We have until now concentrated on the regime of weak coupling, $NU_0 < 1$. If the pump laser is tuned closer to resonance, or if the number of atoms is increased, so that $NU_0 > 1$, we observe instabilities in the coupled atom-field dynamics, which critically depend on the pump intensities [942]. Imagine a sample of atoms trapped in an optical lattice formed by a symmetrically pumped ring cavity, $\eta_+ = \eta_-$. The system is stationary, the atoms are confined at the antinodes of the standing wave, the light fields are equal in strength, $\alpha_+ = \alpha_-$. At time $t = 0$ we suddenly reduce the pump rate η_- of the non-stabilized mode by only a few percent. The response of the system observed in experiment [942] is to completely break down the field α_-. The disappearance of the standing wave ejects most atoms and reduces NU_0, until the coupling gets so weak that the dynamics is essentially governed by the injected fields. The system recovers a stationary state, with much less atoms.

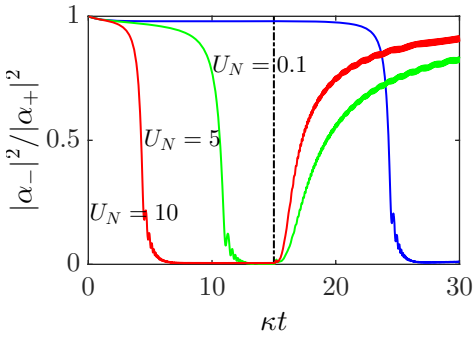

Figure 42.10: (code) Dynamics simulated with equations (42.46). At time $\kappa t = 0$ the pump rate η_- is reduced by 1%. After a certain time that depends on NU_0, the standing wave breaks down ejecting atoms from the mode volume. Here, we simulate this via an artificial linear trap loss process setting in at time $\kappa t = 15$. As a result of the diminishing NU_0 the standing wave recovers.

The physical explanation for the instability is reminiscent to the CARL behavior described in previous sections. Because atom-field coupling is strong, a small imbalance of the injected beam intensities is sufficient to displace the atoms to a location, where the light which they scatter into the reverse direction interferes destructively

with the injected light. A simple argument explains, why the standing wave is attracted towards a position where it gets unstable. We treat the imbalance $\eta_+ > \eta_-$ as if it was due to a scatterer fixed in space inside the mode volume sitting on an edge of the standing wave (corresponding to a $\pi/4$ phase shift), such that it only scatters light from α_+ into α_-, but not the other way round. Whether the phase of the standing wave adjusts itself to that of pump field or such that the scatterer sits at the bottom of the potential well depends on the ratio of the coupling to the external field (given by κ) and to the scatterer (given by U_0). If U_0 is stronger, the field is pulled towards the scatterer dragging along the atoms which are free to move. The stationary situation is therefore a displacement of the standing wave and the atoms by $\lambda/4$, which is just the position where the cavity field α_- and the injected field $\alpha_-^{(in)}$ are out of phase. The injected light is not transmitted through the cavity any more.

Note that the instability occurs in a plane wave situation, there is no need to consider the transversal motion. Furthermore, it is a single-atom effect, since we assume perfect bunching. We may therefore consider a single atom strongly coupled to the cavity and use the set of equations (42.46). In the *undepleted pump approximation* we assume $\dot{\alpha}_+ = 0$, and if the atom adiabatically follows the dynamics of the potential valley, $\ddot{x} = 0$, so that,

$$0 = -\chi\alpha_+ - \imath U_0 \sqrt{\frac{\alpha_+\alpha_-^*}{\alpha_+^*\alpha_-}}\alpha_- + \eta_+ \ , \tag{42.72}$$

$$\dot{\alpha}_- = -\chi\alpha_- - \imath U_0 \sqrt{\frac{\alpha_+^*\alpha_-}{\alpha_+\alpha_-^*}}\alpha_+ + \eta_- \ .$$

The first equation yields,

$$\alpha_+ = \frac{\eta_+}{\chi + \imath U_0 \frac{|\alpha_-|}{|\alpha_+|}} \ , \tag{42.73}$$

$$|\alpha_+| \approx \frac{\eta_+}{\chi}\left(1 - \frac{U_0^2}{2\eta_+^2}|\alpha_-|^2\right) \ .$$

Plugging this result into the second equation and assuming the laser on resonance, $\Delta_c = NU_0$, so that we may replace χ by κ, we get,

$$\dot{\alpha}_- \approx -\kappa\alpha_- - \frac{\imath U_0\eta_+}{\kappa}\frac{\alpha_-}{|\alpha_-|} + \frac{\imath U_0^3}{2\kappa\eta_+}|\alpha_-|\alpha_- + \eta_- \ . \tag{42.74}$$

This equation describes *optical bistability*.

42.2.5 Phononic coupling of atoms mediated by a ring cavity

Phonons can be understood as vibrational excitations of quantum particles (atoms) in quantized traps. When atoms are interconnected in vibrational lattices, phonons can be transferred and shared between atoms [11]. Due to the particularity of the

[11] This is similar to the situation in micromasers, where several atoms can share a single photon.

ring cavity of conserving the photonic momentum at each backscattering event, the photonic momentum can be understood as a phononic excitation, propagating in one dimension along the optical axis of the cavity.

We now consider a symmetrically pumped ring cavity [482]. The atoms are very cold and deep in the Lamb-Dicke regime. Using blue-detuned light the atoms will be trapped at the nodes of the standing wave, $kz_j = \pi/2 + kZ_j$, where Z_j are small displacements. Hence, we may expand,

$$e^{\mp 2\imath k z_j} \simeq -(1 \mp 2\imath k Z_j) \ . \tag{42.75}$$

With the abbreviation $\chi \equiv \kappa - \imath(\Delta_c - NU_0)$ and defining the center-of-mass of the small displacements, $Z_{cm} = \frac{1}{N}\sum_j Z_j$, the equation for the two field modes are,

$$\dot{\alpha}_\pm \simeq -\chi\alpha_\pm + \imath NU_0(\mp 2\imath k Z_{cm})\alpha_\mp + \eta \ . \tag{42.76}$$

Neglecting the impact of the atom on the amplitudes of the fields, we may derive the steady-state solution,

$$\alpha_\pm = \eta \frac{\chi + \imath NU_0(1 \mp 2\imath k Z_{cm})}{\chi^2 + N^2U_0^2} \ . \tag{42.77}$$

As shown in (42.28) the normalized field intensity can be written as,

$$\tfrac{1}{2\varepsilon_0 c E_1^2} I(z,t) = |\alpha_+|^2 + |\alpha_-|^2 + 2|\alpha_+||\alpha_-|\cos(2kz + 2\theta) \ , \tag{42.78}$$

provided the field amplitudes are expressed by,

$$\alpha_\pm = |\alpha_\pm| e^{\pm\imath\theta} \quad \text{such that} \quad \alpha_+\alpha_-^* = |\alpha_+||\alpha_-| e^{2\imath\theta} \quad \text{and} \quad \tan 2\theta = \frac{\mathfrak{Im}\ \alpha_+\alpha_-^*}{\mathfrak{Re}\ \alpha_+\alpha_-^*} \ . \tag{42.79}$$

Now,

$$\begin{aligned} \tan 2\theta &= \frac{\mathfrak{Im}\ [\chi + \imath NU_0(1 - 2\imath k Z_{cm})][\chi^* - \imath NU_0(1 - 2\imath k Z_{cm})]}{\mathfrak{Re}\ [\chi + \imath NU_0(1 - 2\imath k Z_{cm})][\chi^* - \imath NU_0(1 - 2\imath k Z_{cm})]} \\ &= 4NU_0 k Z_{cm} \frac{-\Delta_c + 2NU_0}{-\kappa^2 - \Delta_c^2 + 4\Delta_c NU_0 - 4N^2U_0^2 + 4N^2U_0^2(kZ_{cm})^2} \\ &\simeq \frac{4NU_0(\Delta_c - 2NU_0)}{\kappa^2 + (\Delta_c - 2NU_0)^2} k Z_{cm} \ . \end{aligned} \tag{42.80}$$

An individual atom in this optical potential feels the dipolar force,

$$\begin{aligned} m\ddot{z}_j &= [-\hbar U_0 \partial_z I]_{z=z_j} = 4\hbar k U_0 |\alpha_+||\alpha_-| \sin(2kz_j + 2\theta) \\ &= 4\hbar k U_0 \eta^2 \frac{|(\chi + iNU_0)^2 - 4N^2U_0^2(kZ_{cm})^2|}{|\chi^2 + N^2U_0^2|^2} \sin\left(2kz_j + \frac{2NU_0(\Delta_c - 2NU_0)}{\kappa^2 + (\Delta_c - 2NU_0)^2} 2kZ_{cm}\right) \\ &\simeq \frac{4\hbar k U_0 \eta^2}{\kappa^2 + \Delta_c^2} \sin\left(2kz_j + \frac{2NU_0(\Delta_c - 2NU_0)}{\kappa^2 + (\Delta_c - 2NU_0)^2} 2kZ_{cm}\right) \equiv \frac{m}{2k}\omega_0^2 \sin(2kz_j - 2\mu_j k Z_{cm}) \ , \end{aligned} \tag{42.81}$$

where,

$$m\omega_0^2 \equiv \frac{8\hbar k^2 U_0 \eta^2}{\kappa^2 + 4U_0^2} \qquad \text{and} \qquad \mu_j \equiv \frac{2NU_0|2NU_0 - \Delta_c|}{\kappa^2 + (2NU_0 - \Delta_c)^2} \ . \tag{42.82}$$

Expanding this equation around the nodes we readily obtain,

$$\boxed{k\ddot{Z}_j + \omega_0^2 \mu_j \simeq \mu_j k Z_{cm} = \frac{\mu_j}{N} \sum_j k Z_j} \ , \tag{42.83}$$

which describes the force on a single atom. Note that the harmonic force, $\omega_0^2 k Z_j$, on the atom is continuously fed by the center-of-mass force, $\omega_0^2 \mu_j k Z_{cm}$. The above equation can be rewritten as,

$$\begin{pmatrix} k\ddot{Z}_1 \\ k\dot{Z}_1 \\ k\ddot{Z}_2 \\ k\dot{Z}_2 \\ . \end{pmatrix} = \begin{pmatrix} 0 & -\omega_0^2(1-\frac{\mu_j}{N}) & 0 & -\omega_0^2\frac{\mu_j}{N} & . \\ 1 & 0 & 0 & 0 & . \\ 0 & -\omega_0^2\frac{\mu_j}{N} & 0 & -\omega_0^2(1-\frac{\mu_j}{N}) & . \\ 0 & 0 & 1 & 0 & . \\ . & . & . & . & . \end{pmatrix} \begin{pmatrix} k\dot{Z}_1 \\ kZ_1 \\ k\dot{Z}_2 \\ kZ_2 \\ . \end{pmatrix} \ . \tag{42.84}$$

The eigenvalues of the matrix are $e = \imath\omega_0, \imath\omega_0\sqrt{1-\mu_j}$. Therefore, we expect, in addition to the secular frequency ω_0, a second oscillation frequency,

$$\omega_{cm} = \omega_0\sqrt{1-\mu_j} \ . \tag{42.85}$$

We find splitting in the strong coupling regime, $g > \Gamma$, but we consider the weak coupling regime, $g < \Gamma$, to implement the phononic coupling.

Example 273 (*Two-coupled atoms*): Here we rewrite the field equations for two atoms in center-of-mass coordinates,

$$Z = \frac{z_1 + z_2}{2} \qquad \text{and} \qquad z = z_2 - z_1 \ ,$$

finding,

$$\dot{\alpha}_\pm = (-\kappa + \imath\Delta_c - 2\imath U_0)\alpha_\pm - 2\imath U_0 \alpha_\mp e^{\mp 2\imath k Z} \cos kz + \eta \ .$$

42.2.5.1 Probing the phonon spectrum

To probe the phonon spectrum, we can measure (or simulate) the oscillation of a single atom $z_j(t)$ in the presence of several atoms. The Fourier spectrum of the oscillation should reveal the frequency components of the center-of-mass motion $Z(t)$ and the relative motion.

An experimental method for observing normal modes consists in parametrically exciting the atomic motion at a modulation frequency ω_ϕ and watch out for a resonant enhancement of the vibration amplitude near the secular frequency ω and the collective frequency ω_{cm} both defined in (42.82). In practice, the atomic vibration can be excited by an external force, for example, a Bragg spectroscopic setup as it is used for driving recoil-induced resonances (RIR),

$$\dot{p}_j = 2\imath\hbar k U_0(\alpha_+^*\alpha_- e^{-2\imath k z_j} - \alpha_+\alpha_-^* e^{2\imath k z_j}) + F_{rir}\sin\omega_\phi t \ . \tag{42.86}$$

Alternatively, we may shake the intracavity standing wave by modulating the phase of the pump field,

$$\eta_\pm(t) = \eta e^{\pm \imath \phi_0 \sin \omega_\phi t} \ . \tag{42.87}$$

Fig. 42.11 shows typical resonance curves obtained by simulating the CARL equations (42.50) together with the modulation term (42.87). Being shaken for a while, the atoms suffer parametric heating visible as a noticeable increase of their kinetic energy, as seen in Fig. 42.11(a). The atomic motion, in turn, acts back on the intracavity field fields leading to a modulated photon imbalance between both.

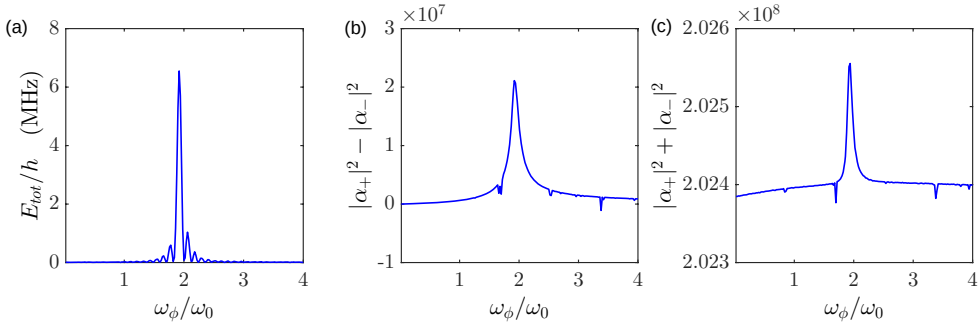

Figure 42.11: (code) Response of the cavity field to a phase modulation of the pump light. (a) Kinetic energy, (b) photon imbalance, and (c) total photon number. The simulation assumes $N = 10^6$ strontium atoms initially at $T = 1\,\mu\text{K}$ driven on the $\lambda = 689\,\text{nm}$ line and $\kappa/2\pi = 3.4\,\text{MHz}$, $\Delta_c = 2U_0$, $\eta = 10^4\kappa$, $NU_0/\kappa = -.02$, $\phi_0 = 0.01$. The calculated secular frequencies are $\omega_0 = 0.35\kappa$ and $\omega_0\sqrt{1-\mu_N} = 0.32\kappa$.

Note, that the phase modulation frequency should not exceed the cavity decay time, $\omega_\phi < \kappa$. Otherwise, even in the absence of atoms, we expect a low-pass behavior as discussed in Sec. 40.1.2, impeding that the applied phase modulation be transformed into an efficient shaking of the phase θ of the intracavity standing wave.

42.2.6 Doppler limit of cavity cooling

The interaction with an optical cavity can reduce the atomic movement. In the case of individual atoms, ... See also (watch talk).

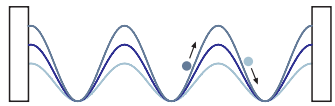

Figure 42.12: The principle of cavity cooling.

For blue detuning and strong coupling [482], the cavity backaction produces a friction force, which can be explained as follows. The field reacts to the atomic displacement with a small time-lag due to κ, which when designed properly produces a stronger deceleration when the atom moves uphill, then an acceleration when it moves

downhill. The cavity backaction thus provides a feedback mechanism to influence the atomic motion. In equilibrium with diffusion, the final temperature is given by,

$$\left(\frac{\partial E}{\partial t}\right)_{cool} = Fv = -m\beta_{fric}v^2 \tag{42.88}$$
$$\left(\frac{\partial E}{\partial t}\right)_{heat} = \frac{\hbar^2k^2}{2m}2R = \hbar\varepsilon R = \hbar\varepsilon\frac{8U_0^2\eta^2}{\kappa(\kappa^2+4U_0^2)} = \hbar\omega_0^2\frac{U_0}{\kappa} \ .$$

For strong coupling, the diffusion rate, $R = 2\frac{\eta^2}{\kappa} = 2\kappa n$, has a simple interpretation as the rate of photon losses by cavity decay. For weak coupling, $R = 8U_0^2\frac{\eta^2}{\kappa^3} = 2\kappa n\left(\frac{2U_0}{\kappa}\right)^2$, the diffusion occurs by redistribution between the cavity modes. In equilibrium,

$$k_BT = mv^2 = \frac{\hbar\varepsilon R}{\beta_{fric}} = -\hbar U_0\left(1+\frac{\kappa^2}{4U_0^2}\right) \ , \tag{42.89}$$

which is roughly on the same order as the Vuletic cooling. For example with the cavity described above and $\Delta\lambda = 0.7$ nm, so that $\Delta_a = \frac{c}{\lambda^2}\Delta\lambda = 2\pi\times 345$ GHz, we have $U_0 = 2.8\times10^{-6}\kappa$. With 10^6 atoms, we expect $T \approx 2.7\ \mu$K.

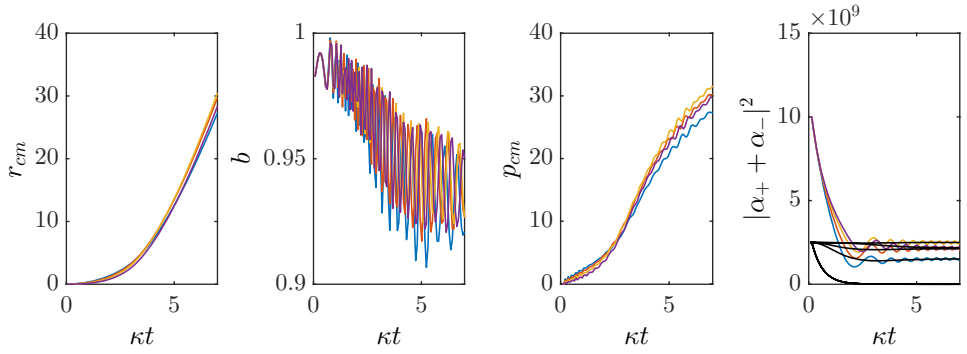

Figure 42.13: (code) Cavity cooling for various detunings.

A more rigorous treatment [482] reveals the dependence of the friction and the diffusion on the detuning,

$$\beta_{fric}^{(\Delta_c)} = \frac{32\varepsilon\eta^2U_0^2\kappa(\Delta_c-U_0)(\kappa^2-2\Delta_cU_0+\Delta_c^2)}{(\kappa^2+\Delta_c^2)^2[\kappa^2+(2U_0-\Delta_c)^2]^2} \ , \tag{42.90}$$

$$\left(\frac{\partial E}{\partial t}\right)_{heat}^{(\Delta_c)} = \hbar\varepsilon\frac{8\kappa U_0^2\eta^2}{(\kappa^2+\Delta_c^2)[\kappa^2+(2U_0-\Delta_c)^2]},$$

$$k_BT^{(\Delta_c)} = \frac{\hbar(\kappa^2+\Delta_c^2)[\kappa^2+(2U_0-\Delta_c)^2]}{4(\Delta_c-U_0)[\kappa^2-\Delta_c(2U_0-\Delta_c)]} \ .$$

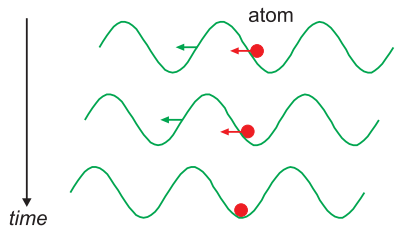

Figure 42.14: Cavity-cooling.

When the energy dissipation is made by the cavity rather than internal degrees of freedom [1349]. The cooling limit for *cavity-cooling* is than,

$$k_B T = \frac{1}{2}\hbar\kappa \left(1 + \frac{k^2 w^2}{6Q}\right) \ . \tag{42.91}$$

For a typical ring-cavity $T \approx 5\ \mu$K. The cooling power is,

$$P = \hbar\kappa.... \tag{42.92}$$

It depends a lot on the Doppler-shift of the moving atom. The capture range is limited to $kv < \kappa$.

42.2.6.1 Dissipation in cavities

We showed above that the center-of-mass motion of the atomic ensemble interacting with a symmetrically pumped ring cavity is rapidly damped. But this is not true for the motion of the individual atoms, that is, the temperature of the set is not easily reduced. To see this we look at the CARL equation (42.26) for the dipole force,

$$m\ddot{z}_j = 2\imath\hbar k U_0(\alpha_+^*\alpha_- e^{-2\imath k z_j} - \alpha_+\alpha_-^* e^{2\imath k z_j}) \ , \tag{42.93}$$

and we consider two atoms initially located in the positions $z_{1,2} = \pm z_0$. We notice that the force on the relative motion is zero,

$$m\ddot{z}_1 - m\ddot{z}_2 = 0 \ . \tag{42.94}$$

That is, the number of photons backscattered by each atom is compensated, such that the light field does not take notice of the motion of the two atoms and therefore can not dissipate its energy.

The first order fluctuations of the positions are $\langle z\rangle = 0$, but second order fluctuations, i.e. the temperature $\sim \langle z^2\rangle$, can eventually interact with the light field. Other ideas are needed to lower the temperature.

42.2.6.2 Sideband cooling in cavities

In a ring-cavity the coupling of the counter-propagating modes results in a Stark-splitting by $2U_0$ into two modes. The mode at $\Delta_c = 2U_0 < 0$ supports atoms, the one at $\Delta_c = 0$ is empty. Since $\kappa < \omega_z$, for $2U_0 \approx \omega_z$ we can do cavity sideband-cooling.

Furthermore, bunching of the atoms into the nodes modifies $\sum_k U_0 e^{-2\imath k z_k}$, which can result in self-locking. Also the laser locks automatically to the red-shifted atom-filled mode [415].

The transition can be decomposed into a spontaneous Raman transition (cavity field driven excitation followed by spontaneous emission into free space modes) and a stimulated Raman transition (cavity field driven excitation followed by cavity-stimulated emission). Let $\tilde{\Gamma}_{free} = k^3 d^2/6\pi\varepsilon_0\hbar$ be the free-space scattering rate. The scattering into a cavity mode is enhanced by $\eta_c = \tilde{\Gamma}_{cav}/\tilde{\Gamma}_{free} = 12F/\pi k^2 w^2$ [1349]. The transition between vibrational sidebands must be weighted by $\eta_{LD} = \varepsilon_{recoil}/\omega_{vib}$. If the emission takes place on a sideband which is not resonant to a cavity mode, the transition rate is reduced by the factor $\xi = (1 + (2\omega_{vib}/\kappa)^2)^{-1}$. Thus ...

42.2.7 Exercises

42.2.7.1 Ex: Anticorrelated atoms

Study the CARL equations (42.50) for the case of two fixed atoms sitting at positions $kz_1 = kz_2 - \pi$.

Solution: *For two atoms the CARL equations become,*

$$\dot{\alpha}_\pm = -\kappa\alpha_\pm - \imath U_0 e^{\mp 2\imath k z_1}\alpha_- - \imath U_0 e^{\mp 2\imath k z_2}\alpha_\mp + \eta_\pm \ .$$

Inserting the positions,

$$\dot{\alpha}_\pm = -\kappa\alpha_\pm + \eta_\pm \ ,$$

we find that the equations decouple, such that the impact of the atoms on the light modes vanishes.

42.2.7.2 Ex: Coupled motion of Rb and Cs atoms in a ring-cavity

Find out by simulation of the classical CARL equation, whether the motion of a Rb atom and a Cs atom can be coupled to the same mode of a ring cavity.

Solution: *a. For a single Rb and a single Cs atom the result is shown in the following movie (watch movie).*
b. For a rubidium and cesium cloud the result is shown in the following movie (watch movie). We how the rubidium cloud accelerates the initially resting cesium cloud.

42.2.7.3 Ex: Inertially moving atom in a ring-cavity

Illustrate by simulation of the classical CARL equation, how an inertially moving single atom pushes the wave formed by two counterpropagating modes of a ring cavity.

Solution: *The result is shown in the following movie (watch movie).*

42.2.7.4 Ex: CARL in a harmonic potential

Extend the CARL dynamics by an additional harmonic potential for the atoms and study the steady state gain as a function of cavity detuning Δ_c.

Solution: *Assuming a real and constant pump α_+ and using the abbreviation $\theta_j \equiv 2kx_j$, the fundamental equations of the CARL are [173],*

$$\dot{\alpha}_- = (-\kappa + \imath\Delta_c - \imath NU_0)\alpha_- - \imath U_0\alpha_+ \sum_j e^{-\imath\theta_j}$$
$$\ddot{\theta}_j = 8\imath\omega_{rec}U_0\alpha_+(\alpha_- e^{-\imath\theta_j} - \alpha_-^* e^{\imath\theta_j}) - \nu^2\theta_j \ .$$

Integrating the equation for the field,

$$\alpha_- = \alpha_{0-} + e^{(-\kappa+\imath\Delta_c-\imath NU_0)t}\imath U_0\alpha_+ \int_0^t d\tau e^{(\kappa-\imath\Delta_c+\imath NU_0)\tau} \sum_j e^{-\imath\theta_j(\tau)} \ .$$

Now we make the ansatz of a sinusoidal motion, $\theta_j(t) = \theta_{j0}\cos(\nu t + \phi_{j0})$, and use the expansion $e^{\imath\xi_0\sin\varphi} = \sum_n \mathcal{J}_n(\xi_0)e^{\imath n\varphi}$,

$$\begin{aligned}
\alpha_- &\simeq e^{(-\kappa-\imath U_0+\imath\Delta_c)t}\imath NU_0\alpha_+ \int_0^t d\tau e^{(\kappa+\imath NU_0-\imath\Delta_c)\tau} \sum_{j=1}^N e^{-\imath\theta_{j0}\cos(\nu\tau+\phi_{j0})} \\
&= e^{(-\kappa-\imath U_0+\imath\Delta_c)t}\imath NU_0\alpha_+ \int_0^t d\tau e^{(\kappa+\imath NU_0-\imath\Delta_c)\tau} \sum_{j=1}^N \sum_{n=-\infty}^{\infty} \mathcal{J}_n(\theta_{j0}) e^{\imath n(\nu\tau+\phi_{j0}-\pi/2)} \\
&= e^{(-\kappa-\imath U_0+\imath\Delta_c)t}\imath NU_0\alpha_+ \sum_{j=1}^N \sum_{n=-\infty}^{\infty} \mathcal{J}_n(\theta_{j0}) e^{-\imath n(\phi_{j0}-\pi/2)} \int_0^t d\tau' e^{(\kappa+\imath U_0-\imath\Delta_c-\imath n\nu)t'} \\
&= \imath NU_0\alpha_+ \sum_{j=1}^N \sum_{n=-\infty}^{\infty} \mathcal{J}_n(\theta_{j0}) e^{-\imath n(\phi_{j0}-\pi/2+\nu t)} \frac{1 - e^{(-\kappa-\imath NU_0+\imath\Delta_c+\imath n\nu)t}}{\kappa + \imath NU_0 - \imath\Delta_c - \imath n\nu} \\
&\overset{t\to\infty}{\longrightarrow} \sum_{n=-\infty}^{\infty} \sum_{j=1}^N \mathcal{J}_n(\theta_{j0}) \frac{\imath NU_0\alpha_+ e^{-\imath n(\phi_{j0}-\pi/2+\nu t)}}{\kappa + \imath NU_0 - \imath\Delta_c - \imath n\nu} \ .
\end{aligned}$$

We find [1406] that, unlike the original CARL, the system evolves to a steady state and continuously emits light. As shown in Fig. 42.15, the probe is strongly amplified when its detuning coincides with multiples of the secular frequency of harmonic potential. This effect is due to a collective response of the atomic motion to the incident pumping beam, inducing a synchronization of its oscillations in the potential.

42.2.7.5 Ex: Impact of potential barriers on CARL

Illustrate by simulation of the classical CARL equations how (a) mirror backscattering and (b) an external harmonic trapping potential influence the dynamics of an atom interacting with two counterpropagating modes of a ring cavity.

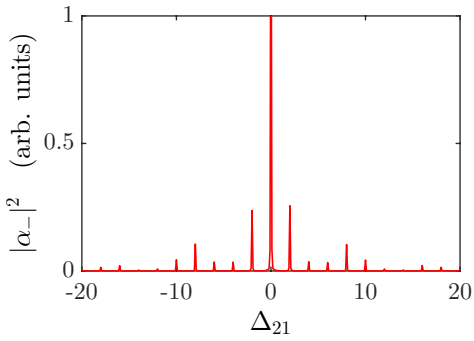

Figure 42.15: (code) Gain spectrum of the CARL confined to a harmonic potential.

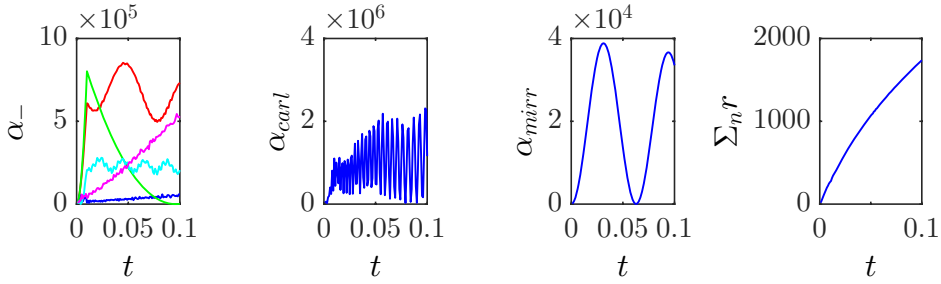

Figure 42.16: (code) Influence of mirror backscattering on CARL.

Solution: *a. The result is shown in Fig. 42.16.*
b. The result is shown in Fig. 42.17.

42.2.7.6 Ex: CARL without cavity

Discuss whether CARL can be observed without a ring-cavity.

Solution: *a. The result is shown in Fig. 42.18.*

42.2.7.7 Ex: Cavity cooling in a ring cavity

Study cavity cooling in a ring cavity as a function of (a) friction and (b) detuning.

Solution: *a. The result is shown in Fig. 42.19. b. The result is shown in Fig. 42.20.*

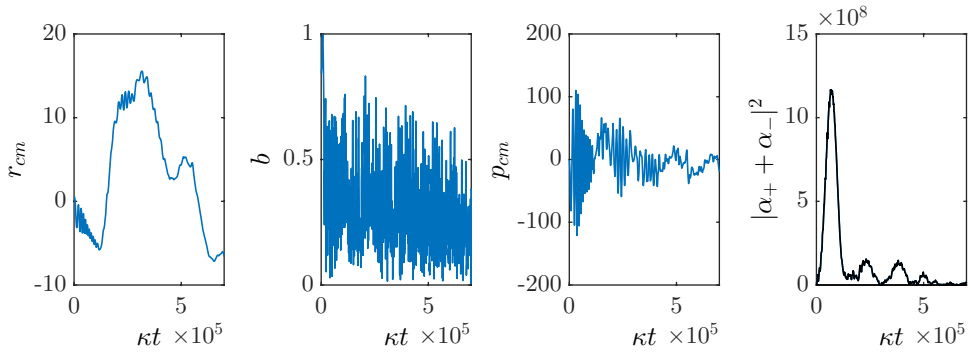

Figure 42.17: (code) Atoms in a harmonic trap irradiated by a pump laser, universally scaled version.

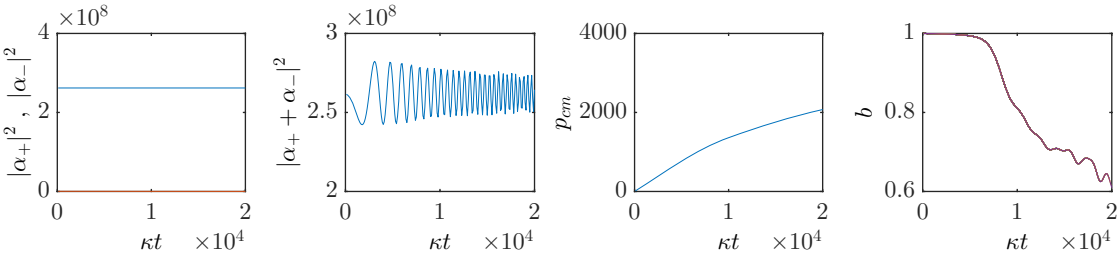

Figure 42.18: (code) One-sided switch-off experiments with/out cavity.

42.2.7.8 Ex: Motion of atoms in a ring-cavity including internal states

Motion of atoms in a ring-cavity, including internal states.

Solution: *The result is shown in Fig. 42.21.*

42.3 Phenomena related to CARL

The *collective atomic recoil laser* (CARL) unifies the principles of the FEL and LWI. Assume two-level atoms in their ground state moving against the pump beam $\mathbf{k}_2$. An (at first) weak probe beam k_1 which is blue detuned with respect to $\mathbf{k}_2$ builds a together with $\mathbf{k}_2$ a standing wave fraction moving in direction $\mathbf{v}$. This fraction gives rise to a moving dipole potential $V(\mathbf{r})$ and a light force on the atoms. If the moving standing wave is slower than the atoms (and the light frequency detuning from the atomic resonance is suitable), the atoms fall into the potential valleys by rescattering photons from the pump into the probe wave. This way they amplify the probe (they push the ponderomotive wave like the FEL), deepen the light potential valleys, are therefore further focused, etc.. We get a self-amplifying avalanche and feedback. In this process, the kinetic energy of the atoms is transformed into laser light. Or to resume: Collective recoil with self-bundeling produced by cooperative

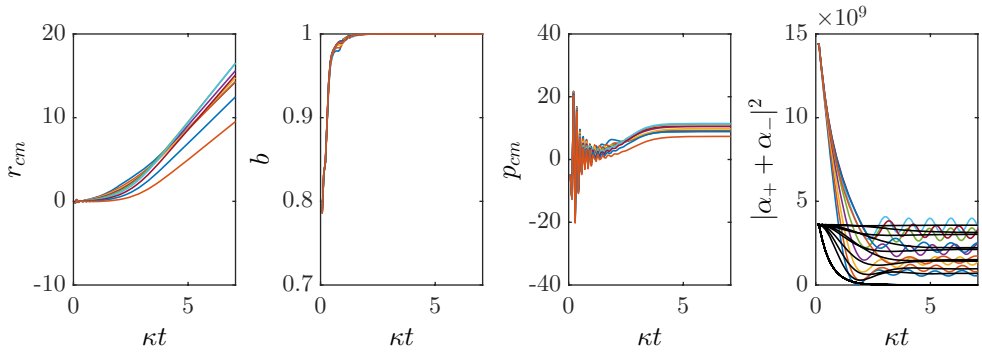

Figure 42.19: (code) Cavity cooling in a ring cavity as a function of friction.

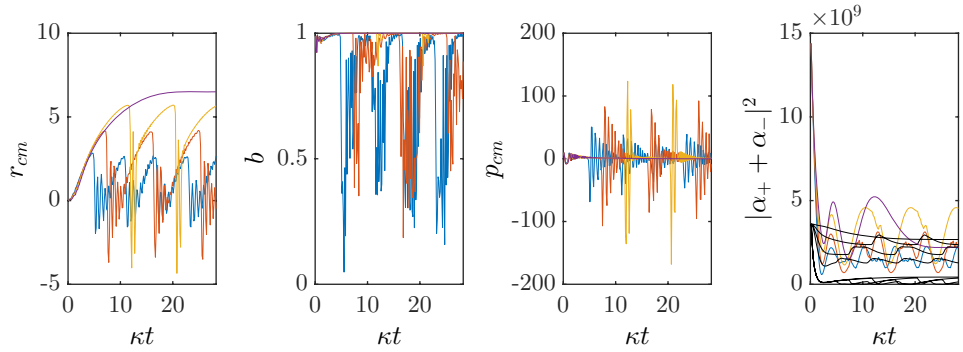

Figure 42.20: (code) Cavity cooling in a ring cavity for various detunings.

Compton-scattering generates coherent laser light [173].

The following notes first discuss the basic equations of motion in the limit of very far detuning, where the internal dynamics can be adiabatically eliminated. Then we turn our attention to some characteristic features of CARL.

42.3.1 Doppleron resonances

According to Stenholm [1262] the Raman type alternating absorption and emission can be interpreted as emission and absorption of *dopplerons*, the following conditions are equivalent,

$$\omega_0 = (l+1)(\omega + \mathbf{k}\cdot\mathbf{v}) - l(\omega - \mathbf{k}\cdot\mathbf{v}) \ . \tag{42.95}$$

The Hamiltonian is,

$$\hat{H} = \hbar\Delta\sigma^+\sigma^- + kvb^\dagger b + g/2(\sigma^+ + \sigma^-)(b^\dagger + b) \ , \tag{42.96}$$

where $\Omega \approx \sqrt{n}g$ and $b^\pm$ denotes absorption out of the wave $\omega \pm \mathbf{kv}$ or emission into the wave $\omega \mp \mathbf{k}\cdot\mathbf{v}$. Doppleron resonances can be observed experimentally.

In the experiment we sometimes observe subharmonics. The question arises whether these could be interpreted as higher-order photon scattering processes. There are

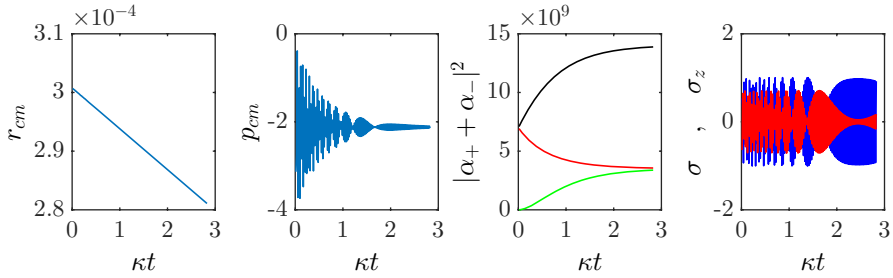

Figure 42.21: (code) Close to resonance.

two possibilities: Multiple scattering with real intermediate states or Doppleron-resonances.

Doppleron resonances are velocity-tuned resonances. The detuning of the intermediate state from the dispersion relation follows from,

$$d_1 = \omega_{pp} - \omega_{pr} - \frac{(p+2\hbar k)^2}{2m} + \frac{p^2}{2m} \qquad (42.97)$$
$$2(\omega_{pp} - \omega_{pr}) = \frac{(p+4\hbar k)^2}{2m} - \frac{p^2}{2m} \ .$$

By eliminating $\omega_{pp} - \omega_{pr}$ we find $d_1 = 2\hbar\varepsilon$. For our parameter regime $\omega_{pr} \gg \varepsilon$. Single photon $\omega_{pr} = \omega_{pp} - kv$, Doppleron $\omega_{pr} = \frac{1}{2}\omega_{pr}$ higher orders $\omega_{pr} = 2\omega_{pp} - kv - \varepsilon_1 - \varepsilon_2$.

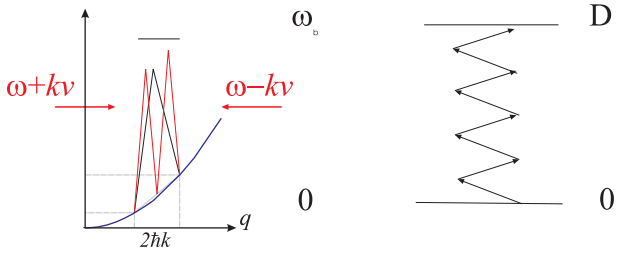

Figure 42.22: Scheme of Doppleron resonances.

42.3.2 Recoil-induced resonances

The *recoil-induced resonances* (RIR) can be explained in two complementary pictures [305]. In the Raman picture, an atomic transition stimulates Raman transitions between momentum states of the free atom without influencing the atomic excitation (the atom remains in a dark state) $\rho_{atom} \otimes |\mathbf{p}\rangle\langle\mathbf{p} + 2\hbar\mathbf{k}|$. Absorption $\Delta > 0$ or amplification $\Delta > 0$ of the probe field $\mathbf{k}_s$ by the pump field $\mathbf{k}_p$ is a result of the population imbalance. However, it is not an excitation imbalance (compare LWI) $\rho_{atom} \otimes |\mathbf{p} + 2\hbar\mathbf{k}\rangle\langle\mathbf{p} + 2\hbar\mathbf{k}| - \rho_{atom} \otimes |\mathbf{p}\rangle\langle\mathbf{p}|$. In the Rayleigh picture the RIRs are an effect of coherent backward *Bragg scattering* of the probe wave at the phase-lag

between the induced light-shift grating and the atomic density grating resulting from the periodic optical potential.

42.3.2.1 RIR-spectroscopy

Two laser beams 1 and 2 having each two different frequencies $\omega - \Delta\omega/2$ and $\omega + \Delta\omega/2$ are irradiated from two different directions enclosing a small angle θ into the atomic trap,

$$\begin{aligned} \mathcal{E}(\mathbf{r},t) &= \mathcal{E}_1 + \mathcal{E}_2 \\ &= \mathcal{E}^{(0)} \left[\cos\left(\mathbf{k}_1\cdot\mathbf{r} - (\omega - \tfrac{1}{2}\Delta\omega)t\right) + \cos(\mathbf{k}_2\cdot\mathbf{r} - \left(\omega + \tfrac{1}{2}\Delta\omega\right)t)\right] \\ &\approx 2\mathcal{E}^{(0)} \cos\left(\mathbf{K}\cdot\mathbf{r} - \omega t\right)\cos\left(\tfrac{1}{2}\mathbf{q}\cdot\mathbf{r} - \tfrac{1}{2}\Delta\omega t\right) \ , \end{aligned} \tag{42.98}$$

where $\mathbf{q} \equiv \mathbf{k}_2 - \mathbf{k}_1$ and $\mathbf{k} \equiv \frac{1}{2}(\mathbf{k}_2 + \mathbf{k}_1)$. The cycle-averaged intensities are $I_i(t) = 2\varepsilon_0 c|\mathcal{E}_i|^2 = 4\varepsilon_0 c\mathcal{E}^{(0)} \cos\left(\frac{1}{2}\mathbf{q}\cdot\mathbf{r} - \frac{1}{2}\Delta\omega t\right)$. Atoms coherently interacting with the light fields (which are tuned far from any atomic resonance) can redistribute the photons between the optical modes in a *nearly-degenerate* four-wave mixing process (4WM) thus modifying the amplitudes $\mathcal{E}_i^{(0)}$ so that a signal occurs.

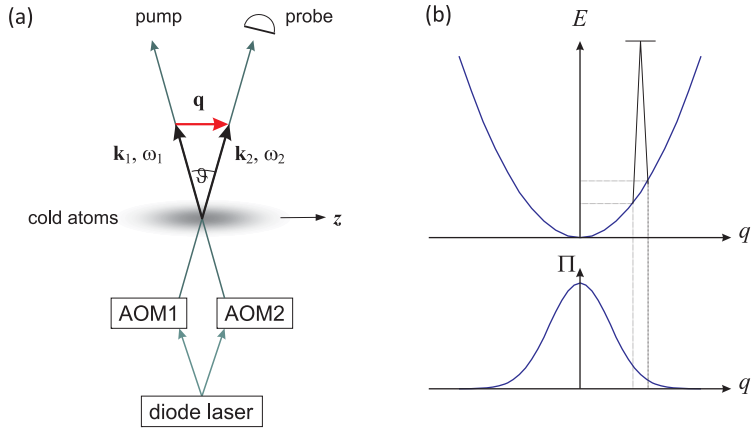

Figure 42.23: Principle scheme for RIR spectroscopy.

From symmetry considerations, it is easy to see that a homogeneous density distribution (along $\mathbf{q}$) of the motionless atoms does not give rise to a signal, neither. So let us assume that the atoms be bunched inside an optical grating according to some periodic distribution $n(z) = n_0 \sin^2 k_\lambda z$, but disregard their kinetics. The signals then generalize to,

$$\begin{aligned} \mathcal{E}_1(z,t) &= \mathcal{E}_1 + \beta n(z)\chi^{(3)}(\mathcal{E}_1 + \mathcal{E}_2)\mathcal{E}_1\mathcal{E}_2\mathcal{E}_1 + \beta n(z)\chi^{(3)}(\mathcal{E}_1 + \mathcal{E}_2)\mathcal{E}_1\mathcal{E}_2\mathcal{E}_1 \\ &= \mathcal{E}_1 + \beta n(z)\chi^{(3)}\left(2\mathcal{E}^{(0)}\cos\left(\tfrac{1}{2}qz - \tfrac{1}{2}\Delta\omega t\right)\right)\mathcal{E}_1\mathcal{E}_2\mathcal{E}_1 \end{aligned} \tag{42.99}$$

and analogous for $\mathcal{E}_2(z,t)$. Or following Lambert-Beer [748],

$$\begin{aligned} I_1(x,z,t) &= |\mathcal{E}_1|^2 \exp\left(2\imath\frac{\pi}{\lambda}\int \chi^{(3)}\left(2E^{(0)}\cos\left(\tfrac{1}{2}qz-\tfrac{1}{2}\Delta\omega t\right)\right)dy\right) \\ &= |\mathcal{E}_1|^2 \exp\left(2\imath\frac{\pi}{\lambda}\int n(x,y,z)...dy\right) \\ &= |\mathcal{E}_1|^2 \exp\left(2\imath\frac{\pi}{\lambda}n_0\sin^2 k_\lambda z\int ...dy\right) \\ I_1(t) &= \int I_1(x,z,t)dxdz\ . \end{aligned} \tag{42.100}$$

Regarding the momentum transfer, the 4WM process can be interpreted as Bragg scattering af the atoms at one of the two counterpropagating standing waves. We develop the theory if Bragg scattering in Sec. 47.2.

