Abstract. The possibility of observing phenomena peculiar to long-range interactions, and more specifically in the so-called quasi-stationary state (QSS) regime, is investigated within the framework of two devices, namely the free-electron laser (FEL) and the collective atomic recoil laser (CARL). The QSS dynamics has been mostly studied using the Hamiltonian mean-field (HMF) toy model, demonstrating in particular the presence of first-order and second-order out-of-equilibrium phase transitions from magnetized to unmagnetized regimes. Here, we give evidence of the strong connections between the HMF model and the dynamics of the two aforementioned devices, and we discuss the perspectives for observing some specific QSS features experimentally. In particular, a dynamical analog of the phase transition is present in the FEL and in the CARL in its...
conservative regime. As regards the dissipative CARL, a formal link is established with the HMF model. For both FEL and CARL, calculations are performed with reference to existing experimental devices, namely the FERMI@Elettra FEL under construction at Sincrotrone Trieste (Italy) and the CARL system at LENS in Florence (Italy).

**Keywords:** classical phase transitions (theory), classical phase transitions (experiment), phase diagrams (theory), phase diagrams (experiment)

### 1. Introduction

Long-range interactions have now been shown to be central in a wide range of scientific contexts such as astrophysics [1], hydrodynamics [2] and nuclear physics [3]. However, the possibilities of investigating the long-range features via dedicated experiments are more restricted: non-neutral plasmas [4], cold atom and wave–particle systems [5] are among the most serious candidates. The purpose of this paper is to investigate the possibility of using existing set-ups based on the wave–particle interactions to probe long-range features of the dynamics, in particular out-of-equilibrium transitions.

As an introduction to long-range interactions, let us start from the Hamiltonian mean-field (HMF) model [6], a paradigmatic system on which many theoretical studies focused. This one-dimensional model describes the interaction of $N$ particles on a circle through a collective field, which depends only on their phase $\theta_j$. This $N$-body dynamics is described by the following Hamiltonian:

$$H = \sum_{j=1}^{N} \left( \frac{p_j^2}{2} + \epsilon \sum_{k=1}^{N} (1 - \cos (\theta_j - \theta_k)) \right),$$

(1)

associated with the canonical bracket in $(\theta_j, p_j)$. Here, $\epsilon = \pm 1$ corresponds either to a ferromagnetic (+) or to an antiferromagnetic (−) system. In this model, the particles are collectively interacting through the so-called magnetization $M = M e^{i\phi} = (\sum_j e^{i\theta_j})/N$, since the dynamics of a single particle is given by

$$\dot{\theta}_j + \epsilon M \sin(\theta_j - \phi) = 0.$$  

(2)

Long-range systems can exhibit interesting equilibrium features, such as ensemble inequivalence (see e.g. [7] for the antiferromagnetic two-dimensional version of the HMF model).
model or [8] for a recent review). However, the HMF model mainly revealed itself as a perfect playground for studying out-of-equilibrium long-range features. Indeed, starting from generic non-stationary initial conditions, the system will typically have a fast transient dynamics until a nearly stationary state, generally called a quasi-stationary state (QSS), is reached: not only does the QSS dynamics substantially differ from the equilibrium one, but also the system actually stays trapped in it for very long times [6].

More specifically, several authors demonstrated that the lifetime of the said QSS diverges when the number of particles in interaction increases. For example, numerical works report that the time of relaxation to equilibrium for the Hamiltonian mean-field model scales as \( N^{1.7} \) [9], in a regime of parameters yielding homogeneous QSS. To gain insight into the emergence of QSS, one can resort to a continuous picture, the formal limit of the governing discrete Hamiltonian. A rigorous mathematical procedure leads to the Vlasov equation for the evolution of the single-particle distribution function, the continuous representation of the particle density in phase space which is recovered when making the number of bodies \( N \) tend to infinity. The stability of QSS in the infinite \( N \) limit suggests that these latter states can be potentially interpreted as Vlasov stationary states, an ansatz that opens up the perspective for further analytical progress, a fact to which we shall return in the following. Operating in this context and explicitly accounting for finite size corrections beyond the idealized Vlasov picture, the authors of [10] proved rigorously that the relaxation of the \( N \)-body system towards its expected equilibrium, as driven by microscopic collision effects, would occur on timescales larger than \( N \), in qualitative agreement with the numerical evidence. Clearly, QSS are supposedly the only regimes which are made experimentally accessible, in all physical situations where a large number of microscopic constituents evolve in mutual interaction. The experimental time of observation is in fact limited, and not sufficient to allow for equilibration. From this perspective, unraveling the puzzle of QSS and so building a comprehensive dynamical picture for their existence and evolution represents a major challenge, with undoubtedly many practical implications.

