K_P = \frac{1}{K_r}$, $T_1 = \frac{1}{K_IK_r}$
I-servo with yielding feedback		*PI-T*$_1$	$K_P = \frac{K_IT_r}{1+K_IK_r}$, $T_n = T_r$, $T_1 = \frac{T_r}{1+K_IK_r}$

Figure 58.8: Some examples for feedback regulators. The columns show from left to right: the nomenclature, the circuit diagram, the behavior, and the constants of the LTI system.

58.2.4.2 MIMO control systems

In this script we restrict to *single-input single-output control systems* (*SISO*), which is the simplest and most common type, in which one output is controlled by one control signal. Examples are the temperature control or an audio system, in which the control input is the input audio signal and the output is the sound waves from the speaker.

In contrast, *multiple-input multiple-output control systems* (*MIMO*) are found in more complicated systems. For example, modern large telescopes such as the Keck and MMT have mirrors composed of many separate segments each controlled by an actuator. The shape of the entire mirror is constantly adjusted by a MIMO active optics control system using input from multiple sensors at the focal plane, to compensate for changes in the mirror shape due to thermal expansion, contraction, stresses as it is rotated and distortion of the wavefront due to turbulence in the atmosphere.

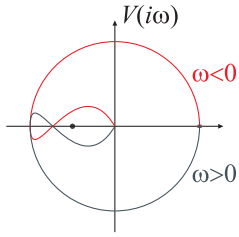

Figure 58.9: Illustration of the Nyquist criterion.

Another example are ultra-stable laser systems stabilized by combinations of fast actuators with low dynamic range and slow actuators with large dynamic range.

Calculate the step response of a low-pass filter using the Laplace transform formalism.

58.3 Characterization of stability

The quality factor of a resonance measured with an oscillator in its function as a measuring apparatus for the resonance frequency is named *precision*. The precision also includes the perturbations to which the controlled oscillator is exposed and can be understood as the standard deviation of the frequency realized by the standard. The temporal or spectral behavior of precision, i.e. the stability can e.g. measured directly by comparing similar but independent standards. The reciprocal of the spread of the frequency realizations of an ensemble of similar standards is called *reproducibility*. The term reproducibility is also used to compare the frequencies of an individual standard before and after readjustment of all its technical parameters.

The *accuracy* is defined as the degree of agreement between the frequency realized by the standard and the defined standard frequency, i.e. the frequency that would be displayed in the fault-free ideal case [3]. The accuracy is always less than the quality of the resonance and the certainty of it center frequency. It includes the precision and limits the reproducibility [13]. The fact that the accuracy is related to the ideal case of absent errors implies that it cannot be measured directly. It must be inferred indirectly through model assumptions regarding the measuring apparatus estimating the probability for presumed or possible errors. We then speak of the *uncertainty* of the measured value [183].

The temporal or spectral behavior of *accuracy* is called *stability*. It is measurable and is quantified in the frequency domain by the *spectral density of fluctuations* and in the time domain best by the *Allan variance*. The noise is now the physical phenomenon that manifests itself as a deviation from the optimal stability.

[3] For example, when a measurement apparatus for the constant π provided the value $x = 3.141\ 59\ (12)$, then the accuracy is $x - \pi$ and the precision 0.000 12.

The stability that an ideal frequency standard can achieve in principle is proportional to quality factor of the resonance $\omega/(\Delta\omega_{nat}+\Delta\omega_{broaden})$ and the signal-to-noise ratio of the control signal S/N. Hence, the stability can be optimized by choosing atomic transitions with small spontaneous decay rates $\Delta\omega_{nat}$. Appropriate techniques for the experimental preparation of the resonance limit the influence of line broadening mechanisms $\Delta\omega$. According to the Fourier theorem, the resolution of narrow lines requires long observation times. Now, the control signal of a feedback regulator can only be determined after a whole observation period. This means that the apparatus already must have an intrinsic stability good enough that the frequency does not leave the control range during a period of observation. Furthermore, a better signal-to-noise ratio can improve the precision with which the line center of the resonance can be determined.

Ultimately, the most promising way to increase the accuracy of a frequency standard seems to be to choose the highest possible transition frequencies ω, provided that the oscillations can still be counted electronically, or be linked in a phase-coherent way to oscillators generating countable oscillations, e.g. using frequency combs. The requirement of phase coherence at optical frequencies puts the laser in the focus of interest in metrology.

58.3.1 Quantifying frequency fluctuations

The following sections deal with perturbation-induced fluctuations of the laser frequency, i.e. frequency noise. To characterize the behavior of an oscillator (especially when used as a frequency standard), it is necessary to introduce some concepts that allow the quantitative description of the noise. The most important are reproducibility, stability, spectral density of fluctuations, Allan variance, and emission bandwidth. The basic work on this has been carried out at the National Bureau of Standards (NBS) in Boulder, Co, USA [12, 13, 63, 212].