42.3.2.2 Temperature measurements via RIR

Temperature measurement are usually carried out by the time-of-flight method followed by absorption imaging. Alternatively, one can perform spectroscopy of RIR resonances. In the latter case, we detect intensity variations in a probe laser beam, i.e. the polarisation of the sample under the influence of *all* irradiated laser beams. In the example 200, we have seen that $\alpha \propto \mathfrak{Im}\ \chi \propto \mathfrak{Im}\ \mathcal{P} \propto \mathfrak{Im}\ \rho_{12}$. It is thus sufficient to calculate the atomic coherences, if necessary including the motional states of the atoms. Calculated by [559]

$$W(t) = \frac{\pi}{2}\frac{\Omega_1\Omega_2}{\Delta}\sqrt{\frac{mv}{k_BT}}\left[\frac{\partial}{\partial v}e^{-mv^2/2k_BT}\right]_{v=\Delta\omega(t)/q}\ . \tag{42.101}$$

42.3.2.3 RIR-spectroscopy on trapped atoms

In the case of free particles, the Raman beams interact for every detuning with a different velocity class of atoms. The atoms are almost not disturbed. In the case of trapped atoms, a coherence can be excited, and since the atoms periodically change their velocity, be read out or reexcited at a later time. The same atom can thus interact with the Raman beams at different times/detunings. If the trap is a standing wave, the situation is complicated by the fact that there are two overlapping gratings: The standing wave and the Raman grating. However, if the trap is much deeper than the Raman grating the atoms can be considered as localized.

The signature of atomic oscillation is a modulation in the RIR signal with the periodicity of the secular frequency [747, 1067].

Let us consider a standing-wave dipole-trap with $\omega_z = 2\pi \times 700\,\mathrm{kHz}$, $\omega_r = 2\pi \times 1\,\mathrm{kHz}$ and $U_{dip} = h \times 30\,\mathrm{MHz}\ = 4000 \times 2\varepsilon = 45\omega_z = 2100\omega_z$. The $100\,\mu\mathrm{K}$ cold atoms are therefore deep inside at the bottom of trap. This implies that the atomic energy levels are sharp and equally distant, and that the transitions are degenerate upon coupling by Raman-beams. If we apply a scan of $\pm 2\pi \times 300\,\mathrm{kHz}$, we will not excite the longitudinal motion. But the radial motion can be excited. As seen earlier the absorption signal is $\alpha \propto \mathfrak{Im}\ \rho_{12}$. What happens to the coherence, if the radiation is swept across a resonance depends on the scanning speed. If the scan is slow, we expect

$\alpha \propto \mathfrak{Im}\ \rho_{12}(\infty)$. We should be able to resolve the resonances [559, 561, 560] as peaks at $\pm\omega_r, \pm 2\omega_r, ...$ In contrast, if the scan is fast, as long as Δ_c is far from resonance, the population of the excited level ρ_{22} is just too small and nothing happens. When Δ_c passes through 0, the coherence ρ_{12} is excited, and can now be driven by the laser even when Δ_c is tuned far away. The coherence precesses faster and faster.

Let us compare to the situation of a laser swept across an electric dipole resonance. In analogy to the cavity response in reflection to a laser scanned across an eigenfrequency, we might expect a ringing coming from interference of the radiating electric dipole (which has been induced while the laser was close to resonance) with the original laser frequency. The radiated electric field is proportional to the excited state population. If we allow for a change of the input field, for example $\Delta_c(t)$, the Bloch-equations must be numerically integrated,

$$\rho(t + dt) = \rho(t) + dt\ M\rho(t)\ . \tag{42.102}$$

It is already clear that we should expect a ringing with exactly the time-dependent frequency $\Delta_c(t)$. Fig. 42.24 shows

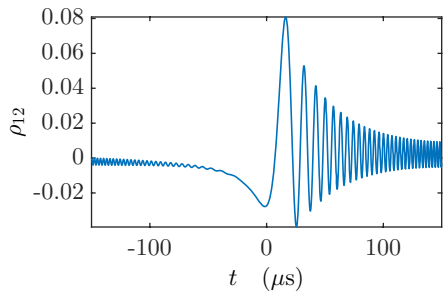

Figure 42.24: (code) Time-evolution of the atomic coherence as the driving laser frequency is swept across resonance. The parameters are $\Gamma = 2\pi \times 8\,\mathrm{kHz}$, $\Omega = 0.2\Gamma$, $\Delta = -50\Gamma..50\Gamma$ and $t = -150..150\,\mu\mathrm{s}$.

This simple mathematical model only assumes a resonance with a given width and a frequency-scanned oscillator. The physical nature of the resonance and the level splitting are not specified and the formalism should be applicable to a variety of situations. A ringing is, in fact, observed for RIR scans, if the scanning speed is too fast, in particular for atoms trapped in optical lattices. Ringing can also be generated in classical harmonic oscillators and laser-driven two-level systems as we will see in Exc. 50.1.10.5.

42.3.2.4 RIR versus CARL

The dynamics is characterized by backaction of the atomic motion onto the cavity field. In this respect there is a connection to RIR resonances in the limit investigated by [748]. While normal RIR is the action of the atomic motion on light fields, they demonstrate that in the same time the Raman-lattice influences the atomic motion. The coherence is limited by the time the photon spends in the sample (similar to the limitation of superradiant Rayleigh scattering, without photonic recycling by a

ring-cavity). Real backaction in the sense of coherent interdependence of the photonic and the kinetic degrees of freedom requires recycling of the photons.

42.3.3 FEL: the free electron laser

Normal lasers work by an inversion in the internal degrees of freedom, that is, bound electrons are excited to energetically higher orbitals, from where they can decay by emitting monochromatic light of well-defined frequency. Because, the *free electron laser* (*FEL*) works with beams of *free* electrons, they are tunable over wide frequency ranges. They have much higher efficiencies above 65%.

The principle is the following: Relativistic electrons are guided through an *undulator*, which is a device producing a magnetic field with periodically alternating polarization. Here, the electrons are subjected to a Lorentz force, $\mathbf{F} = -e\mathbf{v} \times \mathbf{B}$, forcing the electrons to oscillate with the periodicity of the undulator field. This corresponds to a dipole moment interacting with the incident light field. The transverse velocity of the electrons within the magnetic field of an incident light produces a Lorentz force in the axial direction called *ponderomotive force*. This force accelerates the electrons when they are a bit slower than the ponderomotive wave. Otherwise the electrons are decelerated. In the second case, the energy of the electrons is transmitted to the light field, which leads to a *bunching* of the atoms. Because it is a parametric process, there is a continuous energy flow between the field and the motion of the e^- (analogous to parametric Raman cooling). Thus, the FEL converts the kinetic energy of the electron beam into laser radiation. The inversion in a FEL can be interpreted as a relative displacement of the probability distributions for absorption and emission of photons in momentum space,

$$\begin{aligned} W_{abs}(\Delta) &= \operatorname{sinc}^2 \tfrac{1}{2}(\Delta + \varepsilon/2) \\ W_{abs}(\Delta) &= \operatorname{sinc}^2 \tfrac{1}{2}(\Delta - \varepsilon/2) \ , \end{aligned} \tag{42.103}$$

where $\varepsilon = \hbar k^2/2m_e$. The gain is a convolution of the difference of the above distribution with the momentum distribution of the electrons [1177].

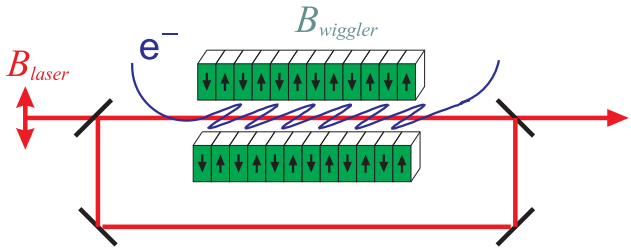

Figure 42.25: Free electron laser.

There various kinds of FELs. In stimulated Compton FELs, described by the shown Feyman graphs, the electrons are scattered by virtual (momentum transfer without energy transfer) photons of the wiggler. In Bremsstrahlungs FEL, the electrons are scattered at a static field. Virtual photons of the static field are scattered at the electrons, who then emit Bremsstrahlung an change their propagation direction. In Raman FELs very dense electron beams produce charge density oscillations,

which provides an additional effect. Free Electron Lasers already have a wide range of application ranging from biology and medicine to lithography and material science.

42.3.4 CARL in an ion storage ring

Bonifacio *et al.* [174] suggested to study collective atomic recoil lasing (CARL) with relativistic atoms. They found that using very fast atoms it should, in principle, be possible to get large CARL frequency shifts and much higher power enhancement factors than observed in free-electron lasers (FEL). Relativistic atomic velocities can be achieved in heavy ion accelerators such as the GSI heavy ion accelerator in Darmstadt and TSR ion storage ring in Heidelberg. Therefore the question arises, if CARL could be an alternative way to produce very energetic and intense UV radiation in concurrence to the FEL. In fact, CARL-based systems may prove more powerful and versatile as their electronic counterparts: Cooling techniques based on electron beams or on hybrid optical-radiofrequency friction forces are able to cool the ionic beams down to mK temperatures.

The CARL which has been predicted ten years ago by Bonifacio *et al.* [173], has recently been observed with cold atoms stored in a high-finesse ring cavity [755, 1343]. This proof of principle, now may motivate a deeper study of the figure of merit of a relativistic CARL. This short note, however, shows that a relativistic CARL is still, in my opinion, far from being realizable.

42.3.4.1 Typical heavy ion accelerator data

In his paper Bonifacio [175] suggests a ^{133}Cs beam with $E = mv^2 = 100\,\mathrm{MeV}/u$. This corresponds to a velocity of $\beta_r = c^{-1}\sqrt{2 \times 133E/m} = 0.46$ and $\gamma_r = 1.13$. The frequency is upshifted by $\omega_{pr}/\omega_{pp} = 2.4$ (from 1330 nm passing 856 nm towards 549 nm). Now ^{133}Cs is neutral, however various ionic species have been accelerated, such as $^{9}Be^{+}$ or $^{7}Li^{+}$. Bonifacio also assumes a beam density of $10^{17}\,\mathrm{m}^{-3}$ corresponding to a ion current of $I = 20\,\mathrm{A}$ and a radius of 1 mm. This current seems excessively high for state-of-the-art technologies. For comparision the following table resumes a few typical heavy ion accelerator data.

	Exper. at TSR	Exper. at GSI	Bonifacio's proposal
Ion species	$^{9}Be^{+}$	$^{7}Li^{+}$	^{133}Cs
Cooling resonance	$D2$ @ 313 nm		$D2$ @ 856 nm
Hyperfine splitting	1.3 GHz		
Ion energy $E = mv^2$	7.3 MeV		100 MeV/u
Ion velocity in β_r	0.042		0.46
Ion number N	10^7		
Circumference l	55.4 m		
Ion distance $d = l/N$	5.54 µm		
Beam diameter σ	0.4 mm		1 mm
Density $n = N/\sigma^2 l$	5×10^8 m^{-3}		10^{17} m^{-3}
Revolution time $t_{rev} = l/c\beta_r$	4.4 µs		
Ion current $I = Ne^-/t_{rev}$	0.36 µA	1 mA	20 A
Ion current density		10 A/cm^2 of 50 ns duration	
Beam temperatures	optical cooling	e^- beam cooling	
Pump laser wavelength	300 nm		1330 nm
Pump laser power			50000 W

42.3.4.2 Questions and suggestions

1. The low ion beam densities may constitute a major problem to relativistic CARL. The 20 A assumed in [175] are far from being realistic, i.e. about 7 orders of magnitude too high. For comparison: Typical electron beam densities are $n = 10^7$ cm^{-3}.

2. The assumed pump power is very high. Cavity-enhancement of the pump power could be envisaged. $P_{pump} = 100$ W seem more realistic. However, at high laser intensities higher-order nonlinear processes may happen, like multiphoton ionization.

3. The ions are passing multiple times through the interaction region. At every corner of the storage ring the quadrupole magnets induce heating by micromotion. The heating has higher-order Fourier components, and thus leads to complicated non-thermal velocity distribution. This means the ions do not stay bunched very well, at least not in momentum space. Therefore the atoms run out of phase with the pump laser after a round-trip. The question is how strong this diffusion process is compared to the CARL force.

4. Ion beams are cooled either by electron beams or optically. Electron beams exert friction forces and could be used for viscous CARL. Optical cooling is achieved by balancing the acceleration force of a copropagating laser with the counterforce exerted by an electric rf-field synchronized with the ion revolution frequency. This method might also provide optical molasses for *viscous CARL* [**?**]. According to Matthias Weidemüller only the electron beam cooling works, today. But it is connected with a strong diffusion force working against the CARL force. Fortunately, the electron beam forces only act in momentum space, i.e. one scattered electron does not noticeably modify an ion's trajectory.

5. Intrabeam scattering (IBS) by Coulomb-repulsion is a dominant heating process. Optical cooling seems to lead to a sudden Coulomb ordering, in which case IBS disappears. There is one successful crystallization experiment in a miniature non-relativistic storage ring. The ions have macroscopic distances. In a relativistic storage ring the distance would be on the order of centimeters, which is very long compared to the CARL laser wavelength. A problem which may occur is that crystallization due to Coulomb forces may perturb CARL bunching.

6. Pulsed operation may be possible. This depends on the time-scale for bunching.

7. In [175] neither the pump nor the probe laser are recycled, but the ions are. Imagine however, we could build a 10 m long high finesse ring cavity. Free spectral range $\delta = 30\,\mathrm{MHz}$. Waist $w_0 = 500\,\mathrm{mm}$. Cavity mode volume $V_{mde} = \frac{\pi}{2} L w_0^2 = 4\,\mathrm{cm}^3$. Single-photon Rabi frequency $g = (2\pi)2.3\,\mathrm{kHz}$.

42.3.4.3 Method

Talking to Matthias Weidemüller he seemed pretty reserved about the feasibility of the project at TSR. Perhaps at GSI.

Assume an atomic beam moving at $\beta_r = v/c$ with $\gamma_r = \sqrt{1-\beta_r^2}^{-1}$ irradiated by a laser beam k with a frequency ω in the lab frame. In the atomic rest frame the frequency is Doppler-shifted towards,

$$\omega' = \omega\sqrt{\frac{1-\beta_r}{1+\beta_r}} = \frac{\omega}{\gamma_r(1+\beta_r)} \ , \tag{42.104}$$

such that $\omega' \lessgtr \omega$ if $kv \gtrless 0$. Now consider two laser beams ω_{pp} and ω_{pr}. In the moving frame defined by $\omega' \equiv \omega'_{pr} = \omega'_{pp}$,

$$\omega' = \gamma_r\omega_{pp}(1+\beta_r) = \gamma_r\omega_{pr}(1-\beta_r) \ . \tag{42.105}$$

Assume there is an atomic resonance $\omega'_0 \approx \omega'$. Then the pump is red-detuned from the resonance by the same amount the probe is blue-detuned:

$$\frac{\omega_{pr}}{\omega'_0} = \frac{\omega'_0}{\omega_{pp}} \ . \tag{42.106}$$

Furthermore the atomic rest energy is,

$$E' = \gamma_r mc^2 \ . \tag{42.107}$$

The recoil energy in the rest frame is,

$$\omega'_{rec} = \frac{2\hbar k'^2}{m} = \frac{2\hbar\omega'^2_0}{mc^2} = \frac{2\hbar\omega_{pp}\omega_{pr}}{mc^2} \ . \tag{42.108}$$

42.3.4.4 Radiated power

The CARL equations are to be formulated in the rest frame [175]. The parameters which are adjusted in the lab frame have to be Lorentz-transformed properly, before being used in the CARL formalism. The coupling parameter in the moving frame is,

$$g' = \frac{d\mathcal{E}_1}{\hbar} = d\sqrt{\frac{\omega'}{\hbar\varepsilon_0 V'}} \ , \tag{42.109}$$

where $\mathcal{E}_1 = \sqrt{\hbar\omega/2\varepsilon_0 V_{mode}} \approx 3.6\,\mathrm{V/m}$. Therefore the dipole moment is just like ours $d \approx \sqrt{3\pi\varepsilon_0\hbar\Gamma/k^3} \approx 2.5\times10^{29}\,\mathrm{J/V}$. Because length is relativistically contracted, $\sqrt{V'/V} = \gamma_r$, in the lab frame,

$$g = \gamma_r^{-1/2} g' = d\sqrt{\frac{\omega'}{2\hbar\varepsilon_0\gamma_r^2 V}} \ . \tag{42.110}$$

Bonifacio's treatment yields the FEL parameter,

$$\rho = \frac{1}{1+\beta_r}\left(\frac{g^2 N S_0^2}{8\gamma_r^2 q\omega_{pp}^2}\right)^{1/3} \ , \tag{42.111}$$

where $S_0 < \frac{1}{4}$. The FEL and CARL parameter are related by the energy ratio,

$$q = \frac{\rho_c}{\rho} = \frac{E_{atom}}{E_{photon}} = \frac{\gamma_r mc^2}{\hbar\omega_{pr}} \ . \tag{42.112}$$

Using $N = nV$ the FEL parameter can also be written,

$$\rho = \frac{\gamma_r\omega_{pp}}{\omega'}\left(\frac{d^2\omega'}{\hbar\varepsilon_0\gamma_r^2 V}\frac{NS_0^2}{8\gamma_r^2\omega_{pp}^2}\frac{\hbar\omega_{pr}}{\gamma_r mc^2}\right)^{1/3} = \left(\frac{d^2 n S_0^2}{8\gamma_r\varepsilon_0 mc^2}\right)^{1/3} \ . \tag{42.113}$$

The CARL parameter is also,

$$\rho_c = \frac{1}{1+\beta_r}\left(\frac{g^2 N S_0^2}{4\gamma_r^2\omega_{pp}^2}q^2\right)^{1/3} = \frac{1}{1+\beta_r}\left(\frac{g^2 N S_0^2}{\omega_{rec}'^2}\right)^{1/3} \ , \tag{42.114}$$

which for $\beta_r \to 0$ becomes the non-relativistic CARL parameter. The energy flux density is found to be ,

$$u_{pp,pr} = |A_{pp,pr}|^2(1\mp\beta_r^2)\rho_c\hbar\omega_{pp,pr}nc \ . \tag{42.115}$$

The power is,

$$P_{in,out} = V u_{pr}\frac{1}{vt_{rev}} = |A_{pr}|^2(1\mp\beta_r^2)\rho_c\frac{\hbar\omega_{pr}}{e}\frac{Ne}{t_{rev}}\frac{c}{v} \ . \tag{42.116}$$

Assuming saturation $|A_{pr}| \approx 1$,,

$$P_{in,out}(\mathrm{W}) \approx \frac{1\mp\beta_r^2}{\beta_r}\rho_c E_{photon}(\mathrm{eV})\imath(\mathrm{A}) \ . \tag{42.117}$$

with $I = Ne^-/t_{rev}$ and at saturation $|A_{pr}|^2 \approx 1$. The gain length is,

$$l_g \approx \frac{c\beta_r\gamma_r}{2\sqrt{3}\rho\omega_0'} \ . \tag{42.118}$$

42.3.5 Matter wave superradiance

There is a close relationship between CARL and the phenomenon of *matter wave superradiance* (or *superradiant Rayleigh scattering*) [170, 1136], which will be discussed in the following sections.

In 1999 the group of W. Ketterle at the MIT made a surprising observation, when it illuminated an elongated Bose-Einstein condensate with a short linearly polarized laser pulse traversing the condensate perpendicularly to the long axis [649]. Instead of producing radiation with a dipole pattern, as we might expect for a polarized atomic cloud undergoing Rayleigh scattering, they observed emission of directional light bursts along the symmetry axis of the condensate. They also observed that some of the atoms were accelerated at angles of 45°. And these atoms could emit other generations of atoms at angles of 45°.

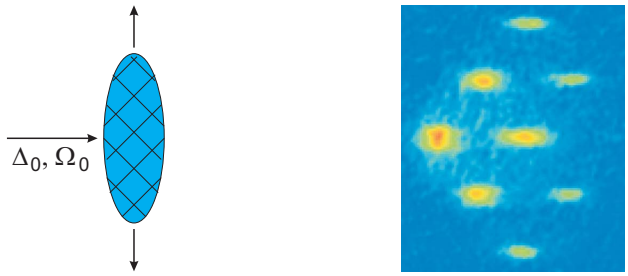

Figure 42.26: (code) Flight-of-time measurement of the atomic momentum distribution after matter wave superradiance.

The phenomenon was explained as follows. Let us imagine a first photon scattered by an atom into the direction of the long axis of the condensate. This atom will be accelerated by the photonic recoil in a direction of 135° with respect to the direction of the photon, and it will interfere with the rest of the condensate thus generating a standing matter wave of oriented in such a way, that the following photons are scattered into the same direction as the first one via Bragg scattering. This reinforces the contrast of the matter wave, etc.. We obtain an exponential gain of photons in the mode defined by the first scattered photon, as well as of the mode receiving the scattered matter wave. As the path of the gain is longer along the long axis of the condensate, this mode is favored. That is, the condensate can be considered as a cavity embracing the solid angle Ω_{sol}.

The Rayleigh scattering rate for a single atom is,

$$R_1 = \sin^2\theta\sigma(\Delta_a)\frac{I}{\hbar\omega}\frac{3\Omega_{sol}}{8\pi} \ , \tag{42.119}$$

where $\theta$is the angle between the polarization of the incident laser (intensity I) and the direction into which the light is scattered. The cross-section is $\sigma(\Delta_a) = \sigma_0\frac{\Gamma^2}{4\Delta^2+2\Omega^2+\Gamma^2}$, where $\sigma_0 = 3\frac{\lambda^2}{2\pi}$. Now, for the set of atoms, the superradiant scattering rate is not only amplified by the number of condensed atoms, N, but also by the number of atoms, N_r, already being in the mode receiving scattered atoms,

$$R_{sr} = R_1 N\frac{N_r+1}{2} \ . \tag{42.120}$$

This is the *superradiance matter wave*.

42.3.5.1 Ketterle and Dicke superradiance: The Dicke picture of CARL

At first glance there seems to be a paradox: On one hand, the collectiveness of the CARL lies in the motion, *not* in the scattering properties: Light is *localized* during the scattering process. On the other hand, superradiance means that atoms *feel* the scattering of photons by other atoms, i.e. radiatively. The relationship between Dicke superradiance and Ketterle superradiance gets clear, when we see that the momentum exchange in CARL corresponds to the same dipole-dipole force, which is at the origin of electrostriction.

The role of atoms and photons is inversed in the new understanding of cavity CARL and Ketterle superradiance: In CARL subsequent scattering processes are correlated via optical modes, in SR via atom motional coherences.

Note that quantum degeneracy is *not* essential [713]. The only property of BECs which is exploited in Ketterle's superradiance experiment is the large coherence length: Every atom is delocalized over the complete BEC. This helps! To see new effects due to quantum degeneracy, one must look at higher-order correlations, interaction-induced effects, the influence of the phonon field superimposed on the BEC.

For Ketterle's superradiant Rayleigh scattering the coherence is excited between two atomic momentum states. The correlation happens between successive scattering events, as long as atom is inside the condensate. In Dicke's idea (if atoms are closer than λ) the coherence is excited between a ground and excited electronic state. The correlation occurs between successively emitted photons, i.e. if the photons coupled to the same radiation mode. The superradiant lifetime is limited by natural decay.

What is the analogy between CARL (or Ketterle superradiance) and Dicke superradiance, exactly. Consider an ensemble of non-interacting atoms that can exist in *only two* sharp momentum states, $|k_0\rangle$ and $|k_1\rangle = |k_0 + 2q\rangle$, where $q = 2\pi/\lambda$. They interact with two counterpropagating quantized light modes, $\hat{a}_0$ and $\hat{a}_1$. We write the scattering process as $\hat{\Psi}_1^\dagger \hat{\Psi}_0 = |k_0 + 2q\rangle\langle k_0| = e^{-2iq\hat{r}}$. The Hamiltonian is then,

$$\hat{H} = \frac{k_0^2}{2m}\hat{\Psi}_0^\dagger\hat{\Psi}_0 + \frac{k_1^2}{2m}\hat{\Psi}_1^\dagger\hat{\Psi}_1 + \omega_0\hat{a}_0^\dagger\hat{a}_0 + \omega_1\hat{a}_1^\dagger\hat{a}_1 + U\hat{a}_1^\dagger\hat{a}_0\hat{\Psi}_1^\dagger\hat{\Psi}_0 + U\hat{a}_0^\dagger\hat{a}_1\hat{\Psi}_0^\dagger\hat{\Psi}_1 \ . \quad (42.121)$$

The important issue are the parametric terms $\hat{a}_1^\dagger\hat{\Psi}_1^\dagger$. For superradiance it is essential that the provenience of the emitted photons be undefined. For Dicke superradiance, photons are emitted through synchronized relaxation of the internal atomic coherence. For CARL, photons are scattered through synchronized relaxation of the motional atomic coherence. The CARL Dicke states are labeled by $|S, M\rangle$, where $2S$ is the total number of atoms and $2M$ the number of atoms in momentum state $|k_1\rangle$ minus the number of atoms in momentum state $|k_0\rangle$. Define $\hat{S}_- \equiv \hat{\Psi}_0^\dagger\hat{\Psi}_1$, and we get the usual SU(2) spin algebra,

$$\langle S, M-1|\hat{S}_-|S, M\rangle = \sqrt{S(S+1) - M(M+1)} \ . \quad (42.122)$$

the Hamiltonian

$$H = \frac{k_0^2}{2m}(S - \tfrac{1}{2}\hat{S}_z) + \frac{k_1^2}{2m}(S + \tfrac{1}{2}\hat{S}_z) + \omega_0\hat{a}_0^\dagger\hat{a}_0 + \omega_1\hat{a}_1^\dagger\hat{a}_1 + U\hat{a}_1^\dagger\hat{a}_0\hat{S}_+ + U\hat{a}_0^\dagger\hat{a}_1\hat{S}_- \ . \quad (42.123)$$

42.3.5.2 Superfluorescence as bosonic stimulation

There are two ways to understand SF. According to [366] it is *cooperative spontaneous emission* with interference of the radiation patterns. Alternatively, we may imagine that the first spontaneously scattered photon stimulates the other to emit. The scattering rate for every atom is Bose-enhanced by the presence of N other atoms by a factor $N+1$. The scattering rate for the total cloud is therefore $W \sim N(N+1) \approx N^2$. SR is [Dicke] the exponentially accelerated decay of the initial state (oscillating macroscopic dipole moment)^2, or [Ketterle] (contrast of interference pattern)^2 [172, 175].

In general, bosonic stimulation may take place by any mode taking part in the coherent scattering process, i.e. matter-wave momentum sidemodes or optical modes, as discussed by [1239, 1166].

Also interpretable as Bragg scattering of matter waves assisted by spontaneously scattered photons. The photons allow for *momentum conservation* and *irreversibilty of the gain*. Spontaneous emission is not a single-atom process, but a collective porcess, leaving atoms in a coherent superposition of ground and excited state [1216, 549].

42.3.5.3 Superfluorescence versus superradiance

It is interesting to look at Vuletic's experiment. Atoms located inside the cavity mode volume scatter light into the resonator modes. This is spontaneous emission, however modified by the mode structure of the available phase space. However, he observed higher scattering rates as expected. This is probably due to *bosonic stimulation* of the scattering process by photons which are already in the cavity. This stimulation can only be efficient, if the scattered photons are in the same mode as the stimulating ones. For Vuletic, this is satisfied because he has a large κ. In contrast we have the choice: If $kv \ll \kappa$, we may also observe SR. If $kv \gg \kappa$, only CARL. Note that Γ does not play a role, because spontaneous decay is inhibited in the cavity.

Without any symmetry breaking features, superradiance occurs in a random direction determined by the first scattered photon. In the presence of a cavity superradiance occurs in the direction of the cavity mode. If there are concurrent effects wanting to determine the direction, this only reduces the efficiency. This means for Vuletic's experiment that, since the superradiant pulse must be at 90°, the atoms must be arranged in periods such that the scattered photons interfere constructively. The spatial ordering proposed by Ritsch to explain Vuletic's observation corresponds to Inouye's BEC matter-wave grating.

If the scattered photons are in phase with the cavity, they can stimulate all the atoms having the same phase as the scattering ones $+n2\pi$.

It is all dynamical: Before the bunching is complete $|\alpha_-|^2 \lesssim N^2$. At the SR-peak, $|\alpha_-|^2 \propto N^2$.

42.3.5.4 Steady-state superradiance in a viscous CARL

Bonifacio points out [1106] the interesting fact that in the regime, where the CARL frequency does not leave the cavity resonance, the scattering amplitude is proportional

to the square of the numbers of scatterers. This behavior is typical for superradiance. The new thing is that our CARL would be a continuously superradiating system.

Consider spontaneous emission in an inverted gas. If the density is low, $n^{-1/3} \gg \lambda$, an emitted photon will leave the gas without being interacting with other photons. Otherwise, stimulated emission will occur and eventually give rise to a superradiant burst. What really counts is the *optical density*, if the emitted photon is off-resonant, it can not stimulate other atoms. What also helps is recycling of the light in a cavity: CARL is a good example, but the photons can only be rescattered if the recoiled atoms stay on resonance, $kv \ll \kappa$.

42.3.5.5 Equivalence of light and matter waves in 4WM

The exponential gain is due to a feedback. With two coupled momentum modes the matter wave is described by, $\psi \propto e^{(n+2)\imath qz} + e^{n\imath qz}$. The modes of light are, $\alpha_\pm = e^{\imath k_\pm z}$. Hence,

$$\langle \psi_2 | light | \psi_1 \rangle = \langle e^{(n+2)\imath qz} | \alpha_+^* \alpha_- | e^{n\imath qz} \rangle = \langle e^{(n+2)\imath qz} | e^{\imath(k_+ - k_-)z} | e^{n\imath qz} \rangle \qquad (42.124)$$

and,

$$\langle \alpha_2 | matter | \alpha_1 \rangle = \langle e^{\imath k_+ z} | \psi^* \psi | e^{n\imath k_- z} \rangle = \langle e^{\imath k_+ z} | e^{(n+2)\imath qz - n\imath qz} | e^{n\imath k_- z} \rangle \ . \qquad (42.125)$$

42.3.5.6 Symmetry breaking due to superradiance

For scattering between counterpropagating waves, SR is not based on bunching [1103]. Superradiance can be described classically if $k_B T > \hbar\varepsilon$, but $k_B T$ must be small enough to prevent SF to be destroyed by Doppler broadening.

The scattered power is $\propto N^2$, the scattering time is $\propto \tau/N$ or $\propto 1/kv$, the scattered energy is $\propto N^2 \times \tau/N$. Without recoil SF is symmetrical about Δ_a. With recoil it's asymmetric.

Without cavity 1. SF frequency is at ω_a, 2. no recoil-induced asymmetry, need cavity to see recoil effects on SF.

42.3.5.7 Different regimes

The relative size of kv and $\varepsilon\rho$ should delimit the classical from the quantum CARL regime.

	good cavity ($\kappa \ll kv$ or $\varepsilon\rho$)	bad cavity ($\kappa \gg kv$)
cold cloud	CARL, collective motion	SR, collective gain
warm cloud	CARL & threshold	non-collective RIR

The CARL equations in our regime read [755],

$$\beta = \frac{-iNU_0\eta_+}{\kappa\,(\kappa + 2\imath kv)} \qquad \text{and} \qquad k\dot{v} = \frac{-8\varepsilon N U_0^2 \eta_+^2}{\kappa(\kappa^2 + 4k^2v^2)} - \gamma_{frc} kv \ . \qquad (42.126)$$

Our solution for this equation for $\kappa \ll kv$ is,

$$|\beta|^2 = \frac{N^{4/3} U_0 \eta_+ \gamma_{frc}}{8\kappa^2 \varepsilon} \sim N^{4/3} \qquad \text{and} \qquad kv = \left(\frac{\varepsilon N U_0^2 \eta_+^2}{\kappa \gamma_{frc}} \right)^{1/3} \sim N^{1/3} \ . \qquad (42.127)$$

In contrast for $\kappa \gg kv$ we get from Eq. (42.126),

$$|\beta|^2 = \frac{N^2 U_0^2 \eta_+^2}{4\kappa^4} \sim N^2 \qquad \text{and} \qquad kv = \frac{-2\varepsilon N U_0^2 \eta_+^2}{\gamma_{frc}\kappa^3} \sim N \ . \tag{42.128}$$

This means we are actually in the CARL regime. If we could increase the friction such that the laser frequency would stay within the cavity resonance, we would be in the *superradiant* regime. Actually, the lowest frequency ever reached with molasses is $2kv \approx 2\pi \times 100$ kHz, which is a factor of 5 larger than the cavity linewidth. We could try to reach the superradiant regime by lowering the finesse of the cavity. Then however we also should increase U_0, i.e. reduce the detuning Δ_a, to keep staying in the coherent coupling regime. In conclusion this seems to be feasible. A major problem would however be the actual poor repeatability, i.e. shot-to-shot noise, which somewhat reduces our confidence into absolute atom number measurements.

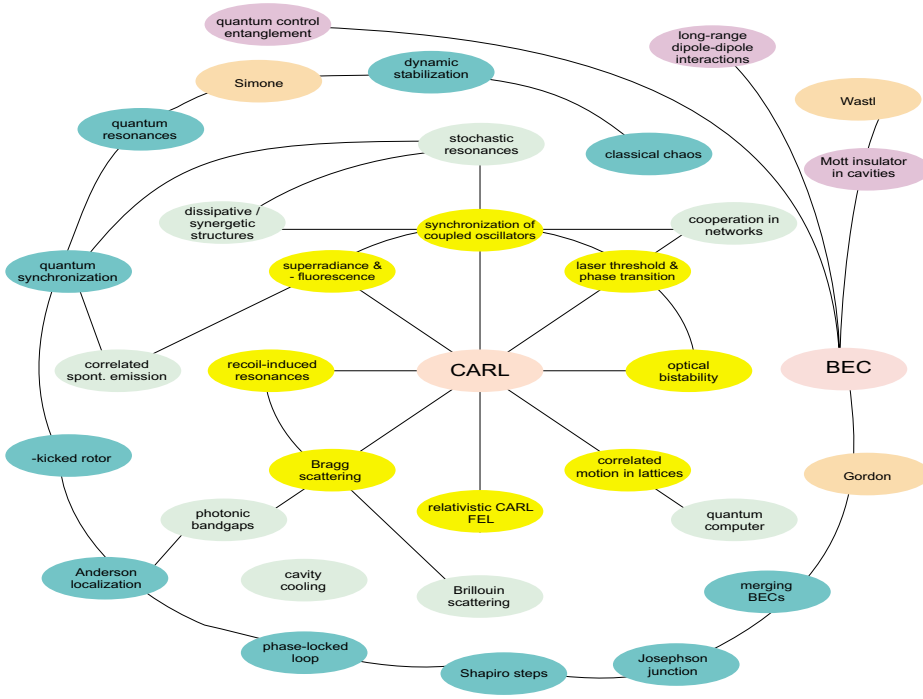

Figure 42.27: CARL and consorts.

42.3.6 Superradiance and CARL for ultracold atoms

Piovella has classified the various regimes of CARL and superradiance in the classical and the superradiant regimes. Let L be the length of the condensate or, if present, of the cavity. w is the waist and F is the finesse. We use the following definitions for the cavity decay width $\kappa = \pi c/LF$ the recoil shift $\omega_r = \hbar k^2/2m$, the dipole moment $d = \sqrt{3\pi\varepsilon_0\hbar\Gamma/k^3} = 2.5 \times 10^{-29}$ Asm and the volume of the condensate $V = \pi L w^2$. If

there is a ring cavity, V denotes the cavity mode volume. Furthermore we introduce the one-photon field strength $\mathcal{E}_1 = \sqrt{\hbar\omega_p/2\varepsilon_0 V}$, the coupling constant $\Omega_1 = d\mathcal{E}_1/\hbar$, the Rabi frequency $\Omega_I = \Omega_1|\alpha_\pm|$ and the one-photon light shift $U_1 = \Omega_1^2/\Delta_a$, where Δ_a is the atom-field detuning. We have $I/I_s = 2\Omega^2/\Gamma^2$, with $I_s = 2.5 \ \ \mathrm{mW/cm^2}$. The CARL parameter is now,

$$\rho = \left(\frac{\Omega_I}{2\Delta_a}\right)^{2/3}\left(\frac{\omega_p d^2 N}{V\hbar\varepsilon_0\omega_r^2}\right)^{1/3} = \left(\frac{NU_1^2|\alpha_\pm|^2}{2\omega_r^2}\right)^{1/3} \ , \tag{42.129}$$

where $|\alpha_\pm|^2$ is the number of photons in the cavity. Alternatively, define the coupling constant,

$$g = \frac{\Omega_I}{2\Delta_a}\left(\frac{\omega_p d^2}{2V\hbar\varepsilon_0}\right)^{1/2} = \frac{\Omega_i\Omega_1}{2\Delta_a} = \tfrac{1}{2}U_1|\alpha| = \frac{U_d}{2|\alpha|} \ . \tag{42.130}$$

Remember,

$$r_\beta = -\frac{k}{\pi w_0^2}\frac{\mathfrak{Re}\ (\alpha_{pol})}{\varepsilon_0} = \frac{U_d}{P/\hbar\omega} \ . \tag{42.131}$$

The superradiant gain is,

$$G_{sr} = \frac{2g^2 N}{\kappa} = \frac{NU_1^2|\alpha|^2}{2\kappa} \ . \tag{42.132}$$

Note that G_{sr} is exactly the width of the power broadened Rabi type coupling between the counterpropagating cavity modes. Therefore,

$$\rho^3\omega_r^2 G_{sr}\kappa\tfrac{1}{2}NU_1^2|\alpha|^2 \ . \tag{42.133}$$

We compare the Ketterle superradiance situation with our classical and our BEC ring cavity data. Early experiments [649, 1166] had been performed with ^{23}Na, but they were repeated with ^{87}Rb so that we concentrate on this latter case.

Robb [1105] has given a new interpretation to the observations by Schneble [1166].

regimes	bad cavity $\kappa \ll G$	good cavity $\kappa \gg G$
semiclass. $\omega_r < G$	MW superradiance { Kapitza-Dirac $\tau^{-1} > \omega_r$; Bragg $\tau^{-1} < \omega_r$ }	CARL
quantum $\omega_r > G$	MW superradiance { Kapitza-Dirac $\tau^{-1} > \omega_r$; Bragg $\tau^{-1} < \omega_r$ }	?

The temperature is an essential parameter. We do not need BEC, but we want $k_BT/\hbar < \kappa, \omega_r, g^2N/\kappa, \Gamma, ...$ Therefore $T \ll 480$ nK.

42.3.6.1 Raman superradiance

The SR gain can be either linear in the atom number N (single-atom or RIR gain) or non-linear (collective or CARL gain). Instabilities only occur in the collective gain regime. For a collective gain the SR mode decay rate κ and the thermal (or other type of inhomogeneous) broadening κ_R must be small compared to g^2N/κ. For Rayleigh SR the transition between the two regimes is studied by [650]. For Raman SR atom number threshold N_{thr} is too high, so that the experiments [1165, 1412, 1413] are in the linear gain regime .

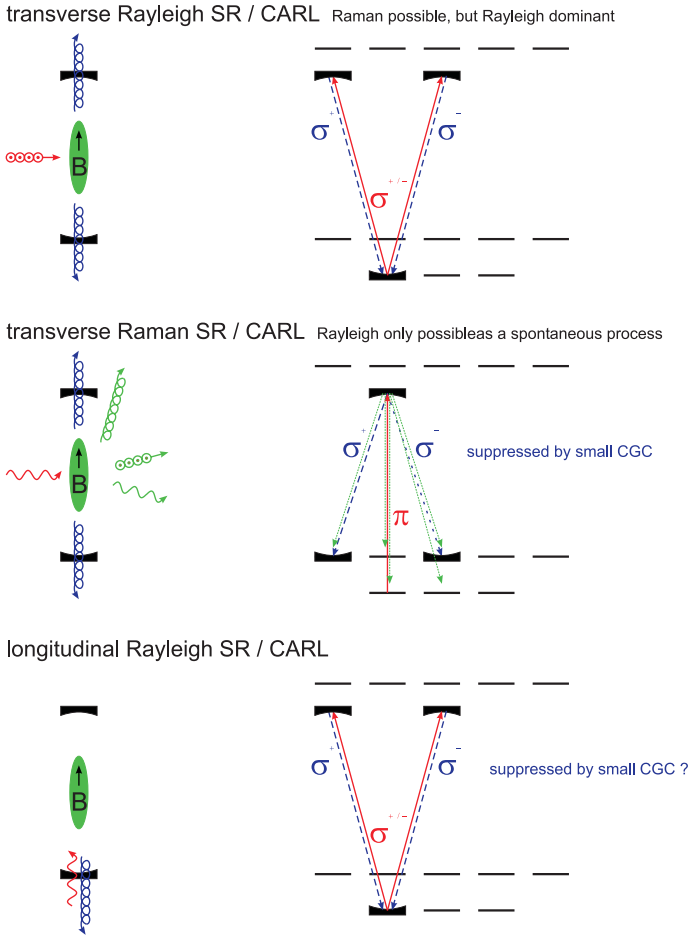

Figure 42.28: Configurations for Rayleigh and Raman CARL.

42.3.6.2 CARL

The claim [1038] is basically that CARL and superradiant Rayleigh scattering is the same process in different regimes. Both rely on collective gain, in contrast to recoil-induced resonances. Experimental signatures [649, 755] are a collective instability

resulting in bunching and directional SR light bursts. Both processes are described by the same equations (42.182). Those equations contain two free parameters: The decay rate of the optical field κ_c and the collective coupling strength ρ.

The decay rate of our ring cavity is $\kappa_c = (2\pi)$ 22 kHz, the recoil shift is $\omega_r = (2\pi)$ 14 kHz. Typical values for our experiments are $P = 1$ W, $\Delta_a = -(2\pi)$ 1 THz and $N = 10^5$. From this we derive $\eta^2 = P/(\hbar\omega\delta_{fsr}) \approx 10^9$ and $U_0 = g_1^2/\Delta_a = 3\Gamma\delta_{fsr}/k^2w^2\Delta_a \approx (2\pi)$ 340 Hz. The ρ parameter measures number round trips a photon must perform before it acquires enough Doppler shift to run out of cavity resonance,

$$\rho^3 = \frac{2NU_0^2\eta^2}{\omega_r^2} = \frac{2NU_d^2}{\eta\omega_r^2} \approx 4^3 \tag{42.134}$$

with $U_d = U_0\alpha_+^2$. For our typical conditions $\rho \gg 1$ and thus $\kappa = \kappa_c/\rho\omega_r \ll 1$. Hence, we are in the semiclassical good-cavity regime with the gain $G = \frac{1}{2}\omega_r\rho\sqrt{3} \approx (2\pi)$ 50 kHz. By reducing the collective coupling $NU_0^2\eta^2$, we may be able to reach the quantum regime $\rho < 1$. However, since $\kappa_c > \omega_r$ the quantum regime is only accessible in the superradiant limit, $\kappa > 1$. Let us assume we could reach $\rho = 0.8$. Then the gain would be $G_{SR-QT} = \frac{1}{2}\frac{\omega_r\rho^2}{\kappa} \approx (2\pi)$ 5 kHz. To reach the quantum good-cavity regime a better finesse of the cavity would be necessary; e.g. with the original finesse $F = 300000$ we would have $\kappa_c = 0.4\omega_r$. The κ - ρ phase diagram according to the above estimations is shown in Fig. 42.29.

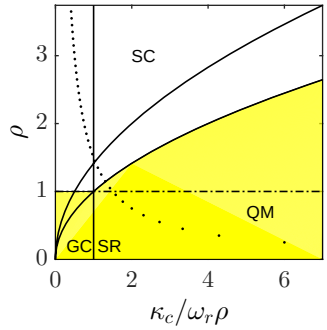

Figure 42.29: (code) Regimes of CARL. The range accessible to our experiment is denoted by the dotted line.

42.3.6.3 Cavity-enhanced superradiance

A few years ago, Ketterle and coworkers have demonstrated superradiant Rayleigh scattering from a Bose-Einstein condensate [649]. A short laser pulse shone into a BEC gave rise to motional sidemodes coupled out of the condensate, while at the same time a superradiant light pulse is emitted into the long axis of the condensate (see Fig. 42.31, left drawing). Various pictures have been stressed to explain the observations, and the close analogy to CARL has been pointed out.

In Ketterle's superradiance experiment, one may associate the part of the BEC that corresponds to atoms which have scattered a photon with an atom number

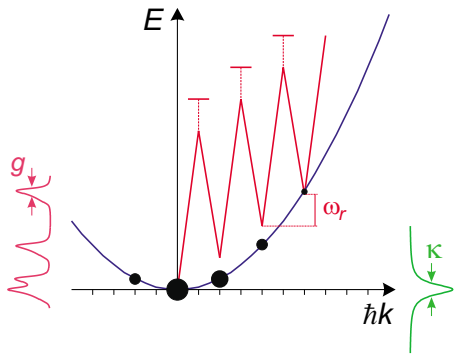

Figure 42.30: Scheme of CARL. The range accessible to our experiment is denoted by the dotted line.