An important step forward explaining the presence of the QSS was eventually achieved thanks to the theory of violent relaxation of Lynden-Bell (LB) [11]. This is a statistical theory which embeds the self-consistent knowledge of the governing Vlasov dynamics. The approach is justified from first principles and allows us to resolve the intermediate regime of the discrete \( N \)-body evolution, when the system is presumably assimilable to a continuum Vlasov model, before finite size corrections come eventually into play. The theory is based on the maximization of the following entropic functional of the distribution function (DF) \( \bar{f} \):

\[
s[\bar{f}] = - \int dp d\theta \left[ \frac{\bar{f}}{f_0} \ln \frac{\bar{f}}{f_0} + \left( 1 - \frac{\bar{f}}{f_0} \right) \ln \left( 1 - \frac{\bar{f}}{f_0} \right) \right],
\]

where \( f_0 \) describes the initial state of the system, whereas \( \bar{f} \) stands for a coarse-grained distribution function of the final state that one wishes to recover via a predictive approach. The above formulation holds for a two-step initial distribution function (waterbag): \( f \) at time 0 is equal to either zero or \( f_0 \). Whereas the exact evolution according to the Vlasov equation imposes that the DF is only allowed to take 0 and \( f_0 \) values at all times, the coarse-grained point of view implies a continuous DF \( \bar{f} \) that is expected to be valid if one averages over small patches of phase space. As a side comment we notice that the
functional (3) can be readily generalized to account for a continuous collection of different density levels, beyond the waterbag hypothesis.

The maximization of $s$ is performed under the macroscopic constraints of normalization, energy and momentum which are conserved by the dynamics. An underlying hypothesis of the theory is that the system explores in an ergodic-like fashion all states allowed by the constraints. The dynamical evolution of the Vlasov equation departs from that of a system sampling the equilibrium microcanonical ensemble, giving rise to different predictions which reflect the out-of-equilibrium nature of the problem. The application of the above predictive strategy to the study of the QSS dynamics of the HMF model [12,34], free-electron lasers [13] and gravitational systems [14] has confirmed its adequacy.

The LB approach also provided some new insights into the HMF phenomenology. For example, the abrupt change in the QSS magnetization when smoothly tuning the initial state of the system was interpreted as an out-of-equilibrium phase transition, which not only depends on the energy of the system—as happens at equilibrium—but also on the precise way in which the system is prepared. More specifically, the initial magnetization of the system was shown to have an important role, and phase transitions of both first and second order could be observed, depending on the value of this latter parameter. This memory effect—the system keeps track of the detail of its initial state for very long times—makes the QSS dynamics significantly richer than the equilibrium one. For example, as regards the HMF model, an out-of-equilibrium tricritical point was identified, which does not exist at equilibrium.

The purpose of this paper is to determine whether some of the QSS features predicted for the HMF toy model can be observed in experiments run for a dedicated class of devices. Motivated by this working hypothesis, we shall turn to considering the wide field of wave–particle interaction and focus in particular on two different experiments, namely the free-electron laser (FEL) and the collective atomic recoil laser (CARL) ones. In both cases the dynamics reflects the long-range nature of the interaction, along the lines depicted above with reference to the simplified HMF setting. Operating in this framework, we will show that some features of the QSS dynamics, like those previously outlined, may be observed in direct experiments. Moreover, such properties, though peculiar to the wave–particle dynamics considered, bear some traits reminiscent of the HMF model, to which both FEL and CARL are intimately connected. Finally, the associated experimental set-ups are briefly detailed, on the basis of existing machines and current technology.