58.3.1.1 Stability in the frequency domain, spectral fluctuation density

The instantaneous amplitude of an oscillator, e.g. the electric field of a laser radiation, can be written,

$$\mathcal{E}(t) = \mathcal{E}_0(t)e^{\imath\phi(t)} \ . \tag{58.56}$$

noise afflicts phase and amplitude. In the following we will neglect amplitude noise, $\mathcal{E}_0(t) = \mathcal{E}_0$, and if the frequency fluctuations only deviate slightly from a mean value, $\omega_0 \gg |\dot{\varphi}(t)|$, we may write,

$$\phi(t) \equiv \omega_0 t + \varphi(t) \ . \tag{58.57}$$

In the following, we will often consider normalized frequency fluctuations,

$$y(t) = \dot{\varphi}(t)/\omega_0 \ . \tag{58.58}$$

When measuring stability, one must differentiate between *deterministic fluctuations* and *stochastic noise*. Deterministic fluctuations are usually due to inadequate control of equipment parameters. They generate systematic errors and slow drifts $y_{sys}(t)$ which, if one recognizes them as such in time domain measurements (measure for sufficiently long times!), can be subtracted and disregarded. Stochastic noise,

however, is stationary:

$$\overline{y_{sto}(t)} = \overline{y(t) - y_{sys}(t)} = 0 \qquad \text{defining} \qquad \overline{y(t)} \equiv \lim_{T\to\infty} \frac{1}{T}\int_0^T y(t)dt \tag{58.59}$$

as the time average. In the following only stationary stochastic fluctuations are considered.

Let us take a look at the *autocorrelation function* of the phase defined as,

$$\boxed{R_y(\tau) \equiv \overline{y^*(t)y(t+\tau)} = \lim_{T\to\infty} \frac{1}{T}\int_0^T y^*(t)y(t+\tau)\rangle d\tau} \tag{58.60}$$

and the *spectral density of phase fluctuations* which, according to the *Wiener-Khintchine theorem*, can be obtained as the Fourier transform of the autocorrelation function,

$$\boxed{S_y(f) \equiv \mathcal{F}R_y(\tau) = \int_{-\infty}^{\infty} R_y(\tau)e^{-2\pi\imath f\tau}d\tau} \ . \tag{58.61}$$

The normalized density of frequency fluctuations $S_y(f)$ is a spectral quantity with the unit 1/Hz. Frequency and phase fluctuations are linked by:

$$S_{\dot{x}}(f) = f^2 S_x(f) \ , \tag{58.62}$$

as will be shown in Exc. 58.3.3.1. Also,

$$S_{ax}(f) = a^2 S_x(f) \ , \tag{58.63}$$

If the integral of the spectral fluctuation density is finite it corresponds, according to the definition (58.62), to the noise power or the mean square deviation of a measured variable:

$$\int_0^{\infty} S_y(f)df = R_y(0) = \overline{|y(t)|^2} < \infty \ . \tag{58.64}$$

58.3.1.2 Model of noise

Measurements seem to confirm today that stochastic fluctuations in frequency standards can be traced back to a few additive noise processes with different physical origins and different frequency responses [12]:

$$\boxed{S_y(f) = \sum_{\beta=-2}^{2} h_\beta f^\beta} \ . \tag{58.65}$$

The table below lists the most common ones.

This noise model is based on the assumption that the noise processes it describes operate in all Fourier frequency ranges, which violates the requirement (58.64). The dilemma does not arise in experiment, since the integration over an unlimited Fourier frequency range is not a realistic concept in that each measurement only takes a finite time τ, so that very low frequencies below a cut-off frequency $f_{min} = 2\pi/\tau$ are not

noise type	$S_x(f)$	$S_y(f)$	$\sigma_y^2(\tau)$
white phase noise	h_2	$h_2 f^2$	$\propto \frac{h_2}{\tau^2}$
flicker phase noise	$h_1 f^{-1}$	$h_1 f^1$	$\propto \frac{h_1}{\tau^2}$
white frequency noise	$h_0 f^{-2}$	$h_0 f^0$	$\frac{h_0}{2\tau}$
flicker frequency noise	$h_{-1} f^{-3}$	$h_{-1} f^{-1}$	$h_{-1} 2 \ln 2$
random walk frequency drifts	$h_{-2} f^{-4}$	$h_{-2} f^{-2}$	$h_{-2} \frac{(2\pi)^2}{6} \tau$

Table 58.1: *Spectral fluctuation density and Allan-variance for common noise processes [63].*