N_r. The remaining part consists of N atoms. The density is modulated by interference between the two parts of the wave function, and the number of atoms that form the density modulation is $N_{mod} \propto \sqrt{NN_r}$. As for usual Bragg scattering or Dicke superradiance the number of photons n scattered at the density modulation is $n \propto N_{mod}^2 \propto N_r$. Since every scattered photon generates a recoiling atom, the number of recoiling atoms increases like $\dot{N}_r \propto n$, and we get $\dot{N}_r = GN_r$, i.e. an exponential increase of recoiling atoms with a gain factor G. This increase is mirrored by an identical increase of the number of scattered photons, which results in a gain mechanism for the scattered light mode. The incident and the scattered light mode are coherently coupled, just like in the case of CARL, so that in principle the scattered photons can be scattered back into the incident mode. Let U_0 be the Rabi frequency of the coherent mode coupling, i.e. the rate at which photons are exchanged between the modes. The collective Rabi frequency involving N atoms and n photons is then $U_0\sqrt{Nn}$. The superradiant gain corresponds to the transition rate associated with the coupling, which according to Fermi's golden rule is given by $G = U_0^2 Nn\ \rho(\omega)$.[12] Approximating the density-of-states in the vicinity of the cavity resonance by $\rho(\omega) \approx \kappa^{-1}$, where κ is the rate at which the scattered light mode decays, we see that the gain can be given the meaning of a CARL bandwidth, i.e. the width of the spectral range where the light scattering is exponentially amplified [**?**]. The prediction is to be tested.

The important point is now, that the various regimes in which CARL and superradiance may occur are characterized by the *size of the CARL gain bandwidth* as compared to the decay width κ and the recoil frequency ω_r. On one hand, we may distinguish the semiclassical regime, where the gain bandwidth is large enough to amplify many adjacent momentum states of the quantized motion, $G \gg \omega_r$ from the quantum regime, where only one momentum state can be amplified at a time, $G \ll \omega_r$. In this quantum regime the CARL interaction only couples *two momentum states* of the atomic motion.

[12]The gain bandwidth can also be understood as the power broadening of the cavity linewidth due to the collective coupling. In our CARL experiments the power broadening exceeds the cavity linewidth by more than an order of magnitude, which explains why CARL works even at very large pump-probe detunings.

In addition one has to distinguish between situations called the *good and the bad-cavity limits*. We find that conventional superradiant Rayleigh scattering from a BEC corresponds to the bad-cavity limit,[13] where the decay rate κ is much broader than the gain bandwidth. In fact, the decay width is calculated as $\kappa = c/2L$, where L is the size of the condensate along the axis into which the light is scattered. The time the scattered photons spend inside the BEC corresponds to the lifetime of a cavity. The bad-cavity limit is the regime studied by [1166]. By varying the gain bandwidth, they have been able to implement the semiclassical regime, as well as the quantum regime.[14] The various regimes of CARL are summarized in Fig. 42.31.

In contrast, our thermal CARL experiment was done in the semiclassical good-cavity limit. The field decay rate coincided with the linewidth of our ring cavity and was 7 *orders of magnitude smaller* than in the superradiance experiments. The most interesting regime can be identified by the requirement that the superradiant gain bandwidth G and the cavity field decay width κ both be smaller than the recoil shift ω_r. In terms of the parameter $\rho \equiv \sqrt[3]{G\kappa/\omega_r^2}$, which has been introduced by Bonifacio and coworkers as a universal scaling parameter for the equations of motion of the CARL system, it means that $\rho < 1$ [1106]. In this case only a single amplified momentum sideband couples to the atomic cloud. The result is a Rabi-type oscillation between the initial and the final momentum state.

Obviously for this scheme to work, the temperature of the atomic cloud must be lower than the recoil limit. By choosing appropriate parameters for our classical CARL setup we could in principle reach the quantum good-cavity regime. However, the interesting new features expected for this limit are blurred due to the high temperature. A major goal of our future research will be to study CARL with ultra-cold atoms in the yet unknown regime where $\rho < 1$. Our hope is to better understand the intricate relationship between CARL and superradiance in a regime, where the coupling between radiative and matter-wave modes is completely coherent, and for which the prospect of a robust quantum entanglement of the modes has been pointed out.

In the original superradiance experiments [649, 1166], the pulsed pump light drove a transient dynamics. The cavity in our proposed experiment will allow for much longer interaction times, and continuous superradiance will take place over a time scale at which dissipative effects due to cavity cooling will become effective.

Let us now turn to the superradiant gain experiment [649]. According to Ketterle the superradiant gain can be expressed as,

$$G = RN\frac{\Phi_s}{8\pi/3} \ , \tag{42.135}$$

where $R = \Gamma\Omega^2/(4\Delta^2 + 2\Omega^2 + \Gamma^2)$ is the single-atom Rayleigh scattering rate, with Γ being the linewidth of the atomic resonance, Δ the detuning, and Ω the Rabi

[13] Note that while the atom-field coupling constant is larger than the cavity decay width, it is much smaller than the spontaneous emission decay width of the atomic transition, so that we are still far from the cavity QED regime and may regard the light fields in our cavity as being classical.

[14] Let us add here that Schneble *et al.*[1166] gave a divergent interpretation of their observations: The bad-cavity limit was interpreted as Kapitza-Dirac scattering and the good-cavity limit as Bragg scattering scattering. As stated by Robb *et al.* [**?**] the different interpretations imply different dynamics which may be tested by experiment.

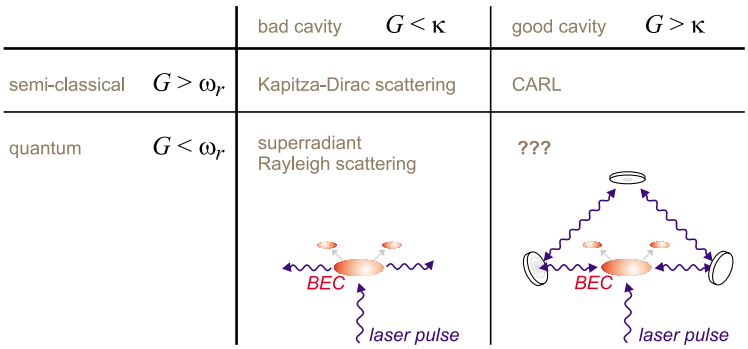

Figure 42.31: The idea of the superradiance experiment.

frequency generated by the incident laser beam. $\Phi_s \simeq \lambda^2/\frac{\pi}{4}w^2$ is the scattering solid angle, with w being the waist of the condensate. Hence, far from resonance,

$$G = \frac{\Omega^2}{\Delta^2} N \frac{3\Gamma}{2k^2 w^2} \ . \tag{42.136}$$

In Ketterle's experiments ($\Delta \simeq 100\Gamma$, $w = 15$ μm, $N = 10^5$, $\Omega \simeq 10\Gamma$) the gain is on the order of $G \simeq 170000$ kHz.

Interpreting the BEC as a cavity with finesse $F = 1$, i.e. $\kappa_c F/\pi = \delta_{fsr} = c/L$, we obtain,

$$G = \frac{\Omega^2}{2\Delta^2} \frac{\pi N}{\kappa_c} \frac{3\Gamma\delta_{fsr}}{k^2 w^2} = \frac{\Omega^2}{2\Delta} \frac{N}{\kappa_c} \frac{\Omega_{1s}}{2} 2\Delta \ , \tag{42.137}$$

where $\Omega_{1s} = 3\Gamma\delta_{fsr}/k^2w^2$ is the one-photon Rabi frequency inside the BEC cavity.

When the BEC is inside an optical cavity, the mode volumes for Ω and Ω_{1s} are equal, so that $\Omega^2 = n\Omega_{1s}^2$ and,

$$G \simeq \frac{nN_0U_0^2}{\kappa_c} = \tfrac{1}{2}\frac{\omega_r \rho^2}{\kappa} \ . \tag{42.138}$$

This is exactly the gain calculated from the above theory for the superradiant quantum regime.

Replace Γ by Γ_{sc}. For BEC decoherence is slow, so that modest gain suffices, atoms delocalized over BEC volume. At higher temperatures fast decoherence, but in cavity gain is larger, BEC coherence volume replaced by cavity volume, collectiveness transmitted differently.

Robb defines the 'gain rate',

$$g = \frac{U_0}{2}|\alpha| = \frac{\Omega}{2\Delta}\sqrt{\frac{\omega d^2}{2\hbar\varepsilon_0 V}} = \frac{\Omega}{2\Delta}\frac{dE_{1s}}{\hbar} = \frac{\Omega}{2\Delta}\Omega_{1s} \tag{42.139}$$

and the superradiant gain,

$$G = \frac{2g^2N}{\kappa} = \frac{\Omega^2}{2\Delta}\frac{N}{\kappa}\frac{\Omega_{1s}^2}{\Delta} \ . \tag{42.140}$$

Figure 42.32: Illustration of vicious circle of the CARL.

Note that g^2/κ is power broadening due to mode coupling. Typically, $g = 0.1\kappa$, so that $g^2/\kappa = 0.01\kappa \ll \omega_r$,

$$G = \frac{NU_0^2 n}{2\kappa} \ . \tag{42.141}$$

Decoherence of superradiance decreases with the delocalization of the atoms, but it does not depend on their degeneracy with other atoms. Quantum degeneracy could be interpreted as a phase-synchronized delocalization of many atoms.

Why does CARL work with (relatively) hot atoms? Thermal de Broglie wavelength at $T = 1$ μK $\lambda_{dB} = \sqrt{2\pi\hbar^2/mk_BT} \approx 200$ nm. Size of our thermal cloud $\bar{r} = \omega_r^{-1}\sqrt{k_BT/m} \approx 30$ μm and $\bar{z} \approx 8$ μm. Thomas-Fermi radii of our condensed cloud is not much different.

Note that alternative models have been stressed to describe for the various regimes of superradiant Rayleigh scattering, e.g. accounting for propagation effects (next section) [1439] and Kapitza-Dirac scattering. Superradiant pulse width $\tau_{sr} \simeq 200$ μs. Fourier width of gain profile $G = \tau_{sr}^{-1} \simeq 5000\ s^{-1}$.

42.3.6.4 Propagation effects

[1438] and [1439] developed a useful treatment for describing the Ketterle superradiance in the Raman-Nath (short strong pulse, $R \approx \omega_r$, $G \gg \omega_r$) as well as in the (long weak pulse, $R \ll \omega_r$, $G \ll \omega_r$) Bragg regime.

It is however unclear whether this treatment can be extended to account for the presence of a ring cavity. The ring cavity does more than increasing the BEC-light interaction time, $L \to \infty$. In fact, propagation effects introduce a spatial dependence of the intensity of the end-fire modes along the condensate axis. The self-injection

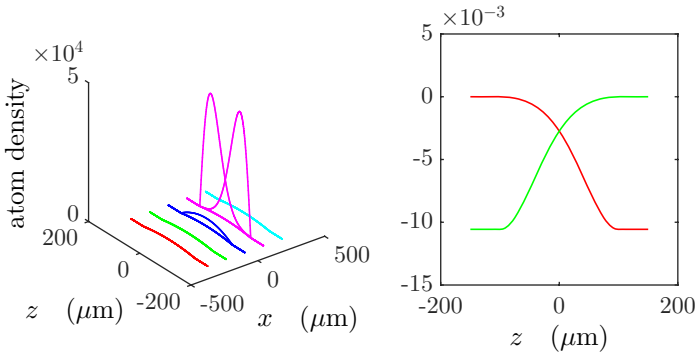

Figure 42.33: (code) Ketterle superradiance [1438].

due to photonic recycling by the ring cavity necessitates a self-organization of the spatial longitudinal mode profile.

42.3.7 Exercises

42.3.7.1 Ex: Good and bad cavity regime

What are the characteristics distinguishing the good from the bad cavity limit.

Solution:

42.3.7.2 Ex: Ringing in resonant systems

In this exercise we study ringing in (a) an excited classical harmonic oscillator and (b) in a laser-driven two-level system.

Solution: *The results are shown in Figs. 42.34.*

42.4 Quantization of the atomic motion in cavities

At the beginning of this chapter we set up the complete Hamiltonian of the coupled atom-cavity system. Then tracing over dissipative degrees of freedom, we derived the master equation or derived the Heisenberg equations for the operators appearing in the remaining Hamiltonian quantum mechanically. But then for CARL we restricted to a classical treatment of the motion, as well as of the cavity modes.

Resuming the discussion started in Sec. 42.1.5 we will, in the remaining sections of this chapter, analyze effects due to the *quantization* of degrees of freedom represented by operators. The present section will (i) on a quantum description of the motion (with and without adiabatic elimination of the internal atomic dynamics and (ii) on issues arising from the presence of many atoms.

42.4.1 Quantum description of the motion

Concretely, let us analyze again the situation of a single atom interacting with a ring cavity. We assume validity of the adiabatic elimination of the internal atomic excitation and want to treat the light fields as classical. In contrast, the atomic motion is considered as quantum:

$$|\psi\rangle = |z\rangle_{motion} \otimes \cancelto{\text{classical}}{|\alpha_+\rangle \otimes |\alpha_-\rangle} \otimes \cancelto{\text{adiab.elim.}}{|i\rangle_{electron}} \to |z\rangle \ . \tag{42.142}$$

Since the motion, being the only quantum degree of freedom, is not subject to dissipation, we may use the Schrödinger equation in addition to Heisenberg equations for the light fields. Then, following the procedure outlined in Sec. 42.1.5, with z being the only quantum number, we find that the system is completely described by the dynamics of the expansion coefficients,

$$\begin{aligned} \imath\hbar \frac{d}{dt}\langle z|\psi(t)\rangle &= \langle z|\hat{H}|\psi(t)\rangle \\ \dot{\alpha}_\pm &= \langle z|\tfrac{\imath}{\hbar}[\hat{H},\hat{a}_\pm] - \kappa\hat{a}_\pm|z\rangle \ . \end{aligned} \tag{42.143}$$

Plugging in the Hamiltonian (42.26), we obtain the Schrödinger equation for the particle's motional wavefunction [15],

$$\imath\hbar \frac{d}{dt}\langle z|\psi(t)\rangle = \frac{p^2}{2m}\langle z|\psi(t)\rangle + U_0\langle z|\hat{a}_+^\dagger\hat{a}_- e^{-2\imath kz} + \hat{a}_+\hat{a}_-^\dagger e^{2\imath kz}|\psi(t)\rangle \ , \tag{42.144}$$

and the Heisenberg equations for the light fields,

$$\begin{aligned} \dot{\alpha}_\pm &= \langle z|(-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_\pm + \imath U_0 e^{\mp 2\imath k\hat{z}}\hat{a}_\mp + \eta_\pm|z\rangle \\ &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\langle z|\int dz|\psi(t)\rangle\langle\psi(t)|e^{\mp 2\imath k\hat{z}}|z\rangle + \eta_\pm \\ &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\int dz|\psi(z,t)|^2 e^{\mp 2\imath kz} + \eta_\pm \ . \end{aligned} \tag{42.145}$$

[15] Terms of the Hamiltonian (42.26) which do not depend on z or p have been ignored, as they can be removed form the Schrödinger equation by a simple unitary transformation. Note that this can be done even though these terms depend on the field amplitudes $\alpha_\pm$.

In summary,

$$\boxed{\begin{aligned}\dot{\psi}(z) &= \frac{\imath\hbar}{2m}\frac{d^2}{dz^2}\psi(z) - \imath U_0\left(\alpha_+^\dagger\alpha_- e^{-2\imath kz} + \alpha_+\alpha_-{}^\dagger e^{2\imath kz}\right)\psi(z)\\ \dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\int dz|\psi(z)|^2 e^{\mp 2\imath kz} + \eta_\pm\end{aligned}} \quad . \tag{42.146}$$

These are the new CARL equations that should be used in cases when the particle is *slower than the recoil velocity*, in which its motion must be described as a propagating matter wave. Note, that under this form, the equations can easily be generalized to apply to macroscopic wavefunctions such as a Bose-Einstein condensate.

The expectation value of the particle's position is then calculated via,

$$\begin{aligned} z(t) &= \langle\psi(0)|\hat{z}(t)|\psi(0)\rangle = \langle\psi(0)e^{-\imath\hat{H}t}|\hat{z}|e^{\imath\hat{H}t}\psi(0)\rangle \\ &= \langle\psi(t)|\hat{z}|\psi(t)\rangle = \int\langle\psi(t)|z\rangle\langle z|\hat{z}|z'\rangle\langle z'|\psi(t)\rangle dz dz' = \int z|\psi(t,z)|^2 dz \ . \end{aligned} \tag{42.147}$$

We can verify that the expectation value of the particle's position satisfies the classical equation of motion,

$$\begin{aligned} m\ddot{z} &= \langle\psi(t)|m\ddot{\hat{z}}|\psi(t)\rangle = 2\imath\hbar kU_0\left(\hat{a}_+^\dagger\hat{a}_-\langle\psi(t)|e^{-2\imath k\hat{z}}|\psi(t)\rangle - \hat{a}_+\hat{a}_-^\dagger\langle\psi(t)|e^{2\imath k\hat{z}}|\psi(t)\rangle\right) \\ &= 2\imath\hbar kU_0\left(\hat{a}_+^\dagger\hat{a}_- e^{-2\imath k\langle\psi(t)|\hat{z}|\psi(t)\rangle} - \hat{a}_+\hat{a}_-^\dagger e^{2\imath k\langle\psi(t)|\hat{z}|\psi(t)\rangle}\right) \\ &= 2\imath\hbar kU_0\left(\hat{a}_+^\dagger\hat{a}_- e^{-2\imath kz} - \hat{a}_+\hat{a}_-^\dagger e^{2\imath kz}\right) \ . \end{aligned} \tag{42.148}$$

42.4.1.1 About the origin of quantized motion

The quantization of the light field into photons is, as discussed in Chp. 35, an intrinsic property of light. In contrast, the quantization of atomic motion is less obvious, because the atoms are not confined in a trapping potential. The reason for it lies in the monochromaticity of the driving laser fields and the one-dimensional geometry of the system, which allow us to write the recoil operator (??) or (??) as,

$$\boxed{e^{2\imath k\hat{z}} = \int |p + 2\hbar k\rangle\langle p| dp} \ . \tag{42.149}$$

Inserting it into the interaction part of the CARL Hamiltonian,

$$\hat{H}_{int} = U_0(e^{-2\imath k\hat{z}}\hat{a}_+^\dagger\hat{a}_- + e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger) \ , \tag{42.150}$$

the Schrödinger equation for the expanded wavefunction

$$|\psi\rangle = \int c(p)|p\rangle dp \tag{42.151}$$

yields,

$$\begin{aligned} \imath\hbar\frac{d}{dt}\langle p|\psi\rangle &= U_0\hat{a}_+^\dagger\hat{a}_-\langle p|e^{-2\imath k\hat{z}}|\psi\rangle + U_0\hat{a}_+\hat{a}_-^\dagger\langle p|e^{2\imath k\hat{z}}|\psi\rangle \\ = \imath\hbar\frac{d}{dt}c(p) &= U_0[\hat{a}_+^\dagger\hat{a}_- c(p + 2\hbar k) + \hat{a}_+\hat{a}_-^\dagger c(p - 2\hbar k)] \ . \end{aligned} \tag{42.152}$$

That is, if the initial momentum distribution is narrow, $\Delta p \ll 2\hbar k$, and if CARL-induced recoil due to backscattering of photons between counterpropagating modes is the only force acting on the atoms, the momentum of the atoms can only adopt discrete values in units of $2\hbar k$, *as if the atomic velocity were quantized.* That is, the quantization of the field is, in some way, imprinted on the distribution of the atomic moment, so that we may as well use a discrete notation,

$$|\psi\rangle = \sum_\nu c_\nu |\nu\rangle \ , \tag{42.153}$$

such that [16],

$$\imath\hbar \frac{d}{dt} c_\nu = U_0 \hat{a}_+^\dagger \hat{a}_- c_{\nu+1} + U_0 \hat{a}_+ \hat{a}_-^\dagger c_{\nu-1} \ . \tag{42.154}$$

Example 274 (*Analogy to the Bose-Hubbard Hamiltonian*): Interestingly the CARL Hamiltonian with quantized motion (42.150) has, in momentum space, a similar shape as the 1D Bose-Hubbard Hamiltonian in position space,

$$\begin{aligned} \hat{H} &= \sum_\nu \hbar\omega_{rec}\nu^2 + U_0 \sum_\nu \left(|\nu-1\rangle\langle\nu| \hat{a}_+^\dagger \hat{a}_- + |\nu-1\rangle\langle\nu| \hat{a}_+ \hat{a}_-^\dagger \right) \\ &= \hbar\omega_{rec} \sum_\nu \nu^2 + U_0 \hat{a}_+^\dagger \hat{a}_- \sum_\nu \hat{A}_{\nu-1}^\dagger \hat{A}_\nu + U_0 \hat{a}_+ \hat{a}_-^\dagger \sum_\nu \hat{A}_{\nu+1}^\dagger \hat{A}_\nu \ . \end{aligned}$$

Now, it is important to understand that the statement that *photonic recoil is quantized does not mean that the dipolar optical force can only be transmitted in units of* $2\hbar k$, as if the force needed to accumulate a certain amount of energy before it makes a sudden transition to a different momentum state. Rather, the probability to find an initially resting atom subject to a force in the momentum state $2\hbar k$ gradually increases with time. The atom gradually evolves into a coherent superposition of states $|0\rangle + |2\hbar k\rangle + |4\hbar k\rangle + ..$, and only when we *measure* the momentum distribution will it have to decide in which state it ended up. The expectation value of the center-of-mass momentum linearly, as long as the force is constant. A slide show on the quantized CARL can be viewed at (watch talk).

42.4.2 Discretization of the momentum states

We will now assume that, for the physical reasons described above, the motional state of the atom can only exist with momenta corresponding to multiples of twice the photonic recoil.

[16] Note that, instead of expanding the state $|\psi\rangle$, we could expand the motional wavefunction into plane waves,

$$\langle z|\tilde{\psi}\rangle = \tilde{\psi}(z) = \tfrac{1}{\sqrt{2\pi}} \sum_n c_n(t) e^{2\imath n k z} \qquad \text{normalized as} \qquad \int dz |\tilde{\psi}(z)|^2 = 1 = \sum_n |c_n(t)|^2 \ .$$

Insertion of this expansion into the quantized CARL equations (42.146) yields the same results.

42.4.2.1 Schrödinger equation approach

We basically repeat the treatment of Sec. 42.4.1, but now expanding the motion on a discrete basis of momenta labeled by an integer number ν,

$$|\psi\rangle = |\nu\rangle_{motion} \otimes \cancelto{\text{classical}}{|\alpha_+\rangle \otimes |\alpha_-\rangle} \otimes \cancelto{\text{adiab.elim.}}{|i\rangle_{electron}} \to |\nu\rangle \ . \tag{42.155}$$

Applying the recipe detailed at the beginning of Sec. 42.4, we write down the same Schrödinger equation as in (42.144) [17], but now projecting on $\langle\nu|$ rather than on $\langle z|$ and inserting the expansion (42.153) and,

$$e^{2\imath k\hat{z}} = \sum_\nu |\nu+1\rangle\langle\nu| \qquad \text{and} \qquad \hat{p} = \sum_\nu \nu 2\hbar k|\nu\rangle\langle\nu| \ . \tag{42.156}$$

We get,

$$\begin{aligned}\langle\nu|\imath\hbar\frac{d}{dt}\sum_{\nu''} c_{\nu''}|\nu''\rangle = \langle\nu|\sum_{\nu'}\frac{(\nu' 2\hbar k)^2}{2m}|\nu'\rangle\langle\nu'| \\ + U_0\left(\sum_{\nu'}|\nu'-1\rangle\langle\nu'|\hat{a}_+^\dagger\hat{a}_- + \sum_{\nu'}|\nu'+1\rangle\langle\nu'|\hat{a}_+\hat{a}_-^\dagger\right) \ .\end{aligned} \tag{42.157}$$

And from the Heisenberg equation (42.15) for light modes,

$$\langle\psi|\dot{\hat{a}}_\pm|\psi\rangle = \langle\psi|(-\kappa+\imath\Delta_c-\imath U_0)\hat{a}_\pm - \imath U_0 e^{\mp\imath 2k\hat{z}}\hat{a}_\mp + \eta_\pm|\psi\rangle \ , \tag{42.158}$$

we get,

$$\sum_{\nu',\nu''}\langle\nu'|c_\nu^*\dot{\hat{a}}_\pm c_{\nu''}|\nu''\rangle = \sum_{\nu,\nu',\nu''}\langle\nu'|c_{\nu'}^*\left[(-\kappa+\imath\Delta_c-\imath U_0)\hat{a}_\pm - \imath U_0|\nu\mp 1\rangle\langle\nu|\hat{a}_\mp+\eta_\pm\right]c_{\nu''}|\nu''\rangle \ . \tag{42.159}$$

Finally,

$$\boxed{\begin{aligned}\dot{c}_\nu &= -4\imath\omega_{rec}\nu^2 c_\nu - \imath U_0\left(\alpha_+^*\alpha_- c_{\nu+1} + \alpha_+\alpha_-^* c_{\nu-1}\right) \\ \dot{\alpha}_\pm &= (-\kappa+\imath\Delta_c-\imath U_0)\alpha_\pm - \imath U_0\alpha_\mp\sum_\nu c_{\nu\mp1}^* c_\nu + \eta_\pm\end{aligned}} \ . \tag{42.160}$$

In Exc. 42.4.7.1 and 42.4.7.2 we study the equations (42.160) in the presence of a constant external force.

42.4.2.2 Master equation approach

As in the situation under study the motion is the only quantum degree of freedom and not subject to dissipation, a master equation approach is useless, and we will show it here only for completeness.

[17] Here again, as done in Sec. 42.4.1, we ignore terms of the Hamiltonian (42.26) which do not depend on z or p.

In 42.4.7.3 we show a derivation obtained by directly inserting the adiabatically simplified Hamiltonian (42.26) into the Liouville equation (42.8). The result is,

$$\boxed{\begin{aligned}\dot{\rho}_{\mu,\nu} &= \imath(\nu-\mu)\left[(\nu+\mu)\omega_{rec}-\Delta_c\right]\rho_{\mu,\nu} \\ &\quad +\imath U_0\left[\alpha_+^*\alpha_-(\rho_{\mu,\nu-1}-\rho_{\mu+1,\nu})+\alpha_-^*\alpha_+(\rho_{\mu,\nu+1}-\rho_{\mu-1,\nu})\right] \\ \dot{\alpha}_\pm &= (-\kappa+\imath\Delta_c-\imath U_0)\alpha_\pm-\imath U_0\alpha_\mp\sum_\nu\rho_{\nu,\nu\mp1}+\eta_\pm\end{aligned}} \quad . \tag{42.161}$$

42.4.3 Quantization of the atomic motion without adiabatic elimination

So far we have discussed the quantization of the atomic motion in the CARL equations, which were obtained by adiabatic elimination of the electronically excited state. In the following, we will quantize the motion directly in the equations of motion (42.15) for the observables and in the Liouville equation for the density operator. We quantize the atomic motion along the optical z-axis simply by assuming that, in this direction, the momentum only exists in multiples of $\hbar k$, and organize up the Hilbert space like this,

$$|\psi\rangle = |\nu\rangle_{motion}\otimes|i\rangle_{electron}\otimes\cancel{|n\rangle_+\otimes|n\rangle_-}^{\text{classical}} \rightarrow |\nu,i\rangle \ , \tag{42.162}$$

that is, skipping the quantum number counting the photons, we will treat the light fields classically, $\hat{a}_\pm = \alpha_\pm$,

$$\begin{aligned}\hat{p} &= \sum_\nu \nu\hbar k|\nu\hbar k\rangle\langle\nu\hbar k|\otimes\mathbb{I} \\ e^{-\imath k\hat{z}} &= \sum_\nu |\nu\hbar k-\hbar k\rangle\langle\nu\hbar k|\otimes\mathbb{I} \\ \hat{\sigma}^+ &= \mathbb{I}\otimes|2\rangle\langle1| \\ \hat{\rho} &= |\psi\rangle\langle\psi| = \sum_{\mu,\nu,i,j} c^*_{\mu,i}c_{\nu,j}|\mu\rangle\langle\nu|\otimes|i\rangle\langle j|\end{aligned} \ , \tag{42.163}$$

where in the last equation we defined $c_{\nu,j} = \langle p,j|\psi(t)\rangle = \langle\nu\hbar k,j|\psi(t)\rangle = \langle\nu,j|\psi(t)\rangle$, such that,

$$\rho_{\mu,\nu;i,j} \equiv \langle\mu,i|\hat{\rho}|\nu,j\rangle = c^*_{\mu,i}c_{\nu,j} \ . \tag{42.164}$$

Adopting the short notation $|\nu\rangle \equiv |\nu\hbar k\rangle$ we can write the state of the system,

$$
\begin{aligned}
|\psi(t)\rangle &= \sum_\nu c_{\nu,1}|\nu\hbar k,1\rangle + c_{\nu,2}|\nu\hbar k,2\rangle \qquad (42.165)\\
\langle\psi(t)|\hat{p}|\psi(t)\rangle &= \hbar k \sum_\nu \nu(|c_{\nu,1}|^2 + |c_{\nu,2}|^2)\\
\langle\psi(t)|e^{\pm\imath k\hat{z}}|\psi(t)\rangle &= \sum_\nu (c^*_{\nu\pm1,1}c_{\nu,1} + c^*_{\nu\pm1,2}c_{\nu,2})\\
\langle\psi(t)|\hat{a}|\psi(t)\rangle &= \alpha\sum_\nu (|c_{\nu,1}|^2 + |c_{\nu,2}|^2) = \alpha\\
\langle\psi(t)|\hat{\sigma}^-|\psi(t)\rangle &= \sum_\nu c^*_{\nu,1}c_{\nu,2}\\
\langle\psi(t)|\hat{\sigma}_z|\psi(t)\rangle &= \sum_\nu (|c_{\nu,2}|^2 - |c_{\nu,1}|^2)\ .
\end{aligned}
$$

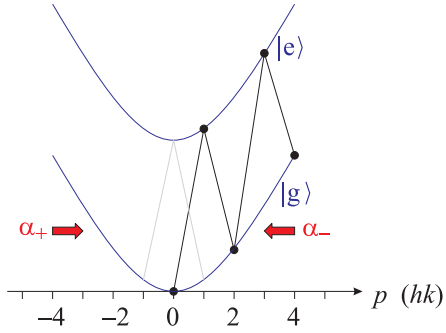

Figure 42.35: Illustration of the quantized motion.

To describe the dynamics of the system we could use the Schrödinger equation, but the Hamiltonian (42.4) does not contain spontaneous emission nor cavity decay. So, let us employ the equations of motion (42.15), which were derived from a master equation. The equation of motion for the field yields,

$$
\begin{aligned}
\dot{\alpha}_\pm &= \langle\psi(t)|\dot{\hat{a}}_\pm|\psi(t)\rangle = \langle\psi(t)|(-\kappa + \imath\Delta_c)\hat{a}_\pm - \imath g\hat{\sigma}^- e^{\mp\imath k\hat{z}} + \eta_\pm|\psi(t)\rangle \qquad (42.166)\\
&= (-\kappa + \imath\Delta_c)\alpha_\pm + \eta_\pm - \imath g\sum_\nu c^*_{\nu\mp1,1}c_{\nu,2}\\
&= (-\kappa + \imath\Delta_c)\alpha_\pm + \eta_\pm - \imath g\sum_\nu \rho_{\nu\mp1,\nu;1,2}\ .
\end{aligned}
$$

For the atomic motion we get,

$$
\dot{x} = \langle\psi(t)|\dot{\hat{x}}|\psi(t)\rangle = \frac{1}{m}\langle\psi(t)|\hat{p}|\psi(t)\rangle = \frac{\nu\hbar k}{m}\ , \qquad (42.167)
$$

and

$$\begin{aligned}\dot{p} &= \langle\psi(t)|\dot{\hat{p}}|\psi(t)\rangle \qquad (42.168)\\ &= \langle\psi(t)|\imath g\hbar k\hat{\sigma}^-\left(\hat{a}_+^\dagger e^{-\imath kz}-\hat{a}_-^\dagger e^{\imath kz}\right)-\imath g\hbar k\hat{\sigma}^+\left(\hat{a}_+e^{\imath kz}-\hat{a}_-e^{-\imath kz}\right)|\psi(t)\rangle\\ &= \sum_\nu \imath g\hbar k\left(\alpha_+^*c_{\nu-1,1}^*c_{\nu,2}-\alpha_-^*c_{\nu+1,1}^*c_{\nu,2}-\alpha_+c_{\nu+1,1}c_{\nu,2}^*+\alpha_-c_{\nu-1,1}c_{\nu,2}^*\right)\\ &= \sum_\nu \imath g\hbar k(\alpha_+^*\rho_{\nu-1,\nu;1,2}-\alpha_-^*\rho_{\nu+1,\nu;1,2}-\alpha_+\rho_{\nu,\nu+1;2,1}-\alpha_-\rho_{\nu,\nu-1;2,1})\ .\end{aligned}$$

42.4.3.1 Maxwell-Bloch equations without adiabatic elimination

Analogously to the treatment in Sec. 34.4.1, we will now derive the master equation without adiabatic elimination of the excited state (in this case called *Maxwell-Bloch equations* from the Liouville equation [first line of Eq. (42.8)] using the Hamiltonian (42.4). The coherent part is,

$$\begin{aligned}\dot{\rho}_{\mu,\nu;i,j} &\equiv \langle\mu,i|\dot{\hat{\rho}}|\nu,j\rangle = -\imath\langle\mu,i|[\hat{H},\hat{\rho}]|\nu,j\rangle \qquad (42.169)\\ &= -\imath\sum_{p,u}\langle\mu,i|\hat{H}|p,u\rangle\rho_{p,\nu;u,j}+\imath\sum_{p,u}\rho_{\mu,q;i,v}\langle p,u|\hat{H}|\nu,j\rangle\\ &= -\imath\left[\frac{(\mu\hbar k)^2}{2m}-\Delta_a\delta_{i2}-\Delta_c(|\alpha_+|^2+|\alpha_-|^2)-\imath\eta_+(\alpha_+-\alpha_+^*)-\imath\eta_-(\alpha_--\alpha_-^*)\right]\rho_{\mu,\nu;i,j}\\ &\quad-\imath g\left[\alpha_+^*\delta_{i1}\rho_{\mu+1,\nu;2,j}+\alpha_+\delta_{i2}\rho_{\mu-1,\nu;1,j}+\alpha_-^*\delta_{i1}\rho_{\mu-1,\nu;2,j}+\alpha_-\delta_{i2}\rho_{\mu+1,\nu;1,j}\right]\\ &\quad+\imath\left[\frac{(\nu\hbar k)^2}{2m}-\Delta_a\delta_{j2}-\Delta_c\left(|\alpha_+|^2+|\alpha_-|^2\right)-\imath\eta_+(\alpha_+-\alpha_+^*)-\imath\eta_-(\alpha_--\alpha_-^*)\right]\rho_{\mu,\nu;i,j}\\ &\quad+\imath g\left[\alpha_+^*\delta_{j2}\rho_{\mu,\nu-1;i,1}+\alpha_+\delta_{j1}\rho_{\mu,\nu+1;i,2}+\alpha_-^*\delta_{j2}\rho_{\mu,\nu+1;i,1}+\alpha_-\delta_{j1}\rho_{\mu,\nu-1;i,2}\right]\\ &= \left[\imath\frac{(\nu^2-\mu^2)(\hbar k)^2}{2m}+\imath\Delta_a(\delta_{i2}-\delta_{j2})\right]\rho_{\mu,\nu;i,j}\\ &\quad+\imath g\left[\alpha_+^*\left(\delta_{j2}\rho_{\mu,\nu-1;i,1}-\delta_{i1}\rho_{\mu+1,\nu;2,j}\right)+\alpha_+\left(\delta_{j1}\rho_{\mu,\nu+1;i,2}-\delta_{i2}\rho_{\mu-1,\nu;1,j}\right)\right.\\ &\qquad\left.+\left(\alpha_-^*\delta_{j2}\rho_{\mu,\nu+1;i,1}-\delta_{i1}\rho_{\mu-1,\nu;2,j}\right)+\alpha_-\left(\delta_{j1}\rho_{\mu,\nu-1;i,2}-\delta_{i2}\rho_{\mu+1,\nu;1,j}\right)\right]\ .\end{aligned}$$

The incoherent part comprises the spontaneous decay [second line of Eq. (42.8)],

$$\begin{aligned}\langle\mu,i|\mathcal{L}_{atom-vac}\hat{\rho}|\nu,j\rangle &= -\gamma\langle\mu,i|\left[\hat{\sigma}^+\hat{\sigma}^-\hat{\rho}-2\hat{\sigma}^-\hat{\rho}\hat{\sigma}^++\hat{\rho}\hat{\sigma}^+\hat{\sigma}^-\right]|\nu,j\rangle \qquad (42.170)\\ &= -\gamma\sum_{p,u}\langle\mu,i|\hat{\sigma}^+\hat{\sigma}^-|p,u\rangle\rho_{p,\nu;u,j}+2\gamma\sum_{p,u,q,v}\langle\mu,i|\hat{\sigma}^-|p,u\rangle\rho_{p,q;u,v}\langle q,v|\hat{\sigma}^+|\nu,j\rangle.\\ &\quad-\gamma\sum_{p,u}\rho_{\mu,p;i,u}\langle p,u|\hat{\sigma}^+\hat{\sigma}^-|\nu,j\rangle\\ &= -\gamma\left[\delta_{i2}\rho_{\mu,\nu;i,j}-2\delta_{i1}\delta_{j1}\rho_{\mu,\nu;2,2}+\delta_{j2}\rho_{\mu,\nu;i,j}\right]\end{aligned}$$

and the cavity decay [third line of Eq. (42.8)],

$$\langle\mu,i|\mathcal{L}_{cavity-vac,\pm}\hat{\rho}|\nu,j\rangle = -\kappa\langle\mu,i|\hat{a}_\pm^\dagger\hat{a}_\pm\hat{\rho}-2\hat{a}_\pm\hat{\rho}\hat{a}_\pm^\dagger+\hat{\rho}\hat{a}_\pm^\dagger\hat{a}_\pm|\nu,j\rangle = 0\ . \qquad (42.171)$$

Finally, using the definition of the recoil shift $\omega_{rec} = \hbar k^2/2m$ we get,

$$\boxed{\begin{aligned}
\dot{\rho}_{\mu,\nu;1,1} &= \imath(\nu^2-\mu^2)\omega_{rec}\rho_{\mu,\nu;1,1} + 2\gamma\rho_{\mu,\nu;2,2} \\
&+ \imath\hbar g\left[-\alpha_+^*\rho_{\mu+1,\nu;2,1} + \alpha_+\rho_{\mu,\nu+1;1,2} - \alpha_-^*\rho_{\mu-1,\nu;2,1} + \alpha_-\rho_{\mu,\nu-1;2,1}\right] \\
\dot{\rho}_{\mu,\nu;1,2} &= \left[\imath(\nu^2-\mu^2)\omega_{rec} - \imath\hbar\Delta_a\right]\rho_{\mu,\nu;1,2} - \gamma\rho_{\mu,\nu;1,2} \\
&+ \imath\hbar g\left[\alpha_+^*\rho_{\mu,\nu-1;1,1} - \alpha_+^*\rho_{\mu+1,\nu;2,2} + \alpha_-^*\rho_{\mu,\nu+1;1,1} - \alpha_-^*\rho_{\mu-1,\nu;2,2}\right] \\
\dot{\rho}_{\mu,\nu;2,1} &= \left[\imath(\nu^2-\mu^2)\omega_{rec} + \imath\hbar\Delta_a\right]\rho_{\mu,\nu;2,1} - \gamma\rho_{\mu,\nu;2,1} \\
&- \imath\hbar g\left[\alpha_+\rho_{\mu-1,\nu;1,1} - \alpha_+\rho_{\mu,\nu+1;2,2} + \alpha_-\rho_{\mu+1,\nu;1,1} - \alpha_-\rho_{\mu,\nu-1;2,2}\right] \\
\dot{\rho}_{\mu,\nu;2,2} &= \imath(\nu^2-\mu^2)\omega_{rec}\rho_{\mu,\nu;2,2} - 2\gamma\rho_{\mu,\nu;2,2} \\
&+ \imath\hbar g\left[\alpha_+^*\rho_{\mu,\nu-1;2,1} - \alpha_+\rho_{\mu-1,\nu;1,2} + \alpha_-^*\rho_{\mu,\nu+1;2,1} - \alpha_-\rho_{\mu+1,\nu;1,2}\right] \\
\dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm + \eta_\pm - \imath g\sum_\nu \rho_{\nu\mp1,\nu;1,2}
\end{aligned}} \tag{42.172}$$

We note $\hat{\rho}_{\mu,\nu;2,1} = \hat{\rho}^*_{\nu,\mu;1,2}$.

The equations (42.172) form a set a equations to describe the quantized CARL without adiabatic elimination. And as shown in the derivation of the CARL equations (42.25), they contain radiation pressure. In Exc. 42.4.7.4 we study the quantized CARL Maxwell-Bloch equations without adiabatic elimination of the excited state for a three-level system.

42.4.4 Quantized motion with many particles

The Hamiltonian (42.144) holds for a single atom. If clouds of thermal atoms are considered, we may switch to a classical description of the motion, as done in (42.46). In the case of very cold (below the recoil limit) but still independent atoms, we may assume that they all are coherently distributed over the same momentum states. We may then apply a unique momentum state expansion for all atoms, as shown in the subsequent section.

If on the other hand quantum statistics play a role, then we need to replace the wavefunction in the Schrödinger equation (42.144) by field operators, as done in Sec. 47.5. In the following sections, we will restrict to single atoms that can be in a coherent superposition of momentum states or many atoms in a matter wave that can be treated as a c-number, e.g. a Bose-condensate without fluctuations.

42.4.4.1 Modal expansion of the motion of many independent atoms in the adiabatic approximation for one-sided pumping

Our starting point is the quantum version of the CARL equations (42.25), where we neglect spontaneous emission, $\gamma_0 = 0$. Setting $\alpha_+ = \eta_+/\kappa$ and $\eta_- = 0$ we get,

$$\boxed{\begin{aligned}
\dot{\hat{a}}_- &= (-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_- - \imath U_0\tfrac{\eta_+}{\kappa}e^{-2\imath k\hat{z}_j} \\
m\ddot{\hat{z}}_j &= 2\imath\hbar k U_0(\hat{a}_+^\dagger\hat{a}_- e^{-2\imath k\hat{z}_j} - \hat{a}_+\hat{a}_-^\dagger e^{2\imath k\hat{z}_j})
\end{aligned}}, \tag{42.173}$$

where the index j runs over all atoms. For this case, the total momentum is a constant of motion for N atoms is,

$$[\hat{H}, 2\hbar k\hat{a}_-^\dagger \hat{a}_- + \sum_{j=1}^{N} \hat{p}_j] = 0 \ . \tag{42.174}$$

where the Hamiltonian is obtained from (42.26) by eliminating the mode α_+ and summing over all atoms,

$$\hat{H} = \sum_j \left[\frac{\hat{p}_j^2}{2m} + \frac{\eta_+}{\kappa} U_0 \left(e^{-2\imath k\hat{z}_j} \hat{a}_- + e^{2\imath k\hat{z}_j} \hat{a}_-^\dagger \right) \right] + (U_0 - \Delta_c)\hat{a}_-^\dagger \hat{a}_- \ . \tag{42.175}$$

To treat the motion as being quantized we define a base $|\nu\rangle_j$,

$$\hat{p}_j|\nu\rangle_j = 2\hbar k\nu|\nu\rangle_j \qquad \text{and} \qquad |\psi(z_j)\rangle = \sum_\nu c_{j,\nu}|\nu\rangle_j \ , \tag{42.176}$$

and calculate the expected value of the equations (42.173) regarding the atomic motion,

$$\begin{aligned} \frac{d\hat{a}_-}{dt} &= (-\kappa - \imath\Delta_c)\hat{a}_- - \imath U_0 \tfrac{\eta_+}{\kappa} \sum_j \langle\psi(z_j)|e^{-2\imath k\hat{z}_j}|\psi(z_j)\rangle \\ &= (-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_- - \imath U_0 \tfrac{\eta_+}{\kappa} \sum_{j,\mu,\nu} c_{j,\mu}^* c_{j,\nu\, j} \langle\mu|e^{-2\imath k z_j}|\nu\rangle_j \\ &= (-\kappa + \imath\Delta_c - \imath U_0)\hat{a}_- - \imath U_0 \tfrac{\eta_+}{\kappa} \sum_{j,\nu} c_{j,\nu}^* c_{j,\nu+1} \ . \end{aligned} \tag{42.177}$$

We do not use the second equation (42.173), but instead we use the Schrödinger equation $\imath\hbar\frac{d|\psi(z_j\rangle}{dt} = \hat{H}|\psi(z_j)\rangle$, which yields,

$$\begin{aligned} \imath\hbar \sum_\nu \frac{dc_{j,\nu}}{dt}|\nu\rangle_j = \sum_\nu \frac{1}{2m} p_j^2 c_{j,\nu}|\nu\rangle_j + \hbar\Delta_c \hat{a}_-^\dagger \hat{a}_- \sum_\nu c_j(\nu)|\nu\rangle_j \\ + \hbar U_0 \eta \sum_\nu (\hat{a}_-^\dagger e^{-2\imath k z_j} + \hat{a}_- e^{2\imath k z_j}) c_{j,\nu}|\nu\rangle_j \ . \end{aligned} \tag{42.178}$$

Projecting on ${}_j\langle\mu|$, we obtain [278],

$$\boxed{\begin{aligned} \dot{c}_{j,\mu} &= -4\imath\omega_{rec}\mu^2 c_{j,\mu} - \imath\Delta_c \hat{a}_-^\dagger \hat{a}_- c_{j,\mu} - \imath U_0 \eta [\hat{a}_-^\dagger c_{j,\mu+1} + a_- c_{j,\mu-1}] \\ \dot{\hat{a}}_- &= -(\kappa + \imath\Delta_c)\hat{a} + N U_0 \eta \sum_\nu c_{j,\nu}^* c_{j,\nu+1} \end{aligned}} \ , \tag{42.179}$$

where we took the expectation value of Eq. (42.177). The equations (42.179) can be used for numerical simulations [1102].