Section 2 is devoted to FELs. The aim of such devices is to produce high-power short-wavelength light pulses by exploiting the radiation emitted by ultra-relativistic electrons when passing through the static and periodic magnetic field generated by an undulator. Starting from generic initial conditions, the wave power grows to a maximum, and then starts oscillating, keeping a lively exchange of energy with the particles, over times diverging with the number of particles, a characteristic of the QSS. As for the case of the HMF, the QSS of a FEL depends not only on the energy of the system, but also on the details of its initial state. Thus, after presenting the FERMI@Elettra FEL, we discuss how to manipulate the electron beam to produce the different initial states sought. Finally, the dynamical transition present in the system is described.

Section 3 is dedicated to discussing the collective atomic recoil laser (CARL), an experiment where a probe wave is amplified thanks to a grating of cold atoms
Experimental perspectives for long-range interactions

Figure 1. Left: electron phase space in the QSS regime (at \( \bar{t} = 50 \)). Right: normalized laser intensity versus normalized time \( \bar{t} \). Simulations were performed with \( N = 8000 \) particles, starting with a waterbag with \( b_0 = 0 \), \( \Delta p = 0.05 \), and a negligible intensity \( I_0 = 10^{-6} \).

(back)scattering photons of an incident pump laser beam. As for the FEL, its dynamics is dominated by long-range effects in the one-dimensional limit, an approximation which holds for the CARL experiment based at the European Laboratory for Nonlinear Spectroscopy (LENS). We then focus on the conservative regime, when the dynamics formally reduces to that of the FEL: the possibilities for observing for the CARL the QSS phenomenology as depicted for the FEL is investigated. On the other hand, when the wave amplification takes place in a cavity, a damping has to be accommodated: a formal link between this operational regime of CARL and the HMF dynamics is derived, as well as the experimental perspectives for detecting the associated out-of-equilibrium transitions.

Finally, in section 4, we discuss the measurements that could be performed for both CARL and FEL in order to unravel the imprint of the QSS that indirectly materializes in the existence of distinct out-of-equilibrium regimes.

2. The free-electron laser as a long-range interacting system

FELs are powerful light sources able to deliver coherent pulses of photons over a large and tunable wavelength range. With that aim, ultra-relativistic electrons of energy \( \gamma \) are injected into the periodic magnetic field (of period \( \lambda_w \) and deflection parameter \( K \)) produced by an undulator, where they start to wiggle and emit synchrotron radiation around the following wavelength:

\[
\lambda = \frac{\lambda_w}{2\gamma^2} \left( 1 + K^2 \right).
\]

The light produced by the electrons traps the electrons themselves, resulting in a periodic modulation of the electron density (see figure 1) called bunching: this bunching is the source of the coherent emission. Eventually, under a condition of resonance for the electrons and the wave, the strong interplay between coherent emission and particle trapping inside the wave potential leads to the nonlinear growth of the wave (see figure 1) and to the emission of a powerful light pulse. Due to the high energy of the electrons (of order 1 GeV typically), the system can be in a first approximation considered as one-dimensional, since the angle of the cone of light radiated goes as the inverse of the electron...
Figure 2. Schematic layout of the HGHG scheme: the electron beam is synchronized with the seed laser, which creates an energy modulation in the former inside the modulator. In the dispersive section, the energy modulation is converted into a spatial one; this is called microbunching. In the radiator, the microbunched electron beam emits coherently at one of the harmonics of the seed.

---

As for the radiation, it can generally be described in terms of a mean-field wave, leading to the set of equations \[ \frac{d\theta_j}{dt} = p_j, \quad \frac{dp_j}{dt} = -\left(Ae^{i\theta_j} + A^*e^{-i\theta_j}\right), \quad \frac{dA}{dt} = \frac{1}{N} \sum_j e^{-i\theta_j} + i\delta A, \] (5)

where \( \theta_j \) is the phase of electron \( j \) with respect to the ponderomotive potential, \( p_j \) its normalized energy, whereas \( A \) stands for the complex amplitude of the synchrotron radiation. The normalized variables are defined as \( \theta_j = (k + k_w)z_j - \omega t - \delta t \), with \( z_j \) the position of particle \( j \) along the propagation axis, \( p_j = (\gamma_j - \gamma_0)/\rho\gamma_0 \), \( \gamma_0 \) the average electron energy, \( k \) and \( \omega \) the radiation wavenumber and frequency, \( \delta = (\gamma_0 - \gamma_R)/\rho\gamma_0 \) the detuning parameter and \( \gamma_R \) the resonant energy defined by equation (4).