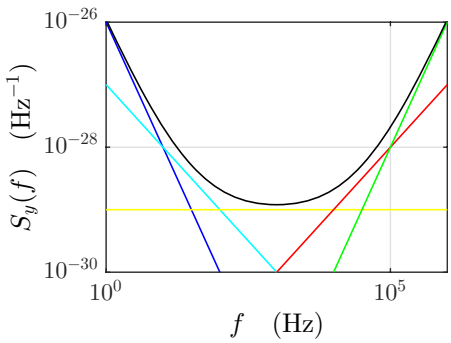

Figure 58.10: Noise model according to (58.65).

perceived. In addition, every real data acquisition system has a low-pass behavior with a cut-off frequency f_{max}, so that high frequencies also do not contribute to the integral. These bandwidth constraints enforce the condition (58.64) for the five noise processes assumed by (58.65) [570]. The measure for the noise power in any case has the form: $\int_{f_{min}}^{f_{max}} S_y(f) df$.

58.3.1.3 Description of stability in the time domain, Allan variance

Temporal frequency fluctuations of an oscillator can be measured by *discriminating the frequency fluctuations at the dispersive profile of a resonance* (or error signal) and convert it into voltage fluctuations. It is just the curve exhibited by a spectrum analyzer to which the error signal is fed, as illustrated by the left setup of Fig. 58.12.

Like any physical quantity, frequency fluctuations can only be measured as an average over an *integration time interval* τ imposed by the measuring apparatus. The k-th measurement of the quantity y at the time t_k results in the measured value:

$$y_k(\tau) = \frac{1}{\tau} \int_{t_k}^{t_k+\tau} y(t) dt \ . \tag{58.66}$$

Assuming that the dead time of the measuring apparatus is negligible (if necessary, technical precautions must be taken to meet this requirement approximately), the

variance of stochastic noise can be expressed as follows:

$$\sigma_y^2(\tau) = \frac{1}{N-1}\sum_{k=1}^{N} y_k^2 \qquad \text{where} \qquad \overline{y_k} = 0\ . \tag{58.67}$$

The variance is a direct measure of the stability of an oscillator in time domain. It is measured from a discrimination of the error signal in a similar way as the fluctuation density $S_y(f)$. However, as illustrated by the left setup of Fig. 58.12, the discriminated signal is recorded in time domain, e.g. by an oscilloscope.

The variance can be linked to the spectral density of frequency fluctuations in frequency domain by Fourier transformation. With the Heaviside step function Θ the following relationship can be given [212, 12, 40],

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f)|\mathcal{F}\zeta_1(f)|^2 df \qquad \text{where} \qquad \zeta_1(t) = \frac{1}{\tau}\Theta_{[-\tau,0]}(t)\ , \tag{58.68}$$

is the area-normalized jump function, which models the duration of the integration time τ. Its Fourier-transform is the transfer function of the equivalent filter.

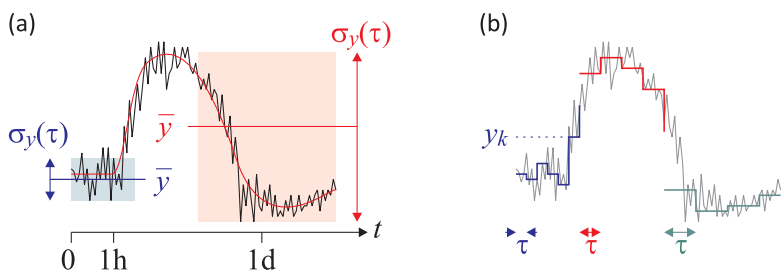

Figure 58.11: (a) Noise can exhibit very different short and long time behavior. (b) Any measurement needs a minimum integration time.

It turns out that the variance for $1/f$ noise and for stochastic drifts ($1/f^2$ noise) diverges at the lower limit, i.e. this variance is not useful for practical applications. The divergence comes from the fact that for longer and longer measurements ($N \to \infty$), respectively, smaller and smaller Fourier frequencies ($f \to 0$), longer and longer periodic fluctuations can be identified as such, while for shorter measurements they appear as linear drifts. One way out is to calculate the variance for a limited number k of measurement data and to average the variances of M of such data sets of length k. This variance converges for a larger number of noise processes. This so-called pair variance ($k = 2$) or *Allan variance* is widely used:

$$\boxed{\sigma_y^2(\tau) = \frac{1}{2M}\sum_{j=1}^{M}(y_{2j} - y_{2j-1})^2}\ . \tag{58.69}$$

Like the normal variance, the Allan variance can also be related to the spectral density of frequency fluctuations:

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f)|\mathcal{F}\zeta_2(f)|^2 df \qquad \text{where} \qquad \zeta_2(t) \equiv \tfrac{1}{\sqrt{2}}[\zeta_1(t) - \zeta_1(-t)]\ . \tag{58.70}$$

The Fourier transforms of the step functions $\zeta_1(t)$ and $\zeta_2(t)$ will be calculated in Exc. 58.3.3.2, as well as the variances for white noise.