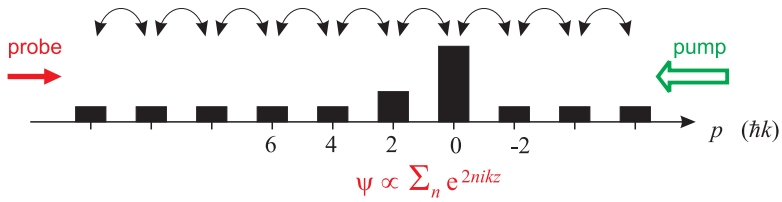

Figure 42.36: Probe light and 'bunching' when the temperature is raised.

42.4.4.2 Equations for the density matrix

The equations (42.179) allow to calculate the derivatives of the density matrix given by,

$$\varrho_{\mu,\nu} \equiv e^{-\imath(\mu-\nu)\Delta_c t}\frac{1}{N}\sum_j c_j^*(\mu)c_j(\nu)\ , \tag{42.180}$$

yielding,

$$\begin{aligned}\frac{d\varrho_{\mu,\nu}}{dt} &= e^{-\imath(\mu-\nu)\Delta_a t}N^{-1}\sum_j\left(\dot{c}^*_{j,\mu}c_{j,\nu}+c^*_{j,\mu}\dot{c}_{j,\nu}-\Delta_c c^*_{j,\mu}c_{j,\nu}\imath(\mu-\nu)\right) \\ &= e^{-\imath(\mu-\nu)\Delta_a t}N^{-1}\sum_j[\imath\omega_r(\mu^2-\nu^2)-\Delta_c\imath(\mu-\nu)]c^*_{j,\mu}c_{j,\nu}+ \\ &\quad +\imath U_0\eta\left[ac^*_{j,\mu+1}c_{j,\nu}-ac^*_{j,\mu}c_{j,\nu-1}+\hat{a}^\dagger c^*_{j,\mu-1}c_{j,\nu}-\hat{a}^\dagger c^*_{j,\mu}c_{j,\nu+1}\right]\ .\end{aligned} \tag{42.181}$$

Introducing $\tilde{a}\equiv ae^{\imath\Delta_c t}$ we finally obtain,

$$\boxed{\begin{aligned}\frac{d\varrho_{\mu,\nu}}{dt} &= \imath(\mu-\nu)[\omega_r(\mu+\nu)-\Delta_c]\varrho_{\mu,\nu} \\ &+ \imath U_0\eta\left[\tilde{a}(\varrho_{\mu+1,\nu}-\varrho_{\mu,\nu-1})+\tilde{a}^\dagger(\varrho_{\mu-1,\nu}-\varrho_{\mu,\nu+1})\right] \\ \frac{d\tilde{a}}{dt} &= -\kappa\tilde{a}-\imath NU_0\eta\sum_\nu\varrho_{\nu,\nu+1}\end{aligned}}\ . \tag{42.182}$$

These are the CARL equations for the density matrix. In 42.4.7.3 we show an alternative derivation obtained by directly inserting the adiabatically simplified Hamiltonian (42.26) into the Liouville equation (42.8).

We note, that $\sum_\nu \varrho_{\nu,\nu+1}$ is the 'bunching' and that $\varrho^*_{\mu,\nu}=\varrho_{\nu,\mu}$. The average moment is given by $\langle p\rangle=\sum_\nu \nu\varrho_{\nu,\nu}$. In the Figs. 42.37 and 42.38 we show simulations in the semi-classical regimes $\rho\gg 1$ in the 'bad-cavity' limit, $\kappa>1$, and the 'good-cavity' limit $\kappa\ll 1$.

Here are some movies illustrating the quantum CARL dynamics, simulated using the momentum state expansion (watch movie) and (watch movie). The following dynamics were calculated via direct integration of the Schrödinger equation without momentum state expansion: Bloch oscillations (watch movie), CARL dynamics (watch movie), and joint Bloch and CARL dynamics (watch movie). See also (watch talk).

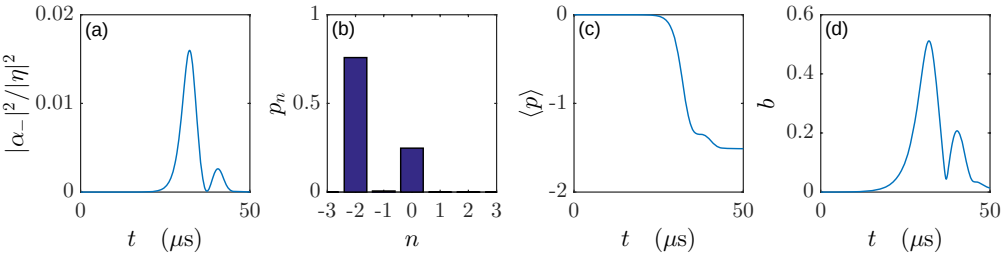

Figure 42.37: (code) Simulation of the CARL equation (42.179) in the superradiant, semi-classical, 'bad-cavity' regime for $\kappa_c = 4$, $\rho = 4$, $\Delta_c = 0$.

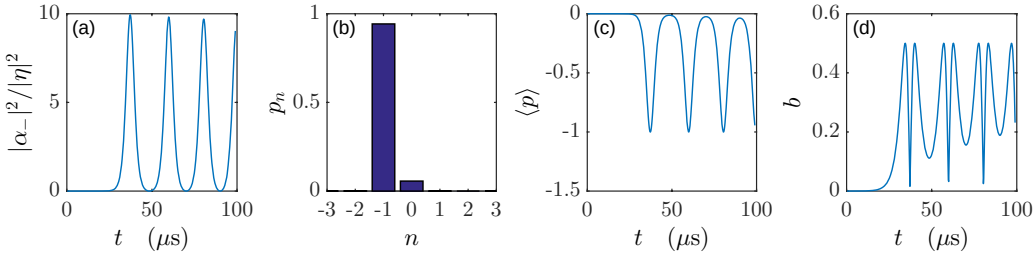

Figure 42.38: (code) Simulation of the CARL equation (42.179) in the superradiant, semi-classical, 'good-cavity' regime for $\kappa_c = 0.02$, $\rho = 4$, $\Delta_c = 0$.

42.4.5 Approximation for a bimodal momentum distribution

We observe that in the quantum regime the momentum distribution of the matter wave is bimodal, that is, only two momentum states are simultaneously populated. This justifies a simplification of the equations (42.182), assuming that at a given time, atoms must either be in a specific state $|\mu\rangle_j$ or in a superposition of this state is an adjacent state $|\mu-1\rangle_j$. Hence,

$$\begin{aligned}
\frac{d\varrho_{\mu,\mu}}{dt} &= -\imath U_0\eta(\tilde{a}\varrho_{\mu,\mu-1} - \tilde{a}^\dagger\varrho_{\mu-1,\mu}) = -\frac{d\varrho_{\mu-1,\mu-1}}{dt} \\
\frac{d\varrho_{\mu-1,\mu}}{dt} &= -\imath[(2\mu-1)\omega_r - \Delta_c]\varrho_{\mu-1,\mu} + \imath U_0\eta\tilde{a}(\varrho_{\mu,\mu} - \varrho_{\mu-1,\mu-1}) \\
\frac{d\tilde{a}}{dt} &= -\imath N U_\mu\eta\varrho_{\mu-1,\mu} - \kappa_c\tilde{a}\ .
\end{aligned} \tag{42.183}$$

Introducing the coherence $S_\mu = \varrho_{\mu-1,\mu}$ and the inversion $W_\mu = \varrho_{\mu,\mu} - \varrho_{\mu-1,\mu-1}$ and postulating the normalization $1 = \varrho_{\mu,\mu} + \varrho_{\mu-1,\mu-1}$,

$$\begin{aligned}
\frac{dW_\mu}{dt} &= -2\imath U_0\eta(\tilde{a}S_\mu^* - \tilde{a}^\dagger S_\mu) \\
\frac{dS_\mu}{dt} &= -\imath[(2\mu-1)\omega_r - \Delta_c]S_\mu + \imath U_0\eta\tilde{n}aW_\mu \\
\frac{d\tilde{a}}{dt} &= -\imath N U_0\eta S_\mu - \kappa_c\tilde{a}\ .
\end{aligned} \tag{42.184}$$

42.4.5.1 Linearization and stability analysis

We assume that the atoms are initially 'bunched' in a specific state $|\mu\rangle_j$. Only adjacent momentum states are coupled,

$$\begin{aligned}
\frac{d\varrho_{\mu+1,\mu}}{dt} &= \imath[\omega_r(2\mu+1)-\Delta_c]\varrho_{\mu+1,\mu} + \imath U_0\eta\tilde{a}^\dagger(\varrho_{\mu,\mu}-\varrho_{\mu+1,\mu+1}) \\
\frac{d\varrho_{\mu-1,\mu}}{dt} &= -\imath[\omega_r(2\mu-1)-\Delta_c]\varrho_{\mu-1,\mu} + \imath U_0\eta\tilde{a}(\varrho_{\mu,\mu}-\varrho_{\mu-1,\mu-1}) \\
\frac{d\tilde{a}}{dt} &= -\imath NU_0\eta(\varrho_{\mu,\mu+1}+\varrho_{\mu-1,\mu}) - \kappa_c\tilde{a}\ .
\end{aligned} \tag{42.185}$$

Conjugate the upper equation and build the sum and difference, $B_\mu \equiv \varrho_{\mu,\mu+1}+\varrho_{\mu-1,\mu}$ and $D_\mu \equiv \varrho_{\mu,\mu+1}-\varrho_{\mu-1,\mu}$,

$$\begin{aligned}
\frac{dB_\mu}{dt} &= \imath(\Delta_c - 2\mu\omega_r)B_\mu - \imath\omega_\mu D_\mu + \imath U_0\eta\tilde{a}(\varrho_{\mu+1,\mu+1}-\varrho_{\mu-1,\mu-1}) \\
\frac{dD_\mu}{dt} &= \imath(\Delta_c - 2\mu\omega_r)D_\mu - \imath\omega_r B_\mu - 2\imath U_0\eta\tilde{a} + \imath U_0\eta\tilde{a}(\varrho_{\mu+1,\mu+1}-2\varrho_{\mu,\mu}+\varrho_{\mu-1,\mu-1}) \\
\frac{d\tilde{a}}{dt} &= -\imath NU_0\eta B_\mu - \kappa_c\tilde{a}\ .
\end{aligned} \tag{42.186}$$

Use $\varrho_{\mu,\mu} \simeq 1$ and abbreviate $\delta_\mu \equiv 2r\omega_\mu - \Delta_c$,

$$\begin{aligned}
\frac{dB_\mu}{dt} &= -\imath\delta_\mu B_\mu - \imath\omega_r D_\mu \\
\frac{dD_\mu}{dt} &= -\imath\omega_r B_\mu - \imath\delta_r D_\mu - 2\imath U_0\eta\tilde{a} \\
\frac{d\tilde{a}}{dt} &= -\imath NU_0\eta B_\mu - \kappa_c\tilde{a}\ .
\end{aligned} \tag{42.187}$$

Seeking solution proportional to $x \equiv \bar{x}e^{\imath(\lambda-\delta_\mu)t}$,

$$\begin{aligned}
\imath\lambda\bar{B}_\mu &= -\imath\omega_\mu\bar{D}_\mu \\
\imath\lambda\bar{D}_\mu &= -\imath\omega_\mu\bar{B}_\mu - 2\imath U_\mu\eta\bar{a} \\
\imath(\lambda-\delta_\mu)\bar{a} &= -\imath NU_0\eta\bar{B}_\mu - \kappa_c\bar{a}\ .
\end{aligned} \tag{42.188}$$

Abbreviating $\Lambda_m \equiv \delta_m + \imath\kappa_c$, the characteristic equation is,

$$\det\begin{pmatrix} \lambda & \omega_r & 0 \\ \omega_r & \lambda & 2U_0\eta \\ NU_0\eta & 0 & \lambda-\Lambda_\mu \end{pmatrix} = \lambda^3 - \Lambda_\mu\lambda^2 - \omega_r^2\lambda + \omega_r^2\Lambda_\mu + 2NU_0^2\eta^2\omega_r = 0\ . \tag{42.189}$$

The gain is given by the imaginary part of λ. We have exponential amplification if $\mathrm{Im}\,\lambda < 0$. Hence, we search for solution with the lowest imaginary value.

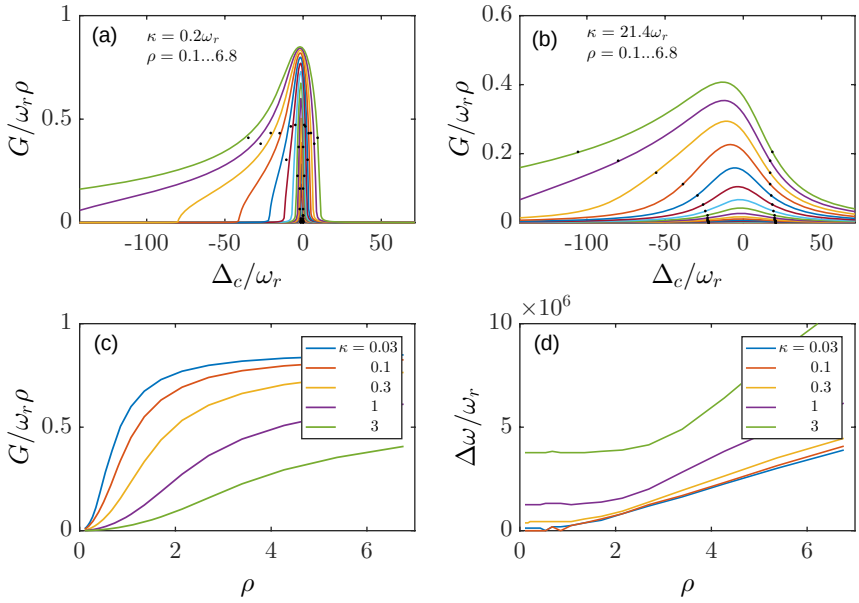

Figure 42.39: (code) Gain dependence on ρ and κ.

42.4.5.2 Universal scaling

To simplify the formulae simplify, we rescale them. We start from Eq. (42.182) and use the substitution for universal scaling,

$$\begin{aligned} \theta_j \equiv 2kz_j \quad &\text{and} \quad \bar{p}_j \equiv 2kv_j/\rho\omega_r \\ \tau \equiv \rho\omega_r t \quad &\text{and} \quad \kappa \equiv \kappa_c/\omega_r\rho \\ \bar{\lambda} \equiv \lambda/\omega_r\rho \quad &\text{and} \quad \bar{\delta}_\mu \equiv \delta_\mu/\omega_r\rho = 2\mu/\rho + \Delta_c/\omega_r\rho \\ \bar{A} \equiv (2/N\rho)^{1/2}\bar{a} \quad &\text{and} \quad \eta U_\mu \equiv \sqrt{\rho^3\omega_r^2/2N}\ . \end{aligned} \tag{42.190}$$

This reproduces the Bonifacio notation,

$$\begin{aligned} \bar{\lambda}\bar{B}_\mu + \rho^{-1}\bar{D}_\mu &= 0 \\ \bar{\lambda}\bar{D}_\mu + \rho^{-1}\bar{B}_\mu + \rho\bar{A} &= 0 \\ (\bar{\lambda} - \bar{\delta}_\mu - \imath\kappa)\bar{A} + \bar{B}_\mu &= 0\ . \end{aligned} \tag{42.191}$$

Skipping the bars, the characteristic equation reads,

$$\det \begin{pmatrix} \lambda & \rho^{-1} & 0 \\ \rho^{-1} & \lambda & \rho \\ 1 & 0 & \lambda - \delta_\mu - \imath\kappa \end{pmatrix} = (\lambda - \delta_\mu - \imath\kappa)(\lambda^2 - \rho^{-2}) + 1 = 0\ . \tag{42.192}$$

Let us first discuss the semiclassical limit, $\rho \gg 1$. In the good-cavity regime, $\kappa \simeq 0$, we may neglect the recoil shift, $2m\omega_r \to 0$, so that $\Lambda = \Delta_c$. The gain is largest

when $\Delta_c \to 0$. The characteristic equation reduces to $\lambda^3 = -1$, yielding the solutions $\lambda = 1, \frac{1}{2}(1 \pm \imath\sqrt{3})$. Hence, the gain $G = -\Im\mathfrak{m}\ \lambda$, is

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\sqrt{3} \\ \Delta\omega_G &\simeq \omega_r\rho \gg \kappa_c, \omega_r\ . \end{aligned} \tag{42.193}$$

The gain bandwidth $\Delta\omega_G$ being much larger than the recoil frequency, the Bragg condition for scattering between different momentum states is approximately fulfilled for a large number of initial momenta. I.e. although the momentum transfer is quantized, $\Delta_c = n\omega_r$, the atoms can be accelerated to high velocities. From Eq. (42.186)(a) we see $|\bar{D}_\mu/\bar{B}_\mu| = \rho|\bar{\lambda}| \gg 1$, i.e. $\varrho_{\mu,\mu+1} \simeq \varrho_{\mu-1,\mu}$.

In the superradiant regime, $\kappa > 1$, of the semiclassical limit the characteristic equation reduces to $\lambda^2 = -\imath/\kappa$, i.e. $\lambda = \pm(1-\imath)/\sqrt{2\kappa}$.[18] Hence, the gain is,

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\sqrt{2/\kappa} \\ \Delta\omega_G &\simeq \kappa_c = \omega_r\rho\kappa \gg \omega_r\ . \end{aligned} \tag{42.194}$$

In fact, the relative gain bandwidth is on the order of $\Delta\omega_G/\omega_r \simeq \rho \propto \left(nNU_0^2\right)^{1/3}$. Since recoil can be neglected we can have absorption or emission. The gain results from the difference bewteen the average rates of both.

Now we turn to the quantum limit, $\rho < 1$. In the good-cavity regime, $\kappa \simeq 0$, $\lambda = \rho^{-1} + \frac{1}{2}(\delta_m - \rho^{-1}) - \frac{1}{2}\sqrt{(\delta_m - \rho^{-1})^2 - 2\rho}$. Hence, the gain is,

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\Im\mathfrak{m}\ \sqrt{(\delta_m - \rho^{-1})^2 - 2\rho} \simeq \tfrac{1}{2}\omega_r\rho\sqrt{2\rho} \\ \Delta\omega_G &= \omega_r\rho^{3/2} < \omega_r\ . \end{aligned} \tag{42.195}$$

In fact, the relative gain bandwidth is on the order of $\Delta\omega_G/\omega_r \simeq \rho^{3/2} \propto \sqrt{nNU_0^2}$. Here recoil plays a role so that we have emission without absorption. Gain results exclusively from emission. From Eq. ((42.186)a) we see $|\bar{D}_m/\bar{B}_m| = \rho|\bar{\lambda}| \simeq 1$, i.e. $\varrho_{m,m+1} \ll \varrho_{m-1,m}$.

In the superradiant regime, $\kappa > 1$, of the quantum limit, $\lambda = \rho^{-1} + \frac{\rho}{2}[(\delta_m - \rho^{-1}) + \imath\kappa]^{-1}$. Hence,

$$\begin{aligned} G &= \tfrac{1}{2}\omega_r\rho\frac{\rho\kappa}{(\delta_m - \rho^{-1})^2 + \kappa^2} \simeq \tfrac{1}{2}\frac{\omega_r\rho^2}{\kappa} \\ \Delta\omega_G &= \kappa_c > \omega_r\rho\ . \end{aligned} \tag{42.196}$$

The various regimes may be summarized in the following phase diagram. We will see later, that each region produces qualitatively different solutions of the full (non-linearized) equations.

[18] The assertion $\Re\mathfrak{e}\ \lambda \ll \kappa$ used to simplify the characteristic equation is compatible with the solution.

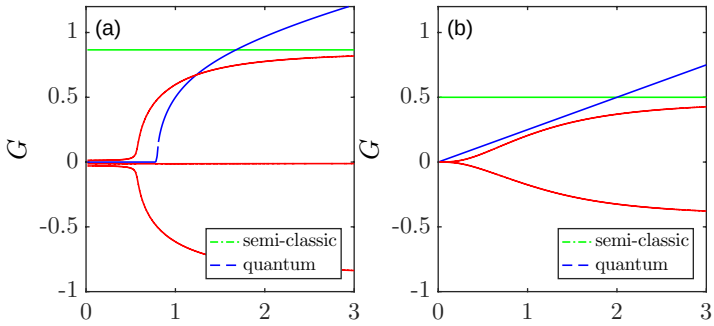

Figure 42.40: (code) Analytical approximations of the characteristic equation for the various regimes in the good-cavity limit $\kappa = 0.03$ (a) and the superradiant limit $\kappa = 2$ (b).

42.4.6 Simulation of random quantum trajectories

Spontaneous emission can induce a random walk of the atoms, which be accounted for by a proper master equation. We write the master equation for the density operator of a dissipative system, as shown in (41.74) [233, 1431],

$$\boxed{\dot{\hat{\rho}} = \imath[\hat{\rho}, \hat{H}] - \tfrac{1}{2}\sum_\mu \{\hat{\rho}, \hat{L}_\mu^\dagger \hat{L}_\mu\} + \sum_\mu \hat{L}_\mu \hat{\rho} \hat{L}_\mu^\dagger} \ . \tag{42.197}$$

The first term describes the coherent part, the second part dissipation, and the third quantum jumps. The dissipative operators $\hat{L}_\mu$ appearing in the Lindblad terms model the impact of the environment. An alternative to solving the master equation consists in simulating single trajectories of the system with a Schrödinger equation, accounting for dissipation by a non-Hermitian effective Hamiltonian and for quantum fluctuations by a stochastic noise term.

As an example, let us consider the Hamiltonian for an atom interacting with a standing wave potential,

$$\hat{H} = \frac{\hat{p}^2}{2m} + U \cos k\hat{x} \ , \tag{42.198}$$

where $\hat{p} = \hbar q \hat{\nu} = -\imath\hbar d/dx$. We define a momentum basis $|\phi(\tau_0)\rangle = \sum_\nu c_\nu |\nu\rangle$ with $\sum_\nu |c_\nu|^2 = 1$. In this basis, the momentum and the position operator can be expanded as usual,

$$\hat{p} = \hbar q \sum_{\nu=-\infty}^{\infty} \nu |\nu\rangle\langle\nu| \quad \text{and} \quad \cos k\hat{x} = \tfrac{1}{2} \sum_{\nu=-\infty}^{\infty} (|\nu+1\rangle\langle\nu| + |\nu-1\rangle\langle\nu|) \ , \tag{42.199}$$

where $\hbar q$ is the momentum transferred upon a kick. The expectation value for the momentum and the position are then,

$$\langle\hat{p}\rangle = \sum_\nu \hbar q \nu |c_\nu|^2 \qquad \text{and} \qquad \langle\cos k\hat{x}\rangle = \tfrac{1}{2}\sum_\nu (c_\nu^* c_{\nu-1} + c_\nu^* c_{\nu+1}) \ . \tag{42.200}$$

The Lindblad operators describe deceleration of the rotor. With $\mu = \pm$, we get,

$$\hat{L}_\pm = g \sum_{\nu=0}^{\infty} \sqrt{\nu+1} |\pm\nu\rangle\langle\pm\nu \pm 1| \ , \tag{42.201}$$

such that,

$$\hat{L}_\pm^\dagger \hat{L}_\pm = g^2 \sum_{\nu=0}^{\infty} \nu |\pm\nu\rangle\langle\pm\nu| \quad \text{and} \quad \hat{L}_+^\dagger \hat{L}_+ + \hat{L}_-^\dagger \hat{L}_- = g^2 \sum_{\nu=-\infty}^{\infty} |\nu|\, |\nu\rangle\langle\nu| \ . \tag{42.202}$$

Now, as we have seen in Sec. 34.5.3, we may treat the first part of the Lindblad terms in (42.197) as the dissipative part of an an *effective Hamiltonian*,

$$\boxed{\hat{H}_{eff} = \hat{H} - \tfrac{\imath}{2} \sum_\mu \hat{L}_\mu^\dagger \hat{L}_\pm} \ . \tag{42.203}$$

That is, we can attempt a *quantum Monte Carlo wavefunction simulation* of an effective Schrödinger equation.

We define the quantity $dp_\pm \equiv \langle\phi(\tau_0)|\hat{L}_\pm^\dagger \hat{L}_\pm|\phi(\tau_0)\rangle d\tau$,

$$\frac{dp_+}{d\tau} = g^2 \sum_\nu |c_\nu|^2 \quad \text{and} \quad \frac{dp_-}{d\tau} = g^2 \sum_\nu |c_{-\nu}|^2 \ . \tag{42.204}$$

To perform simulations, we start with $|\phi(\tau_0)\rangle$. After a time $d\tau$, we generate a uniform random number ζ. After infinitesimal time, we compare the random number to the accumulated probability. If $\zeta > dp_\mu$, we say that a quantum jump occurred. The new wavefunction is,

$$|\phi(\tau_0)\rangle \to \frac{\hat{L}_\pm|\phi(\tau_0)\rangle}{\|\hat{L}_\pm|\phi(\tau_0)\rangle\|} = \frac{\sum_{\nu\geq 0}\sqrt{\nu+1}c_{\pm\nu\pm1}|\nu\rangle}{\sqrt{\sum_{\nu\geq 0}\nu|c_{\pm\nu}|^2}} \ . \tag{42.205}$$

If in contrast, $\zeta < 1 - \sum_\mu dp_\mu$, then the system continues to evolve slowly. However, dissipation losses have to be compensated by renormalization,

$$|\phi(\tau_0)\rangle \to \frac{(1 - \frac{\imath}{\hbar}\hat{H}_{eff}dt)|\phi(\tau_0)\rangle}{\sqrt{1 - \sum_k dp_k}} \ , \tag{42.206}$$

where the evolution is

$$\begin{aligned}
(|\phi(dt)\rangle &= 1 - \imath\hat{H}_{eff}dt/\hbar)|\phi(\tau_0)\rangle \qquad (42.207)\\
&= \left(1 - \tfrac{\imath}{\hbar}dt\frac{\hat{p}^2}{2m} - \tfrac{\imath}{\hbar}dtU\cos k\hat{x} - \tfrac{1}{2\hbar}dt\sum_\pm \hat{L}_\pm^\dagger \hat{L}_\pm\right)\sum_\nu c_\nu|\nu\rangle\\
&= \sum_\nu c_\nu|\nu\rangle - \tfrac{\imath}{\hbar}dt\tfrac{1}{2}\sum_\nu c_\nu\hbar^2\nu^2|\nu\rangle - \tfrac{\imath}{\hbar}dt\tfrac{1}{2}\sum_\nu c_\nu U(|\nu+1\rangle + |\nu-1\rangle)\\
&\quad - \frac{g^2}{2\hbar}dt\sum_{\nu\geq 0}\nu(c_\nu|\nu\rangle + c_{-\nu}|-\nu\rangle)\\
&= |\phi(\tau_0)\rangle - \frac{\imath}{2\hbar}dt\sum_\nu c_\nu\left[\nu(\hbar^2\nu - \imath g^2)|\nu\rangle + U|\nu+1\rangle + U|\nu-1\rangle\right] \ .
\end{aligned}$$

With this we can now follow the evolution of observables, such as $\langle\phi(t)|\nu\rangle\langle\nu|\phi(t)\rangle$, $\langle\phi(t)|\hat{p}|\phi(t)\rangle$, and $\langle\phi(t)|\cos k\hat{x}|\phi(t)\rangle$, in time.

42.4.7 Exercises

42.4.7.1 Ex: Quantized CARL equations in the presence of a constant external force

a. Generalize the quantized CARL equations (42.146), respectively, (42.160) for the presence of a constant external force.
b. Now, we consider a unidirectionally pumped ring cavity, with the pump laser locked to a cavity mode, in the presence of an external periodic potential. Show that this system is equivalent to CARL in a ring cavity pumped from both sides.

Solution: *a. The procedure is analogous to [1138] when we remove the external potential, but consider the dynamics of both counterpropagating modes. We simply add the external potential to the equations of motion (42.146),*

$$\begin{aligned} \imath\hbar\frac{d}{dt}\psi(z) &= -\frac{\hbar^2}{2m}\frac{d^2}{dz^2}\psi(z) + \hbar U_0\left(\alpha_+^*\alpha_- e^{-2\imath kz} + \alpha_+\alpha_-^* e^{2\imath kz}\right)\psi(z) - maz\psi(z) \\ \dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm + \imath U_0\alpha_\mp\int dz|\psi(z)|^2 e^{\mp 2\imath kz} + \eta_\pm \end{aligned} \quad .$$

With the unitary transformation $\psi = \tilde{\psi}e^{\imath maz t/\hbar}$ the Schrödinger equation simplifies to,

$$\dot{\tilde{\psi}}(z) = \frac{\imath\hbar}{2m}\left(\frac{d}{dz} + \frac{\imath mat}{\hbar}\right)^2\tilde{\psi}(z) - \imath U_0\left(\alpha_+^\dagger\alpha_- e^{-2\imath kz} + \alpha_+\alpha_-^\dagger e^{2\imath kz}\right)\tilde{\psi}(z) \ ,$$

and with the mode expansion $\tilde{\psi} = \frac{1}{\sqrt{2\pi}}\sum_\nu c_\nu(t)e^{2\imath\nu kz}$, we obtain,

$$\begin{aligned} \dot{c}_\nu &= -4\imath\omega_{rec}(\nu + \nu_{blo}t)^2 c_\nu - \imath U_0\left(\alpha_+^*\alpha_- c_{\nu+1} + \alpha_+\alpha_-^* c_{\nu-1}\right) \\ \dot{\alpha}_\pm &= (-\kappa + \imath\Delta_c - \imath U_0)\alpha_\pm - \imath U_0\alpha_\mp\sum_\nu c_{\nu\mp1}^* c_\nu + \eta_\pm \end{aligned} \quad ,$$

where,

$$\nu_{blo} \equiv \frac{ma}{2\hbar k}$$

is the so-called Bloch oscillation frequency. A simulation of such Bloch oscillations is exhibited in Figs. 42.41. See also Fig. 26.5.
b. The starting point is [1138],

$$\begin{aligned} \imath\hbar\frac{d}{dt}\psi &= -\frac{\hbar^2}{2m}\frac{d^2}{dz^2}\psi + \hbar U_0(\alpha_+^*\alpha_- e^{2\imath kz} + \alpha_+\alpha_-^* e^{-2\imath kz})\psi - maz\psi + \frac{\hbar W_0}{2}\sin(2kz+\phi)\psi \\ \alpha_+ &= \frac{\eta_+}{\kappa} \\ \dot{\alpha}_- &= -\kappa\alpha_- + NU_0\alpha_+\int|\psi|^2 e^{-2\imath kz}dz \ , \end{aligned}$$

where we used that the laser is locked to a cavity mode, $\Delta_c = U_0$. Introducing $\tilde{\alpha}_- - \alpha_- = \alpha_0 \equiv e^{2\imath\phi}W_0/4U_0$ and $\psi = \tilde{\psi}e^{\imath maz t/\hbar}$, we simplify the first and third

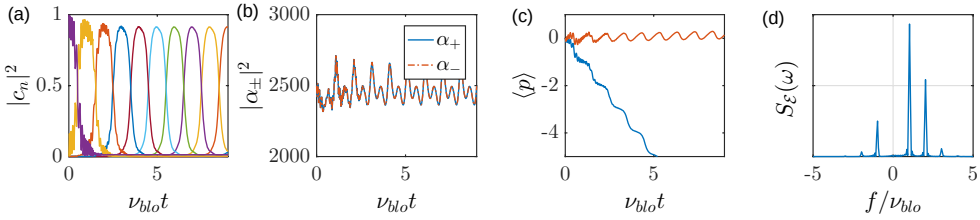

Figure 42.41: (code) Simulation of the coupled atom-ring cavity dynamics for symmetric pumping and in the presence of gravity. (a) Momentum state populations $|c_\nu|^2$, (b) photon numbers $|\alpha_\pm|^2$ in the counterpropagating cavity modes, and (c) Spectrum of the cavity modes. The parameters are $N = 20000$, $\omega_{rec} = (2\pi)\ 4.8\,\mathrm{kHz}$, $\nu_{blo} = 0.05\omega_{rec}$, $\kappa = 90\omega_{rec}$, $U_0 = -0.00035\omega_{rec}$, and $\eta_\pm = 4500\omega_{rec}$.

equation to,

$$\imath\hbar\frac{d}{dt}\tilde{\psi} = -\frac{\hbar^2}{2m}\frac{d^2}{dz^2}\tilde{\psi} + \hbar U_0(\alpha_+^*\tilde{\alpha}_- e^{2\imath kz} + \alpha_+\tilde{\alpha}_-^* e^{-2\imath kz})\tilde{\psi}$$
$$\dot{\tilde{\alpha}}_- = -\kappa(\tilde{\alpha}_- - \alpha_0) + NU_0\alpha_+\int |\tilde{\psi}|^2 e^{-2\imath kz}dz\ .$$

With the definition $\eta_- \equiv \kappa\alpha_0$, the last equation can be simplified to,

$$\dot{\tilde{\alpha}}_- = -\kappa\tilde{\alpha}_- + NU_0\alpha_+\int |\tilde{\psi}|^2 e^{-2\imath kz}dz + \eta_-\ .$$

The expansion into momentum states demonstrated in part (a) yields the final set of equations,

$$\dot{c}_\nu = -4\imath\omega_{rec}(\nu + \nu_{blo}t)^2 c_\nu - \imath U_0\frac{\eta_+}{\kappa}\left(\tilde{\alpha}_- c_{\nu+1} + \tilde{\alpha}_-^* c_{\nu-1}\right)$$
$$\dot{\tilde{\alpha}}_- = -\kappa\tilde{\alpha}_- + \imath U_0\frac{\eta_+}{\kappa}\sum_\nu c_\nu^* c_{\nu\pm1} + \eta_-\ ,$$

where the ration between the Bloch and CARL coupling strength is given by,

$$\frac{W_0}{U_0} = \frac{\eta_- e^{-2\imath\phi}}{\kappa}\ .$$

A simulation of these equations yields very similar results to the ones exhibited in Fig. 42.41, except that the cavity mode α_+ now is fixed.

42.4.7.2 Ex: Competition between CARL and Bloch oscillations

Reproduce the simulations of [1138].

Solution: *The result is exhibited in Fig. ??.*

42.4.7.3 Ex: Alternative derivation of the Maxwell-Bloch with adiabatic elimination

Derive the directly from the Liouville equation (42.8) using the Hamiltonian (42.26) in adiabatic elimination.

Solution: *Inserting the Hamiltonian into the Liouville equation we get,*

$$\begin{aligned}
\langle\mu|\dot{\hat{\rho}}|\nu\rangle &= -\imath\langle\mu|[\hat{H},\hat{\rho}]|\nu\rangle \\
&= -\imath\sum_q \langle\mu|\hat{H}|q\rangle\rho_{q,\nu} + \imath\sum_q \rho_{\mu,q}\langle q|\hat{H}|\nu\rangle \\
&= -\imath\left[\frac{(\mu\hbar k)^2}{2m} + (U_0-\Delta_c)(|\alpha_+|^2+|\alpha_-|^2) - \imath\eta_+(\alpha_+-\alpha_+^*) - \imath\eta_-(\alpha_- - \alpha_-^*)\right]\rho_{\mu,\nu} \\
&- \imath U_0\sum_q\left(\alpha_+^*\alpha_-\langle\mu|e^{-2\imath k\hat{z}}|q\rangle + \alpha_-^*\alpha_+\langle\mu|e^{2\imath k\hat{z}}|q\rangle\right)\rho_{q,\nu} \\
&+ \imath\left[\frac{(\nu\hbar k)^2}{2m} + (U_0-\Delta_c)(|\alpha_+|^2+|\alpha_-|^2) - \imath\eta_+(\alpha_+-\alpha_+^* - \imath\eta_-(\alpha_- - \alpha_-^*)\right]\rho_{\mu,\nu} \\
&+ \imath U_0\sum_q\left(\alpha_+^*\alpha_-\langle q|e^{-2\imath k\hat{z}}|\nu\rangle + \alpha_-^*\alpha_+\langle q|e^{2\imath k\hat{z}}|\nu\rangle\right)\rho_{\mu,q} \\
&= \imath(\nu^2-\mu^2)\omega_{rec}\rho_{\mu,\nu} + 2\imath U_0\left[\alpha_+^*\alpha - (\rho_{\mu,\nu-1}-\rho_{\mu+1,\nu}) + \alpha_-^*\alpha_+(\rho_{\mu,\nu+1}-\rho_{\mu-1,\nu})\right] .
\end{aligned}$$

Transforming $\tilde{\rho}_{\mu,\nu} \equiv e^{\imath(\mu-\nu)\Delta_c t}\rho_{\mu,\nu}$,

$$\begin{aligned}
\langle\mu|\dot{\tilde{\rho}}|\nu\rangle &= \langle\mu|\dot{\hat{\rho}}|\nu\rangle + \imath(\mu-\nu)\Delta_c\langle\mu|\hat{\rho}|\nu\rangle \\
&= \imath(\nu-\mu)\left[(\nu+\mu)\omega_{rec} - \Delta_c\right]\rho_{\mu,\nu} \\
&+ \imath U_0\left[\alpha_+^*\alpha_-(\rho_{\mu,\nu-1}-\rho_{\mu+1,\nu}) + \alpha_-^*\alpha_+(\rho_{\mu,\nu+1}-\rho_{\mu-1,\nu})\right] .
\end{aligned}$$

The incoherent part is,

$$\langle\mu|\mathcal{L}_{atom-vac}|\nu\rangle = 0 = \langle\mu|\mathcal{L}_{cavity-vac,\pm}|\nu\rangle .$$

42.4.7.4 Ex: Maxwell-Bloch equations without adiabatic elimination

Derive the Maxwell-Bloch equations for a three-level system coupled to a ring cavity without adiabatic elimination, but with quantized motion.

Solution: *We start from (42.15), generalize for three electronic levels, consider classical fields* $\hat{a} = \alpha$*, convert to matter wave description, and perform modal expansion,*

$$\hat{\rho}_{motion}\otimes\hat{\rho}_{atom} = |\mu\rangle\langle\nu|\otimes|\imath\rangle\langle j| \qquad with \qquad \mu,\nu\in\mathbb{Z} \qquad and \qquad i,j = 1,2,3 .$$

Expand,

$$|\psi(z,t)\rangle = \tfrac{1}{\sqrt{2\pi}}\sum_\nu c_\nu(t)e^{2\imath\nu kz}|\imath\rangle = \tfrac{1}{\sqrt{2\pi}}\sum_{\nu,i} c_{\nu,i}(t)e^{2\imath\nu kz}|\nu,\imath\rangle .$$

The only quantized degrees of freedom subject to dissipation is the atomic excitation (via spontaneous emission Γ). The optical field modes, which are also dissipated (via cavity decay κ), are treated classically. And the atomic motion is not damped. Hence, it should be sufficient to treat the atomic excitation by Bloch equations and the atomic motion by a Schrödinger equation,

42.4.7.5 Ex: Linearized quantum CARL

Analyze the quantum CARL according to [1038].

Solution: *The result is shown in Fig. 42.42.*

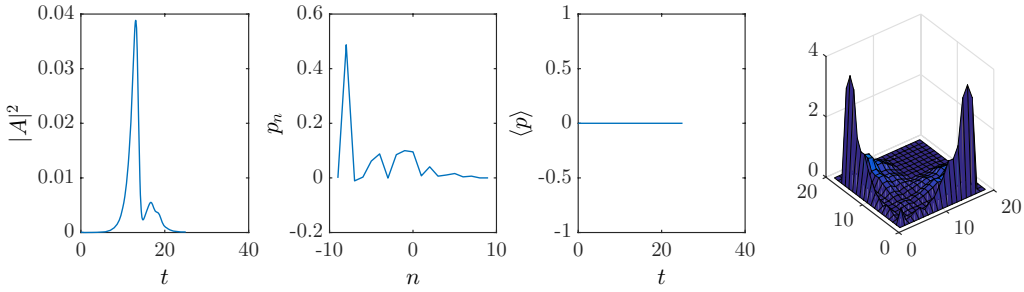

Figure 42.42: (code) Quantum CARL according to [1038].

42.5 Quantized light interacting with atoms moving in cavities

Cavity QED has been studied extensively in the context of the Jaynes-Cummings model in Sec. 35.4 and of cooperative scattering in Sec. 40.2, however, without addressing the issue of atomic motion which, via photonic recoil, inevitably influences the dynamics. We also started a discussion on the role of photonic recoil in Sec. 38.3, which will be continued in the following sections in the context of ring cavities,

$$\dot{c}_{n_+,n_-,i} = \frac{d}{dt}\langle \mathbf{r}, \alpha_+, \alpha_-, i|\psi(t)\rangle = \langle \mathbf{r}, \alpha_+, \alpha_-, i|\frac{-\imath}{\hbar}\hat{H}|\psi(t)\rangle \tag{42.208}$$
$$\dot{\alpha}_\pm = \langle\psi(t)|\dot{a}_\pm|\psi(t)\rangle = \langle\psi(t)|\tfrac{\imath}{\hbar}[\hat{H},\hat{a}_\pm] - \kappa\hat{a}_\pm|\psi(t)\rangle \ .$$

Concretely, we will be using the Hamiltonian (42.26), obtained after adiabatic elimination of the excited state.

42.5.1 QED in ring cavities

Macroscopic high-finesse ring cavities interacting with a cloud of cold atoms allowed to enter the regime of strong collective coupling. However, new interesting aspects arise from the regime of strong coupling on the level of individual atoms.

Todays research projects on cold atoms in cavities are essential divided into two classes, each class realizing an opposite regime: Cavity quantum electrodynamics (CQED) experiments as they are done by the groups of Rempe [758] and Kimble use microcavities having mode volumes so small that few photons give rise to macroscopic field strength. In such cavities the atom-field coupling is made to exceed all other decay rates. The other regime is that of cavity-cooling mainly investigated by Vuletic at the MIT and, in the case of ring cavities, of the collective atomic recoil laser (CARL) realized in the Tübingen research group. In this second regime the cavities are so large that the light fields can be considered as classical.

An interesting question is, whether the two regimes can be married to realize a system, where collective effects and entanglement between optical and atomic modes can be observed. The central idea is not to increase the coupling strength by reducing the mode volume, but to reduce the decay rates, in particular the natural linewidth of the atomic transition by choosing an atomic species that can be laser-cooled on a narrow intercombination line.

Example 275 (*CQED by reducing the ring cavity mode volume*): Technically a ring cavity design with $(w, L, F) = (30\,\mu\text{m}, 4\,\text{cm}, 200000)$ is feasible. This is enough to get below the critical atom number, but this is not sufficient to get into the CQED regime. Reducing Γ seems unavoidable.
The isotope ^{88}Sr posses a narrow transition which can be used for optical cooling. The following table compares the various systems, i.e. a CQED example taken from Rempe, the macroscopic ring cavity with rubidium used in our Tübingen CARL experiments and a cavity tuned close to the strontium intercombination line.

experiment	Rempe, Rb	Tübingen, Rb	São Carlos, Sr
Γ	$(2\pi)6$ MHz	$(2\pi)6$ MHz	$(2\pi)7.6$ kHz
F	440000	80000	200000
κ	$(2\pi)0.7$ MHz	$(2\pi)22$ kHz	$(2\pi)19$ kHz
w	29 µm	100 µm	30 µm
L	500 µm	8.5 cm	4 cm
g	$(2\pi)4$ MHz	$(2\pi)88$ kHz	$(2\pi)13$ kHz
N_{crit}	0.5	34	1.6
n_{sat}	1.1	2312	0.16

With $N = 10^4$ the cooperativity parameter N/N_{crit} is in all cases well above 1.

42.5.2 Description of quantized light fields in cavities

In order to calculate the evolution of photon distributions in the counter-propagating modes $\hat{a}_\pm$ of a ring cavity, we develop CARL in a Fock basis. For simplicity, we first consider the *motion of a single atom as classical* and fixed (i.e. not as a degree of

freedom), and we apply the adiabatic approximation. I.e. we have only two quantized degrees of freedom, which we organize like,

$$|\psi\rangle = \cancel{|\nu\rangle_{motion}}^{\text{classical}} \otimes \cancel{|i\rangle_{electron}}^{\text{adiab.elim.}} \otimes |n\rangle_+ \otimes |n\rangle_- \to |n_+, n_-\rangle \ , \quad (42.209)$$

Expanding the fields into Fock states,

$$\boxed{|\psi\rangle = \sum_{n_+,n_-} c_{n_+,n_-} |n_+, n_-\rangle} \ , \quad (42.210)$$

the field operators and the density matrix read,

$$\begin{aligned} \hat{a}_+ &= \sum_{n_+} \sqrt{n_+}|n_+ - 1\rangle\langle n_+| \otimes \mathbb{I} = \sum_{n_+,n_-} \sqrt{n_+}|n_+ - 1, n_-\rangle\langle n_+, n_-| \quad (42.211) \\ \hat{a}_- &= \mathbb{I} \otimes \sum_{n_-} \sqrt{n_-}|n_- - 1\rangle\langle n_-| = \sum_{n_+,n_-} \sqrt{n_+}|n_+ - 1, n_-\rangle\langle n_+, n_-| \\ \hat{\rho} &= |\psi\rangle\langle\psi| = \sum_{m_+,m_-,n_+,n_-} c^*_{m_+,m_-} c_{n_+,n_-} |m_+, m_-\rangle\langle n_+, n_-| \ . \end{aligned}$$

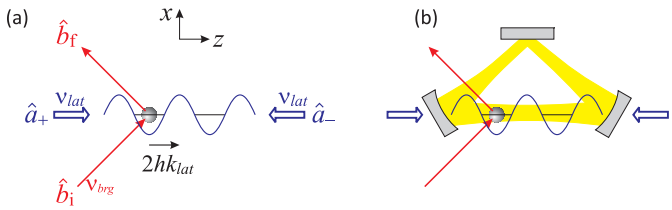

Figure 42.43: (a) Bragg scattering at a 1D optical lattice. (b) Same as in (a), but now the optical lattice is generated by the mode of an optical ring cavity.