\[ \rho = \left(\frac{I}{I_A}\right)^{1/3}(\lambda_wa_w/2\pi\sigma)^{2/3}/2\gamma_0 \] is the so-called Pierce parameter, \( a_w = \sqrt{2k} \), \( I = ne^2\pi\sigma^2ec \) the electron current, \( n_e \) the electron density and \( I_A = 17 \text{kA} \) the Alfvén current. \( A \) corresponds to the normalized electric field of the wave, according to \( A = E\sqrt{\epsilon_0/(mc^2\gamma_0n_e\epsilon_0\rho)} \), while the rescaled time \( \bar{t} \) is given by \( \bar{t} = 2k_w\rho z \), with \( z \) the position along the propagation axis.

Following the HMF approach, we focus on waterbag initial conditions, since they give a good description of the electron bunch as a first approximation [13]: the initial wave is initially of zero amplitude, while the particles are bunched into a homogeneous rectangle in the \((\theta, p)\) phase space, i.e. spread between \(-\Delta\theta\) and \(+\Delta\theta\) in phase, and between \(-\Delta p\) and \(+\Delta p\) in momentum. Experimentally, shaping the initial electron bunch is part of the high-gain harmonic generation (HGHG) scheme [33], where use is made of two distinct stages of interaction (see figure 2): in the first undulator sections, called the ‘modulator’, electrons interact with an external coherent light source, e.g., a high-power laser (called the ‘seed’). Such an interaction induces the electron bunching at the seed wavelength, \( \lambda_{\text{seed}} \), and at the harmonics of the latter. In a second undulator section, tuned at one of the seed harmonics wavelength and called the ‘radiator’, electrons emit coherently.

In general, the wave grows, first quadratically, then exponentially, until it reaches a maximum and starts oscillating around an average value \( \bar{I} \). As for the electrons, they bunch together, thus allowing the coherent emission; the transfer of energy to the wave leads to a decrease in the electron energy, adversely affecting the condition of resonance (4). The amplification process stops when the particles are no longer in resonance with the wave (saturation). Note however that when the energy spread \( \Delta p \) is too large (typically...

$\Delta p \geq 1.5$), the interplay between the wave and the electrons will not even trigger, and the wave amplification will not happen.

The FERMI@ELETTRA is a new FEL, currently under construction at the Sincrotrone Trieste laboratory. It aims at producing GW optical pulses in the 4–100 nm range, thanks to the HGHG process: in this scheme, when considering a jump from $\lambda_{\text{seed}}$ in the modulator to its $n$th harmonic ($\lambda_{\text{rad}} = \lambda_{\text{mod}}/n$, with $n$ an integer) in the radiator, the bunching at the entrance of the radiator is given by 

$$|b_n| = \langle e^{in\theta} \rangle = e^{-(1/2)n^2\sigma_{\gamma}^2d^2} J_n(n\rho\Delta \gamma),$$

(6)

where $\langle \rangle$ is the average over the particles, $J_n$ the $n$th Bessel function of the first kind, $\sigma_{\gamma}$ the initial energy spread of the electron beam, and $\Delta \gamma$ the ‘coherent’ energy spread generated by the modulation (see [32] for details, and table 1 for the FERMI parameters). Here, $d$ is the strength of the dispersive section, whose role is to convert the energy modulation into a spatial one.

From now on, let us consider a HGHG configuration where the seed wave is $\lambda_{\text{mod}} = 200$ nm, associated with a harmonic jump of $n = 2$ ($\lambda_{\text{rad}} = 100$ nm), with an electron injected at $\gamma_0 = 1760$ into a $z = 18.4$ m long radiator (see table 1 for the FERMI FEL parameters). Then, the maximum bunching is reached when the Bessel function $J_2$ is maximized, that is for $nd\Delta \gamma \approx 3.05$, and setting the $n^2\sigma_{\gamma}^2d^2$ term close to zero. Thus, a dispersive section strength of $d = 0.63/(n\sigma_{\gamma})$ leads to a decrease of 20% in $|b_n|$ for the exponential term, and corresponds to $\Delta \gamma \approx 3.5\sigma_{\gamma}$. The initial and coherent energy spreads accumulating as $\sigma_{\gamma,\text{tot}} = \sqrt{\sigma_{\gamma}^2 + (\Delta \gamma)^2}/2$, we get $\sigma_{\gamma,\text{tot}} \approx 0.12$, whereas the bunching factor created is $|b_n| \approx 0.4$.