58.3.2 Power spectral density

It is important not to confuse the spectral density of frequency fluctuations with the power spectral density of the oscillator defined via the *autocorrelation function of the field amplitude* [4],

$$\boxed{R_{\mathcal{E}}(\tau) \equiv \langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle = \mathcal{E}_0^2 \langle e^{\imath[\phi(t+\tau)-\phi(t)]}\rangle = \mathcal{E}_0^2 e^{\imath\omega_0\tau}\langle e^{\imath[\varphi(t+\tau)-\varphi(t)]}\rangle} \ , \quad (58.71)$$

as its Fourier transform,

$$\boxed{S_{\mathcal{E}}(\omega) = \mathcal{F}R_{\mathcal{E}}(\tau)} \ . \quad (58.72)$$

The power spectral density is typically measured as the beat frequency of two independent oscillators. It is just the curve exhibited by a spectrum analyzer to which the beat signal is fed, as illustrated in the right setup of Fig. 58.12.

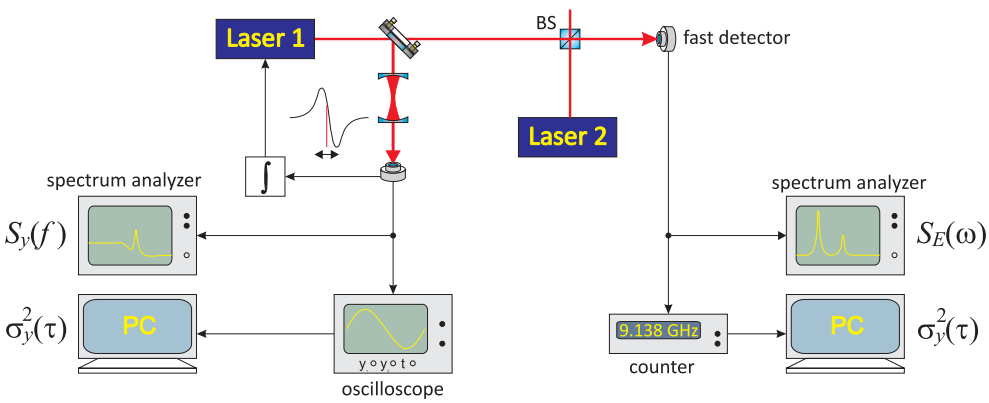

Figure 58.12: (left) Setup for measuring the spectral density of frequency fluctuations $S_y(f)$ and the Allan variance $\sigma_y^2(\tau)$ of laser 1 discriminating it at the slope of transmission signal of an optical cavity. (right) The power spectral density $S_{\mathcal{E}}(\omega)$ can be found as the beat signal between two lasers and either be exhibited on a spectrum analyzer $S_{\mathcal{E}}(\omega)$ or counted and processed to an Allan variance $\sigma_y^2(\tau)$.

The beat spectrum is the convolution of the emission bandwidth of the two oscillators,

$$S_{\mathcal{E}}(\omega) = S_{\mathcal{E},laser1}(\omega) * S_{\mathcal{E},laser2}(\omega) \ . \quad (58.73)$$

In particular, for the case that we have good reasons to believe that one laser is much narrower than the other, the power spectral density $S_{\mathcal{E}}(\omega)$ will reflect the emission spectrum of just the broader laser. Note that the power spectral density derived

[4] Note that the *first-order coherence* is just the normalized autocorrelation,

$$g^{(1)}(\tau) \equiv \frac{\langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle}{\langle \mathcal{E}^*(t)\mathcal{E}(t)\rangle} = \frac{R_{\mathcal{E}}(\tau)}{R_{\mathcal{E}}(0)} \ .$$

.

from a beat of two independent (uncorrelated) oscillators gives us information on their true emission bandwidths, which is relevant e.g. for resolving narrow atomic transitions. On the other hand, the stability measures $S_y(f)$ and $\sigma_y^2(\tau)$ derived from a discriminated error signal (left setup in Fig. 58.12) only tell us the stability of an oscillator with respect to the reference from which the error signal was derived, e.g. the transmission slope of an optical cavity.

58.3.2.1 Spectral noise power density in the case of white noise

The spectral noise power density $S_{\mathcal{E}}(\omega)$ of the field $\mathcal{E}(t)$ of an oscillator can, in the case of white frequency noise, be related to the spectral density of its frequency fluctuations. In the case of a laser oscillator, the half-width half maximum of the spectral noise power density, i.e. the emission bandwidth, is often specified. We will, in the following, derive the emission spectrum for the case of white Gaussian noise [888, 293, 269].