Note that the master equation using the Lindbladt operator traces over the reservoir. Hence, the master equation only treats the cavity modes, but does not allow predictions on the quantum behavior of outcoupled fields. In order to describe e.g. quantum correlations in output field, one needs an input-output theory [283, 488].

In the case of classical motion quantum light fields,

$$\boxed{\begin{aligned} \dot{c}_{n_+,n_-} &= \imath(\Delta_c - U_0)(n_+ + n_-)\, c_{n_+,n_-} \\ &- \imath U_0 \left(e^{-2\imath kz} \sqrt{n_+(n_- + 1)}\, c_{n_+-1,n_-+1} - e^{2\imath kz} \sqrt{(n_+ + 1)n_-}\, c_{n_++1,n_--1} \right) \\ &- \eta_+ \left(\sqrt{n_+ + 1}\, c_{n_++1,n_-} - \sqrt{n_+}\, c_{n_+-1,n_-} \right) \\ &- \eta_- \left(\sqrt{n_- + 1}\, c_{n_+,n_-+1} - \sqrt{n_-}\, c_{n_+,n_--1} \right) \\ \dot{z} &= 2\imath\hbar k U_0 \sum_{n_+,n_-} \left(e^{-2\imath kz} \sqrt{(n_+ + 1)n_-}\, c^*_{n_++1,n_--1} c_{n_+,n_-} \right. \\ &\qquad \left. - e^{2\imath kz} \sqrt{n_+(n_- + 1)}\, c^*_{n_+-1,n_-+1} c_{n_+,n_-} \right) \end{aligned}} \ . \quad (42.212)$$

42.5.3 Photon backscattering for fixed atomic position

To tackle the problem of quantized light field we first assume an atom fixed in space, that is, we completely *disregard the motional degree of freedom* by setting $\hat{p} = 0$ and restricting to the Hamiltonian,

$$\hat{H} = \sum_{\pm} \omega_{\pm} \hat{a}_{\pm}^{\dagger} \hat{a}_{\pm} - \imath\eta_{\pm}(\hat{a}_{\pm} - \hat{a}_{\pm}^{\dagger}) + U_0(\hat{a}_{+}^{\dagger}\hat{a}_{-}e^{-2\imath kz} + \hat{a}_{-}^{\dagger}\hat{a}_{+}e^{2\imath kz}) \ . \tag{42.213}$$

In Exc. 42.5.7.1 we show how to cast the Hamiltonian into a matrix form using an appropriate basis already used in the discussion of the beam splitter in the photon representation in Sec. 35.8.1.

In Exc. 42.5.7.2(a) we derive the equations of motion for the components c_{n_+,n_-} of the state vector from the Schrödinger equation cavity decay. In Exc. 42.5.7.3(a) we derive the equations of motion for the components $\rho_{m_+,n_+;m_-n_-} = \langle m_+, m_-|\hat{\rho}|n_+, n_-\rangle$ of the density operator. Simulations performed based on these equations of motion are shown in Fig. 42.44).

The simulations reveal a number of interesting facts:

- The field amplitudes $|\alpha_{\pm}|^2$ execute oscillations due to CARL coupling, but with preserved Poissonian shape of the photon number distributions.
- When simulations are done with initial Fock states, they eventually relax to a Glauber state.
- The mean photon numbers and the atomic coordinates evolve in a continuous way.

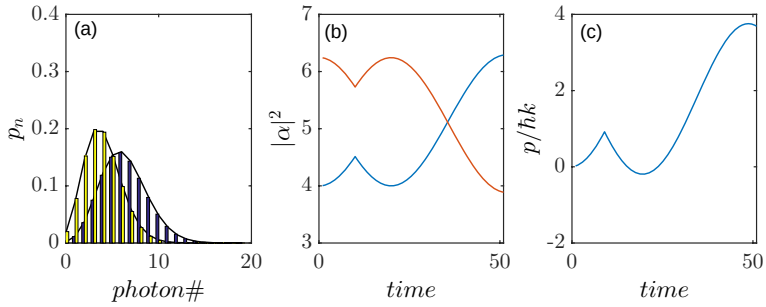

Figure 42.44: (code) Time-evolution of CARL with one classical atom and two quantized field modes. (a) Photon number distributions of two modes after some evolution time t. (b) Time-evolution of the mean photon number; at time $t = 10$, the atom is suddenly displaced. (c) Time-evolution of the (classical) atomic trajectory.

These observations are not surprising, once we understood the backscattering as a linear coupling between the modes being mediated by a beam splitter Hamiltonian of type (35.317) [19],

$$\hat{H}_{int} = U_0(\hat{a}_{+}^{\dagger}\hat{a}_{-}e^{-2\imath kz} + \hat{a}_{+}\hat{a}_{-}^{\dagger}e^{2\imath kz}) \ , \tag{42.214}$$

[19] Which itself represents a generalized displacement operator,

$$\hat{H}_{int} \simeq U_0(\alpha_{+}^{*}e^{-2\imath kz}\hat{a}_{-} + \alpha_{+}e^{2\imath kz}\hat{a}_{-}^{\dagger}) \equiv \imath\hbar\beta^{*}\hat{a}_{-} - \imath\hbar\beta\hat{a}_{-}^{\dagger} \ ,$$

for which we found the relationship (35.318),

$$\boxed{e^{-\imath\hat{H}_{int}t}\hat{a}_{\pm}e^{\imath\hat{H}_{int}t} = \hat{a}_{\pm}\cos U_0 t \pm \hat{a}_{\mp}e^{\mp 2\imath kz}\sin U_0 t} \ . \tag{42.215}$$

This means, that we expect (for a fixed location z of the atom) an oscillatory behavior of the field amplitudes $|\alpha_{\pm}|^2$ and also of the phase (encoded in $\alpha_+^*\alpha_-$), but no modification of the coherent photon statistics. On the contrary, as shown in Sec. 35.8.1, a beam splitter tends to transform sub-Poissonian states into Poissonian ones. In fact, *CARL is nothing else than a movable beam splitter.*

Non-linearity may come into play, if photonic recoil is included, i.e. if the *atomic motion itself becomes a degree of freedom.* This is the next step of our problem, that needs to be solved.

42.5.4 Quantized light fields and quantized recoil

The simulations of the preceding section show that the CARL Hamiltonian (42.214), despite the appearance of photon creation and annihilation operator, does not request recoil to be quantized: If an arbitrary momentum kick of the atom can be absorbed by the light fields, then an arbitrary dipole force can be transmitted to the atomic momentum! The momentum conservation law (42.17) does not imply quantization of photonic recoil. The question is now, how to conceal this fact with the observation of discrete momentum sidemodes [1217]. We have seen earlier, that the quantization of the motion is transferred from the quantized photon fields via the operator (42.149) to the atom: An initially resting atom can only adopt motional states with momenta equal to a multiple of $2\hbar k$.

We will now take the quantization of the atomic momentum for granted and study quantized light modes coupled by *recoiling atoms*, we extend our Hilbert space like,

$$|\psi\rangle = |\nu\rangle_{motion} \otimes \cancel{|i\rangle_{electron}}^{\text{adiab.elim.}} \otimes |n\rangle_+ \otimes |n\rangle_- \to |\nu, n_+, n_-\rangle \ , \tag{42.216}$$

Expanding the motion and fields [20],

$$\boxed{|\psi\rangle = \sum_{\nu,n_+,n_-} c_{\nu,n_+,n_-}|\nu, n_+, n_-\rangle} \ , \tag{42.217}$$

the momentum kick operator reads,

$$e^{-2\imath k\hat{z}} \otimes \mathbb{I} \otimes \mathbb{I} = \sum_{\nu} |\nu\hbar k - 2\hbar k, n_+, n_-\rangle\langle\nu\hbar k, n_+, n_-| \ . \tag{42.218}$$

since defining $\beta \equiv \frac{\imath U_0}{\hbar}\alpha_+ e^{2\imath kz}$, we find,

$$B(\beta t) = e^{-\imath\hat{H}_{int}t/\hbar} = e^{\beta^* t\hat{a}_- - \beta t\hat{a}_-^\dagger} \ .$$

[20] Note the fact, which is important for computation, that the dimension of the Hilbert space increases a lot, that is like dim $\nu \cdot$ dim $n_+ \cdot$ dim n_-, where $\nu, n_\pm$ are the numbers of states considered.

The equations of motions derived in Exc. 42.5.7.2 from the Schrödinger equation are now generalized to,

$$\begin{aligned}\dot{c}_{\nu,n_+,n_-} &= \imath(\Delta_c - U_0)(n_+ + n_-)c_{\nu,n_+,n_-} \\ &- \imath U_0\left(\sqrt{n_+(n_- + 1)}c_{\nu-1,n_+-1,n_-+1} - \sqrt{(n_+ + 1)n_-}c_{\nu+1,n_++1,m_--1}\right) \\ &- \eta_+\left(\sqrt{n_+ + 1}c_{\nu,n_++1,n_-} + \sqrt{n_+}c_{\nu,n_+-1,n_-}\right) \\ &- \eta_-\left(\sqrt{n_- + 1}c_{\nu,n_+,n_-+1} + \sqrt{n_-}c_{\nu,n_+,n_--1}\right)\end{aligned} \; . \tag{42.219}$$

Note that the general shape of fully quantized Schrödinger equations looks like,

$$\dot{c}_{\nu',n'_+,n'_-} = \begin{pmatrix} \ddots & \vdots & \\ \cdots & \mathcal{B}_{\{\nu',n'_+,n'_-\};\{\nu,n_+,n_-\}} & \cdots \\ & \vdots & \ddots \end{pmatrix} c_{\nu,n_+,n_-} \tag{42.220}$$

and for fully quantized master equations,

$$\begin{aligned}&\dot{\rho}_{\{\mu',m'_+,m'_-\};\{\nu',n'_+,n'_-\}} \\ &= \begin{pmatrix} \ddots & \vdots & \\ \cdots & \mathcal{L}_{\{\mu',m'_+,m'_-;\nu',n'_+,n'_-\};\{\mu,m_+,m_-;\nu,n_+,n_-\}} & \cdots \\ & \vdots & \ddots \end{pmatrix} \rho_{\{\mu,m_+,m_-\};\{\nu,n_+,n_-\}} \; .\end{aligned} \tag{42.221}$$

However, the mere inclusion of a third degree of freedom coupled to the other two degrees in the same linear fashion will modify the behavior of the system, which will continue to oscillate as it did before, now just involving the atomic motion in this dynamics. This behavior can only change, when we additionally consider the force equation,

$$\dot{\hat{p}} = 2\hbar k U_0(\hat{a}_+^\dagger \hat{a}_- e^{-2\imath kz} - \hat{a}_+ \hat{a}_-^\dagger e^{2\imath kz}) \; , \tag{42.222}$$

which will lead to feedback. Inserting the expansion (42.217),

$$\dot{c}_{\nu,n_+,n_-} = 2\hbar k U_0\left(c_{\nu,n_+,n_-}\sqrt{n_+(n_- + 1)} - c_{\nu,n_+,n_-}\sqrt{n_+(n_- + 1)}\right) \; . \tag{42.223}$$

Note that, in contrast to CARL equations, the fully quantized equations (42.219) *are linear*. That is, it is the 'classization' [21] of the degrees of freedom which introduces the non-linearities, which are typical for CARL, e.g. the feedback introduced by classical light fields. The process of 'classization' corresponds to *tracing* over degrees of freedom, which we want to treat classically and thus remove from the Hamiltonian.

42.5.4.1 Calculation of observables

Once the time evolution of the coefficients $c_{\nu,n_+,n_-}(t)$ has been determined by solving the differential equation (42.219) we can calculate the observables in the following

[21] As opposed to the term quantization.

way. The probability distribution for photon numbers in the mode α_+ is given by,

$$\begin{aligned} P_{n_+}(t) &= \langle\psi(t)|\mathbb{I}\otimes|n_+\rangle\langle n_+|\otimes\mathbb{I}|\psi(t)\rangle \\ &= \sum_{\nu,n_-}\langle\nu,n_+,n_-|\nu,n_+,n_-\rangle = \sum_{\nu,n_-}|c_{\nu,n_+,n_-}(t)|^2 \ , \end{aligned} \tag{42.224}$$

the mean photon number by,

$$\langle\hat{n}_+(t)\rangle = |\alpha_+(t)|^2 = \sum_{n_+} n_+ P_{n_+}(t) = \sum_{\nu,n_+,n_-} n_+|c_{\nu,n_+,n_-}(t)|^2 \ , \tag{42.225}$$

and similarly for α_-. The probability distribution for momentum states is given by,

$$P_\nu(t) = \sum_{n_+,n_-}|c_{\nu,n_+,n_-}(t)|^2 \ , \tag{42.226}$$

the mean momentum by,

$$\langle\hat{p}(t)\rangle = \sum_{\nu,n_+,n_-}\nu\hbar k|c_{\nu,n_+,n_-}(t)|^2 \ , \tag{42.227}$$

the mechanical kinetic energy by,

$$\begin{aligned} E_{kin}(t) = \frac{\langle\hat{p}^2\rangle}{2m} &= \sum_{\nu,n_+,n_-}\frac{(\nu\hbar k)^2}{2m}|c_{\nu,n_+,n_-}(t)|^2 \\ &= \sum_{\nu,n_+,n_-}\nu^2\hbar\omega_{rec}|c_{\nu,n_+,n_-}(t)|^2 \ , \end{aligned} \tag{42.228}$$

and the potential energy by,

$$\begin{aligned} E_{pot}(t) &= \hbar U_0\langle e^{-2\imath k\hat{z}}\hat{a}_+^\dagger\hat{a}_- + e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger\rangle \\ &= \hbar U_0\sum_{\nu,n_+,n_-}\Big(c^*_{\nu+1,n_++1,n_--1}c_{\nu,n_+,n_-}\sqrt{(n_++1)n_-} \\ &\qquad + c^*_{\nu-1,n_+-1,n_-+1}c_{\nu,n_+,n_-}\sqrt{n_+(n_-+1)}\Big) \ . \end{aligned} \tag{42.229}$$

With this we can check conservation of the total photon number,

$$\langle\hat{n}_+(t)\rangle + \langle\hat{n}_-(t)\rangle = const \ , \tag{42.230}$$

of the mechanical energy,

$$E_{kin}(t) + E_{pot}(t) = const \ , \tag{42.231}$$

and of total linear momentum,

$$\hbar k[\langle\hat{n}_+(t)\rangle - \langle\hat{n}_-(t)\rangle] - \langle\hat{p}(t)\rangle = const \ . \tag{42.232}$$

42.5.4.2 Master equation for CQED with atomic recoil in the adiabatic approximation

Using the Hamiltonian (42.26) or (42.144), the expansion of the recoil operator (42.149), the expansion of the photon field operators (42.211), and the matrix representation of the density operator (34.105), that is,

$$\hat{\rho} = \sum_{\mu,\nu;m_+,n_+;m_-,n_-} |\mu, m_+, m_-\rangle \rho_{\mu,\nu;m_+,n_+;m_-,n_-} \langle \nu, n_+, n_-| \,, \tag{42.233}$$

the master equation (42.8) becomes,

$$\boxed{\langle \mu, m_+, m_-|\dot{\hat{\rho}}|\nu, n_+, n_-\rangle = -\imath\langle \mu, m_+, m_-|[\hat{H}, \hat{\rho}]|\nu, n_+, n_-\rangle + \mathcal{L}_{cavity-vac,\pm}\hat{\rho}} \,, \tag{42.234}$$

with the coherent contributions,

$$\langle \mu, m_+, m_-|[\tfrac{\hat{p}^2}{2m}, \hat{\rho}]|\nu, n_+, n_-\rangle = \omega_{rec}(\mu^2 - \nu^2)\rho_{\mu,\nu;m_+,n_+;m_-,n_-} \tag{42.235}$$

$$\langle \mu, m_+, m_-|[(U_0 - \Delta_c)\hat{a}_\pm^\dagger \hat{a}_\pm, \hat{\rho}]|\nu, n_+, n_-\rangle = (U_0 - \Delta_c) n_\pm \rho_{\mu,\nu;m_+,n_+;m_-,n_-}$$

$$\begin{aligned}
&\langle \mu, m_+, m_-|[-\imath\eta_+(\hat{a}_+ - \hat{a}_+^\dagger), \hat{\rho}]|\nu, n_+, n_-\rangle \\
&= -\imath\eta_+ \Big(\sqrt{m_+}\rho_{\mu,\nu;m_+-1,n_+;m_-,n_-} - \sqrt{m_+ + 1}\rho_{\mu,\nu;m_++1,n_+;m_-,n_-} \\
&\qquad + \sqrt{n_+}\rho_{\mu,\nu;m_+,n_+-1;m_-,n_-} - \sqrt{n_+ + 1}\rho_{\mu,\nu;m_+,n_++1;m_-,n_-} \Big)
\end{aligned}$$

$$\begin{aligned}
&\langle \mu, m_+, m_-|[-\imath\eta_-(\hat{a}_- - \hat{a}_-^\dagger), \hat{\rho}]|\nu, n_+, n_-\rangle \\
&= -\imath\eta_- \Big(\sqrt{m_-}\rho_{\mu,\nu;m_+,n_+;m_--',n_-} - \sqrt{m_- + 1}\rho_{\mu,\nu;m_+,n_+;m_-+1,n_-} \\
&\qquad + \sqrt{n_-}\rho_{\mu,\nu;m_+,n_+;m_-,n_--1} - \sqrt{n_- + 1}\rho_{\mu,\nu;m_+,n_+;m_-,n_-+1} \Big)
\end{aligned}$$

$$\begin{aligned}
&\langle \mu, m_+, m_-|[U_0 e^{-2\imath k\hat{z}}\hat{a}_+^\dagger \hat{a}_-, \hat{\rho}]|\nu, n_+, n_-\rangle \\
&= U_0 \Big(\sqrt{m_+(m_- + 1)}\rho_{\mu+1,\nu;m_+-1,n_+;m_-+1,n_-} + \sqrt{(m_+ + 1)m_-}\rho_{\mu-1,\nu;m_++1,n_+;m_--1,n_-} \Big)
\end{aligned}$$

$$\begin{aligned}
&\langle \mu, m_+, m_-|[U_0 e^{2\imath k\hat{z}}\hat{a}_+\hat{a}_-^\dagger, \hat{\rho}]|\nu, n_+, n_-\rangle \\
&= U_0 \Big(\sqrt{(n_+ + 1)n_-}\rho_{\mu,\nu-1;m_+,n_++1m_-,n_--1} + \sqrt{n_+(n_- + 1)}\rho_{\mu,\nu+1;m_+,n_+-1;m_-,n_-+1} \Big) \,,
\end{aligned}$$

and the incoherent contributions,

$$\begin{aligned}
&\langle \mu, m_+, m_-| - \kappa[\hat{a}_+^\dagger \hat{a}_+\hat{\rho} - 2\hat{a}_+\hat{\rho}\hat{a}_+^\dagger + \hat{\rho}\hat{a}_+^\dagger \hat{a}_+]|\nu, n_+, n_-\rangle \\
&\qquad = -\kappa \big(m_+\rho_{\mu,\nu;m_+,n_+;m_-,n_-} + n_+\rho_{\mu,\nu;m_+,n_+;m_-,n_-} \\
&\qquad\qquad -2\sqrt{(m_+ + 1)(n_+ + 1)}\rho_{\mu,\nu;m_++1,n_++1;m_-,n_-} \big)
\end{aligned} \tag{42.236}$$

$$\begin{aligned}
&\langle \mu, m_+, m_-| - \kappa[\hat{a}_-^\dagger \hat{a}_-\hat{\rho} - 2\hat{a}_-\hat{\rho}\hat{a}_-^\dagger + \hat{\rho}\hat{a}_-^\dagger \hat{a}_-]|\nu, n_+, n_-\rangle \\
&\qquad = -\kappa \big(m_-\rho_{\mu,\nu;m_+,n_+;m_-,n_-} + n_-\rho_{\mu,\nu;m_+,n_+;m_-,n_-} \\
&\qquad\qquad -2\sqrt{(m_- + 1)(n_- + 1)}\rho_{\mu,\nu;m_+,n_+;m_-+1,n_-+1} \big) \,.
\end{aligned}$$

42.5.5 Kicking and forcing an atom in a ring cavity

The question we want to elucidate here is, how a coupled atom-ring cavity system reacts to a kick transferring an arbitrary amount of momentum to the atom. We studied

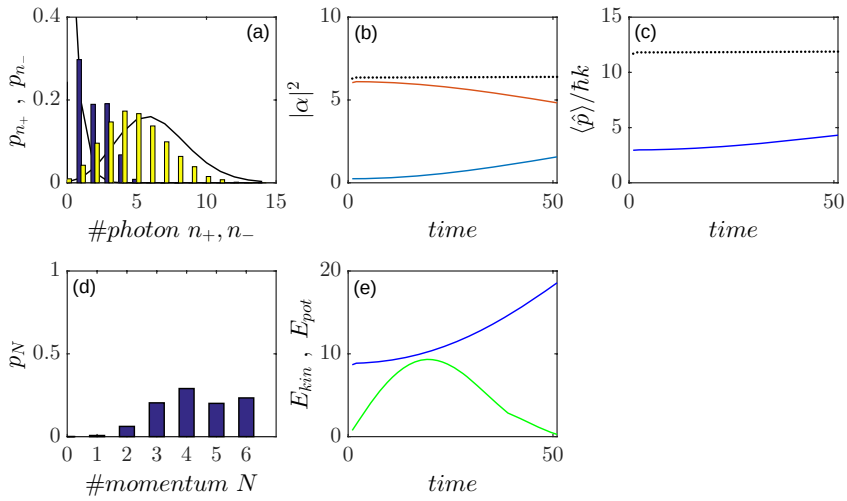

Figure 42.45: (code) Time-evolution of CARL with one classical atom and two quantized field modes. (a) Photon number distributions of two modes after some evolution time t. (b) Time-evolution of the mean photon number; at time $t = 10$, the atom is suddenly displaced. (c) Time-evolution of the (classical) atomic trajectory.

a similar question when studying the kicking of a harmonic oscillator in Sec. 24.6.2, however, the situation is quite different now because, in contrast to the harmonic oscillator, the motion of an atom subject to CARL dynamics is not localized and, hence, *not quantized*. That is, an arbitrarily kicked atom is not bound to join one of those momentum states it would populate when kicked by photonic recoil. Hence, a momentum state expansion like (42.153) is not appropriate, so that we have to go a step back and consider the Hamiltonian (42.26) again. See also (watch talk).

42.5.5.1 Kicking

Let us first describe the kick as an incoherent disruptive one time event transforming operators, the Hamiltonian and the system's state like,

$$\hat{A} \longrightarrow e^{-\imath q\hat{z}}\hat{A}e^{\imath q\hat{z}} \quad , \quad |\psi\rangle \longrightarrow e^{\imath q\hat{z}}|\psi\rangle \tag{42.237}$$

and in particular,

$$\hat{H} \longrightarrow e^{-\imath q\hat{z}}\hat{H}e^{\imath q\hat{z}} = \hat{H}(\hat{z}, \hat{p} - \hbar q) \quad , \quad \langle p|\psi\rangle \longrightarrow \langle p|e^{\imath q\hat{z}}|\psi\rangle = \langle p - \hbar q|\psi\rangle \ . \tag{42.238}$$

The Schrödinger equation tells us the system's evolution after the kick,

$$\imath\hbar\frac{d}{dt}\langle p|\psi\rangle = \frac{p^2}{2m}\langle p|\psi\rangle + U_0\left(\langle p|e^{-2\imath k\hat{z}}|\psi\rangle\hat{a}_+^\dagger\hat{a}_- + \langle p|e^{2\imath k\hat{z}}|\psi\rangle\hat{a}_+\hat{a}_-^\dagger\right) \ . \tag{42.239}$$

We remind that this equations contains CARL feedback via the simultaneous presence of $\hat{z}$ and $\hat{p}$. If we want to disregard the CARL force (assuming, for example, that the motion is totally imposed by an external force, as done in Sec. 40.2.8 in order to focus on the behavior of the light fields), we must not project the Schrödinger equation on $\langle p|$ but treat the motional degree of freedom as classical.

42.5.5.2 Forcing

Let us now describe the kick as a force $F(t) = mg\theta(t)$ being switched on at a given time, but being constant afterward,

$$\hat{H} = \frac{\hat{p}^2}{2m} + U_0 \left(e^{-2\imath k\hat{z}} \hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}} \hat{a}_+ \hat{a}_-^\dagger \right) + mg\hat{z} \ . \tag{42.240}$$

We note that with (23.167) the Hamiltonian transformed into the accelerated frame reads,

$$\begin{aligned} \hat{H} &\longrightarrow e^{-\imath mg\hat{z}t/\hbar} \hat{H} e^{\imath mg\hat{z}t/\hbar} + \imath\hbar \left(\frac{d}{dt} e^{\imath mg\hat{z}t/\hbar} \right)^\dagger e^{\imath mg\hat{z}t/\hbar} = \hat{H}(\hat{z}, \hat{p} - mgt) - mg\hat{z} \\ &= \frac{(\hat{p} - mgt)^2}{2m} + U_0 \left(e^{-2\imath k\hat{z}} \hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}} \hat{a}_+ \hat{a}_-^\dagger \right) \ . \end{aligned} \tag{42.241}$$

The Schrödinger equation for the transformed wavefunction $|\psi\rangle = |\tilde{\psi}\rangle e^{\imath mg\hat{z}t/\hbar}$, which tells us the system's evolution during the force,

$$\imath\hbar \frac{d}{dt} \langle p|\tilde{\psi}\rangle = \frac{(p - mgt)^2}{2m} \langle p|\tilde{\psi}\rangle + U_0 \left(\langle p|e^{-2\imath k\hat{z}}|\tilde{\psi}\rangle \hat{a}_+^\dagger \hat{a}_- + \langle p|e^{2\imath k\hat{z}}|\tilde{\psi}\rangle \hat{a}_+ \hat{a}_-^\dagger \right) \ , \tag{42.242}$$

has a similar shape to Eq. (42.239).

42.5.5.3 Vibrating

Another option might be to additionally confine the atom in a harmonic potential [1406],

$$\begin{aligned} \hat{H} &= \frac{\hat{p}^2}{2m} + U_0 \left(e^{-2\imath k\hat{z}} \hat{a}_+^\dagger \hat{a}_- + e^{2\imath k\hat{z}} \hat{a}_+ \hat{a}_-^\dagger \right) + \frac{m}{2} \omega^2 \hat{z}^2 \\ &= \hbar\omega (\hat{A}^\dagger \hat{A} + \tfrac{1}{2}) + U_0 \left[D^\dagger(\alpha) \hat{a}_+^\dagger \hat{a}_- + D(\alpha) \hat{a}_+ \hat{a}_-^\dagger \right] \ , \end{aligned} \tag{42.243}$$

where $D(\alpha) \equiv e^{\alpha \hat{A}^\dagger - \alpha^* \hat{A}}$ with $\alpha \equiv \frac{2\imath k a_{ho}}{\sqrt{2}}$.

42.5.5.4 Quantized equations of motion

In both cases, 'kicking' and 'forcing', we may discretize momentum space, although in the latter case we need to transform back into the lab frame after having solved the Schrödinger equation (42.219).

42.5.6 Quantum correlations

Superradiant or CARL scattering exist due to a correlation of subsequent scattering events. In the quantum regime, the emergence of quantum correlations, such as entanglement and squeezing is to be expected as a consequence of CARL dynamics [918, 1036, 1061, 1050, 1051, 1325, 279, 280, 281]. The advantage of doing CARL with BECs is the possibility to exploit the instability in the good-cavity regime to

parametrically amplify optical and matter waves, manipulate matter wave coherence properties and generate entanglement.

For the description of the dynamics of the fields, i.e. the momentum sidemodes and the cavity modes, a first-quantized treatment of the atomic motion [1038] would be sufficient. All information can be extracted from a numerical simulation of the quantum CARL equations. However, here we are also interested in quantum correlations. Hence, in a first-quantized treatment of the atomic motion, the coefficients $\hat{c}_n$ must be treated as field operators. Alternatively, we derive the basic equations rigorously from a second-quantized treatment.

42.5.6.1 Generation of squeezing and entanglement via CARL

An experiment by [1069] produces squeezing in transmission of a cavity resonantly interacting with single atoms. The effect was induced by vacuum Rabi-splitting. In our case we have a ring cavity, we operate far from equilibrium, we have classical Stark splitting. Hence, we may expect squeezing and entanglement from the CARL dynamics.

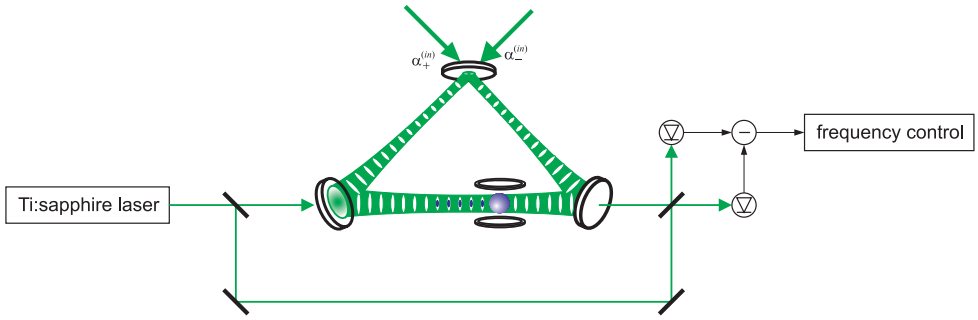

Figure 42.46: Production and detection of squeezing.

Differences between entanglement and correlation (correlations involve time or space coordinates $g(\tau)$, particles correlate across space and time, coherence).

Bragg scattering of light at an atomic grating (or simply the splitting of light at a beam splitter) is an irreversible process (see Sec. 35.8). CARL can be interpreted in terms of Bragg scattering of light at an atomic grating, which is generated itself by the Bragg scattering. Hence, the scattering of early photons influences the scattering of late photons, i.e. the scattering processes get correlated, the dynamics gets a history. The correlation between subsequent scattering processes is what preserves the coherence in CARL and superradiant Rayleigh scattering.

It is now interesting to ask how this classical correlations will behave in the quantum regime, i.e. upon 1. quantization of the motion of individual atoms and upon 2. quantization of atomic particle field. Following [918, 917, 920, 919, 1036, 1037, 1050, 1051], non-classical correlations such as entanglement of matter wave modes, and entanglement between matter-wave and optical modes is expected.

42.5.6.2 Quantum non demolition measurements with CARL

According to [1051], a ring cavity could lend itself to quantum non demolition measurements. They consider our ring cavity being pumped from both sides through an incoupling mirror. A so-called pump mode is injected with a p-polarized light field, and a probe mode with a s-polarized light field. The light of the probe mode leaking through a mirror gives information about the atoms (e.g. via the refraction index). The counterpropagating pump light gives access to higher-order moments of the atom distribution.

The problem is that the effect is based on photon exchange between the modes, and those are orthogonally polarized. Even more problematic is that, in practice, the modes have different frequencies. Other work on this subject has been done by [70, 409, 870, 872, 250].

42.5.7 Exercises

42.5.7.1 Ex: Analogy between CARL and two-atom Dicke states

a. Write the Hamiltonian (42.213) in matrix form using the basis,

$$\psi_k = \{|0,0\rangle, |0,1\rangle, |1,0\rangle, |0,2\rangle, |1,1\rangle, |2,0\rangle, ...\} \ .$$

b. Now restrict to the finite number of states $\psi_k = \{|0,0\rangle, |0,1\rangle, |1,0\rangle, |1,1\rangle\}$ and discuss the analogy between CARL and two-atom Dicke states.

Solution: *a. The Hamiltonian becomes,*

$$\hat{H} = \begin{pmatrix} 0 & -\imath\eta_- & -\imath\eta_+ & 0 & 0 & 0 & \\ \imath\eta_- & \omega_- & U & -\sqrt{2}\imath\eta_- & -\imath\eta_+ & 0 & \\ \imath\eta_+ & U & \omega_+ & 0 & -\imath\eta_- & -\sqrt{2}\imath\eta_+ & \\ 0 & \sqrt{2}\imath\eta_- & 0 & 2\omega_- & \sqrt{2}U & 0 & \\ 0 & \imath\eta_+ & \imath\eta_- & \sqrt{2}U & \omega_+ + \omega_- & \sqrt{2}U & \\ 0 & 0 & \sqrt{2}\imath\eta_+ & 0 & \sqrt{2}U & 2\omega_+ & \\ & & & & & & \ddots \end{pmatrix} .$$

b. The analogy with the two-atom Dicke Hamiltonian becomes apparent, when we restrict ourselves to the finite basis $\psi_k = \{|0,0\rangle, |0,1\rangle, |1,0\rangle, |1,1\rangle\}$,

$$\hat{H} = \begin{pmatrix} 0 & -\imath\eta_- & -\imath\eta_+ & 0 \\ \imath\eta_- & \omega_- & U & -\imath\eta_+ \\ \imath\eta_+ & U & \omega_+ & -\imath\eta_- \\ 0 & \imath\eta_+ & \imath\eta_- & \omega_+ + \omega_- \end{pmatrix} .$$

This however presupposes that coupling U and pumping $\eta_\pm$ to higher photons number states is inhibited.
Assume one photon is pumped into mode a_1. The state is then $|\psi\rangle = (0010)$. This can be written $|\psi\rangle = \frac{1}{\sqrt{2}}[(0010) + (0100)] + \frac{1}{\sqrt{2}}[(0010) - (0100)]$. The superposition

state $\frac{1}{\sqrt{2}}[(0010)+(0100)]$ *decays, but not by loss of energy, but through phase noise. How to detect state* $\frac{1}{\sqrt{2}}[(0010)-(0100)]$ *of the cavity?*
Interestingly, in the absence of pumping (and dissipation), the Hamiltonian takes the form of the Dicke Hamiltonian, where the two coupled systems are the two modes of the ring cavity. We indeed find that the singlet and triplet states $|0,1\rangle \pm |1,0\rangle$ *decouple. In analogy to Dicke states, if the modes couple to the same vacuum radiation field, there might be sub- or superradiance, or collective quantum jumps. This could be done by combining the two output ports of the ring cavity on a beam splitter. The vacuum fluctuations entering through the beam splitter ports couple simultaneously to both modes.*

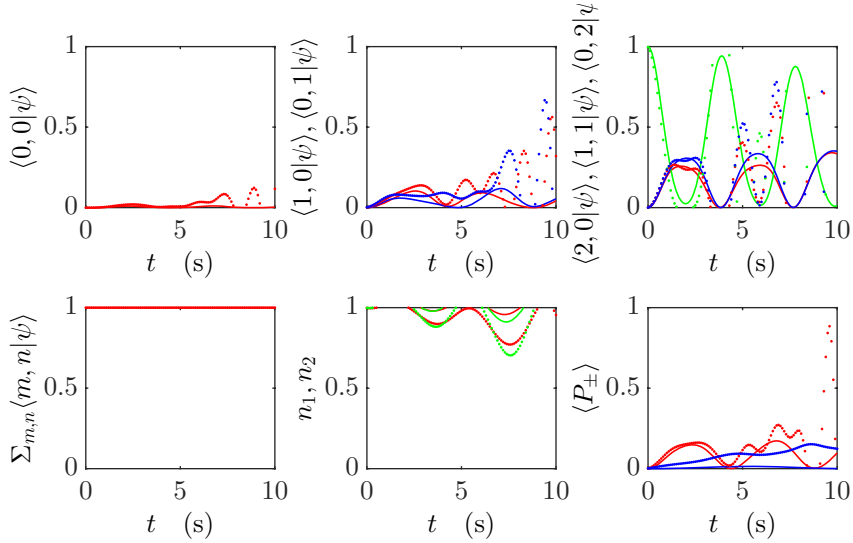

Figure 42.47: (code) Simulation of the above Hamiltonian with initial 2 photons in one mode and no pumping.

42.5.7.2 Ex: Cavity QED with Schrödinger equation

Assume a symmetrically pumped ring cavity in equilibrium with an atom at a fixed position.
a. Derive the equations of motion for the components for the probability amplitudes in a Fock state basis.
b. Express the possible initial states $|\alpha_+,\alpha_-\rangle$, $|\alpha_+,n_-\rangle$, and $|n_+,n_-\rangle$ in the Fock state basis. How to calculate the photon distribution p_{n_+}, the amplitudes of field modes $\alpha_\pm$, and the atom's position and momentum at later times of the evolution?

Solution: *a. If for simplicity we assume totally isolated cavity modes,* $\kappa = 0$*, we*

can use the Schrödinger equation,

$$\imath\hbar\frac{d}{dt}|\psi\rangle = -\hat{H}|\psi\rangle = \imath\hbar\frac{d}{dt}\sum_{n_+,n_-} c_{n_+,n_-}|n_+,n_-\rangle$$

$$= \left(\sum_{\pm}(U_0-\Delta_c)\hat{a}^\dagger_\pm\hat{a}_\pm + U_0\left(e^{-2\imath kz}\hat{a}^\dagger_+\hat{a}_- + e^{2\imath kz}\hat{a}_+\hat{a}^\dagger_-\right) - \imath\sum_{\pm}\eta_\pm(\hat{a}_\pm - \hat{a}^\dagger_\pm)\right)\sum_{n_+,n_-} c_{n_+,n_-}|n_+,n_-\rangle$$

$$= \sum_{n_+,n_-} c_{n_+,n_-}\left[(U_0-\Delta_c)(n_+ + n_-)|n_+,n_-\rangle\right.$$

$$+U_0e^{-2\imath kz}c_{n_+,n_-}\sqrt{(n_++1)n_-}|n_++1,n_--1\rangle + U_0e^{2\imath kz}c_{n_+,n_-}\sqrt{n_+(n_-+1)}|n_+-1,n_-+1\rangle$$

$$\left.-\imath\eta_+\sqrt{n_+}|n_+-1,n_-\rangle + \imath\eta_+\sqrt{n_++1}|n_++1,n_-\rangle - \imath\eta_-\sqrt{n_-}|n_+,n_--1\rangle + \imath\eta_-\sqrt{n_-+1}|n_+,n_-+1\rangle\right] .$$

Projecting the Schrödinger equation onto the state $\langle m_+,m_-|$ we get,

$$\dot{c}_{m_+,m_-} = \imath(\Delta_c-U_0)(m_++m_-)c_{m_+,m_-}$$
$$-\imath U_0e^{-2\imath kz}c_{m_+-1,m_-+1}\sqrt{m_+(m_-+1)} - \imath U_0e^{2\imath kz}c_{m_++1,m_--1}\sqrt{(m_++1)m_-}$$
$$-\eta_+c_{m_++1,m_-}\sqrt{m_++1} + \eta_+c_{m_+-1,m_-}\sqrt{m_+} - \eta_-c_{m_+,m_-+1}\sqrt{m_-+1} + \eta_-c_{m_+,m_--1}\sqrt{m_-} .$$

The motion, which is assumed to be classical, is modeled by,

$$\ddot{z} = \langle\psi|\ddot{\hat{z}}|\psi\rangle = 2\imath\hbar kU_0\left(\langle\psi|e^{-2\imath kz}\hat{a}^\dagger_+\hat{a}_-|\psi\rangle - \langle\psi|e^{2\imath kz}\hat{a}_+\hat{a}^\dagger_-|\psi>\right)$$
$$= 2\imath\hbar kU_0\sum_{n_+,n_-}\left(e^{-2\imath kz}\sqrt{(n_++1)n_-}c^*_{n_++1,n_--1}c_{n_+,n_-}\right.$$
$$\left.-e^{2\imath kz}\sqrt{n_+(n_-+1)}c^*_{n_+-1,n_-+1}c_{n_+,n_-}\right) .$$

b. Simulations of the above set of differential equations will be started from initially coherent states,

$$|\alpha_+,\alpha_-\rangle = e^{-|\alpha_+|^2/2-|\alpha_-|^2/2}\sum_{n_+,n_-}\frac{\alpha_+^{n_+},\alpha_-^{n_-}}{\sqrt{n_+!n_-!}}|n_+,n_-\rangle .$$

The other states, $|n_+,n_-\rangle$ and $|\alpha_+,n_-\rangle$ are trivial. At later times t the photon distributions can be extracted from the wavefunction via,

$$p_{n_+}(t) = \sum_{n_-}\langle n_+,n_-|\psi(t)\rangle = \sum_{n_-}c_{n_+,n_-}(t) .$$

The amplitudes of field modes follow from,

$$\alpha_\pm(t) = \sum_{n_\pm} n_\pm p_{n_\pm}(t) .$$

Finally, the position and momentum follow directly from the differential equation.

42.5.7.3 Ex: Cavity QED with density matrix

Assume a symmetrically pumped ring cavity in equilibrium with an atom at a fixed position.
a. Derive the equations of motion for the components of the density operator.
b. Write down the density operator describing two decoupled Glauber states? How to retrieve the Fock state populations from the density operator?
c. Now, assume that the atom can move. What will be the evolution of the motional state?