As for the detuning, it is induced by shifting the resonant energy in the radiator from the average electron energy $\gamma_0$, according to the relation

$$\delta = \frac{\gamma_0 - \gamma_R}{\rho\gamma_0}. $$

(7)

The $\bar{I} > 0$ saturated regime of the FEL was shown to be accurately described by the LB approach [13]: the intensity and bunching reached by the laser are in good agreement with those determined by the maximization of entropy principle. This seems however not to apply to the non-lasing regime, when the condition for resonance of the wave and the electrons is no longer satisfied. A recent work [31] reported that as regards the LB principle, two solutions of the maximization problem exist: the one associated with a positive laser intensity is always entropically favored, but the system dynamics can actually be trapped in the vicinity of a zero-intensity solution, where the electrons stay unbunched.

This dynamical trapping exhibits striking similarities with the phase transition encountered in HMF. Indeed, when monitoring control parameters such as the initial
Figure 3. Intensity radiated versus control parameter ($\delta$ on the left (at fixed $b_0$), and $b_0$ on the right (at fixed $\delta$)). The intensities for the FEL (dashed lines) are simulated using the FERMI parameters ($\gamma_0 = 1760$, $\lambda = 100$ nm, $\rho = 4.35 \times 10^{-3}$, $z = 18.4$ m, $\sigma_{\gamma,\text{tot}} = 0.12$); for the CARL (plain lines), the LENS parameters have been used ($\rho_C = 1000$, $t = 1$ $\mu$s and energy spread $\sigma_p = 20\hbar k$). The saturated intensity $\bar{I}$ of the QSS regime (dotted lines) is calculated as the average of the intensity between $t = 50$ and 100. Simulations were performed with $N = 10000$, and no initial wave. In the last picture, the CARL curve is represented three times larger.

bunching $b_0$ or the energy spread $\Delta p$, a transition from a $\bar{I} > 0$ regime to a $\bar{I} \approx 0$ one occurs, which can be sharp or smooth (see [31]). Let us focus on the parameters $b_0$ and detuning $\delta$: figure 3 shows how the $\bar{I} > 0$ regime may abruptly end for $b_0 = 0.1$ or values of the detuning $\delta = 2$ (top panels), whereas the transition to low-$\bar{I}$ regimes is smooth for $b_0 = 0.5$ or $\delta = 2.6$ (bottom panels). It is worth noting that working at finite undulator length does not substantially modify the transition characteristics (dashed lines of figure 3).

The regions of parameters where each transition will occur are summarized in figure 4 (left panel), where the diagram of saturated intensity is depicted as a function of both parameters: it reveals that for $b_0$ below some $b_c \approx 0.3$, as well as for $\delta$ below $\delta_c \approx 2.3$ (top panels), the transition is sharp, whereas beyond these values, it turns out to be smooth. Thus, $(b_c, \delta_c)$ represents the critical values of parameters beyond which the transition from lasing to non-lasing turns into a smooth one: although it is in no way supported by an entropic approach as it was for HMF, it can be seen as a dynamical version of the tricritical point present in the latter toy model.

As regards the possibilities for observing this peculiar phenomenology on the FERMI@Elettra FEL, a similar phase diagram has been plotted in figure 4 (middle panel), which accounts for the finite interaction length of the machine. It reveals that, despite the deep saturation perhaps not being well established within the undulator length available, the two areas where a sharp (versus smooth) transition could be observed are quite well separated.

doi:10.1088/1742-5468/2010/06/P06009
Experimental perspectives for long-range interactions

Figure 4. Intensity as a function of \((b_0, \delta)\) in the QSS regime (left), and at the exit of the FERMI@Elettra FEL (center) and CARL of LENS (right). Bright areas correspond to high intensities, dark ones to low-intensity regimes. The white lines represent the transition between the \(I > 0\) regime and the \(I \approx 0\) one, with a transition either sharp (plain line) or smooth (dashed line). The white dot stands for the tricritical point \((b_c, \delta_c)\), when the transition in the intensity goes from sharp to smooth. Simulations were performed under the same conditions as for figure 3.