In Exc. 58.3.3.3 we show that for a *Gaussian noise process* holds [222, 293],

$$\left\langle e^{-\imath[\varphi(t)-\varphi(t+\tau)]}\right\rangle = e^{-\left\langle[\varphi(t)-\varphi(t+\tau)]^2\right\rangle/2} \ . \tag{58.74}$$

Now we set $\varphi(t) = \omega_0 \int_0^t y(t')dt'$ using (58.58) and obtain,

$$\begin{aligned}\left\langle[\varphi(t)-\varphi(t+\tau)]^2\right\rangle &= \left\langle \omega_0^2\left[\int_0^\tau y(t')dt'\right]^2\right\rangle = \omega_0^2\int_0^\tau\int_0^\tau \langle y(t')y(t'')\rangle\, dt'dt'' \\ &= \omega_0^2\int_0^\tau\int_0^\tau R_y(t'-t'')dt'dt'' = 2\omega_0^2\int_0^\tau(\tau-t)R_y(t)dt \ .\end{aligned} \tag{58.75}$$

Using (58.61), we now substitute the autocorrelation function by its Fourier transform, the spectral fluctuation density, $R_y(t) = \int_0^\infty S_y(f)e^{2\pi\imath ft}df$:

$$\begin{aligned}\left\langle[\varphi(t)-\varphi(t+\tau)]^2\right\rangle &= 2\omega_0^2\int_0^\infty S_y(f)\int_0^\tau(\tau-t)e^{2\pi\imath ft}dtdf \\ &= 2\omega_0^2\int_0^\infty S_y(f)\left(\frac{\sin\pi f\tau}{2\pi f}\right)^2 df + \text{imaginary part} \ .\end{aligned} \tag{58.76}$$

We neglect the imaginary part.

For Markovian white noise the phase fluctuations are δ-distributed, which means,

$$R_y \equiv \langle y^*(t)y(t+\tau)\rangle = h_0\delta(\tau) \qquad \text{and} \qquad S_y(f) = h_0 = const. \tag{58.77}$$

I.e. the so-called *white noise* is characterized by a constant spectral density of phase fluctuations. Carrying on the calculation (58.76) for the case of white frequency noise we get,

$$\left\langle[\varphi(t)-\varphi(t+\tau)]^2\right\rangle = \frac{h_0\omega_0^2|\tau|}{\pi}\int_0^\infty\left(\frac{\sin x}{x}\right)^2 dx = \frac{h_0\omega_0^2|\tau|}{2} \ . \tag{58.78}$$

With this result, we can undertake to calculate the autocorrelation function of the field amplitude (58.71),

$$R_{\mathcal{E}}(\tau) = \mathcal{E}_0^2 e^{\omega_0\tau}e^{-h_0\omega_0^2|\tau|/2} \ . \tag{58.79}$$

The resulting *power spectral density* (58.72) is [5]:

$$\boxed{S_{\mathcal{E}}(\omega) = \mathcal{E}_0^2 \int_{-\infty}^{\infty} R_{\mathcal{E}}(\tau) e^{-\imath(\omega-\omega_0)\tau} d\tau = \frac{2h_0\omega_0^2}{4\Delta^2 + (h_0\omega_0^2/2)^2}} \,, \tag{58.80}$$

where $\Delta \equiv \omega - \omega_0$ is the deviation of the oscillator frequency from the center frequency ω_0. Thus, the the emission spectrum for the case of white Gaussian noise is a Lorentzian profile with the *laser emission bandwidth*,

$$\boxed{\beta = \tfrac{1}{2} h_0 \omega_0^2} \,. \tag{58.81}$$

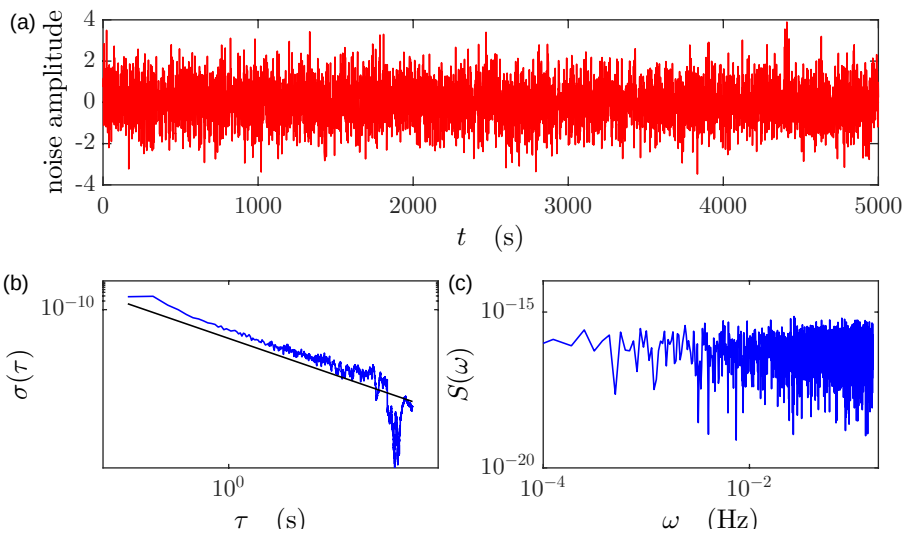

Figure 58.13: (code) Allan variance (b) and spectral density of frequency fluctuations (c) calculated from a randomly generated data set (a).