Solution: *a. The evolution of the density matrix* $\rho_{m_+,n_+;m_-n_-} = \langle m_+, m_-|\hat{\rho}|n_+, n_-\rangle$ *is derived from the master equation (42.8) in the adiabatic approximation inserting the Hamiltonian (42.26),*

$$\begin{aligned}
\hat{H} &= \sum_{\pm}(U_0 - \Delta_c)\hat{a}_{\pm}^{\dagger}\hat{a}_{\pm} + U_0(e^{-2\imath kz}\hat{a}_{+}^{\dagger}\hat{a}_{-} + e^{2\imath kz}\hat{a}_{+}\hat{a}_{-}^{\dagger}) - \imath\sum_{\pm}\eta_{\pm}(\hat{a}_{\pm} - \hat{a}_{\pm}^{\dagger}), \sum_{m,n} c_m^* c_n |m\rangle\langle n| \\
&= (U_0 - \Delta_c)\sum_{n_+,n_-}(n_+ + n_-)|n_+, n_-\rangle\langle n_+, n_-| \\
&\quad + U_0\sum_{n_+,n_-}\Big(e^{-2\imath kz}\sqrt{(n_+ + 1)n_-}|n_+ + 1, n_- - 1\rangle\langle n_+, n_-| \\
&\qquad + e^{2\imath kz}\sqrt{n_+(n_- + 1)}|n_+ - 1, n_- + 1\rangle\langle n_+, n_-|\Big) \\
&\quad - \imath\eta_+\sum_{n_+,n_-}\Big(\sqrt{n_+}|n_+ - 1, n_-\rangle\langle n_+, n_-| - \sqrt{n_+ + 1}|n_+ + 1, n_-\rangle\langle n_+, n_-|\Big) \\
&\quad - \imath\eta_-\sum_{n_+,n_-}\Big(\sqrt{n_-}|n_+, n_- - 1\rangle\langle n_+, n_-| - \sqrt{n_- + 1}|n_+, n_- + 1\rangle\langle n_+, n_-|\Big) \ .
\end{aligned}$$

We get for the coherent evolution,

$$\begin{aligned}
&\dot{\hat{\rho}}_{m_+,n_+;m_-n_-} \equiv \langle m_+, m_-|\dot{\rho}|n_+, n_-\rangle = -\imath\langle m_+, m_-|[\hat{H}, \hat{\rho}]|n_+, n_-\rangle \\
&= -\imath\sum_{p_+,p_-}\langle m_+, m_-|\hat{H}|p_+, p_-\rangle\hat{\rho}_{p_+,n_+;p_-,n_-} + \imath\sum_{p_+,p_-}\hat{\rho}_{m_+,p_+;m_-,p_-}\langle p_+, p_-|\hat{H}|n_+, n_-\rangle \ ,
\end{aligned}$$

giving,

$$\begin{aligned}
&\dot{\hat{\rho}}_{m_+,n_+;m_-n_-} = -\imath(U_0 - \Delta_c)(m_+ + m_- - n_+ - n_-)\hat{\rho}_{m_+,m_+;n_-,n_-} \\
&- \imath U_0 e^{-2\imath kz}\sqrt{m_+(m_- + 1)}\hat{\rho}_{m_+-1,n_+;m_-+1,n_-} - \imath U_0 e^{2\imath kz}\sqrt{(m_+ + 1)m_-}\hat{\rho}_{m_++1,n_+;m_--1,n_-} \\
&+ \imath U_0 e^{-2\imath kz}\sqrt{(n_+ + 1)n_-}\hat{\rho}_{m_+,n_++1;m_-,n_--1} + \imath U_0 e^{2\imath kz}\sqrt{n_+(n_- + 1)}\hat{\rho}_{m_+,n_+-1;m_-,n_-+1} \\
&- \eta_+\sqrt{m_+ + 1}\hat{\rho}_{m_++1,n_+;m_-,n_-} + \eta_+\sqrt{m_+}\hat{\rho}_{m_+-1,n_+;m_-,n_-} \\
&+ \eta_+\sqrt{n_+}\hat{\rho}_{m_+,n_+-1;m_-,n_-} - \eta_+\sqrt{n_+ + 1}\hat{\rho}_{m_+,n_++1;m_-,n_-} \\
&- \eta_-\sqrt{m_- + 1}\hat{\rho}_{m_+,n_+;m_-+1,n_-} + \eta_-\sqrt{m_-}\hat{\rho}_{m_+,n_+;m_--1,n_-} \\
&+ \eta_-\sqrt{n_-}\hat{\rho}_{m_+,n_+;m_-,n_--1} - \eta_-\sqrt{n_- + 1}\hat{\rho}_{m_+,n_+;m_-,n_-+1} \ .
\end{aligned}$$

For the dissipative evolution we get,

$$\mathcal{L}_{cavity-vac,\pm} = -\kappa\{\hat{a}_{\pm}^{\dagger}\hat{a}_{\pm}\hat{\rho}(t) - 2\hat{a}_{\pm}\hat{\rho}(t)\hat{a}_{\pm}^{\dagger} + \hat{\rho}(t)\hat{a}_{\pm}^{\dagger}\hat{a}_{\pm}\} \ .$$

Hence,

$$\langle m_+, m_-|\mathcal{L}_{cavity-vac,\pm}|n_+, n_-\rangle$$
$$= -\kappa \sum_{p_+,p_-} \Big(\langle m_+, m_-|\hat{a}_\pm^\dagger \hat{a}_\pm |p_+, p_-\rangle \rho_{p_+,n_+;p_-,n_-} + \rho_{m_+,p_+;m_-,p_-} \langle p_+, p_-|\hat{a}_\pm^\dagger \hat{a}_\pm |n_+, n_-\rangle \Big)$$
$$- 2\kappa \sum_{p_+,p_-,q_+,q_-} \langle m_+, m_-|\hat{a}_\pm|p_+, p_-\rangle \rho_{p_+,q_+;p_-,q_-} \langle q_+, q_-|\hat{a}_\pm^\dagger|n_+, n_-\rangle \ ,$$

and thus,

$$\mathcal{L}_{cavity-vac,+}\rho_{m_+,n_+;m_-n_-} = -2\kappa\{n_+\rho_{m_+,n_+;m_-,n_-} - \sqrt{n_+(n_++1)}\rho_{m_++1,n_++1;m_-,n_-}\}$$
$$\mathcal{L}_{cavity-vac,-}\rho_{m_+,n_+;m_-n_-} = -2\kappa\{n_-\rho_{m_+,n_+;m_-,n_-} - \sqrt{n_-(n_-+1)}\rho_{m_+,n_+;m_-+1,n_-+1}\} \ .$$

b. Simulations will be started from an initially coherent state,

$$\hat{\rho}(0) = |\alpha_+\rangle\langle\alpha_+| \otimes |\alpha_-\rangle\langle\alpha_-|$$
$$= e^{-|\alpha_+|^2-|\alpha_-|^2} \sum_{m_+,n_+,m_-,n_-} \frac{\alpha_+^{m_+}\alpha_+^{*n_+}\alpha_-^{m_-}\alpha_-^{*n_-}}{\sqrt{m_+!n_+!m_-!n_-!}} |m_+, m_-\rangle\langle n_+, n_-| \ ,$$

such that,

$$\rho_{m_+,n_+;m_-,n_-}(0) = \langle m_+, m_-|\hat{\rho}(0)|n_+, n_-\rangle = e^{-|\alpha_+|^2-|\alpha_-|^2} \frac{\alpha_+^{m_+}\alpha_+^{*n_+}\alpha_-^{m_-}\alpha_-^{*n_-}}{\sqrt{m_+!n_+!m_-!n_-!}} \ .$$

Now, we calculate the photon distributions via,

$$p_{n_+} = Tr\ \hat{\rho}|n_+\rangle\langle n_+| = \langle n_+|Tr_{n_-}\ \hat{\rho}|n_+\rangle = \sum_{n_-}\langle n_+, n_-|\hat{\rho}|n_+, n_-\rangle = \sum_{n_-}\rho_{n_+,n_+;n_-n_-} \ .$$

Of course, we expect that for separable coherent states,

$$p_{n_+} = e^{-|\alpha_+|^2}\frac{|\alpha_+|^{n_+}}{n_+!}e^{-|\alpha_-|^2}\sum_{n_-}\frac{|\alpha_-|^{n_-}}{n_-!} = e^{-|\alpha_+|^2}\frac{|\alpha_+|^{2n_+}}{n_+!} \ .$$

c. We can follow the evolution of the motional degree of freedom directly in the equation of motion of CARL,

$$\dot{\hat{p}} = 2\imath\hbar k U_0(e^{-2\imath kz}\hat{a}_+^\dagger\hat{a}_- - e^{2\imath kz}\hat{a}_+\hat{a}_-^\dagger)$$
$$= 2\imath\hbar k U_0 \sum_{n_+,n_-} \Big(e^{-2\imath kz}\sqrt{(n_++1)n_-}|n_++1, n_--1\rangle\langle n_+, n_-|$$
$$-e^{2\imath kz}\sqrt{(n_-+1)n_+}|n_+-1, n_-+1\rangle\langle n_+, n_-|\Big) \ .$$

giving,

$$\langle\psi|\dot{\hat{p}}|\psi\rangle = \sum_{m_+,m_-,n_+,n_-} c_{m_+,m_-}^* c_{n_+,n_-}\langle m_+, m_-|\dot{p}|n_+, n_-\rangle$$
$$= 2\imath\hbar k U_0 \sum_{n_+,n_-}\Big(\rho_{n_++1,n_+;n_--1,n_-}e^{-2\imath kz}\sqrt{(n_++1)n_-} - \rho_{n_+-1,n_+;n_-+1,n_-}e^{2\imath kz}\sqrt{n_+(n_-+1)}\Big) \ .$$

42.5.7.4 Ex: Photon number and momentum conservation

a. Calculate the evolution under CARL interaction, $e^{-\imath\hat{H}_{carl}t}\hat{n}_{\pm}e^{\imath\hat{H}_{carl}t}$, of the photon numbers in each mode and show that the total photon number is conserved.
b. Assuming conservation of total momentum calculate the evolution of the atomic momentum.

Solution: *a. The CARL Hamiltonian is,*

$$\hat{H}_{carl} = U_0(\hat{a}_+^\dagger \hat{a}_- e^{-2\imath k\hat{z}} + \hat{a}_+\hat{a}_-^\dagger e^{2\imath k\hat{z}}) \ .$$

With this we calculate,

$$\begin{aligned} e^{-\imath\hat{H}_{carl}t}\hat{n}_{\pm}e^{\imath\hat{H}_{carl}t} &= e^{-\imath\hat{H}_{carl}t}\hat{a}_{\pm}^\dagger e^{\imath\hat{H}_{carl}t}e^{-\imath\hat{H}_{carl}t}\hat{a}_{\pm}e^{\imath\hat{H}_{carl}t} \\ &= \left(\hat{a}_{\pm}^\dagger \cos U_0t \pm \hat{a}_{\mp}^\dagger e^{\pm 2\imath k\hat{z}} \sin U_0t\right)\left(\hat{a}_{\pm} \cos U_0t \pm \hat{a}_{\mp} e^{\mp 2\imath k\hat{z}} \sin U_0t\right) \\ &= \hat{a}_{\pm}^\dagger\hat{a}_{\pm}\cos^2 U_0t + \hat{a}_{\mp}^\dagger\hat{a}_{\mp}\sin^2 U_0t \pm \left(\hat{a}_{\pm}^\dagger\hat{a}_{\mp}e^{\mp 2\imath k\hat{z}} + \hat{a}_{\mp}^\dagger\hat{a}_{\pm}e^{\pm 2\imath k\hat{z}}\right)\sin U_0t\cos U_0t \ , \end{aligned}$$

using the result (35.318). Hence,

$$e^{-\imath\hat{H}_{carl}t}(\hat{n}_+ + \hat{n}_-)e^{\imath\hat{H}_{carl}t} = \hat{n}_+ + \hat{n}_- \ .$$

b. We also calculate,

$$\begin{aligned} &e^{-\imath\hat{H}_{carl}t}(\hat{n}_+ - \hat{n}_-)e^{\imath\hat{H}_{carl}t} \\ &\qquad = (\hat{n}_+ - \hat{n}_-)(\cos^2 U_0t - \sin^2 U_0t) + 2\left(\hat{a}_+^\dagger\hat{a}_-e^{-2\imath k\hat{z}} + \hat{a}_-^\dagger\hat{a}_+e^{2\imath k\hat{z}}\right)\sin U_0t\cos U_0t \\ &\qquad = (\hat{n}_+ - \hat{n}_-)\cos 2U_0t + \left(\hat{a}_+^\dagger\hat{a}_-e^{-2\imath k\hat{z}} + \hat{a}_-^\dagger\hat{a}_+e^{2\imath k\hat{z}}\right)\sin 2U_0t \ , \end{aligned}$$

so that,

$$e^{-\imath\hat{H}_{carl}t}\hat{p}e^{\imath\hat{H}_{carl}t} = -e^{-\imath\hat{H}_{carl}t}(\hat{n}_+ - \hat{n}_-)e^{\imath\hat{H}_{carl}t} \ .$$

42.5.7.5 Ex: Self-synchronization of Bloch oscillations

Study the Bloch-CARL dynamics for the case of a sinusoidally modulated CARL pump light intensity. Choose as the modulation frequency the expected Bloch oscillation frequency and a variable phase delay.

Solution:

42.6 Atomic self-organization in light fields

The CARL phenomenon introduced in the previous chapter raises a variety of questions, such as: How does it compare to an ordinary laser? Is there a phase transition?

Of what kind would be this transition (in the Ehrenfest or Landau classification scheme)? What are the coherence properties (measured by correlation functions)? How do these properties depend on the random motion (temperature) of the atoms? These issues will be addressed in this chapter and in the later chapter within the models of Langevin, Fokker-Planck, Vlasov, and Kuramoto.

42.6.1 The Langevin model

42.6.1.1 CARL with damping

We saw in the previous chapter that CARL is a transient phenomenon, the atoms and the phase of the light wave being continuously accelerated. However, it is possible to force stationary behavior by providing additional friction for the atoms. Such friction can be carried out by an *optical molasses* (see Sec. 43.2.1) characterized by a friction coefficient γ_{frc}. The friction force can be added to the CARL equations of motion (42.69),

$$\begin{aligned} \dot{\alpha}_- &= -\kappa\alpha_- - \imath U_0 \alpha_+ \sum_m e^{2\imath k z_m} \\ k\dot{v}_n &= 4i\omega_{rec} U_0 \alpha_+ (\alpha_- e^{-2\imath k z_n} - \alpha_-^* e^{2\imath k z_n}) - \gamma_{frc} k v_n \ . \end{aligned} \tag{42.244}$$

Now, the balance of forces happens at a well-defined atomic velocity, which incidentally corresponds to a well-defined CARL frequency. Assuming perfect 'bunching' $e^{2\imath k z_m} = e^{2\imath k z}$, and balanced forces, $\dot{v}_m = 0$ e $\alpha_- = \beta e^{2\imath k z}$ with $\dot{\beta} = 0$, we obtain for $\kappa \ll 2kv$,

$$\begin{aligned} \alpha_- &= \tfrac{-\imath N U_0 \alpha_+}{\kappa + 2\imath k v} e^{2\imath k z} \\ (kv)^3 &= \frac{2\omega_{rec}\kappa N U_0^2 \alpha_+^2}{\gamma_{fric}} \ . \end{aligned} \tag{42.245}$$

This result will be derived in Exc. 42.6.7.1.

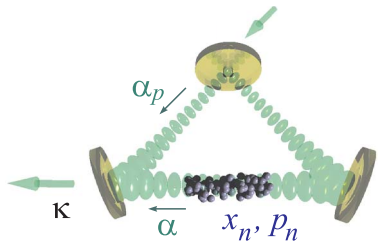

Figure 42.48: Scheme of the ring cavity.

Optical molasses obviously are subject to a cooling limit coming from the random scattering of photons. As a consequence, atoms follow a *random walk* in the momentum space, which leads to the diffusion and heating of atoms and impedes the bunching of atoms. It also turns out that a minimal grouping is required to initialize CARL. Therefore, there is a threshold behavior as a function of the equilibrium

temperature of the molasses,

$$\boxed{\begin{array}{rcl} \dot{\alpha}_- &=& -\kappa\alpha_- - \imath U_0\alpha_+ \sum_m e^{2\imath k z_m} \\ k\dot{v}_n &=& 4\omega_{rec}U_0\alpha_+(\alpha_- e^{-2\imath k z_n} - \alpha_-^* e^{2\imath k z_n}) - \gamma_{frc}kv_n + \xi_n(t) \end{array}} \ . \tag{42.246}$$

The equation corresponds to a *Langevin equation*, where the stochastic term $\xi_n(t)$ describes white noise. We can simulate this equation by a Runge-Kutta method, where the atoms are continually exposed to random momentum changes. For N atoms we need to solve $2N + 2$ Langevin equations to describe the dynamics of all degrees of freedom. The Langevin equations are associated to so-called *Fokker-Planck equations* [1343, 1106, 664, 1342]. These describe the temporal evolution of the atomic density along the optical x-axis. With these equations we replace the $2N$ trajectories of individual particles by a one-dimensional field $P(x, t)$. The *Vlasov equation* represents a different approach: Here we assume that the equilibrium between cooling and heating is achieved by a continuous thermalization process described by a single rate γ_{th} [22].

42.6.1.2 Characterization of an optical molasses

Optical molasses is discussed in Sec. 43.2.1. In Exc. 43.2.5.1 we will show how, through a linearization of the radiative pressure force, we arrive at the following approximation,

$$\mathbf{F} = -\gamma_{frc}\mathbf{v} \qquad \text{with} \qquad \gamma_{frc} \simeq -\sqrt{3}\hbar k^2 s(1+s)^{-3/2} \ , \tag{42.247}$$

where $s = I/I_s$ is the saturation parameter. This formula estimates the maximum friction force, when the lasers are tuned close to an atomic resonance [23].

A more fundamental problem is the interdependence of the molasses friction and the CARL. In fact, because the dipole potential influences the detuning of the molasses beams by light-shifting the D_2 line, the γ_{th} coefficient depends on Δ_a and η_+ (the reverse field $|\alpha_-|$ may be neglected). The threshold equations must then be solved in a self consistent way. It might however be possible to determine γ_{th} only slightly above threshold, where the modification is small, $\gamma_{th} \approx \gamma_{th}^{(thresh)}$.

42.6.1.3 Fluctuation-dissipation theorem

Trajectories of ensembles of particles subject to friction and stochastic forces can be described by *Langevin equations*. The friction and the diffusion forces are related by the *fluctuation-dissipation theorem*. This theorem states that, for a thermal sample of atoms whose coordinates θ_n follow,

$$\ddot{\theta}_n = -\gamma_{frc}\dot{\theta}_n + \xi_n(t) \ , \tag{42.248}$$

[22] Through a linearization of the CARL equations, the cavity dissipation itself is found to exert a friction force to the atoms [590, 482]. This implies the existence of diffusion and a finite equilibrium temperature even at if the atoms are initially at $T = 0$.

[23] We note that atomic species exhibiting a hyperfine structure in the ground state are subject to cooling phenomena called 'polarization gradient cooling', which can cause much higher friction coefficients.
We also note that, when the molasses is applied to atoms confined to a potential, the atomic levels can be displaced (e.g., by light-shift or the Zeeman effect). This causes an inhomogeneous effective detuning of the laser beams generating the molasses.

the Langevin force $\xi(t)$ fluctuates stochastically with,

$$\langle \xi_n(t) \rangle = 0 \qquad \text{and} \qquad \langle \xi_n(t) \xi_m(t+\tau) \rangle = 2\gamma_{frc}^2 D_T \delta_{mn} \delta(\tau) \ . \tag{42.249}$$

Here, the *diffusion coefficient*,

$$D_T = \frac{\sigma^2}{\gamma_{frc}} \tag{42.250}$$

is related to the width of the Maxwell-Boltzmann velocity distribution,

$$\sigma = 2k\sqrt{\frac{k_B T}{m}} \ . \tag{42.251}$$

42.6.1.4 Langevin simulations

The Langevin equations of CARL can be simulated, including the random term of the Langevin force, using the *Runge-Kutta method* [631]. The procedure consists in propagating a general first order differential equation,

$$\boxed{\dot{x} = f(x) + g(t)} \ , \tag{42.252}$$

subject to a deterministic force f and a stochastic noise g satisfying,

$$\langle g(t) \rangle = 0 \qquad \text{and} \qquad \langle g(t) g(t') \rangle = 2D\delta(t-t') \tag{42.253}$$

as follows,

$$\boxed{\begin{array}{rcl} x(dt) & = & x_0 + \frac{1}{2} dt [f(x_0) + f(\tilde{x})] + \zeta (2Ddt)^{1/2} \\ \text{with} \quad \tilde{x} & \equiv & x_0 + f(x_0) dt + \zeta (2Ddt)^{1/2} \end{array}} \ , \tag{42.254}$$

where ζ is a random variable distributed according to a normal (Gaussian) distribution normalized as [24],

$$\langle \zeta \rangle = 0 \qquad \text{and} \qquad \langle \zeta^2 \rangle = 1 \ . \tag{42.255}$$

42.6.1.5 Langevin simulation in the adiabatic approximation

Now, we apply this method to the CARL subject to an optical molasses. Making the adiabatic approximation $\ddot{\theta}_n = 0$, the starting point is,

$$\boxed{\begin{array}{rcll} \dot{\alpha}_- & = & -\kappa \alpha_- - \imath U_0 \alpha_+ \sum_m e^{\imath \theta_m} & \equiv B(\alpha_-, \theta_n) \\ \dot{\theta}_n & = & \frac{8i\omega_{rec} U_0 \alpha_+}{\gamma_{frc}} (\alpha_- e^{-\imath\theta_n} - \alpha_-^* e^{\imath\theta_n}) + \frac{\xi_n(t)}{\gamma_{frc}} & \equiv F(\alpha_-, \theta_n) + \frac{\xi_n(t)}{\gamma_{frc}} \end{array}} \ . \tag{42.256}$$

[24] The MATLAB random number generator satisfies this requirement: $\langle \zeta_n \rangle \triangleq sum(randn(1,N))/N = 0$ and $\langle \zeta_n^2 \rangle \triangleq sum(randn(1,N).\wedge 2)/N = 1$.

In order to apply the Runge-Kutta method (42.254), we identify the variables and functions,

$$x(t) \equiv \begin{pmatrix} \alpha_-(t) \\ \theta_n(t) \end{pmatrix} \quad , \quad f(x) \equiv \begin{pmatrix} B(\alpha_-, \theta_n) \\ F(\alpha_-, \theta_n) \end{pmatrix} \quad , \quad g(t) \equiv \begin{pmatrix} 0 \\ \xi_n(t)/\gamma_{frc} \end{pmatrix} , \tag{42.257}$$

such that,

$$\tilde{x} = \begin{pmatrix} \tilde{\alpha}_- \\ \tilde{\theta}_n \end{pmatrix} = \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \end{pmatrix} + dt \begin{pmatrix} B(\alpha_-(0), \theta_n(0)) \\ F(\alpha_-(0), \theta_n(0)) \end{pmatrix} + \begin{pmatrix} 0 \\ \zeta_n \sqrt{2D_T dt} \end{pmatrix} \tag{42.258}$$

and

$$\begin{aligned} x(dt) &= \begin{pmatrix} \alpha_-(dt) \\ \theta_n(dt) \end{pmatrix} \\ &= \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \end{pmatrix} + \frac{dt}{2} \left[\begin{pmatrix} B(\alpha_-(0), \theta_n(0)) \\ F(\alpha_-(0), \theta_n(0)) \end{pmatrix} + \begin{pmatrix} B(\tilde{\alpha}_-, \tilde{\theta}_n) \\ F(\tilde{\alpha}_-, \tilde{\theta}_n) \end{pmatrix} \right] + \begin{pmatrix} 0 \\ \zeta_n \sqrt{2D_T dt} \end{pmatrix} . \end{aligned} \tag{42.259}$$

The Langevin equation can be used to simulate the temporal evolution of CARL. Fig. 42.49 shows a simulation of the frequency and amplitude of the CARL based on prescription (42.254).

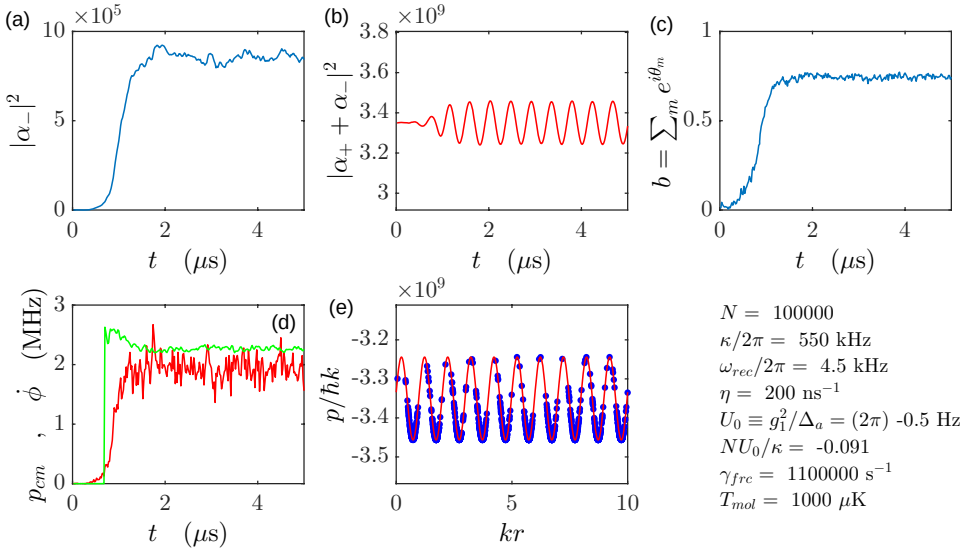

Figure 42.49: (code) Time evolution with phase transition of the viscous CARL in the adiabatic approximation. Shown are (a) the number of photons in the probe mode, (b) the beat signal, (c) the bunching, (d) the phase of the standing wave and the position of the center-of-mass of the cloud, and (e) the dipole potential calculated from (42.21) with the atomic distribution.

42.6.1.6 Langevin simulation of the full dynamics

Without adiabatic approximation, the starting point is,

$$\boxed{\begin{array}{lcll} \dot{\alpha}_- & = & \kappa\alpha_- - \imath U_0 \alpha_+ \sum_m e^{\imath\theta_m} & \equiv B(\alpha_-, \theta_n) \\ \dot{\theta}_n & = & V_n & \\ \dot{V}_n & = & 8i\omega_{rec} U_0 \alpha_+ (\alpha_- e^{-\imath\theta_n} - \alpha_-^* e^{\imath\theta_n}) - \gamma_{frc} V_n + \xi_n(t) & \equiv F(\alpha_-, \theta_n, V_n) + \xi_n(t) \end{array}} \quad . \tag{42.260}$$

In order to apply the Runge-Kutta method (42.254), we identify the variables and functions,

$$x(t) \equiv \begin{pmatrix} \alpha_-(t) \\ \theta_n(t) \\ V_n(t) \end{pmatrix} \quad , \quad f(x) \equiv \begin{pmatrix} B(\alpha_-, \theta_n) \\ V_n \\ F(\alpha_-, \theta_n, V_n) \end{pmatrix} \quad , \quad g(t) \equiv \begin{pmatrix} 0 \\ 0 \\ \xi_n(t) \end{pmatrix} \quad , \tag{42.261}$$

such that,

$$\tilde{x} = \begin{pmatrix} \tilde{\alpha}_- \\ \tilde{\theta}_n \\ \tilde{V}_n \end{pmatrix} \equiv \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \\ V_n(0) \end{pmatrix} + dt \begin{pmatrix} B\left(\alpha_-(0), \theta_n(0)\right) \\ V_n(0) \\ F\left(\alpha_-(0), \theta_n(0), V_n(0)\right) \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ \zeta_n \sqrt{2\gamma_{frc}^2 D_T dt} \end{pmatrix} \tag{42.262}$$

and

$$\begin{aligned} x(dt) = \begin{pmatrix} \alpha_-(dt) \\ \theta_n(dt) \\ V_n(dt) \end{pmatrix} = \begin{pmatrix} \alpha_-(0) \\ \theta_n(0) \\ V_n(0) \end{pmatrix} + \frac{dt}{2} \Bigg[\begin{pmatrix} B\left(\alpha_-(0), \theta_n(0)\right) \\ V_n(0) \\ F\left(\alpha_-(0), \theta_n(0), V_n(0)\right) \end{pmatrix} \\ + \begin{pmatrix} B(\tilde{\alpha}_-, \tilde{\theta}_n) \\ \tilde{V}_n \\ F(\tilde{\alpha}_-, \tilde{\theta}_n, \tilde{V}_n) \end{pmatrix} \Bigg] + \begin{pmatrix} 0 \\ 0 \\ \zeta_n \sqrt{2\gamma_{frc}^2 D_T dt} \end{pmatrix} \quad . \end{aligned} \tag{42.263}$$

42.6.1.7 Simulation of the phase transition

The simulations of the Langevin equations shown in Figs. 42.49 and 42.50 exhibit a *temporal phase transition* due to a spontaneous self-organization of the atoms.

We can also, slowly varying some control parameter, study the threshold behavior. In Fig. 42.51, for example, we first increase and then reduce linearly the injected power α_+. We clearly observe a threshold behavior, but also a hysteresis indicating a bistability of the system. It is also interesting to note a separation of the CARL frequency and the atomic center-of-mass velocity in the green and red curves of Fig. 42.51(c).

In Fig.42.52, we increase and then reduce the temperature linearly.

The following links show simulations of the Langevin equation for CARL (watch movie) and of the Fokker-Planck equation for CARL (watch movie). Furthermore,

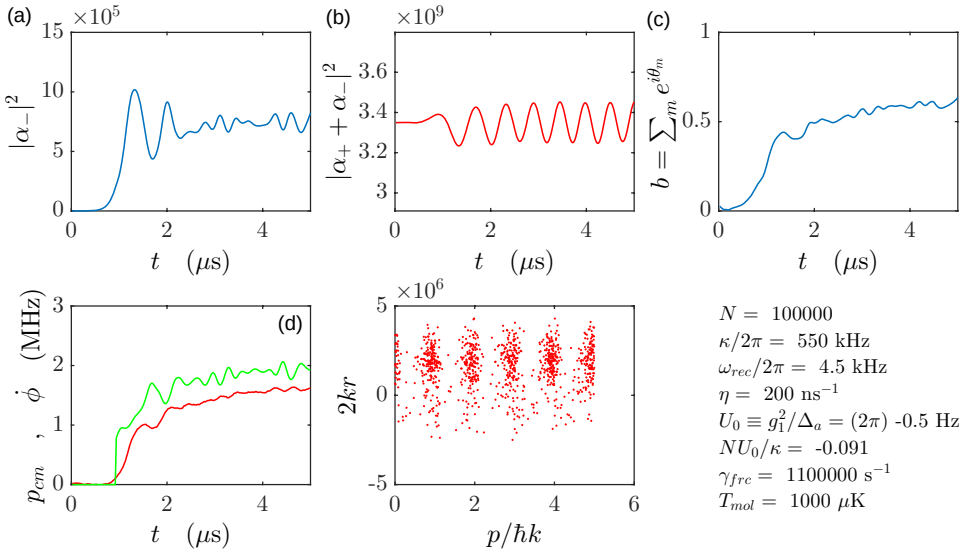

Figure 42.50: (code) Time evolution of the complete dynamics of the viscous CARL with phase transition. Same parameters as in Fig. 42.49. Shown are (a) the number of photons in the probe mode, (b) the beat signal, (c) the bunching, (d) the phase of the standing wave and the position of the center-of-mass of the cloud, and (e) the dipole potential calculated from (42.21) with the atomic distribution.

the following videos show examples of self-synchronizing systems that can be understood via the Kuramoto model: Huygens pendulum clocks (watch movie), synchronizing crickets (watch movie), buzzing mosquitoes (watch movie), singing dunes (watch movie), and the London Millenium bridge (watch movie).

42.6.2 The Fokker-Planck and the Vlasov model

The *Fokker-Planck equation* for a density distribution $Q(\mathbf{r}, t)$,

$$\frac{dQ}{dt} + Q\nabla \cdot \mathbf{v} = D\nabla^2 Q \ , \tag{42.264}$$

represents a generalization of the *continuity equation*, since with $\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla$, we obtain,

$$\frac{\partial Q}{\partial t} = -\nabla \cdot (\mathbf{v}Q) + D\nabla^2 Q \ . \tag{42.265}$$

If ρ is a local density, it the continuity equation reads,

$$\frac{d\rho}{dt} + \rho\nabla \cdot \mathbf{v} = 0 \ . \tag{42.266}$$

Knowing,

$$\frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \ , \tag{42.267}$$

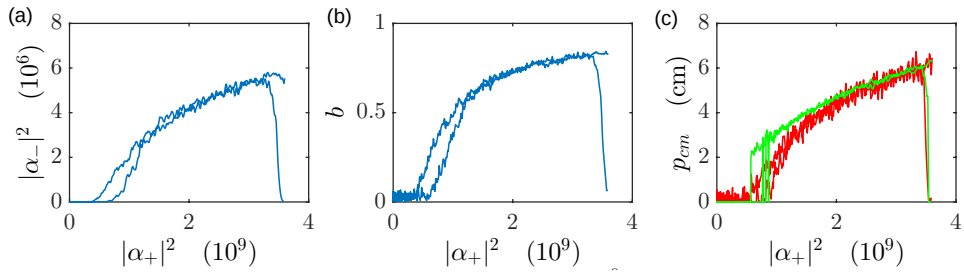

Figure 42.51: (code) (a) Number of atoms in the probe mode, (b) bunching and (c) velocity of the atoms (red) and the frequency of the CARL (green), while the pumping power is ramped.

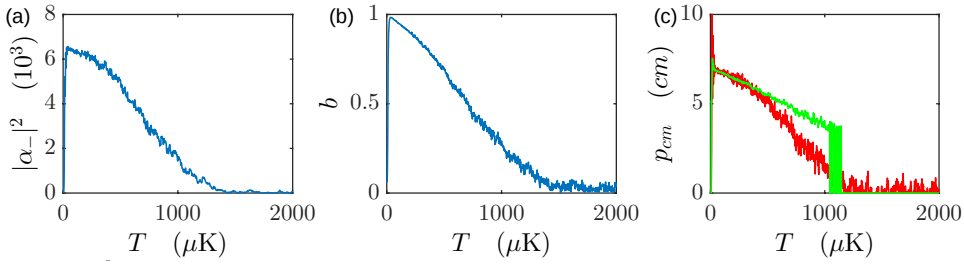

Figure 42.52: (code) Same as Fig. 42.51, but now the temperature is ramped.

we obtain,

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \mathbf{v}) \ . \tag{42.268}$$

The Fokker-Planck equation is just a generalization to include a diffusion process,

$$\frac{d\rho}{dt} + \rho \nabla \mathbf{v} = D_x \frac{\partial^2 \rho}{\partial x^2} \ , \tag{42.269}$$

or

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \mathbf{v}) + D_x \frac{\partial^2 \rho}{\partial x^2} \ . \tag{42.270}$$

42.6.2.1 Thermalization in the Fokker-Planck equation

We now apply the Fokker-Planck equation to the density distribution (42.256) of an atomic cloud subjected to the CARL force [1343, 1106]. As CARL is a one-dimensional process, we can use $\nabla \to \partial\theta$ and replace the velocity field $\mathbf{v} \to \dot{\theta}$:

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\kappa\alpha_- - \imath N U_0 \alpha_+ b \\ \frac{\partial Q}{\partial t} &= \frac{8\imath\omega_{rec} U_0 \alpha_+}{\gamma_{frc}} \frac{\partial}{\partial\theta}\left[(\alpha_- e^{-\imath\theta} - \alpha_-^* e^{\imath\theta})Q\right] + D_\theta \frac{\partial^2 Q}{\partial\theta^2} \end{aligned}} \ . \tag{42.271}$$

The position diffusion coefficient can be estimated by,

$$D_\theta = \frac{\langle k^2 v^2 \rangle}{\gamma_{frc}} \ . \tag{42.272}$$

The normalization and the 'bunching' $|b|$ are given by,

$$1 = \int_0^{2\pi} Q(\theta,t) d\theta \quad , \quad b \equiv \int_0^{2\pi} Q(\theta,t) e^{-\imath\theta} d\theta \ . \tag{42.273}$$

To simulate the equations (42.271) we expand the distribution function in spatial harmonics [1106],

$$Q(\theta,t) \equiv \sum_\nu Q_\nu(t) e^{\imath\nu\theta} \ . \tag{42.274}$$

In this expansion the normalization and the bunching become,

$$Q_0 = 1/2\pi \quad , \quad |b| = 2\pi |Q_1| \ , \tag{42.275}$$

and the equations (42.271) immediately yield,

$$\boxed{\begin{array}{rcl} \dot{\alpha}_- & = & -2\pi\imath N U_0 \alpha_+ Q_1 - \kappa \alpha_- \\ \dfrac{dQ_\nu}{dt} & = & \dfrac{8\omega_{rec} U_0 \alpha_+}{\gamma_{frc}} \nu \left(\alpha_- Q_{\nu+1} + \alpha_-^* Q_{\nu-1} \right) - \nu^2 D_\theta Q_\nu \end{array}} \ . \tag{42.276}$$

We will derive the results (42.275) and (42.276) in Exc. 42.6.7.3. Also,

$$kv = \frac{d}{dt} \arctan \frac{\mathfrak{Im}\ \alpha_-}{\mathfrak{Re}\ \alpha_-} \ , \tag{42.277}$$

and,

$$\begin{aligned} \langle \dot{\theta} \rangle &\equiv \int_0^{2\pi} \dot{Q}(\theta,t) d\theta = \sum_\nu \dot{Q}_\nu(t) \int_0^{2\pi} e^{\imath\nu\theta} d\theta \\ &= \sum_\nu \frac{8\omega_{rec} U_0 \alpha_+}{\gamma_{frc}} \nu \left(\alpha_- Q_{\nu+1} \alpha_-^* Q_{\nu-1} \right) \delta_{\nu 0} = \frac{16\omega_{rec} U_0 \alpha_+}{\gamma_{frc}} \mathfrak{Re}\ (\alpha_- Q_1^*) \ . \end{aligned} \tag{42.278}$$

These equations can be easily simulated.

Matlab simulations of the Fokker-Planck equation, shown in Fig. 42.53, reproduce quantitatively the curves previously obtained by simulations of the Langevin equations.

42.6.2.2 Bistability and instability of the viscous CARL

The threshold can be found by simulating the Fokker-Planck equation while varying a control parameter (pumping power, temperature, number of atoms) sufficiently slowly, that the system always remains in a steady state. Fig. 42.54 shows the behavior of the CARL, while the pump power is linearly reduced and then linearly increased at different velocities. We observe a bistability that slightly depends on the speed of the ramp. The behavior of the mass-center velocity kv_{cm} and the phase of the standing wave, $\dot{\phi}$, are different [1104] [25].

[25] We can expect a second phase transition when the pump power exceeds a critical value, because for $NU_0 > \kappa$, the CARL becomes unstable again: It will unlock from the self-determined frequency

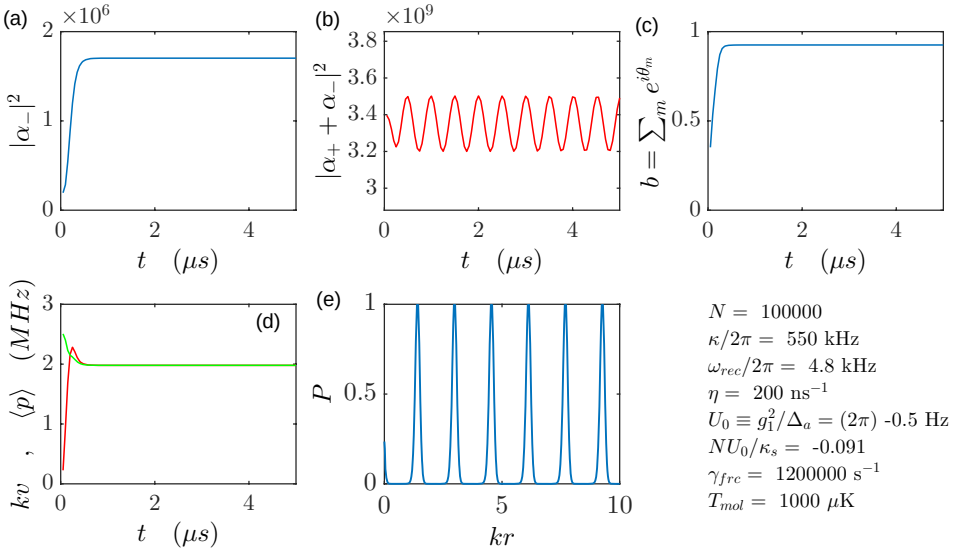

Figure 42.53: (code) Temporal evolution of the complete dynamics with phase transition of the viscous CARL. The same parameters as in Fig. 42.49. Shown are (a) the number of photons in the probe mode, (b) the beat signal, (c) the bunching, (d) the phase of the standing wave and the position of the center-of-mass of the cloud, and (e) the atomic density distribution.

42.6.3 Thermalization in the Vlasov equation

The basic equations describing our ring-cavity filled with atoms are [755],

$$\boxed{\begin{aligned} \dot{\alpha}_- &= \kappa\alpha_- - \imath U_0 \alpha_+ \sum_m e^{\imath\theta_m} \\ \dot{\theta}_n &= V_n \\ \dot{V}_n &= 8\imath\omega_{rec} U_0 \alpha_+ (\alpha_- e^{-\imath\theta_n} - \alpha_-^* e^{\imath\theta_n}) - \gamma_{frc}(V_n - V_n^{(0)}) \end{aligned}} \quad , \tag{42.279}$$

if we assume the pump mode to be stationary $\alpha_+ = \eta_+/\kappa^{-1}$ and define the atomic bunching parameter by $b = \frac{1}{N}\sum_j e^{2ikx_j}$. A non-zero steady-state temperature is reached, if we allow the steady-state velocities of the atoms $v_j^{(0)}$ to be *different* for all atoms and distributed according to a Maxwell-Gaussian velocity distribution. The assumption of a common steady-state velocity for all atoms obviously results in perfect bunching and cooling to $T = 0$.

Let us introduce a local phase space density of the atomic cloud $Q(x, p, t)$ as a two-dimensional field in phase space. The time-evolution of this quantity is given by the so-called *Vlasov equation* (or collisionless Boltzmann equation),

$$0 = \partial_t Q + v\partial_x Q + F\partial_p Q + \gamma_{th}(Q - Q_0) \ , \tag{42.280}$$

and start to oscillate strongly. However, this effect is not described by the equations used for the simulation, which suppose an adiabatic elimination of the inertia.

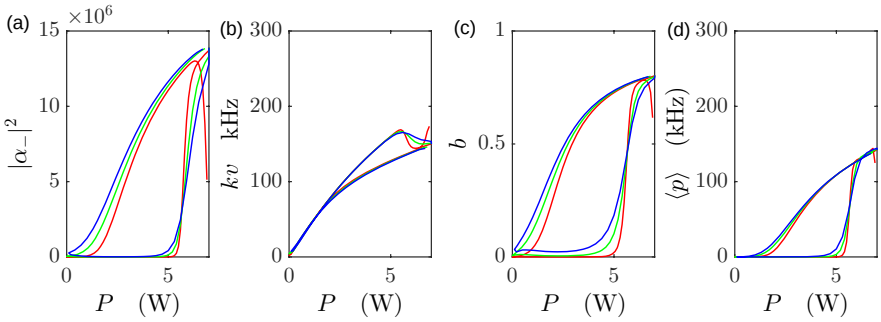

Figure 42.54: (code) Bistability of CARL near the threshold when the power is ramped at different paces.

where v and F are the center-of-mass velocity and force taken from equation (42.279) without the friction term. According to this equation the atomic cloud tends to a stationary distribution Q_0 as time goes on. Following Bonifacio *et al.* [176] and Javaloyes [665, 666, 667], we replace the friction term by an additional (Vlasov) equation:

$$\boxed{\begin{aligned} \dot{\alpha}_- &= -\imath N U_0 \alpha_+ b - \kappa \alpha_- \\ \dot{\theta} &= \omega_{rec} V \\ \dot{V} &= \imath U_0 \alpha_+ (\alpha_- e^{-\imath\theta} - \alpha_-^* e^{\imath\theta}) \\ 0 &= \partial_t Q + \dot{\theta}\partial_\theta Q + \dot{\varrho}\partial_\varrho Q + \gamma_{frc}(Q - Q_0) \end{aligned}} \quad . \tag{42.281}$$

The bunching parameter can now be rewritten in terms of

$$b = \int_0^{2\pi} d\theta \int_{-\infty}^{\infty} d\varrho \; Q(\theta, \varrho, t) \; e^{2\imath\theta} \; . \tag{42.282}$$

The equilibrium distribution is chosen to be a homogeneous cloud with a Maxwell-Boltzmann velocity distribution,

$$Q_0 = \frac{1}{2\pi}\sqrt{\frac{\sigma}{\pi}} e^{-\sigma\varrho^2} \; , \tag{42.283}$$

where $\sigma \equiv \hbar\omega_{rec}/k_B T$ with $\omega_{rec} \equiv \hbar k^2/2m$ such that $\int_0^{2\pi} d\theta \int_{-\infty}^{\infty} Q_0 d\varrho = 1$. We now perform a linear stability analysis. We expand Q around the steady state, $Q(\theta, \varrho, t) = Q_0(\varrho) + Q_1(\theta, \varrho, t)$ and retain to first order,

$$0 = \partial_t Q_1 + \dot{\theta}\partial_\theta Q_1 + \dot{\varrho}\partial_\varrho Q_0 + \gamma_{th} Q_1 \; . \tag{42.284}$$

Now we look for a time-dependent particular solution by inserting the ansatz,

$$\begin{aligned} \alpha_-(t) &= \beta_- e^{\imath\lambda t} \qquad \text{with} \qquad \dot{\beta}_- = 0 \\ Q_1(\theta, \varrho, t) &= H_1(\varrho) e^{-2\imath\theta} e^{\imath\lambda t} + c.c. \; , \end{aligned} \tag{42.285}$$

where $i\lambda \equiv \lambda_g + i\lambda_\omega$ into the field equation (42.281)a, the first order expansion of the Vlasov equation (42.284) (only retaining co-rotating terms) and into the expression for bunching (42.282). This ansatz accounts for the fact that, in steady state, we expect a fixed CARL frequency ν and a spatially modulated density distribution of the atoms. The set of equations becomes,

$$\begin{aligned} qi\lambda\beta_- &= -\kappa\beta_- - \imath N U_0 \tilde{\eta}_+ b e^{-\imath\lambda t} \\ 0 &= \imath\lambda H_1(\varrho) - 4\imath\omega_{rec}\varrho H_1(\varrho) + \imath U_0\tilde{\eta}_+\beta_-\partial_\varrho Q_0 + \gamma_{th} H_1(\varrho) \\ b &= \int_0^{2\pi} d\theta \int_{-\infty}^{\infty} d\varrho\ H_1(\varrho) e^{\imath\lambda t}\ . \end{aligned} \tag{42.286}$$

With the definition,

$$\begin{aligned} \Gamma(\sigma,\gamma_{th},\imath\lambda) &\equiv \int_{-\infty}^{\infty} \frac{d\varrho\ \partial_\varrho Q_0}{\imath\lambda - 4\imath\omega_{rec}\varrho + \gamma_{th}} \\ &= -\int_{-\infty}^{\infty} \frac{d\varrho\ 4\imath\omega_{rec} Q_0}{(\imath\lambda - 4\imath\omega_{rec}\varrho + \gamma_{th})^2}\ , \end{aligned} \tag{42.287}$$

the solution of the above set of equations is,

$$\begin{aligned} H_1(\varrho) &= \frac{-\imath U_0\tilde{\eta}_+\beta_-\partial_\varrho Q_0}{\imath\xi - 4\imath\omega_{rec}\varrho + \gamma_{th}} \\ b &= -e^{\imath\xi t}\imath U_0\tilde{\eta}_+\beta_- 2\pi\Gamma(\sigma,\gamma_{th},\imath\lambda) \\ 0 &= \left[\kappa + \imath\lambda + N U_0^2\tilde{\eta}_+^2\ 2\pi\Gamma(\sigma,\gamma_{th},\imath\lambda)\right]\ \beta_-\ . \end{aligned} \tag{42.288}$$

42.6.3.1 Calculation of the threshold

The bifurcation where the reverse field crosses the threshold to lasing occurs at $\lambda_g = 0$. We divide the field equation in real and imaginary parts,

$$\begin{aligned} \kappa + N U_0^2\tilde{\eta}_+^2\ 2\pi\mathfrak{Re}\ \Gamma(\sigma,\gamma,\imath\lambda_\omega) &= 0 \\ \nu + N U_0^2\tilde{\eta}_+^2\ 2\pi\mathfrak{Im}\ \Gamma(\sigma,\gamma,\imath\lambda_\omega) &= 0\ . \end{aligned} \tag{42.289}$$

Now the condition $\lambda_\omega \mathfrak{Re}\ \Gamma(\sigma,\gamma_{th},\imath\lambda_\omega) = \kappa\mathfrak{Im}\ \Gamma(\sigma,\gamma_{th},\imath\lambda_\omega)$ leads to,

$$\int_{-\infty}^{\infty} \frac{d\varrho\ \varrho e^{-\sigma\varrho^2}(\kappa\lambda_\omega - 2\kappa\varepsilon\varrho + \lambda_\omega\gamma_{th})}{(\lambda_\omega - 2\varepsilon\varrho)^2 + \gamma_{th}^2} = 0\ . \tag{42.290}$$

The values λ_ω where this integral is zero are inserted into one of the equations (42.289). Finally,

$$\tilde{\eta}_+^2 = \frac{-1}{N\tilde{U_0^2}\ 2\pi\mathfrak{Re}\ \kappa\Gamma(\sigma,\gamma_{th},\imath\lambda_\omega)}\ , \tag{42.291}$$

is the expression for the pump power threshold as a function of temperature σ, friction γ_{th}, cavity damping κ and coupling constant U_0. The intracavity CARL power is,

$$P_+ = \hbar\omega\delta\ \tilde{\eta}_+^2\ . \tag{42.292}$$

λ_ω is the associated CARL frequency, i.e. the frequency difference between probe and pump.