3. The collective atomic recoil laser

CARL consists of a collection of cold two-level atoms driven by a far detuned laser pump of frequency \(\omega_p\) which radiates at the frequency \(\omega \sim \omega_p\) in the direction opposite to the pumping [16]. In both the FEL and CARL systems the radiation process arises from a collective instability which originates from a symmetry breaking in the spatial distribution, i.e. a self-bunching of particles which group in regions smaller than the wavelength. In the limit in which the radiation pressure due to the pump laser can be neglected (for instance by significantly detuning the pump frequency from the atomic resonance), the CARL is described by the same dimensionless FEL equations (5)

\[
\frac{d\theta_j}{dt} = p_j \tag{8}
\]

\[
\frac{dp_j}{dt} = -\left(Ae^{i\theta_j} + A^*e^{-i\theta_j}\right) \tag{9}
\]

\[
\frac{dA}{dt} = \frac{1}{N} \sum_{i=1}^{N} e^{-i\delta_j} + i\delta A - \kappa A, \tag{10}
\]

however with the presence of a damping term \(-\kappa A\) in the field equation, accounting for radiation losses from a ring cavity surrounding the atoms. Although CARL and FELs evolve with a similar dynamics, the dimensionless variables of the two systems, and consequently also the typical timescales, are very different. In CARL, the phase and the normalized momentum of the atoms \(j\) are \(\theta_j = 2k(z_j(t) - \langle v_z \rangle_0t)\) and \(p_j = m(v_z(t) - \langle v_z \rangle_0)/\left(2\hbar k\rho_C\right)\) (where \(z_j(t)\) and \(v_z(t)\) are the position and velocity of the \(j\)th atom along the direction of the scattered field and \(\langle v_z \rangle_0\) is the average initial velocity), whereas \(A\) stands for the normalized complex amplitude of the radiation field, \(A = (\epsilon_0/h\omega n_a\rho_C)^{1/2}E_0\), where \(n_a\) is the atomic density. The scaled time is \(\tilde{t} = (8\omega_{\text{rec}}\rho_C)t\), where \(\omega_{\text{rec}} = h^2k^2/2m\) is the recoil frequency, \(\delta = (\omega - \omega_p - 2k\langle v_z \rangle_0)/(8\omega_{\text{rec}}\rho_C)\) is the pump–probe detuning, \(\kappa = \kappa_c/(8\omega_{\text{rec}}\rho_C)\) is the scaled loss of a ring cavity with length \(L_{\text{cav}}\).
Experimental perspectives for long-range interactions

Figure 5. Schematics of superradiant light scattering from a Bose–Einstein condensate. An elongated BEC is illuminated by a far off-resonant laser beam (pump beam) with frequency $\omega$ and wavevector $\vec{k}$ directed along its axial direction. After the backscattering of photons with $\vec{k}_s \simeq -\vec{k}$ and the subsequent recoil of atoms, a matter wave grating forms, due to the quantum interference between the two momentum components of the wavefunction of the condensate. The effect of this grating is to further scatter the incident light in a self-amplifying process.

transmission $T$ and $\kappa_c = cT/L_{cav}$, and finally $\rho_C = (\Gamma/8)(c\sigma_0 n_a/\Delta^2 \omega_{rec}^2)^{1/3}(I/I_{sat})^{1/3}$, where $\Gamma$ is the natural decay rate if the excited state, $\sigma_0 = 3\lambda^2/2\pi$ is the scattering cross section, $\Delta = \omega_0 - \omega_p$ is the pump–atom detuning, $I$ is the pump intensity and $I_{sat} = \hbar \omega \Gamma/2\sigma_0^2$ is the saturation intensity.