The Lorentz shape of the emission profile of an oscillator or a resonance always indicates white noise of the underlying frequency fluctuation density. In this sense, the Lorentz form of the natural broadening of an atomic resonance can also be traced back to the white noise of the vacuum fluctuations. Here, the emission bandwidth has to be replaced by the natural linewidth. The Allan variance in this case is:

$$\sigma_y^2(\tau) = \frac{h_0}{2\tau} = \frac{1}{Q^2}\frac{1}{\Gamma}\frac{1}{\tau} \,. \tag{58.82}$$

with the linewidth (FWHM) $\Gamma = h_0\omega_0^2/2$ and $Q = \omega_0/\Gamma$ and indicates the maximum achievable stability for a frequency standard that is coupled to the resonance ω_0.

[5] Using $\mathcal{F}[e^{-a|x|}] = \int_{-\infty}^{\infty} e^{-a|t|} e^{-\imath\omega t} dt = \frac{2a}{a^2+\omega^2}$.

58.3.2.2 Spectral noise power density in case of periodic phase perturbation

The momentary deflection of the oscillator can be described in the case of a harmonic phase disturbance by equation (58.60) with the additional condition: $\phi(t) = N \sin \Omega t$. The frequency fluctuation density and the Allan variance are obtained in this case:

$$S_y(f) = \left(\frac{fN}{2\omega_0}\right)^2 \delta(f - \Omega) \qquad \text{resp.} \qquad \sigma_y^2(\tau) = \left(\frac{\Omega N}{2\omega_0}\right)^2 \frac{\sin^2 \Omega\tau/2}{\Omega\tau/2} \ . \tag{58.83}$$

The spectral noise power density consists of a discrete spectrum of sidebands, the number and height of which is given by the modulation index N:

$$\boxed{S_{\mathcal{E}}(\omega) = \sum_{n=-\infty}^{\infty} |J_n(N)|^2 \delta(\omega - \omega_0 - \Omega)} \ . \tag{58.84}$$

A full width at half maximum of the spectral noise power density cannot be specified. However, as a measure of the emission bandwidth of the oscillator, the frequency spacing of the sideband of the highest order can be understood, the height of which corresponds to at least half the height of the carrier frequency ω_0.

58.3.3 Exercises

58.3.3.1 Ex: Spectral density of frequency fluctuations

Prove the relationship $S_{\dot{x}}(f) = f^2 S_x(f)$.

58.3.3.2 Ex: Allan variance for white noise

a. Calculate the Fourier transform of step function $\zeta_1(t)$ and the one-point variance for white noise from its definition (58.68).
b. Repeat the calculation for the step function $\zeta_2(t)$ and the Allan variance as defined in (58.70).

58.3.3.3 Ex: Gaussian noise process

Prove the relationship (58.75) for a *Gaussian noise process* characterized by,

$$\frac{\langle A^{2n} \rangle}{(2n)!} = \frac{\langle A^2 \rangle^n}{2^n n!} \qquad \text{and} \qquad \langle A^{2n-1} \rangle = 0 \ .$$

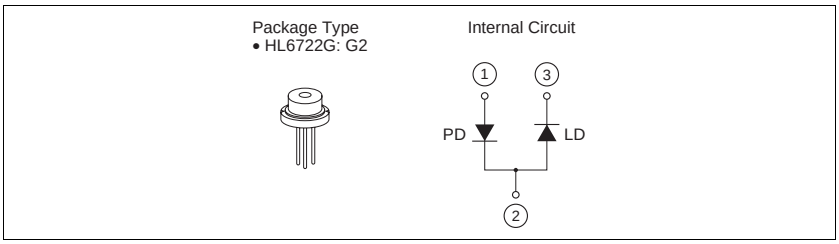
Description

The HL6722G is a 0.67 µm band AlGaInP index-guided laser diode with a multi-quantum well (MQW) structure. It is suitable as a light source for bercode scanner, and various other types of optical equipment. Hermetic sealing of the package assures high reliability.