The final equations show that the threshold power drops as NU_0^2 increases. To see the dependencies of the threshold power on T and γ_{th}, we have to evaluation of the integral (42.290). Fig. 42.55 shows a numerical evaluation of Eqs. (42.290),(42.291) and (42.292) for finite T and γ_{th}.

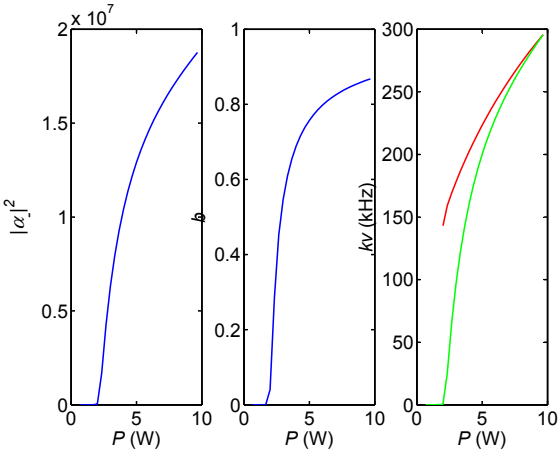

Figure 42.55: (code) Intracavity threshold power as a function of temperature and friction coefficient. The coupling strength is set to $\tilde{U}_0 = -10^{-7}$, the atom number is $N = 10^6$.

Apparently, the threshold pump power drops with vanishing friction and with low temperatures. For typical experimental situations, $T \approx 100$ μK and $\gamma_{th} \approx 10\kappa$, we expect threshold powers on the order of about $P_+ = 1$ W, corresponding to $P_+^{(out)} = 4$ μW leaking out of the cavity.

42.6.4 The Kuramoto model

Ripples on a dusty street driven by cars, rapids in a river arising spontaneously or behind an obstacle, wind blowing over a water surface spontaneously creating waves. Imagine a photon wind blowing over an atomic sea. Just like for water waves friction hinders boundless acceleration. The analogies are wind-molasses-friction, water-atoms, wind-acceleration-field, gravitation-dipole-force. The phenomenon is closely related to the *dissipative structure*. See also (watch talk) and (watch talk).

Our system has the advantage over macroscopic systems, that the hypothesis of uniform coupling is exactly satisfied, because the coupling medium, i.e. the light fields are delocalized within the cavity mode. In contrast, rapids develop exclusively behind the perturbation. There are no delay times effects and no spatial constraints due to a finite size of the individual oscillators.

The viscous CARL system is representative for of the vast class of *Kuramoto systems* [1272] introduced in Sec. ??. This can be seen most appropriately by rewriting the CARL equations in terms of phase and amplitude of individual atoms. Another approach is via the Fokker-Planck equation, for which there already exists a Kuramoto equivalence.

Why is it interesting to investigate yet another coupled oscillator system? Our

CARL is fully classical, although we deal with microscopic particle, such as atoms and photons. However, our system bears the possibility of being transferred to quantum situations, and thus to study the coupling of large ensembles of quantum oscillators. Furthermore, the coupling mechanism is well understood and controlable by experiment. Because the coupling goes through the standing wave fraction, it depends on the atom number and the coupling strength independently. Furthermore, the tunable friction force (temperature) corresponds to a variable width of the distribution of the oscillator frequencies, which we can manipulate in-situ and on-line.

Another realization of the Kuramoto model would be atoms in a ring cavity standing wave. Cold trapped atoms have the same oscillation frequencies. And thus do not need to synchronize. For hot atoms, however, the oscillation period depends on their kinetic energy.

The equation for the phases of the atoms is similar to the Kuramoto model [667],

$$\boxed{\dot{\theta}_n = \frac{K}{N}\sum_m \sin(\theta_n - \theta_m) - \xi_n(t)} \ . \tag{42.293}$$

The CARL equations which describes the dynamics of an ensemble of mean-field coupled oscillators, belong to the class of Kuramoto systems [666]. The main differences are: a Dirac-like distribution of eigenfrequencies and a mean-field self-consistently provided by a dynamical equation. Hence, in contrast to the original Kuramoto model, where the collective oscillation frequency is just the mean of the individual frequencies, the CARL frequency is self-determined and depends also on control parameters. This phenomenon is known from other systems like rhythmic applause, which only takes place by a reduction of the individual frequencies of clapping hands, towards a resonance. For this to happen the mean-field must self-adjust while the individual oscillators synchronize, e.g. the noise produce by the audience must adjust to the average desire of the audience to produce a satisfying level of noise.

In [1373] is stated: 'The essence of the problem is the competition between the intrinsic disorder (i.e. noise and diffusion) and the dynamical coupling strength. In the Kuramoto model, the disorder enters via the distribution of natural frequencies, while the effective coupling strength is set by the parameter combination $K\cos\alpha_j$.'

42.6.4.1 Phase formalism of CARL

The starting point is the CARL equations (42.50). We make ansatz,

$$\alpha_+ \equiv \alpha_1 \quad , \quad \alpha_- \equiv \alpha_2 \ e^{\imath\phi} \quad , \quad \eta_+ \equiv \eta_1 \quad , \quad \eta_- \equiv \eta_2 \ e^{\imath\Delta} \ , \tag{42.294}$$

where the quantities with numeric suffixes are real, such that,

$$|\alpha_+ + \alpha_-|^2 = \alpha_1^2 + \alpha_2^2 + 2\alpha_1\alpha_2 \ \cos\phi \ . \tag{42.295}$$

By this ansatz we assume that a pumping laser is locked to the mode α_+ of the ring cavity, such that the phases of the fields α_+ and η_+ are equal and, without loss of generality, zero. On the other hand, the phase ϕ of the probe mode is a dynamic

variable. Inserting the ansatz into the equations (42.50) we obtain,

$$\begin{aligned}
\dot{\alpha}_1 &= -(\kappa + \imath N U_0 - \imath\Delta_c)\alpha_1 - \imath U_0 \sum_n e^{-\imath\theta_n + \imath\phi}\alpha_2 + \eta_1 \ , \\
\dot{\alpha}_2 + \imath\dot{\phi}\alpha_2 &= -(\kappa + \imath N U_0 - \imath\Delta_c)\alpha_2 - \imath U_0 \sum_n e^{\imath\theta_n - \imath\phi}\alpha_1 + \eta_2 e^{\imath\Delta - \imath\phi} \ , \\
\ddot{\theta}_n &= 16\omega_{rec} U_0 \alpha_1 \alpha_2 \sin(\theta_n - \phi) \ .
\end{aligned} \tag{42.296}$$

The first two equations, which describe the dynamics of the fields, can be separated into real and imaginary parts,

$$\begin{aligned}
\dot{\alpha}_1 &= -\kappa\alpha_1 - U_0 \sum_n \sin(\theta_n - \phi)\alpha_2 + \eta_1 \\
\dot{\alpha}_2 &= -\kappa\alpha_2 + U_0 \sum_n \sin(\theta_n - \phi)\alpha_1 + \eta_2 \cos(\phi - \Delta) \ , \\
\Delta_c &= N U_0 \left(1 + N^{-1} \sum_n \cos(\theta_n - \phi)\frac{\alpha_2}{\alpha_1}\right) \ , \\
\dot{\phi} &= \Delta_c - N U_0 \left(1 + N^{-1} \sum_n \cos(\theta_n - \phi)\frac{\alpha_1}{\alpha_2}\right) - \frac{\eta_2}{\alpha_2}\sin(\phi - \Delta) \ .
\end{aligned} \tag{42.297}$$

Eliminating Δ_c, we can substitute the third and fourth equations for,

$$\dot{\phi} = U_0 \left(\frac{\alpha_2}{\alpha_1} - \frac{\alpha_1}{\alpha_2}\right) \sum_n \cos(\theta_n - \phi) - \frac{\eta_2}{\alpha_2}\sin(\phi - \Delta) \ . \tag{42.298}$$

Defining the 'bunching' parameter,

$$b \equiv |b| e^{\imath\psi} \equiv N^{-1} \sum_n e^{\imath\theta_n} \ , \tag{42.299}$$

we finally obtain, in the presence of friction and dissipation,

$$\boxed{\begin{aligned}
\dot{\alpha}_1 &= -\kappa\alpha_1 - N U_0 \alpha_2 |b| \sin(\psi - \phi) + \eta_1 \\
\dot{\alpha}_2 &= -\kappa\alpha_2 + N U_0 \alpha_1 |b| \sin(\psi - \phi) + \eta_2 \cos(\phi - \Delta) \\
\dot{\phi} &= N U_0 \left(\tfrac{\alpha_2}{\alpha_1} - \tfrac{\alpha_1}{\alpha_2}\right) |b| \cos(\psi - \phi) - \tfrac{\eta_2}{\alpha_2}\sin(\phi - \Delta) \\
\ddot{\theta}_n &= 16\omega_{rec} U_0 \alpha_1 \alpha_2 \sin(\theta_n - \phi) - \gamma_{frc}\dot{\theta}_n + \xi_n
\end{aligned}} \ . \tag{42.300}$$

A particularly interesting case is that of unidirectional pumping, $\eta_2 = 0$. Assuming that the pump mode be not affected,$\dot{\alpha}_1 = 0$, and that the probe mode be weak, $\alpha_1 \gg \alpha_2$, and making the adiabatic approximation, $\ddot{\theta}_n = 0$, of the atomic motion, we

obtain,

$$\boxed{\begin{aligned}\dot{\alpha}_2 &= -\kappa\alpha_2 + NU_0\alpha_1|b|\sin(\psi-\phi)\\ \dot{\phi} &\simeq -\frac{NU_0\alpha_1}{\alpha_2}|b|\cos(\psi-\phi)\\ \dot{\theta}_n &= \frac{\xi_n}{\gamma_{frc}} + \frac{16\omega_{rec}U_0\alpha_1\alpha_2}{\gamma_{frc}}\sin(\theta_n-\phi)\end{aligned}} \quad . \tag{42.301}$$

We note that the equation for the phases of the atoms is similar to the Kuramoto equation (42.293).

42.6.4.2 Relationship between CARL and Kuramoto

The viscous CARL described by the formulas (42.301) corresponds to the Kuramoto model [1272]. Defining $\theta_n \equiv 2kx_n$ as the position of the n^{th} atom, we assume the pump laser to be in resonance and write $\alpha_+ \equiv \eta_+/\kappa$ [755]. The diffusion in the momentum space is a process that limits the temperature in optical molasses.

We start from the Langevin equations (42.256). In addition, we assume that the standing wave propagates at a constant velocity, which is to say that for a strong viscous damping, the system quickly finds a steady state. This condition is formulated by $d_t|\alpha_-| = 0$ and $\dot{\alpha}_- = i\omega_{ca}\alpha_-$ with constant velocity ω_{ca}, which may be different from the velocity of the center of mass kv. We note that this assumption can introduce a considerable error, when used to describe temporal phase transitions, since, as shown by simulations of the complete dynamics (42.260), the mode α_- exhibits a transient behavior, as well. We obtain from the first Eq. (42.256),

$$\alpha_- = -\frac{\imath U_0\alpha_+}{\imath\omega_{ca}+\kappa}\sum_m e^{\imath\theta_m} \ . \tag{42.302}$$

Substituting Eq. (42.302) into the second equation (42.256),

$$\begin{aligned}\dot{\theta}_n &= \frac{\xi_n}{\gamma_{fr}} + \frac{8\omega_{rec}NU_0^2\alpha_+^2}{\gamma_{fr}}\frac{1}{N}\sum_m\left(\frac{e^{\imath\theta_m-\imath\theta_n}}{\imath\omega_{ca}+\kappa} + \frac{e^{-\imath\theta_m+\imath\theta_n}}{-\imath\omega_{ca}+\kappa}\right) \qquad (42.303)\\ &= \frac{\xi_n}{\gamma_{fr}} + \frac{16\omega_{rec}NU_0^2\alpha_+^2}{\gamma_{fr}(\omega_{ca}^2+\kappa^2)}\frac{1}{N}\sum_m\left[\kappa\cos(\theta_m-\theta_n)+\omega_{ca}\sin(\theta_m-\theta_n)\right] \ .\end{aligned}$$

Defining the *order parameter*,

$$b \equiv |b|e^{\imath\psi} \equiv \frac{1}{N}\sum_m e^{\imath\theta_m} \ , \tag{42.304}$$

which also implies,

$$|b|\sin(\psi-\theta_n) = \frac{1}{N}\sum_m \sin(\theta_m-\theta_n) \ , \tag{42.305}$$

we can write Eq. (42.305) as,

$$\dot{\theta}_n = \frac{\xi_n}{\gamma_{fr}} + \frac{8\varepsilon NU_0^2\alpha_+^2\kappa}{\gamma_{fr}(\omega_{ca}^2+\kappa^2)}|b|\left[\cos(\psi-\theta_n) + \frac{\omega_{ca}}{\kappa}\sin(\psi-\theta_n)\right] \ . \tag{42.306}$$

In the 'good cavity' limit, $\kappa \ll \omega$, using $(2kv)^3 = 8\varepsilon N U_0^2 \alpha_+^2 \kappa/\gamma_{fr}$ and additionally assuming small amplitude oscillations, $\psi \approx \theta_n$, that is, good 'bunching',

$$\dot{\theta}_n \approx \frac{\xi_n}{\gamma_{fr}} + \frac{(2kv)^3}{\omega_{ca}^2}|b| + \frac{(2kv)^3}{\kappa\omega_{ca}}|b|\sin(\psi - \theta_n) \; . \tag{42.307}$$

This shows that in the limit of perfect 'bunching' $\omega_{ca} = 2kv$ must be satisfied. If really $\kappa \ll \omega$ is valid, we can despise the cosine. Introducing the Kuramoto coupling constant,

$$K \equiv \frac{16\omega_{rec} N U_0^2 \alpha_+^2 \omega_{ca}}{\gamma_{fr}(\omega_{ca}^2 + \kappa^2)} \approx \frac{1}{\kappa}\left(\frac{16\omega_{rec} N U_0^2 \alpha_+^2 \kappa}{\gamma_{fr}}\right)^{2/3} = (4\omega_{rec}\rho)^2 \left(\frac{4}{\kappa\gamma_{fr}^2}\right)^{1/3} , \tag{42.308}$$

using $2\varepsilon\rho = (4\varepsilon N U_0^2 \alpha_+^2)^{1/3}$, Eq. (42.306) is precisely the one used by the *Kuramoto model* of N coupled harmonic oscillators synchronizing over time,

$$\boxed{\dot{\theta}_n \approx \frac{\xi_n}{\gamma_{fr}} + \frac{\kappa K}{\omega_{ca}}|b| + K|b|\sin(\psi - \theta_n)} \; . \tag{42.309}$$

Oscillators with $\omega_n \leq K|b|$ are locked. For a reasonable 'bunching' this is satisfied in the 'good cavity' limit.

42.6.4.3 Kuramoto model with inertial effects

It is possible to incorporate inertial effects into the Kuramoto model [3]: allowing for $\ddot{\theta}_n \neq 0$, but still assuming $d_t|\alpha_-| = 0$ and $\dot{\alpha}_- = i\omega\alpha_-$, the equation (42.303) becomes,

$$\ddot{\theta}_n = -\gamma_{fr}\dot{\theta}_n + \xi_n + \frac{16\omega_{rec} N U_0^2 \alpha_+^2}{\omega^2 + \kappa^2}\frac{1}{N}\sum_m \left[\kappa\cos(\theta_m - \theta_n) + \omega\sin(\theta_m - \theta_n)\right] \tag{42.310}$$

$$= -\gamma_{fr}\dot{\theta}_n + \xi_n + \frac{\kappa}{\omega}K|b|\cos(\psi - \theta_n) + K|b|\sin(\psi - \theta_n) \; .$$

42.6.4.4 Fokker-Planck equation

Let us write the *Kuramoto equation* including stochastic noise,

$$\dot{\theta}_n = \omega + K|b|\sin(\psi - \theta_n) + \xi_n(t) \; , \tag{42.311}$$

define the order parameter,

$$b = |b|e^{\imath\psi} \; , \tag{42.312}$$

and the Langevin-force $\langle\xi_n(t)\rangle = 0$ and $\langle\xi_n(t)\xi_m(\tau)\rangle = 2D\delta_{ij}\delta(t-\tau)$.

The Fokker-Planck equation associated to Eq. (42.311) reads,

$$\frac{\partial\rho}{\partial t} = -\frac{\partial\rho\;\left[\omega + K|b|\sin(\psi - \theta)\right]}{\partial\theta} + D\frac{\partial^2\rho}{\partial\theta^2} \; , \tag{42.313}$$

where $D = \sigma^2/\gamma_{fr}$. Inserting $\rho(\theta, t) \equiv \sum_\nu \rho_\nu(t)e^{\imath\nu\theta}$,

$$\frac{\partial\rho_\nu}{\partial t} = -(\nu^2 D + \imath\nu\omega)\rho_\nu + \tfrac{1}{2}\nu K\left(b^*\rho_{\nu-1} - b\rho_{\nu+1}\right) \; , \tag{42.314}$$

especially,

$$\int_0^{2\pi} \rho(\theta,t)d\theta = 1 \qquad \Longrightarrow \qquad \rho_0 = \tfrac{1}{2\pi} \ , \tag{42.315}$$

and we defined the bunching as $|b|$, where,

$$b \equiv \int_0^{2\pi} \rho(\theta,t)e^{-i\theta}d\theta \qquad \Longrightarrow \qquad b \equiv 2\pi\rho_1 \ . \tag{42.316}$$

42.6.4.5 Laser-type equation for CARL

Defining the displacement of the n^{th} atomic oscillator as,

$$E_n \equiv e^{\imath\theta_n} \ , \tag{42.317}$$

we can rewrite the second equation (42.256) as,

$$\dot{E}_n = \frac{\imath\xi_n}{\gamma_{fr}}E_n - \frac{8\omega_{rec}U_0\alpha_+}{\gamma_{fr}}(\alpha_- - \alpha_-^* E_n^2) \ . \tag{42.318}$$

Substituting α_- by the integral of the first equation (42.256),

$$\dot{E}_n = \frac{\imath\xi_n}{\gamma_{fr}}E_n + \frac{8\omega_{rec}\imath NU_0^2\alpha_+^2}{\gamma_{fr}}\left(\int be^{-\kappa(t-t')}dt' + E_n^2\int b^* e^{-\kappa(t-t')}dt'\right) \ . \tag{42.319}$$

In the limit $e^{-\kappa(t-t')} = \kappa^{-1}\delta(t-t')$ we obtain an equation similar to that of an ordinary laser,

$$\begin{aligned}\dot{E}_n &= \frac{\imath\xi_n}{\gamma_{fr}}E_n + \frac{8\omega_{rec}\imath NU_0^2\alpha_+^2}{\gamma_{fr}\kappa}(b + b^* E_n^2) \\ &= \frac{\imath\xi_n}{\gamma_{fr}}E_n + \frac{8\omega_{rec}\imath NU_0^2\alpha_+^2}{\gamma_{fr}\kappa}\left(\sum_m E_m + \sum_m E_m^* E_n^2\right) \ .\end{aligned} \tag{42.320}$$

42.6.5 Thermodynamics of the CARL process

There is an analogy between the laser threshold and a second-order phase transition [1184], p. 341 *ff*: '... The usual treatment of laser behavior is a self-consistent field theory. In the laser analysis each atom develops a radiating dipole in an electromagnetic field due to (i.e. emitted by) all the other atoms. The radiation field produced by an ensemble of radiating atoms is then calculated in a self-consistent fashion. (...This) suggests the identification of the laser electric field as the variable corresponding to the (...) order parameter and the atomic population inversion as that corresponding to the temperature.'

Note that numerical simulations revealed that in certain regimes the CARL corresponds to a first-order phase transition: At high temperatures the probe to pump power diagram shows bistability [665] and [1104].

The correspondence between CARL and a common laser is illustrated by the table below. A number of questions arise from the analogy:

The CARL being a laser without inversion, what is the equilibrium parameter? Is it the temperature of the atomic cloud? How to calculate the density of states?

	ferromagnet	laser
control parameter	external magnetic field H	pump intensity $\mathcal{S}$
equilibrium parameter	temperature T	population inversion σ
order parameter	magnetization $\langle M\rangle = \begin{cases} 0 & T > T_c \\ c\sqrt{\frac{T_c - T}{T}} & T < T_c \end{cases}$	electric field $\langle E\rangle = \begin{cases} 0 & \sigma > \sigma_c \\ c\sqrt{\frac{\sigma_c - \sigma}{\sigma}} & \sigma < \sigma_c \end{cases}$
probability density	$P(M) \propto e^{-F(M)/k_B T}$	P-representation $P(x,y) \propto e^{-G(x,y)/K\sigma}$
thermodyn. free energy	$F = F(T,H)$	$G(x,y)$
heat capacity	$C(T) = \frac{\partial E(T)}{\partial T}$	?

	CARL atoms	CARL light
control parameter	pump intensity η	pump intensity η
equilibrium parameter	temperature T	?
order parameter	bunching $b = \begin{cases} 0 & T > T_c \\ ? & T < T_c \end{cases}$	electric field $\langle\alpha\rangle = \begin{cases} 0 \\ ? \end{cases}$
probability density	?	?
thermody. free energy	?	?
heat capacity	?	?

42.6.6 CARL as a laser

Why is CARL a laser? What is the basic difference between CARL and an AOM or a moving Bragg mirror? CARL is essentially based on exponential self-amplification. This self-amplification is in fact observed in our switch-off experiment [755]. But a laser is normally understood as a steady-state system. For CARL to find to a steady-state we have to insert friction forces.

Gordon rewrites the CARL as a common laser: He generalizes the linear stability analysis (previous Sec.) and retains the lowest-order nonlinearity. The Fokker-Planck equations read:

$$\begin{aligned} \frac{dB_n}{d\tau} &= \imath n(aB_{n-1} + a^* B_{n+1}) - n^2 D B_n \\ \frac{da}{d\tau} &= B_1 - \kappa a \ , \end{aligned} \tag{42.321}$$

with $B_0 = 1$ and $B_{-n} = B_n^*$. Linearization means $B_{n>1} = 0$,

$$\begin{aligned} \frac{dB_1}{d\tau} &= \imath a - D B_1 \\ \frac{da}{d\tau} &= B_1 - \kappa a \end{aligned} \tag{42.322}$$

or,

$$\frac{d^2a}{d\tau^2} + (\kappa + D)\frac{da}{d\tau} + (\kappa D - \imath)a = 0 \tag{42.323}$$
$$\frac{d^2B_1}{d\tau^2} + (\kappa + D)\frac{dB_1}{d\tau} + (\kappa D - \imath)B_1 = 0$$

The determinant is,

$$\det\begin{pmatrix} -D-\lambda & \imath \\ 1 & -\kappa-\lambda \end{pmatrix} = (D+\lambda)(\kappa+\lambda) - \imath = 0 \tag{42.324}$$

Including the lowest-order nonlinear term means $B_{n>2} = 0$,

$$\frac{dB_2}{d\tau} = 2\imath a B_1 - 4DB_2 \tag{42.325}$$
$$\frac{dB_1}{d\tau} = \imath a + \imath a^* B_2 - DB_1$$
$$\frac{da}{d\tau} = B_1 - \kappa a$$

Assuming $dB_2/d\tau = 0$,

$$\frac{dB_1}{d\tau} = \imath a - \left(\frac{|a|^2}{2D} + D\right) B_1 \tag{42.326}$$
$$\frac{da}{d\tau} = B_1 - \kappa a$$

or,

$$\frac{d^2B_1}{d\tau^2} + (\kappa + D)\frac{dB_1}{d\tau} + (\kappa D - \imath)B_1 = -\frac{1}{2D}\left(\frac{d}{d\tau} + \kappa\right)|a|^2 B_1 \tag{42.327}$$
$$= -(K_1|a|^2 - K_2|a|^4)B_1$$
$$\frac{d^2a}{d\tau^2} + (\kappa + D)\frac{da}{d\tau} + (\kappa D - i)a = -\frac{|a|^2}{2D}\left(\frac{d}{d\tau} + \kappa\right)a$$

substitute $a(\tau) = A(\tau)e^{\lambda\tau}$ and Eq. (xx),

$$e^{\lambda\tau}\left(\frac{d^2}{d\tau^2} + 2\lambda\frac{d}{d\tau} + \lambda^2\right)A + e^{\lambda\tau}\left((\kappa + D)\frac{d}{d\tau} + (\kappa + D)\lambda\right)A - (\lambda^2 + D\lambda + \kappa\lambda)e^{\lambda\tau}A \tag{42.328}$$
$$= -\frac{|e^{\lambda\tau}A|^2}{2D}\left(e^{\lambda\tau}\frac{dA}{d\tau} + \lambda e^{\lambda\tau}A + \kappa e^{\lambda\tau}A\right)$$

neglect $d^2A/d\tau^2$and $|A|^2 dA/d\tau$,

$$e^{\lambda\tau}2\lambda\frac{dA}{d\tau} + e^{\lambda\tau}(\kappa + D)\frac{dA}{d\tau} = -\frac{|e^{\lambda\tau}A|^2}{2D}\left(\lambda e^{\lambda\tau}A + \kappa e^{\lambda\tau}A\right) \tag{42.329}$$

substitute back $a(\tau) = A(\tau)e^{\lambda\tau}$,

$$\begin{aligned}\frac{da}{d\tau} &= \lambda a - \frac{\lambda+\kappa}{2D(2\lambda+\kappa+D)}|a|^2 a \\ &= \lambda a - C|a|^2 a\end{aligned} \tag{42.330}$$

or,

$$\frac{d|a|^2}{d\tau} = 2|a|^2 \mathfrak{Re}\ \lambda - 2|a|^4 \mathfrak{Re}\ C \tag{42.331}$$

in steady-state,

$$0 = \lambda a - C|a|^2 a\ . \tag{42.332}$$

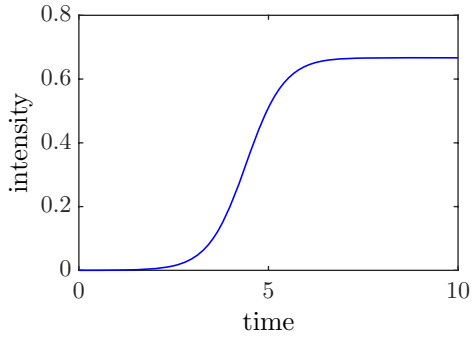

Figure 42.56: (code) Laser crossing the threshold.

According to A. Politi a general laser theory exists, there is no point in repeating this for CARL. The analogy is there and evident.

42.6.6.1 CARL as a ferromagnet

A similar treatment with $a(\tau) = A(\tau)e^{\lambda\tau}$ and $B_1(\tau) = \beta(\tau)e^{\lambda\tau}$ and $d^2\beta/d\tau^2 = 0$ and $|A|^2 d\beta/d\tau = 0$ and $\beta d|A|^2/d\tau = 0$ results in,

$$\begin{aligned}\frac{dB_1}{d\tau} &= \lambda B_1 - \frac{2\lambda+\lambda^*+\kappa}{2D(2\lambda+\kappa+D)}|a|^2 B_1 \\ &= \lambda B_1 - \tilde{C}|a|^2 B_1\ ,\end{aligned} \tag{42.333}$$

i.e. the instability comes from the field and it drives the bunching.

42.6.6.2 Out-of-equilibrium thermodynamics

Strictly speaking the above analogy is flawed. In particular the analogy between CARL bunching and ferromagnetic ordering is not good. While the ferromagnetic ordering occurs as a thermodynamic phase transition, the CARL bunching is driven by a dissipative force, which triggers spatio-temporal instabilities. Therefore viscous

CARL occurs far from thermodynamic equilibrium. This may point towards an interpretation of CARL bunching as a *dissipative structure* along the lines traced by Prigogine, who showed that *non-equilibrium may be a source of order*.

On the other hand, the laser itself is a system operating far from thermal equilibrium, since it requires a pump to emit steady-state radiation. Perhaps a comparison with *estruturas de Bénard* is better than with ferromagnets. Bénard structures occur as spontaneous breaking of translational symmetry, just like CARL. One could say that the periodicity of CARL is predefined by the pump laser wavelength, and thus not surprising. However, the size of the periodic structures is always fixed by boundary conditions in a more or less complicated way. For example, the size of the Bénard structures is fixed by the viscosity, the provided amount of heat, etc., the wavelength of surface waves can be calculated from first principles, i.e. the Navier-Stokes equations and the continuity equation for given boundary conditions. The symmetry breaking resides in the exact *place*, where the Bénard structure develops. It is the *phase*, which is broken, just like for CARL.

The Kuramoto model and the Weiss model of ferromagnetism are both mean field theories [1200]. Despite the fundamental difference that ferromagnetism is a thermodynamic feature and Kuramoto a nonequilibrium phenomenon, they are far-reaching analogies. The role of temperature in ferromagnetism is played by external noise in Kuramoto. CARL is clearly a dissipative structure: *It survives only as long as energy is fed to the system.*

42.6.6.3 Finite and infinite temperature reservoirs

The phase transition is ruled by a competition of dissipation and diffusion. If the reservoir has zero temperature $\gamma_{fric} \neq 0$ but $D = \sigma^2/\gamma_{fric} = 0$, i.e. we have dissipation without diffusion. In this case, we do not expect a threshold behavior. The Lindtbladt operator for coupling to a finite-temperature reservoir is something like $\mathcal{L} \approx \kappa(\bar{n}+1)\{...emission...\} + \kappa\bar{n}\{...absorption...\} + \eta\{...phase\ noise...\}$, where $\bar{n}$ is the mean photon number at thermal equilibrium with a given temperature $T \propto \bar{n}/(\bar{n}+1)$. The interpretation in terms of dissipation without diffusion is correct according to A. Buchleitner. There are three kinds of noises: 0 temperature noise for $\bar{n} \to 0$, ∞ temperature noise for $\bar{n} \approx \bar{n}+1$ and phase noise. Thus for $T = 0$ the energy flux goes only from the system to the reservoir. At $T > 0$ entropy may go from the reservoir to the system. The system reaches its cooling limit when the temperatures of the system and the reservoir are balanced.

But how to explain Doppler cooling or cavity-cooling? The electromagnetic vacuum is an effective $T = 0$ reservoir, but the cooling is nevertheless limited by the spontaneous decay width or the cavity linewidth, resp.. Why does coupling to a zero-temperature reservoir not cool down to zero? Apparently, the coupling is afflicted by vacuum noise. This permits coupling of degrees of freedom having different temperatures without reaching a temperature equilibrium. Examples are the limit of cavity-cooling to the cavity decay width or simply Doppler-cooling by spontaneous emission.

Interprete damping as scattering into continuum!

42.6.7 Exercises

42.6.7.1 Ex: Viscous CARL

Assuming a perfect 'bunching', $e^{2\imath kz_m} = e^{2\imath kz}$, e $\alpha_- \equiv \beta e^{2\imath kz}$ with $\dot{\beta} = 0$ and $\ddot{z} = 0$ derive the equations (42.245).

Solution: *Defining $\alpha_- \equiv \beta e^{2\imath kz}$ we transform the equation (42.244)(i) in,*

$$\dot{\beta} + 2\imath k\beta\dot{z} = -\kappa\beta - \imath N U_0 \alpha_+ \ .$$

Assuming $\dot{\beta} = 0$ the solution is,

$$\beta = \frac{-\imath U_0 \alpha_+}{\kappa + 2\imath k\dot{z}} \ .$$

The equation (42.244)(ii) gives,

$$k\ddot{z} = 4\imath\omega_{rec} U_0 \alpha_+ (\beta - \beta^*) - \gamma_{frc} k v = 4\imath\omega_{rec} U_0 \alpha_+ \left(\frac{-\imath U_0 \alpha_+}{\kappa + 2\imath k\dot{z}} - \frac{\imath U_0 \alpha_+}{\kappa - 2\imath k\dot{z}} \right) - \gamma_{frc} k\dot{z}$$

$$= \frac{8\kappa\omega_{rec} U_0^2 \alpha_+^2}{\kappa^2 + (2k\dot{z})^2} - \gamma_{frc} k\dot{z} \ .$$

Assuming $\ddot{z} = 0$ the solution is,

$$2k\dot{z}[(2k\dot{z})^2 + \kappa^2] = \frac{16\kappa\omega_{rec} U_0^2 \alpha_+^2}{\gamma_{frc}} \overset{2k\dot{z} \gg \kappa}{\longrightarrow} (2k\dot{z})^3 \ .$$

42.6.7.2 Ex: Langevin simulations

Langevin simulations

Solution: *Test of Runge-Kutta method (see program Langevin_OrnsteinUhlenbeckTest),*
Langevin simulation without adiabatic approximation (see program Langevin_CorrelationFunction),
like 'CorrelationFunction' but with an additional harmonic trap (see program Langevin_HarmonicTra
like 'CorrelationFunction' but with an additional standing wave (see program Langevin_StandingWav
without adiabatic approximation one species in a standing wave (see program Langevin_1SpeciesStand
without adiabatic approximation two species in a standing wave (see program Langevin_2SpeciesStand

42.6.7.3 Ex: Fokker-Planck equations

Derive the equations (42.275) and (42.276) from (42.273) and (42.271) applying the expansion (42.274).

Solution: *For the normalization we calculate,*

$$1 = \int_0^{2\pi} Q(\theta, t) d\theta = \sum_\nu Q_\nu(t) \int_0^{2\pi} e^{\imath\nu\theta} d\theta = \sum_\nu Q_\nu(t) 2\pi\delta_{\nu 0} = 2\pi Q_0(t) \ .$$

For the 'bunching' we calculate,

$$b = \int_0^{2\pi} Q(\theta,t)e^{-\imath\theta}d\theta = \sum_\nu Q_\nu(t)\int_0^{2\pi} e^{\imath(\nu-1)\theta}d\theta = \sum_\nu Q_\nu(t)2\pi\delta_{\nu 1} = 2\pi Q_1(t) \ .$$

For the CARL equation,

$$\sum_\nu \frac{\partial Q}{\partial t}e^{\imath\nu\theta}$$
$$= \frac{8\imath\omega_{rec}U_0\alpha_+}{\gamma_{frc}}\sum_\nu Q_\nu\left(-\imath(\nu-1)\alpha_- e^{\imath(\nu-1)\theta} - \imath(\nu+1)\alpha_-^* e^{\imath(\nu+1)\theta}\right) - \nu^2 D_\theta \sum_\nu Q_\nu e^{\imath\nu\theta} \ ,$$

and hence,

$$\frac{\partial Q}{\partial t} = \frac{8\omega_{rec}U_0\alpha_+}{\gamma_{frc}}\nu\left(Q_{\nu+1}\alpha_- + Q_{\nu-1}\alpha_-^*\right) - \nu^2 D_\theta Q_\nu \ .$$

42.6.7.4 Ex: Kuramoto simulations

Implement the Kuramoto model with pendulum clocks.

Solution: *Visualization of the Kuramoto model with pendulum clocks (see FokkerKuram_Illustration, FokkerKuram_Dissipation, FokkerKuram_Shiino).*

42.7 Coherent properties of CARL

In Sec. 42.6.1 we have demonstrated collective interaction of atoms with light fields and how the application of friction via optical molasses can lead to stationary CARL radiation at a self-determined frequency [754]. We have demonstrated that the molasses also lead to diffusion resulting in a threshold behavior and in atomic self-organization at finite temperatures [1106, 1343]. An interesting question is whether the temperature not only determines the collective behavior, but also the deviation from it. The temperature being related to the amount of random walk on top of the center-of-mass motion, we may wonder whether the viscous CARL radiation bears a signature of the atomic temperature not only in the self-determined CARL frequency, but also in the laser emission bandwidth. It is conceivable that the autocorrelation functions and the emission spectrum of the CARL are influenced by the fact that the atoms experience a random walk in momentum space due to the diffusion in the optical molasses.

In this section, we will attempt an analytical approach, present numerical simulations and discuss how to access to the informations experimentally. The Fokker-Planck approach described in Refs. [1106, 1343] is particularly well adapted to calculating collective variables. In contrast the simulation of the Langevin equation conveniently gives access to the noise properties.

42.7.1 Analytical derivation of the coherence

Our starting point are the Langevin equations (42.256) [1106, 1343] in the adiabatic limit, $\ddot{\theta}_n = 0$. The Langevin noise force is uncorrelated,

$$\langle \xi_n^*(t)\xi_m(t+\tau)\rangle \equiv \lim_{T\to\infty}\frac{1}{T}\int_0^T \xi_n^*(t)\xi_m(t+\tau)d\tau = 2D_{\dot\theta}\delta_{mn}\delta(\tau)\ , \tag{42.334}$$

where the momentum diffusion coefficient $D_{\dot\theta} = \gamma_{fr}\sigma^2$ is proportional to the atoms' equilibrium temperature, which is related to the Maxwell-Gaussian velocity spread by $\sigma \equiv 2k\sqrt{k_BT/m}$. In contrast, the trajectories of the atoms are not, because all atoms are motionally coupled by the fields, so that the noise imparted to one atom is sensed by all others. Therefore the relationship (42.335) certainly does not hold for the atomic positions,

$$\langle \theta_n^*(t)\theta_m(t+\tau)\rangle \nsim \delta_{mn}\delta(\tau)\ . \tag{42.335}$$

42.7.1.1 Single atom

So, let us first concentrate on a single atom coupled to the cavity fields. If its velocity only fluctuates a little around a mean value ω_{ca}, we may write $\theta(t) \equiv \omega_{ca}t+\varphi(t)$. The randomized position has a Gaussian statistics leading to a Brownian motion described by a Wiener-Levy stochastic process: $\langle\varphi(t)\rangle = 0$ and $\langle\varphi(t)\varphi(t+\tau)\rangle = D_\theta(2t+\tau-|\tau|)$ ([1184], p. 344),

$$R_{\dot\theta}(\tau) = \langle[\omega_{ca}+\dot\varphi(t)][\omega_{ca}+\dot\varphi(t+\tau)]\rangle = \langle\dot\varphi(t)\dot\varphi(t+\tau)\rangle = 2D_\theta\delta(\tau)\ , \tag{42.336}$$

where $D_\theta = \sigma^2/\gamma_{fr}$ is the position diffusion coefficient. Note that deterministic parts are removed from the function in order to satisfy $\langle\dot\varphi(t)\rangle = 0$. In that case the *spectral density of fluctuations of the atomic phase* is constant,

$$S_{\dot\theta}(f) = \int_{-\infty}^{\infty} R_{\dot\theta}(\tau)e^{-2\pi\imath f\tau}d\tau = 2D_\theta\ . \tag{42.337}$$

Note that $S_{\dot\theta}(f) = f^2S_\theta(f)$. The *variance of the fluctuations* for white noise is or,

$$\sigma_{\dot\theta}^2(\tau) = \langle\dot\varphi(t)^2\rangle = \frac{D_\theta}{\tau}\ . \tag{42.338}$$

Under the assumption $\dot\alpha_- = \imath\omega_{ca}\alpha_-$ and introducing the abbreviation $\alpha_0 \equiv -\imath U_0\alpha_+/(\kappa+\imath\omega_{ca})$, the first equation (42.256) takes the form $\alpha_- = \alpha_0 e^{\imath\theta}$ such that the *autocorrelation function of the field amplitude* reads,

$$\begin{aligned} R_\alpha(\tau) &\equiv \langle\alpha_-^*(t)\alpha_-(t+\tau)\rangle \\ &= |\alpha_0|^2\langle e^{\imath[\theta(t+\tau)-\theta(t)]}\rangle \\ &= |\alpha_0|^2e^{\imath\omega_{ca}\tau}\langle e^{\imath[\varphi(t+\tau)-\varphi(t)]}\rangle = |\alpha_0|^2e^{\imath\omega_{ca}\tau}\langle e^{\imath\tau\dot\varphi(t)}\rangle\ . \end{aligned} \tag{42.339}$$

In the case of a Gaussian distribution for the noise amplitude with $\dot\varphi(t) = \dot\varphi(-t)$, we

have $\langle\dot\varphi^{2k-1}\rangle/(2k-1)!=0$ and $\langle\dot\varphi^{2k}\rangle/\,(2k)!=\langle\frac{1}{2}\dot\varphi^2\rangle^k/k!$ [326, **?**, 414],

$$\begin{aligned}\langle e^{\imath\tau\dot\varphi(t)}\rangle &= \sum_k \frac{\imath^k\langle\tau^k\dot\varphi(t)^k\rangle}{k!} = \sum_k \frac{\imath^{2k}\langle\tau^{2k}\dot\varphi(t)^{2k}\rangle}{(2k)!} \\ &= \sum_k \frac{\langle-\frac{1}{2}\tau^2\dot\varphi(t)^2\rangle^k}{k!} = e^{-\frac{1}{2}\tau^2\langle\dot\varphi(t)^2\rangle}\ .\end{aligned} \tag{42.340}$$

Apparently, noise mainly affects the field's phase and not its amplitude. Note that the *first-order coherence* is just the normalized autocorrelation $g^{(1)}(\tau)\equiv R_\alpha(\tau)/R_\alpha(0)$,

$$\begin{aligned}g^{(1)}(\tau) &= e^{\imath\omega_{ca}\tau}e^{-\omega_{ca}^2\tau^2\sigma_v^2/2} \\ &= e^{\imath\omega_{ca}\tau}e^{-D_\theta|\tau|/2}\ .\end{aligned} \tag{42.341}$$

The *power spectral density* is a Lorentzian,

$$\begin{aligned}S_\alpha(\omega) &= |\alpha_0|^2\int_{-\infty}^{\infty}R_\alpha(\tau)e^{-\imath\omega\tau}d\tau \\ &= \frac{|\alpha_0|^2D_\theta^2}{(\omega-\omega_{ca})^2+D_\theta^2}\ .\end{aligned} \tag{42.342}$$

The CARL *emission bandwidth* is thus $\frac{1}{2}D_\theta$. The above results show that the CARL laser bandwidth increases linearly with temperature and reduces with the friction force. In our experiment we have $\gamma_{fr}=5\kappa$ and $\sigma=10\kappa$, so that $D_\theta=\sigma^2/\gamma_{fr}=20\kappa$. The CARL bandwidth is extremely large as compared to the CARL frequency $\omega_{ca}=5\kappa$. The reason is that we only considered a single atom. The impact of several atoms will partially compensate and reduce the linewidth.

42.7.1.2 Many atoms, hand-waving

In order to account for the combined effect of many atoms, we reconsider the Eq. (42.256). If $\dot\alpha_-=\imath\omega_{ca}\alpha_-$, we may write it like,

$$\begin{aligned}\alpha_- &= \alpha_0\sum_m e^{\imath\theta_m}\ , \\ \dot{\theta_n} &= \frac{4\varepsilon\imath U_0\alpha_+\alpha_0}{\gamma_{fr}}\sum_m\left(e^{\imath\theta_m-\imath\theta_n}+e^{-\imath\theta_m+\imath\theta_n}\right)+\frac{\xi_n}{\gamma_{fr}}\ .\end{aligned} \tag{42.343}$$

The light mode α_- appears to be a superposition of coherent waves having the same frequencies, $\alpha_m(t)=\alpha_0e^{i\omega_{ca}t+i\varphi_m(t)}$, but interrupted by random phase jumps. We may thus try an analogous argumentation as for pressure broadening,

$$\begin{aligned}\langle\alpha_-^*(t)\alpha_-(t+\tau)\rangle &= |\alpha_0|^2\int\sum_n e^{-\imath\omega_{ca}t-\imath\varphi_n(t)}\sum_m e^{\imath\omega_{ca}t+\imath\omega_{ca}\tau+\imath\varphi_n(t+\tau)}dt \\ &= |\alpha_0|^2e^{\imath\omega_{ca}\tau}\sum_{n,m}\int e^{\imath\varphi_m(t+\tau)-\imath\varphi_n(t)}dt = N\langle\alpha_n^*(t)\alpha_m(t+\tau)\rangle\delta_{nm}\ .\end{aligned}$$

Cross-terms vanish, the autocorrelation function is just the sum of the single-atom components. However, while we may view the noise impact of the atoms as coming

from a single atom, the rate of the phase jumps is much higher, than for a single atom. For one atom the probability density for encountering a coherent interval of length τ is given by $p_1(\tau)d\tau = \frac{1}{2}D_\theta e^{-D_\theta|\tau|/2}d\tau$ [816]. Thus,

$$\langle\alpha_1^*(t)\alpha_1(t+\tau)\rangle = |\alpha_0|^2 e^{\imath\omega_{ca}\tau}e^{-D_\theta|\tau|/2} = |\alpha_0|^2 e^{\imath\omega_{ca}\tau}\int_\tau^\infty p_1(\tau')d\tau' \ . \tag{42.344}$$

For N atoms we expect a probability density for encountering a coherent intervall of length τ,

$$p_N(\tau)d\tau = p_1(\tau/N)d\tau = \frac{D_\theta}{2\sqrt{N}}e^{-D_\theta|\tau|/2\sqrt{N}}d\tau \ , \tag{42.345}$$

such that $\int_0^\infty p_N(\tau')d\tau' = 1$. However this remains to prove. Thus,

$$g_N^{(1)}(\tau) = e^{\imath\omega_{ca}\tau}\int_\tau^\infty p_N(\tau')d\tau' = e^{\imath\omega_{ca}\tau - D_\theta|\tau|/2\sqrt{N}} \ . \tag{42.346}$$

The second-order correlation function is,

$$g_N^{(2)}(\tau) = 1 + |g_N^{(1)}(\tau)|^2 \ . \tag{42.347}$$

The laser bandwidth is accordingly reduced by,

$$D_N = \frac{D_\theta}{\sqrt{N}} \ . \tag{42.348}$$

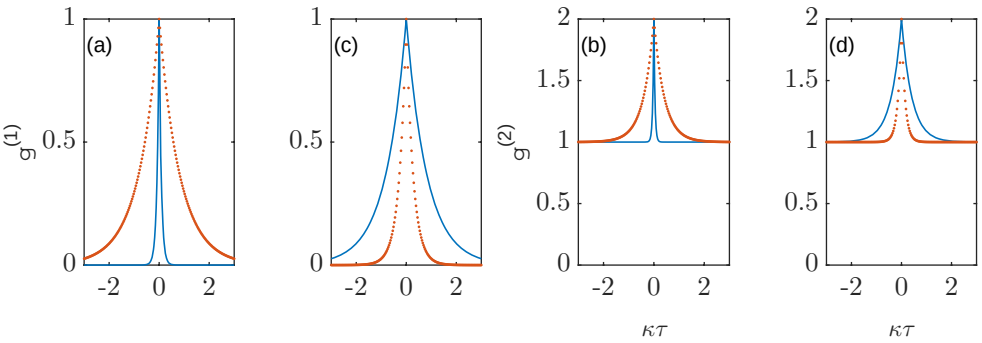

Figure 42.57: (code) First and second-order correlation functions. The solid and dotted lines in (a) and (b) are calculated for $N = 1$ and $N = 100$, resp.. The solid and dotted lines in (c) and (d) are calculated for $T = 100\,\mu\text{K}$ and $T = 300\,\mu\text{K}$, resp..