There have been different experiments that have observed the CARL effect in room temperature gases [17], cold atomic samples from magneto-optical traps (MOT) [18,19] or Bose–Einstein condensates (BEC) [20]–[22]. CARL experiments were performed either in high-finesse optical cavities [18] or in free space [21], where the effect was originally interpreted as superradiant Rayleigh scattering [20]. However, it was later emphasized that these experiments in free space can be seen as a CARL process in the superradiant regime [23,24].

At LENS, the CARL experiment [25] is realized with a cigar-shaped BEC of $^{87}\text{Rb}$ produced in a Ioffe–Pritchard magnetic trap by means of RF-induced evaporative cooling. After 2 ms of free expansion, when the magnetic trap field is completely switched off and the atomic cloud still has an elongated shape (at this time the radial and axial sizes of the condensate are typically 10 and 70 $\mu$m, respectively), a square pulse of light is applied along the $z$-axis (see figure 5). The size of the laser beams is larger than 0.5 mm, far larger than the condensate free fall during the interaction with light. In this geometry the CARL process causes the pump light to be backscattered and the self-amplified matter wave propagates in the same direction as the incident light.

This experiment allows for a great flexibility in the preparation of the initial state of the system (see table 2): for example, it is possible to prepare the atoms in an initially bunched state by imposing an electromagnetic standing wave before the pump laser is activated. As regards the momentum spread, it can be varied by cooling the atoms only partially. Finally, a non-zero pump–probe detuning $\delta$ can be induced by giving the
atoms an initial momentum, which can be up to $1000\hbar k$: indeed to change the initial detuning of the probe, one can either change the initial atomic momentum or change the cavity frequency since conservation of energy imposes the frequency of the backscattered photon [21].

Equilibrium dynamical phase transitions were studied in the CARL context under different hypotheses: for example, using a thermalization hypothesis for the atoms, the CARL will reach equilibria where (equilibria) phase transitions can occur [26]. In the case where dissipation is counterbalanced by a stochastic Langevin force [19], steady states can be identified, as well as a phase transition analogous to the one that occurs in the Kuramoto model [27], yet with a self-generated collective oscillation frequency for the CARL. Both models were also connected when the strong friction is balanced by diffusion [28], a regime for which steady states and phase transitions were also predicted [29]. Yet, the equilibrium condition remains a condition which is hard to satisfy experimentally. In this context, the study of the quasi-stationary regimes, which are not $N$-body equilibrium regimes but rather stationary states of the associated Vlasov dynamics, is all the more relevant experimentally.

Let us first consider the configuration where the CARL amplification is realized inside a ring cavity: the pump and probe light fields are counterpropagating modes of the ring cavity and the time of interaction of the light fields with the atoms can be enhanced by several orders of magnitude, which supports the amplification. Consequently, most of the CARL experiments carried out to date employed ring cavities [18, 19, 22]. Furthermore, in new experiments, especially in the microtrap-based ones, it appeared to be very profitable to introduce a high-finesse optical cavity inside the vacuum system: indeed, in this environment, Fabry–Perot cavities have already been demonstrated to yield very high finesses [30].

Going back to the dynamical equations (8)–(10), it is clear that if the dissipation term $\kappa$ is small ($\kappa \ll 1$), the CARL is governed by the same equations as the FEL. In particular, when monitoring the initial bunching and the detuning parameter, it should exhibit a dynamical transition similar to the one described in section 2. Simulations realized for a good cavity ($\kappa = 0.025$) reveal that the sharp/smooth transitions could indeed be observed in the relevant range of parameters (see figure 4).

On the other hand, the CARL experiment can be realized either without a cavity, or within a low-quality one: this is at the cost of a high damping of the wave, modeled by the $\kappa > 0$ term in equation (10). In this case, if the dissipation is large enough ($\kappa \sim 1$), an adiabatic treatment of the wave dynamics can be performed [23, 25], which corresponds to setting $dA/dt = 0$, which yields

$$A = \frac{1}{\kappa - i\delta} \frac{1}{N} \sum_j e^{-i\theta_j}. \quad (11)$$

Plugging this expression into the particle equations of motion (9), we get the following equation for the momentum of particle $j$ (the equation for its position is unchanged):