Features

- Visible light output at wavelengths up to 680 nm
- Single longitudinal mode
- Continuous operating output: 5 mW CW
- Low voltage operation: 2.7 V Max
- Low current operation: 32 mA Typ
- Built-in monitor photodiode



opnext
Powered by HITACHI

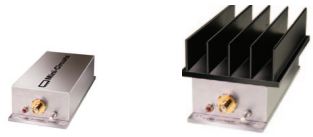
Figure 58.14: Data sheet for the diode laser from Thorlabs, model Hitachi HL6722G.

Coaxial

Amplifier

ZHL-2-8

50Ω Medium High Power 10 to 1000 MHz



ZHL-2-8X ZHL-2-8

SMA version shown

Features

- wideband, 10 to 1000 MHz
- high IP3, +38 dBm typ.
- medium high power, 29 dBm min.

Applications

- VHF/UHF
- test equipment
- cellular
- instrumentation
- laboratory

CASE STYLE: T34

Connectors	Model	Price	Qty.
BNC	ZHL-2-8	$525.00 ea.	(1-9)
BNC	ZHL-2-8X	$515.00 ea.	(1-9)
SMA	ZHL-2-8-S	$535.00 ea.	(1-9)
SMA	ZHL-2-8X-S	$525.00 ea.	(1-9)

Electrical Specifications

ZHL-2-8X*	10	1000	31	35	±1.0	+29	+5	10.0	+38	2.0	2.0	24	0.6

* Heat sink not included
Open load is not recommended, potentially can cause damage.
With no load derate max input power by 20 dB

To order without heat sink, add suffix X to model number. Alternative heat sinking and heat removal must be provided by the user to limit maximum temperature to 65°C, in order to ensure proper performance. For reference, this requires thermal resistance of user's external heat sink to be 1.35°C/W Max.

Maximum Ratings

Operating Temperature	-20°C to 65°C
Storage Temperature	-55°C to 100°C
DC Voltage	+25V Max.

Permanent damage may occur if any of these limits are exceeded.

Coaxial

Voltage Controlled Oscillator

ZOS-100+

Dual Output 50 to 100 MHz

Features

- octave bandwidth
- linear tuning, 4.5 MHz/V typ.
- excellent harmonic suppression, -29 dBc typ.
- rugged shielded case
- protected by US Patent, 6,943,629

CASE STYLE: BR386

Connectors	Model	Price	Qty.
SMA	ZOS-100+	$119.95	(1-9)

+ RoHS compliant in accordance with EU Directive (2002/95/EC)

The +Suffix has been added in order to identify RoHS Compliance. See our web site for RoHS Compliance methodologies and qualifications.

Applications

- auxiliary output freq. monitoring
- load insensitive source

Voltage Variable Attenuator

ZX73-2500+

50Ω 10 to 2500 MHz

FEMALE SMA shown

CASE STYLE: GD958

Maximum Ratings

Operating Temperature	-55°C to 85°C
Storage Temperature	-55°C to 85°C
Absolute Max. Supply Voltage (V+)	12V
Absolute Max. Control Voltage (Vcrtl)	20V
Absolute Max. RF Input Level	+20 dBm

Permanent damage may occur if any of these limits are exceeded.

Features

- Broadband, 10-2500 MHz
- IP3, +43 dBm typ.
- 40 dB attenuation @ 1500 MHz
- Good VSWR at in /out ports over attenuation range
- No external bias and RF matching network required
- Shielded case
- Protected by US Patent 6,790,049

Applications

- Variable gain amplifier
- Power level control
- Feed-forward amplifiers
- ALC circuits

Silicon PIN Photodiodes - Large Area, Fast Response Time – 400 nm to 1100 nm

The FFD series devices are high-quality, large-area, high-speed, N-type Si PIN photodiodes in hermetically sealed TO packages designed for the 400 nm to 1100 nm wavelength range. The FND-100Q has a quartz window to enhance UV responsivity.

Preamplifiers

Preamplifier modules incorporating these photodiodes are available on a custom basis.

Detectors

Silicon Epitaxial PIN Photodiodes - High Speed – 400 nm to 1100 nm

The C30736 series of high-speed epitaxial silicon PIN photodetectors provide fast response and good quantum efficiency in the spectral range between 400 nm and 1100 nm. These devices are optimized for high-speed, high volume and low cost applications. Standard sizes include 0.25 mm, 0.5 mm, 1.0 mm, 1.5 x 1.5 mm, and custom sizes can be accomodated depending on volume required. Available in plastic surface mount packages and in chip form.

MAXIM

Precision, Dual-Supply, SPST Analog Switches

MAX320/MAX321/MAX322

General Description

The MAX320/MAX321/MAX322 are precision, dual, SPST analog switches designed to operate from ±3V to ±8V dual supplies. The MAX320 has two normally open (NO) switches and the MAX321 has two normally closed (NC) switches. The MAX322 has one NO and one NC switch. Low power consumption (1.25mW) makes these parts ideal for battery-powered equipment. They offer low leakage currents (100pA max) and fast switching speeds (t_{ON} = 150ns max, t_{OFF} = 100ns max).

The MAX320 series, powered from ±5V supplies, offers 35Ω max on-resistance (R_{ON}), 2Ω max matching between channels, and 4Ω max R_{ON} flatness.

These switches also offer 5pC max charge injection and a minimum of 2000V ESD protection per Method 3015.7.

For equivalent devices specified for single-supply operation, see the MAX323/MAX324/MAX325 data sheet. For quad versions of these switches, see the MAX391/MAX392/MAX393 data sheet.

Applications

Battery-Operated Systems	Sample-and-Hold Circuits
Heads-Up Displays	Guidance and Control Systems
Audio and Video Switching	Military Radios
Test Equipment	Communications Systems
±5V DACs and ADCs	PBX, PABX

Features

- **Low On-Resistance, 35Ω max (16Ω typical)**
- **R_{ON} Matching Between Channels <2Ω**
- **R_{ON} Flatness <4Ω**
- **Guaranteed Charge Injection <5pC**
- **Bipolar Supply Operation (±3V to ±8V)**
- **Low Power Consumption, <1.25mW**
- **Low Leakage Current Over Temperature, <2.5nA at +85°C**
- **Fast Switching, t_{ON} <150ns, t_{OFF} <100ns**
- **Guaranteed Break-Before-Make (MAX322 only)**

LM741
Operational Amplifier

General Description

The LM741 series are general purpose operational amplifiers which feature improved performance over industry standards like the LM709. They are direct, plug-in replacements for the 709C, LM201, MC1439 and 748 in most applications.

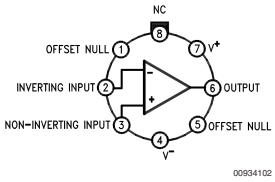
The amplifiers offer many features which make their application nearly foolproof: overload protection on the input and output, no latch-up when the common mode range is exceeded, as well as freedom from oscillations.

The LM741C is identical to the LM741/LM741A except that the LM741C has their performance guaranteed over a 0˚C to +70˚C temperature range, instead of −55˚C to +125˚C.

Features

Connection Diagrams

Metal Can Package



Note 1: LM741H is available per JM38510/10101

Order Number LM741H, LM741H/883 (Note 1)**, LM741AH/883 or LM741CH**

ANALOG DEVICES

Low-Noise, Precision Operational Amplifier

OP27

FEATURES

Low Noise: 80 nV p-p (0.1 Hz to 10 Hz), 3 nV/$\sqrt{\text{Hz}}$
Low Drift: 0.2 μV/°C
High Speed: 2.8 V/μs Slew Rate, 8 MHz Gain Bandwidth
Low V_{OS}: 10 μV
Excellent CMRR: 126 dB at V_{CM} of ±11 V
High Open-Loop Gain: 1.8 Million
Fits 725, OP07, 5534A Sockets
Available in Die Form

GENERAL DESCRIPTION

The OP27 precision operational amplifier combines the low offset and drift of the OP07 with both high speed and low noise. Offsets down to 25 μV and drift of 0.6 μV/°C maximum make the OP27 ideal for precision instrumentation applications. Exceptionally low noise, e_n = 3.5 nV/$\sqrt{\text{Hz}}$, at 10 Hz, a low 1/f noise corner frequency of 2.7 Hz, and high gain (1.8 million), allow accurate high-gain amplification of low-level signals. A gain-bandwidth product of 8 MHz and a 2.8 V/μsec slew rate provides excellent dynamic accuracy in high-speed, data-acquisition systems.

A low input bias current of ±10 nA is achieved by use of a bias-current-cancellation circuit. Over the military temperature range, this circuit typically holds I_B and I_{OS} to ±20 nA and 15 nA, respectively.

The output stage has good load driving capability. A guaranteed swing of ±10 V into 600 Ω and low output distortion make the OP27 an excellent choice for professional audio applications.

WKB approximation, 1015

XOR, 1813
XX-Heisenberg model, 1754

Young
    Thomas, 1494
Young's experiment, 1494
Yukawa
    Hideki, 1142
Yukawa potential, 1142

Zeeman
    Pieter, 1180
Zeeman effect, 368, 808
    anomalous, 1181
    normal, 1181
Zeeman slower, 1445, 1983, 2017
Zeeman splitting, 1180
Zeno
    de Elea, 1537
Zeno effect, 1537
zero point energy, 883
zero sound, 2036
zero temperature reservoir, 2124
Zitterbewegung, 1145, 1161