$$\dot{p}_j = \frac{2}{\delta^2 + \kappa^2} \frac{1}{N} \sum_m (\delta \sin (\theta_j - \theta_m) - \kappa \cos (\theta_j - \theta_m)). \quad (12)$$
If we now consider the extra limit where the detuning $\delta$ is large with respect to $\kappa$ ($|\delta| \gg \kappa$), equation (12) simply turns into
\[
\dot{p}_j = \frac{2}{\delta N} \sum_m \sin (\theta_j - \theta_m). \tag{13}
\]
Then, using the following normalization:
\[
\tilde{\theta}_j = \theta_j, \quad \tilde{p}_j = p_j \sqrt{|\delta|/2}, \quad \tilde{t} = t \sqrt{|\delta|/2}, \quad \tilde{H} = |\delta|H/2, \tag{14}
\]
the system can be mapped into the HMF model (1). New, $\epsilon = -\text{sgn}(\delta)$ positive (negative) describes an (anti)ferromagnetic interaction. Numerical simulations confirm that in the above mentioned limit, despite small differences in the dynamics, the CARL and HMF yield similar QSS regimes (see figure 6).

This formally links the CARL dynamics to the HMF model, in either its ferromagnetic or antiferromagnetic form, making in particular the bridge between the rich phenomenology predicted for the HMF model and a possible experimental realization. For example, as regards the ferromagnetic case, figure 7 depicts the phase diagram of HMF in the $(b_0, U)$ plane as predicted by the LB prescription, and those obtained by direct $N$-body simulations of both the CARL dynamics and the HMF model. They reveal an excellent agreement between the CARL phase diagram and its reduced counterpart, the HMF, as well as with the Lynden-Bell approach. Note that the presence of fringes in the large-$U$ part in the diagrams is due to the short time considered: yet, although the QSS regime is not well established, the transition line is already present and in good agreement with the LB prescription. This allows us to conclude the presence of an out-of-equilibrium phase transition in the CARL device, such as is predicted for the HMF model [34].

4. On the possibility for observing the QSS signature

In this paper, we investigated the out-of-equilibrium dynamics of two long-range models which admit corresponding experimental implementations. We shall now conclude the discussion by elaborating on the experimental possibilities for verifying the correctness of the proposed picture and in particular detecting the predicted phase transitions.

As regards the FEL, the particle phase space is not experimentally accessible since the electrons have relativistic energies. However, by monitoring the laser intensity it should
be in principle possible to detect the transition, as demonstrated in section 2. Depending on the specific initial condition, ultimately characterized by an assigned electron bunching amount, the laser can gain in potency or, alternatively, keep its off mode. Experimentwise, by setting the initial bunching at either zero (no interaction in the modulator) or high values ($b_0 \approx 0.4$), and tuning the electron energy, one should in principle observe either a sharp or a smooth transition, as indicated by the simulation results. This is an interesting feature, an indirect signature of the QSS existence, which bears an intriguing similarity to the HMF behavior. In this latter case, however, the presence of out-of-equilibrium phase transitions of both first-order and second-order types was demonstrated on solid theoretical grounds. A similar theoretical justification is still lacking with reference to the FEL model.

The CARL device, in the regime of small dissipation, is predicted to exhibit a transition similar to that displayed by the FEL. Again, and by analogy with the above, we suggest that the presence of the transition could be successfully evidenced by recording the radiated intensity, under different experimental conditions. In addition, the CARL could also allow us to access direct information on the particle dynamics in phase space. First, the atom density can be recorded, and the presence of fringes used to quantify the degree of bunching. Then, letting the atoms expand after the CARL process ends, and recording their late positions, one can resolve the momentum distribution: such a diagnostic would translate into an independent tool for evidencing the transition between distinct dynamical regimes.

Finally, it is when operating the CARL device in the dissipative HMF-like regime that the possibility of measuring the phase-space structures could be of paramount importance. The fringes, which means bunching, are in principle strongly correlated with the radiated power (see equation (11)). By accessing the distribution of momenta one could eventually detect the two bumps that are predicted to occur in the presence of unbunched QSS, and which are believed to correspond to counterpropagating clusters of particles. More generally, and with reference to the ferromagnetic case [12,35], we shall be interested in accurately investigating the overall velocity profile whose characteristics have been the subject of vigorous debate [36,37].