Fig. 42.57 shows the dependencies of the correlation functions on N and T. For $N = 10^6$ atoms the CARL bandwidth becomes $\beta_N = 0.01\kappa$, which is already well below any mechanical noise. The linewidth reduction with increasing atom numbers is quantitatively supported by numerical simulations (see below).

42.7.1.3 Many atoms, formal

In order to account for the combined effect of many atoms, we reconsider the Eq. (42.256). If $\dot{\alpha}_- = \imath\omega_{ca}\alpha_-$, we get,

$$\alpha_- = -\frac{\imath U_0 \alpha_+}{\kappa + \imath\omega_{ca}} \sum_m e^{\imath\theta_m} \ , \tag{42.349}$$
$$\dot{\theta_n} = \frac{4\varepsilon U_0^2 \alpha_+^2}{\gamma_{fr}\left(\kappa + \imath\omega_{ca}\right)} \sum\nolimits_m \left(e^{\imath\theta_m - \imath\theta_n} + e^{-\imath\theta_m + \imath\theta_n}\right) + \frac{\xi_n}{\gamma_{fr}} \ .$$

The autocorrelation is then,

$$R_\alpha(\tau) \equiv \langle \alpha_-^*(t)\alpha_-(t+\tau)\rangle = \frac{U_0^2\alpha_+^2}{\kappa^2+\omega_{ca}^2} \sum_{n,m} \langle e^{\imath\theta_n(t+\tau)-\imath\theta_m(t)}\rangle \tag{42.350}$$
$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m} \langle e^{\imath\varphi_n(t+\tau)-\imath\varphi_m(t)}\rangle = |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m,k} \frac{\imath^k}{k!} \langle [\varphi_n(t+\tau)-\varphi_m(t)]^k\rangle$$
$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m,k} \frac{\imath^k}{k!} \sum\nolimits_{j=0}^{k} (-1)^j \binom{k}{j} \langle \varphi_n(t+\tau)^j \varphi_m(t)^{k-j}\rangle \ .$$

The main role of cavity-induced interparticle correlations is to self-consistently establish a constant center-of-mass motion ω_{ca}. We may, to first order, neglect the possibility that the coupling correlates the noise, since the noise is imprinted from the outside, i.e. the molasses. Therefore, $\langle \varphi_n(t+\tau)\varphi_m(t)\rangle \propto \delta_{nm}$,

$$\langle \varphi_n(t+\tau)^j \varphi_m(t)^{k-j}\rangle = \sum\nolimits_{all\ pairs} \langle \varphi_n(t+\tau)^2\rangle^{j/2} \langle \varphi_m(t)^2\rangle^{k/2-j/2} \tag{42.351}$$
$$= \frac{j!}{2^{j/2}(j/2)!} \frac{(k-j)!}{2^{(k-j)/2}(k/2-j/2)!} \langle \varphi_n(t+\tau)^2\rangle^{j/2} \langle \varphi_m(t)^2\rangle^{k/2-j/2}$$

so that,

$$R_\alpha(\tau) = |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum_{n,m,k} \frac{\imath^k}{k!} \sum_{j=0}^{k} \binom{k}{j} \frac{j!}{2^{j/2}(j/2)!} \frac{(k-j)!}{2^{(k-j)/2}(k/2-j/2)!} \langle \varphi_n(t+\tau)^2\rangle^{j/2} \langle \varphi_m(t)^2\rangle^{k/2-j/2} \ , \tag{42.352}$$

where j and k are even,

$$R_\alpha(\tau) = |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum\nolimits_{n,m,k} \frac{\imath^k}{2^{k/2}(k/2)!} \sum_{j=0}^{k} \binom{k/2}{j/2} \langle \varphi_n(t+\tau)^2\rangle^{j/2} \langle \varphi_m(t)^2\rangle^{k/2-j/2}$$
$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum_{n,m,k} \frac{1}{(k/2)!} \left(-\frac{1}{2}\langle \varphi_n(t+\tau)^2\rangle - \frac{1}{2}\langle \varphi_m(t)^2\rangle\right)^{k/2} \tag{42.353}$$
$$= |\alpha_0|^2 e^{\imath\omega_{ca}\tau} \sum_n e^{-\frac{1}{2}\langle \varphi_n(t+\tau)^2\rangle} \sum\nolimits_m e^{-\frac{1}{2}\langle \varphi_m(t)^2\rangle} = |\alpha_0|^2 N^2 e^{\imath\omega_{ca}\tau} e^{-\frac{1}{2}\langle \varphi_n(t+\tau)^2\rangle} e^{-\frac{1}{2}\langle \varphi_n(t)^2\rangle} \ .$$

42.7.1.4 Memory effects

Relax adiabaticity, $\dot{\alpha}_- \neq \imath\omega_{ca}\alpha_-$, substitute $\beta = e^{\kappa t}\alpha_-$,

$$\dot{\theta} = \frac{4\varepsilon\imath U_0\alpha_+}{\gamma_{fr}}\left(\beta e^{-\imath\theta-\kappa t} - \beta^* e^{\imath\theta-\kappa t}\right) + \frac{\xi}{\gamma_{fr}} \ , \tag{42.354}$$
$$\beta = -\imath U_0\alpha_+ \int^t e^{\imath\theta+\kappa t'}dt' \ .$$

so that,

$$\begin{aligned} R_\alpha(\tau) &\equiv \langle\alpha_-^*(t)\alpha_-(t+\tau)\rangle = \langle e^{-\kappa t}\beta^*(t)e^{-\kappa t-\kappa\tau}\beta(t+\tau)\rangle \\ &= e^{-\kappa\tau}\langle e^{-2\kappa t}\beta^*(t)\beta(t+\tau)\rangle \\ &= U_0^2\alpha_+^2 e^{-\kappa\tau}\int\int^t\int^{t+\tau} e^{\imath\theta(t'')-\imath\theta(t')+\kappa t'+\kappa t''-2\kappa t}dt''dt'dt \\ &= U_0^2\alpha_+^2 e^{-\kappa\tau}\int\int^t\int^{t+\tau} e^{\imath\omega_{ca}t''-\imath\omega_{ca}t'+\imath\varphi(t'')-\imath\varphi(t')+\kappa t'+\kappa t''-2\kappa t}dt''dt'dt \ . \end{aligned} \tag{42.355}$$

Using the representation of half the δ-distribution $\int^t e^{(\imath\omega_{ca}+\kappa)t'}dt' = \delta_{1/2} = \lim_{\kappa\to 0}\frac{1}{\kappa+\imath\omega_{ca}}$.

42.7.1.5 Schawlow-Townes limit for CARL

The ultimate limit for the spectral purity of a perfectly stable laser oscillator is the *Schawlow-Townes limit* [1150]. The origin of this limitation is the discrete nature of the light field. Similarly to quantum projection noise, which is caused by the discretisation of atomic energy levels, the optical *shot-noise* registered in photodetectors arises from the discrete repartition of electromagnetic energy in photons. With a laser power P, a cavity bandwidth κ and an interrogation time τ, the Allan variance [**?**] and the linewidth of a Schawlow-Townes limited laser are given by,

$$\sigma_{ST}(\tau) = \frac{1}{\omega/\kappa}\frac{1}{\sqrt{(P/\hbar\omega)\tau}} \ , \tag{42.356}$$
$$\beta = \kappa^2\frac{\hbar\omega}{P} \ .$$

In the case of CARL, using $P = \delta\hbar\omega|\alpha_-|^2$ the variance is $\sigma_{ST}^2(\tau) = \kappa/\tau\omega\delta|\alpha_-|^2 \approx 10^{-20}\ \mathrm{s}/\tau$. The shot-noise which limits the CARL is not the one of the CARL light itself, but the random momentum kicks imparted by molasses-cooled atoms. The CARL linewidth is $\beta = \kappa^2/\delta|\alpha_-|^2 = 10^{-14}\kappa$.

The time-lap between two scattering events for a single atom be distributed according to $p_1(\tau)d\tau = \gamma e^{-\gamma\tau}d\tau$. What is the waiting time distribution for two atoms [1154]? Schenzle related the waiting time distribution to the autocorrelation function $g^{(2)}(\tau)$.

Fig. 42.58(e-f) shows spectra of the CARL frequency obtained by Fourier-transforming the autocorrelation function of a Langevin-simulated trajectory of the CARL frequency. The width results from thermal fluctuations in the atomic motion induced by momentum diffusion in the molasses. It is clearly visible that the width is reduced when the atom number is increased, thus confirming Eq. (42.348).

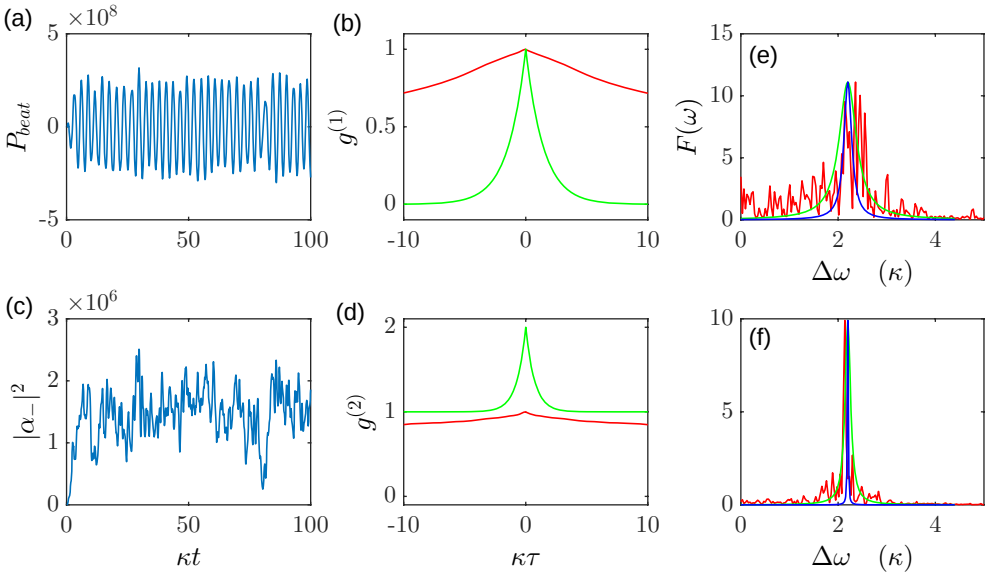

Figure 42.58: Simulated time-dependence of the (a) beat and the (b) intensity signals. Calculated (c) first and second-order correlation functions. The temperature was set to $T = 100\,\mu\text{K}$ and the atom number to $N = 40$. (e-f) Spectra of the CARL laser for (e) 4 and (f) 40 atoms. The total coupling constant NU_0 has been held constant, only the number of atoms whose trajectories are simulated is varied.

42.7.2 Measuring the coherence properties

We may also attempt to verify the predictions in experiment. Our signals are the beams transmitted through the cavity mirrors.

42.7.2.1 Homodyne signal

Ideally in order to get the full information on the the first-order coherence, we should record both the in-phase and the quadrature component of the field $\alpha_- = \mathfrak{Re}\ \alpha_- + i\mathfrak{Im}\ \alpha_-$ by homodyning it with the local oscillator α_+. Thus we need to use both ports of the beamsplitter: For the in-phase component we get,

$$\begin{aligned} P^{(ph)}_{hody} &\propto b^\dagger b - c^\dagger c \\ &= |\alpha_+\sqrt{\eta} + \alpha_-\sqrt{1-\eta}|^2 - |\alpha_+\sqrt{1-\eta} - \alpha_-\sqrt{\eta}|^2 \\ &= (1-2\eta)(|\alpha_-|^2 - |\alpha_+|^2) + 4\sqrt{\eta-\eta^2}\alpha_+\mathfrak{Re}\ \alpha_- \ . \end{aligned} \tag{42.357}$$

For a 50% beamsplitter the offsets disappear, $P^{(ph)}_{hody} \propto= 2\alpha_+\mathfrak{Re}\ \alpha_-$, which means that the homodyne signal is insensitive to intensity noise in the individual ports. Similarly we obtain for the quadrature component,

$$\begin{aligned} P^{(qu)}_{hody} &\propto |\alpha_+\sqrt{\eta} + \imath\alpha_-\sqrt{1-\eta}|^2 - |\alpha_+\sqrt{1-\eta} - \imath\alpha_-\sqrt{\eta}|^2 \\ &= -2\alpha_+\mathfrak{Im}\ \alpha_-. \end{aligned} \tag{42.358}$$

By mounting a piezo on one of the mirrors in the homodyne loop, we can influence which quadrature component to map. Is there a way how to get $\mathfrak{Im}\ \alpha_-$ and $\mathfrak{Re}\ \alpha_-$ simultaneously?

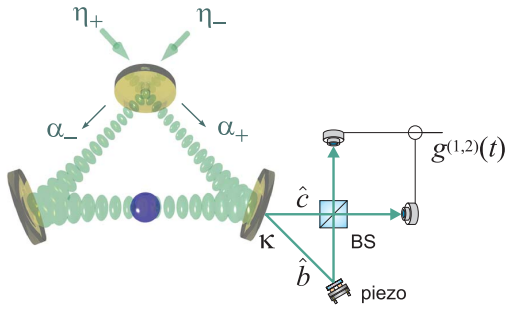

Figure 42.59: Homodyning the counterpropagating beams.

Knowing α_- we can calculate the *first order coherence*,

$$g^{(1)}(\tau) \equiv \frac{\langle \alpha^*(t)\alpha(t+\tau)\rangle}{\langle \alpha^*(t)\alpha(t)\rangle} = \frac{\int \alpha^*(t)\alpha(t+\tau)dt}{\int \alpha(t)^2 dt} \ , \tag{42.359}$$

the *second-order coherence*,

$$\begin{aligned} g^{(2)}(\tau) &\equiv \frac{\langle \alpha^*(t)\alpha^*(t+\tau)\alpha(t+\tau)\alpha(t)\rangle}{\langle \alpha^*(t)\alpha(t)\rangle^2} \\ &= \frac{\int P_-(t)P_-(t+\tau)dt}{\int P_-(t)dt} \ , \end{aligned} \tag{42.360}$$

and the *emission spectrum* (power spectral density),

$$F(\omega) = \frac{1}{\pi}\mathfrak{Re} \int g^{(1)}(\tau)e^{\imath\omega\tau}d\tau \ . \tag{42.361}$$

All these quantities can be evaluated from numerical simulations of the Langevin equations.

Example 276 (*Real Signals*): What is recorded in experiment is the probe field power P_{probe} and only one quadrature component of the beat between the probe and the pump. The probe signal is simply,

$$P_- \propto |\alpha_-|^2 \ . \tag{42.362}$$

So it may be used directly for the $g^{(2)}(\tau)$ intensity correlation function (42.360) analogous to the *Hanbury-Brown-Twiss* experiment.
In contrast, the beat signal is obtained in a *Young* type experiment,

$$P_{beat} \propto |\alpha_+ \pm \alpha_-|^2 = |\alpha_+|^2 + |\alpha_-|^2 \pm 2\alpha_+ \mathfrak{Re}\ \alpha_- \ , \tag{42.363}$$

because we may assume α_+ real. Obviously, the beat signal oscillates between the limits $\pm 2\alpha_+|\alpha_-|$. Using only one port of the beamsplitter, we miss information on the other quadrature phase. The question arises now, how to calculate

the spectrum if only the real part of the field $\mathfrak{Re}\ \alpha$ is known. The interesting quantity is $|g^{(1)}(\tau)|$, because it contains the information on the photon statistics. This function is smooth (it does not oscillate) and should in our case describe an exponential decay (42.341). Fortunately, from numerical calculation it seems that $|g^{(1)}(\tau)|$ is just the convolution of $\langle \mathfrak{Re}\ \alpha(t) \mathfrak{Re}\ \alpha(t+\tau)\rangle / \langle \mathfrak{Re}\ ^2\alpha(t)\rangle$, so that we may recover the informations. For the spectrum, which is calculated from the complex quantity $g^{(1)}(\tau)$ the question is more delicate. It comes down to asking if,

$$F(\omega) \propto \mathfrak{Re} \int \langle \mathfrak{Re}\ \alpha(t) \mathfrak{Re}\ \alpha(t+\tau)\rangle\ e^{\imath\omega\tau} d\tau \tag{42.364}$$

gives the correct spectrum (42.361).

42.7.2.2 Impact of finite time window

Technical noise may overrule the thermal noise just like in ordinary lasers. This situation may change if atom numbers are low, so that we have bad statistics, or if the collective force is strong enough to correlate the noise.

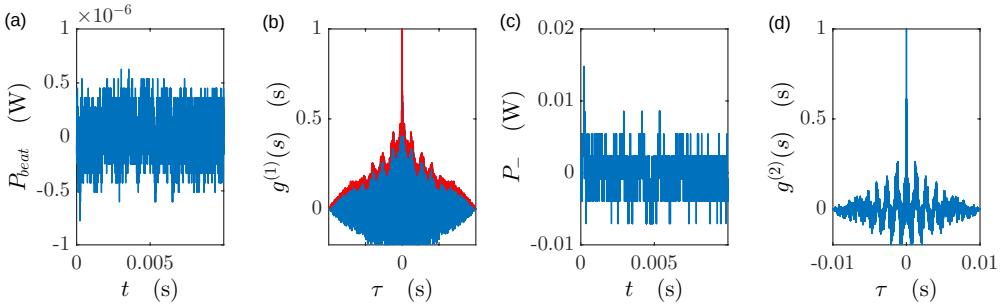

Figure 42.60: (code) Measured trajectories (a) and (b) and correlation functions (c) and (d) of the CARL laser. The coupling constant was $NU_0 = -0.1$.

The spectral width may also be limited by the finite time window $t \in [-\frac{1}{2}t_0, \frac{1}{2}t_0]$, which is taken for computing the spectrum. Even a perfect harmonic oscillation $\alpha_-(t) = \alpha_- e^{\imath\omega_{ca}t}$ will then have a finite bandwidth,

$$\begin{aligned} \mathcal{F}_{a_-}(\omega) &= \mathcal{F}[\alpha_- e^{\imath\omega_{ca}t}] \star \mathcal{F}[\chi_{[-t_0/2,t_0/2]}(t)] \\ &= \alpha_- \delta(\omega-\omega_{ca}) \star \sqrt{\frac{2}{\pi}} \frac{\sin \frac{1}{2}\omega t_0}{\omega} = \alpha_- \sqrt{\frac{2}{\pi}} \frac{\sin \frac{1}{2}(\omega-\omega_{ca})t_0}{(\omega-\omega_{ca})} \ . \end{aligned} \tag{42.365}$$

The spectrum $S_{\alpha_-}(\omega) = |\mathcal{F}_{a_-}(\omega)|^2$ has a bandwidth of $\beta = 5.6/t_0$. For example an oscillation observed for a period 100 times longer than the cavity decay time, $t_0 = 100/\kappa$, the bandwidth will be $\beta = 0.056\kappa$. Simulations are based on the Langevin equation.

42.7.3 Exercises

42.7.3.1 Ex: Autocorrelation functions

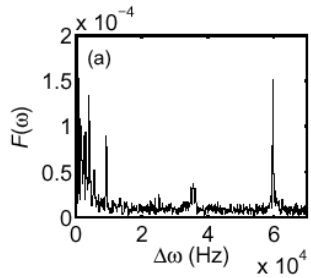

Figure 42.61: Spectrum of the CARL calculated from the first-order correlation function in Fig. 42.60(c). The coupling constant was $NU_0 = -0.1\kappa$.

Solution: *Waiting time distribution for two scatterers (see Autocorrelation0), Autocorrelation function for simple signals (see Autocorrelation1), Generate white noise as random phase jumps (see Autocorrelation2), Finite numbers of oscillations limit the resolution (see Autocorrelation3), and Finite numbers of oscillations limit the resolution (see Autocorrelation4).*

42.7.3.2 Ex: Signal-to-noise ratio of Bloch oscillations

You want to evaluate the stability of a noisy periodic signal. How many noisy oscillations do you have to observe in order to evaluate the oscillation period with a given S/N ratio [1403].

Solution: *Study width of Fourier transform? Measure other forces, e.g. magnetic field using* ^{87}Sr*?*

Atom Optics

Chapter 43

Manipulation of atomic gases

The field of *atom optics* deals with the motion of atoms and its control by technical tools. At high velocities with no external forces, the atoms follow straight paths, similar to light beams in *classical optics*. At low speeds, they propagate as waves, similarly to wave optics in Maxwell's theory of *electrodynamics*. The term *atom optics* emphasizes the analogy and the duality in the behavior of microscopic particles.

The *duality principle* is one of the fundamental ideas of quantum mechanics. The appearance of an object as a wave or as a particle depends on the situation in which it is observed. While the wave nature of light was well established in classical physics since a long time, Louis de Broglie was the first in 1924 to apply the duality principle also to massive particles and to predict that particles, under certain conditions, behave like waves whose wavelengths increase as their velocity decreases. Each particle (or sample of particles) is delocalized along a distance corresponding to the 'de Broglie wavelength'. This feature of the matter was soon discovered experimentally in electron beams and is still used today in commercial devices, for example in electron microscopes.

The laser was discovered in 1956. In a laser, light particles are forced to oscillate synchronously, that is, coherently. By analogy, we can raise the question whether a similar phenomenon can occur with massive particles, and whether it is possible to construct an *atom laser*. Such a device would emit coherent matter waves just as the laser emits coherent light. When a gas is cooled to very low temperatures, the Broglie waves of the atoms become very long and, if the gas is sufficiently dense, eventually overlap. If the gas consists of a single species of bosonic particles with all atoms being in the same quantum state, their Broglie waves interfere constructively thus and form a huge wave of coherent matter. This matter wave is described by a single wavefunction exhibiting long range order and having a single phase. If this wavefunction is formed inside a trap, all atoms accumulate in its ground state. Thus, we obtain a pure quantum state of many bodies in the kinetic degree of freedom [1]. The transition of a gas from individual atoms to a degenerate mesoscopic many-body quantum state occurs as a phase transition named *Bose-Einstein condensation* (BEC) as a homage to Bose and Einstein who predicted the effect already in 1924 [181, 410].

The course begins in this chapter with a presentation of the most important experimental techniques for cooling, trapping, manipulating and detecting atomic gases. The knowledge of these techniques will allow for a better understanding of how it is possible to generate and analyze all the effects mentioned above. Chp. 45 introduces

[1] In particular, for very cold atoms whose internal excitation occurs on a very different energy scale, the corresponding degree freedom is frozen and does not influence the kinetics.

the phenomenon of Bose-Einstein condensation and the following chapters focus on the thermodynamic, superfluid, coherent and dielectric properties of condensates.

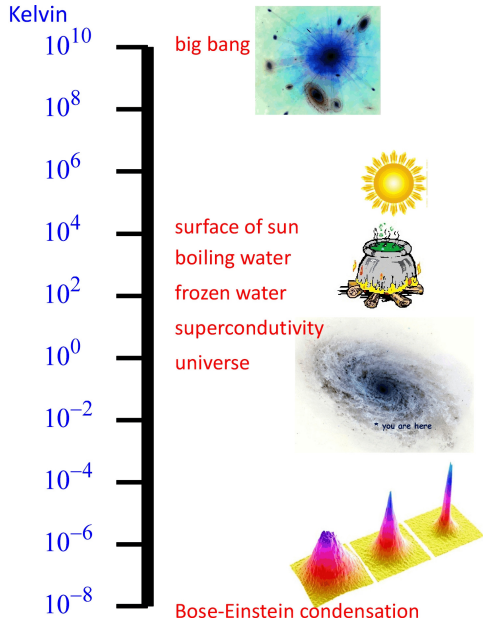

Figure 43.1: Temperature scale.

The incomparable success of atomic optics has been rewarded with 20 nobel prices in the last 25 years (Dehmelt, Paul, Ramsey, Cohen-Tannoudji, Chu, Phillips, Cornell, Wieman, Ketterle, Hänsch, Glauber, Hall, Wineland, Haroche, Ahskin) plus several indirectly related noble prices (De Gennes, Leggett, Thouless, Haldane, Kosterlitz). For review articles on BEC see [999, 319, 297, 512, 1122, 1238], [712] or check in internet sites *http://amo.phy.gasou.edu/bec.html* and *http://jila.edu/bec.html*.

In this chapter we review the basic techniques of *Atomic Optics*, emphasizing the cooling, trapping and measurement of cold atomic gases. See also (watch talk) and (watch talk).

43.1 The atomic motion

43.1.1 The atom as a matter wave

We have already emphasized that atomic optics deals with the motion of atoms in a gas, that is, we are interested only in the external degrees of freedom of the atoms. To describe the motion of a free massive particle in one dimension, we write the Hamiltonian,

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} \ . \tag{43.1}$$

Therefore, the general solution of the stationary Schrödinger equation,

$$\hat{H}\psi(x) = E\psi(x) \ , \tag{43.2}$$

is,

$$\psi(x) = Ae^{\imath kx} + Be^{-\imath kx} \qquad \text{with} \qquad k = \sqrt{\frac{2mE}{\hbar^2}} \ . \tag{43.3}$$

Note, that the wavefunctions $e^{\imath kx}$ are not quadratically integrable. On the other hand, they do not represent real physical systems. In practice, we need to consider wavepackets or specify a finite volume for the particle.

Note also that the eigenvalue spectrum of is continuous. To warrant the interpretation of the wavefunction as a probability density we will require quadratic integrability, $\int |\psi|^2 d^3r = 1$. This means that the wavefunction can not be infinite in a finite volume, but it can be infinite in an infinitely small volume.

The description of the atomic motion by a wave equation emphasizes the fact that microscopic particles have wave properties with each atom corresponding to a velocity-dependent *de Broglie wave*,

$$\boxed{\lambda_{dB} = \frac{h}{p}} \ , \tag{43.4}$$

which describes the coherence length of the atom.

43.1.1.1 Characteristic velocities

The behavior of an atom described by the Schrödinger equation depends very much on its kinetic energy. At high velocities (or short de Broglie waves), it will behave like a classical particle with a well-defined trajectory. At low velocities (or long de Broglie waves), it will propagate like a wave and exhibit phenomena such as diffraction and interference. Therefore, it is important to highlight some characteristic velocity regimes.

Most optical cooling techniques are based on the removal of kinetic energy upon light scattering on electronic transitions. It is, therefore, interesting to compare the kinetic energy (or temperature) of an ensemble of atoms with the width Γ of the transition. The *Doppler limit* is given by (see Exc. 43.1.4.1),

$$k_B T_D = \frac{\hbar}{2}\Gamma \ . \tag{43.5}$$

We can also compare the kinetic energy with the energy transferred to an atom by the absorption of a single photon. The *photonic recoil* energy is given by,

$$k_B T_{rec} = \frac{\hbar^2 k^2}{2m} \ . \tag{43.6}$$

Atomic clouds with temperatures around $T \simeq T_D = 10..1000\,\mu\text{K}$ are called *cold*. Clouds with temperatures around and below $T \lesssim T_{rec} = 0.1..10\,\mu\text{K}$ are called *ultracold*.

In most atomic optical experiments we do not work with individual atoms (or ions), but with relatively dilute ensembles of atoms, called *clouds*. In general, clouds can not be described by a single wavefunction. Either we describe every atom by a separate and independent wavefunction (which only works when the atoms do not interact), or we describe the cloud by probability distributions (such as the 'density

matrix'). Let us now consider a thermal cloud. The *Maxwell-Boltzmann distribution* of velocities is,

$$g(\mathbf{v}) = \sqrt{\frac{m}{2\pi k_B T}}^3 e^{-m\mathbf{v}^2/2k_B T} \ . \tag{43.7}$$

This distribution is normalized, $\int g(\mathbf{v}) d^3\mathbf{v} = \int_0^\infty 4\pi v^2 g(v) dv = 1$. Average velocity is now

$$\bar{v} = \int v g(v) dv = \sqrt{\frac{k_B T}{m}} \ . \tag{43.8}$$

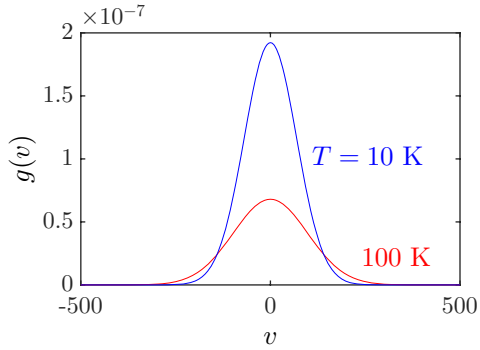

Figure 43.2: (code) Maxwell-Boltzmann distribution.

We define the *thermal de Broglie wavelength* of an atomic ensemble as,

$$\boxed{\lambda_{therm} \equiv \frac{h}{m\bar{v}} = \sqrt{\frac{2\pi\hbar^2}{mk_B T}}} \ . \tag{43.9}$$

It represents an average over the de Broglie wavelengths of all atoms of the sample. When a dense gas is sufficiently dense, so that this quantity exceeds the average distance between atoms,

$$\rho \equiv n\lambda_{therm}^3 > 1 \ , \tag{43.10}$$

where n is the atomic density, we enter a new regime, where the *Maxwell-Boltzmann law* ceases to be valid. Since $\lambda_{therm} \propto T^{-1/2}$, this regime corresponds to low temperatures. The quantity ρ is called *phase space density*. A phase space density approaching 1 means an increased probability of finding *more than one atom per elementary phase space cell*. We then enter the regime of quantum degeneracy, where the Boltzmann statistics must be replaced by the Bose-Einstein statistics, in the case of bosons, or the Fermi-Dirac statistics, in the case of fermions. We will deepen the discussion of quantum statistics of ideal gases in Chp. 44. From the condition $n\lambda_{therm}^3 \simeq 1$, we obtain

$$k_B T_c = \frac{1}{m}\left(\frac{2\pi\hbar}{\lambda_{therm}}\right)^2 = \frac{(2\pi\hbar)^2 n^{2/3}}{m} \ . \tag{43.11}$$

43.1.2 Localized atoms

To avoid perturbative influence of the environment on the atoms, they are often trapped in potentials, which suspend them in a volume distant from massive walls. The Hamiltonian of a trapped atoms is,

$$\hat{H} = -\frac{\hbar^2}{2m}\frac{d^2}{dx^2} + U(x) \ . \tag{43.12}$$

As the wavefunction is now localized, the spectrum of possible energies organizes into discrete levels, and the atoms are allocated in populations of these levels.

Often, a 3D potential can be written in the form,

$$U(x,y,z) = U_x(x) + U_y(y) + U_z(z) \ . \tag{43.13}$$

This is the case, for example, of a rectangular well characterized by $U_x(x) = U_y(y) = U_z(z) = U_0/3$ inside the well. The relationship (43.13) also holds for a harmonic potential,

$$U(\mathbf{r}) = \frac{m}{2}\left(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 z^2\right) \ . \tag{43.14}$$

In these cases, a product ansatz for the wavefunction is generally useful,

$$\psi(\mathbf{r}) = \psi_x(x)\psi_y(y)\psi_z(z) \ , \tag{43.15}$$

since its insertion into the Schrödinger equation,

$$\begin{aligned}&\left[-\frac{\hbar^2}{2m}\left(\frac{d^2}{dx^2} + \frac{d^2}{dy^2} + \frac{d^2}{dz^2}\right) + U_x(x) + U_y(y) + U_z(z)\right]\psi_x(x)\psi_y(y)\psi_z(z) \\ &= E\psi_x(x)\psi_y(y)\psi_z(z) \ ,\end{aligned} \tag{43.16}$$

separates it into three independent one-dimensional equations,

$$-\frac{\hbar^2}{2m}\frac{\psi_x''(x)}{\psi_x(x)} + U_x(x) = const. \equiv E_x \ , \tag{43.17}$$

and similarly for y and z. Since $E = E_x + E_y + E_z$, we can have the same energy for different combinations of E_x, E_y and E_z. That is, multidimensional systems are often degenerate.

43.1.3 Density-of-states of a trapping potential

The way an atomic cloud accommodates itself inside a trapping potential is governed by the density of available states. To calculate this density, we consider the Hamiltonian $H(\mathbf{r},\mathbf{p}) = \frac{\hbar^2 k^2}{2m} + U(\mathbf{r})$. For a cylindrical harmonic oscillator we write,

$$U(\mathbf{r}) = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 \qquad \text{where} \qquad r^2 = x^2 + y^2 \ , \tag{43.18}$$

or $U(\mathbf{x}) = \frac{m}{2}\omega_r^2\rho^2$, where $\rho^2 = x^2 + y^2 + \lambda^2 z^2$ with $\lambda = \omega_z/\omega_r$. We define $\bar{\omega} = (\omega_r^2\omega_z)^{1/3} = \lambda^{1/3}\omega_r$. The single-particle levels of this Hamiltonian are, $\epsilon_{n_x n_y n_z} = \hbar\omega_x n_x + \hbar\omega_y n_y + \hbar\omega_z n_z$, where the n_j are integer numbers.

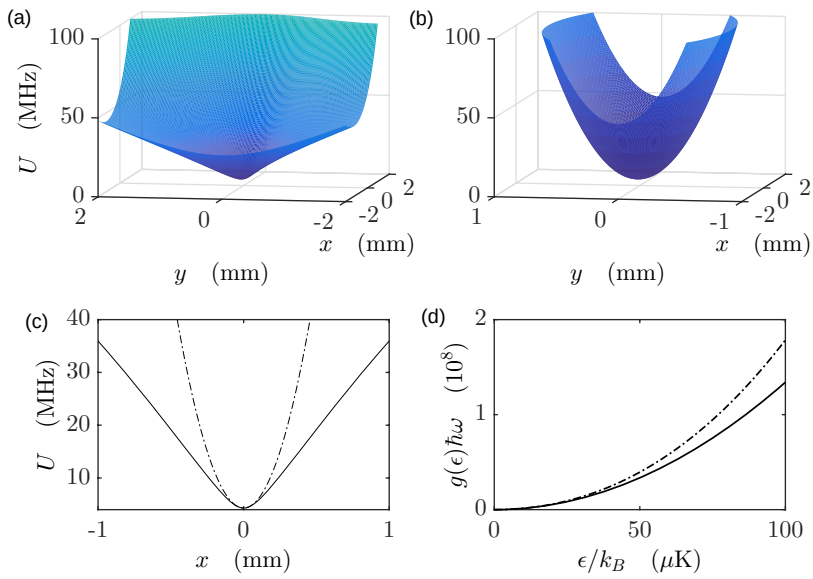

Figure 43.3: (code) (a) The figure shows two dimensions of a Ioffe-Pritchard type magnetic trapping potential (characterized by being approximately linear at large distances from the center and harmonic near the center). (b) Harmonic approximation (most experimentally feasible potentials are approximately harmonic near the center). (c) One-dimensional cut through the potential of (a,b). (d) Density of states for a harmonic (dotted line) and a Ioffe-Pritchard type potential (solid line).

We now introduce the *density of states* $\eta(\epsilon)$ for an arbitrary potential via,

$$\boxed{\int \eta(\epsilon)d\epsilon \equiv \frac{1}{(2\pi)^3}\int d^3r d^3k = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}\int d^3r \int d\epsilon\sqrt{\epsilon - U(\mathbf{r})}} \ . \tag{43.19}$$

For the cylindrical harmonic trap defined in (43.18), we find with a little help from Dr. Bronstein [201],

$$\begin{aligned}\eta(\epsilon) &= \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}\int d^3r\sqrt{\epsilon - \frac{m}{2}\omega_r^2\rho^2} \\ &= \frac{1}{(2\pi)^2}\frac{8\epsilon^2}{(\hbar\bar{\omega})^3}\int_{-1}^{1}d\tilde{x}\int_{-\sqrt{1-\tilde{x}^2}}^{\sqrt{1-\tilde{x}^2}}d\tilde{y}\int_{-\sqrt{1-\tilde{x}^2-\tilde{y}^2}}^{\sqrt{1-\tilde{x}^2-\tilde{y}^2}}d\tilde{z}\sqrt{1-\tilde{x}^2-\tilde{y}^2-\tilde{z}^2}\ .\end{aligned} \tag{43.20}$$

The resolution of the integral gives,

$$\boxed{\eta(\epsilon) = \frac{\epsilon^2}{2(\hbar\bar{\omega})^3}} \quad \text{(harmonic potential)} \ . \tag{43.21}$$

Another example is the box potential. In this case we can simply obtain,

$$\boxed{\eta(\epsilon) = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}\int_V d^3r\sqrt{\epsilon} = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3}V\sqrt{\epsilon}} \quad \text{(box potential)} \ . \tag{43.22}$$

A generalization is discussed in the Exc. 43.1.4.2.

43.1.4 Exercises

43.1.4.1 Ex: Fundamental temperature limits

Calculate the Doppler limit, the recoil limit, and the threshold to quantum degeneracy for an atomic cloud of density $n = 10^{14}\,\mathrm{cm}^{-3}$ for the sodium $D2$ transition ($\lambda = 590\,\mathrm{nm}$, $\Gamma/2\pi = 10\,\mathrm{MHz}$) and the rubidium $D2$ transition ($\lambda = 780\,\mathrm{nm}$, $\Gamma/2\pi = 6\,\mathrm{MHz}$).

Solution: *For sodium* $T_D = 240\,\mu\mathrm{K}$, $T_{rec} = 1.2\,\mu\mathrm{K}$, *and* $T_c = 220\,\mathrm{nK}$. *For rubidium* $T_D = 144\,\mu\mathrm{K}$, $E_R = 180\,\mathrm{nK}$, *and* $T_c = 830\,\mathrm{nK}$.

43.1.4.2 Ex: Density of states for non-harmonic potentials

Calculate the density of states for non-harmonic potentials, $\hat{H} = \frac{\hbar^2 k^2}{2m} + \left|\frac{x}{2\bar{x}}\right|^p + \left|\frac{y}{2\bar{y}}\right|^l + \left|\frac{z}{2\bar{z}}\right|^q$ using Ref. [72]. Apply the result to a quadrupolar potential.

Solution: *This reference found the following solution,*

$$\eta(\epsilon) = \frac{(2m)^{3/2}}{(2\pi)^2\hbar^3} 8\bar{x}\bar{y}\bar{z}F(p,l,q)\varepsilon^{1/p+1/q+1/l+1/2}$$
$$F(p,l,q) = \int_{-1}^{1}(1-\tilde{x}^p)^{1/2+1/q+1/l}d\tilde{x}\int_{-1}^{1}(1-\tilde{x}^l)^{1/2+1/q}d\tilde{y}\int_{-1}^{1}(1-\tilde{x}^q)^{1/2}d\tilde{z}\ .$$

For example, for a quadrupole trap,

$$F(p,l,q) = \frac{2^{10}}{105}\sqrt{2}$$
$$g(\epsilon) = \frac{2^{13}}{105}\frac{m^{3/2}}{\pi^2\hbar^3}\bar{x}\bar{y}\bar{z}\epsilon^{7/2}\ .$$

43.2 Optical cooling

As discussed in Sec. 38.2, the force exerted by a light field on an atom can be of two types: a dissipative force arising called *radiation pressure*, which is often used for optical cooling purposes, and a conservative *dipolar force* which often serves for the engineering of optical trapping potentials. Both applications of optical forces will be detailed in the following sections.

43.2.1 Optical molasses

In the *Doppler cooling* model, we treat the phenomenology of optical forces quantitatively by considering the amplitude, phase and frequency of a classical field interacting with the dipole of an atomic transition in a two-level atom. From Eq. (38.25) and previous definitions of Ω and Ω_{sat}, and with the intensity $I \propto \mathcal{E}^2$, we can write the *saturation parameter*,

$$s = \frac{I}{I_{sat}} = \frac{\Omega^2}{\Omega_{sat}^2} = \frac{\Omega^2}{\Gamma^2/2} \ , \tag{43.23}$$

and

$$\mathbf{F}_{rp} = \frac{\hbar \mathbf{k} \Gamma}{2} \frac{s}{(2\Delta/\Gamma)^2 + 1 + s} \ . \tag{43.24}$$

Now, if we consider an atom propagating in $\mp z$ direction with the velocity v_z counterpropagating to a light wave detuned by Δ from the resonance, the total detuning will be

$$\Delta \longrightarrow \Delta \mp k v_z \ . \tag{43.25}$$

where the term kv_z is the Doppler shift. The force $F_\pm$ acting on the atom will be in the direction opposite to the motion,

$$\mathbf{F}_\pm = \pm \frac{\hbar \mathbf{k} \Gamma}{2} \frac{s}{(2(\Delta \mp k v_z)/\Gamma)^2 + 1 + s} \ . \tag{43.26}$$

Supposing now, that we have two light fields propagating in directions $\pm z$, the total force will be $\mathbf{F} = \mathbf{F}_+ + \mathbf{F}_-$. If kv_z is small compared to Γ and Δ, we find through a Taylor expansion,

$$F_z \simeq 4\hbar k s \frac{k v_z (2\Delta/\Gamma)}{[1 + s + (2\Delta/\Gamma)^2]^2} \ . \tag{43.27}$$

This expression shows that, if the detuning Δ is negative (that is, on the red side of the resonance), then the cooling force will oppose the motion and be proportional to the atomic velocity. Fig. 43.4 shows this decelerating dissipative force as a function of v_z at a detuning $\Delta = -\Gamma$ with $I = I_{sat}/2$. The one-dimensional motion of the atom is thus behaving like being subject to a friction force which is proportional to the atomic velocity,

$$F_z \simeq \alpha_d v_z \qquad \text{with} \qquad \alpha_d = s \frac{-4k^2(2\Delta/\Gamma)}{1 + s + (2\Delta/\Gamma)^2} \ . \tag{43.28}$$

The proportionality factor, is just the *friction coefficient*.

However, the atom will not cool down indefinitely. At some point, the Doppler cooling rate will be balanced by the heating rate coming from the momentum fluctuations of the atom absorbing and remitting photons. The *Doppler cooling limit* is given by,

$$k_B T = \hbar \frac{\Gamma}{2} \ , \tag{43.29}$$

as we will see in Exc. 43.2.5.1. This limit is generally, for alkaline atoms, on the order of dozens of micro-Kelvin. In the early years of cooling and trapping, the Doppler limit was thought to be a real physical barrier. But in 1988, several groups

have shown that, in fact, atoms could be cooled well below the Doppler limit. The effect arises in atoms, whose ground state exhibits a hyperfine structure. We will show simplified one-dimensional models for sub-Doppler cooling in the next section. Resolve the Exc. 43.2.5.2.

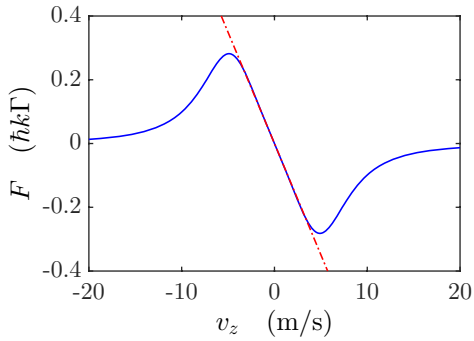

Figure 43.4: (code) Doppler force due to one-dimensional radiative pressure as a function of atomic velocity along the z-axis for red detuning $\Delta = -\Gamma$ at a light intensity of $I = 2I_{sat}$. The solid line shows the exact expression for the restoring force [Eq (43.26)]. The broken line shows the approximate linear expression of the velocity dependence according to Eq. (43.27).

43.2.2 Sub-Doppler cooling

It turns out that atoms with a hyperfine structure in the ground state can be cooled below the Doppler limit (43.5). To explain this unexpected observation, models involving a slow motion of the atoms in polarization gradients of a standing light wave have been invoked. The phenomenon is now known as *polarization gradient cooling*.

Two principal mechanisms for cooling atoms to temperatures below the Doppler limit are based on spatial polarization gradients. These two mechanisms, however, invoke very different physical processes and are distinct by the spatial dependence of the light polarization. A key point is that these sub-Doppler mechanisms only work on atoms with multiple ground state levels. Two parameters, the friction coefficient and the capture velocity, determine the importance of these cooling processes. In this section we compare the expressions for these quantities in the sub-Doppler regime to those found by the conventional one-dimensional Doppler cooling model for optical molasses.

43.2.2.1 Lin ⊥ lin molasses

In the first case, two counterpropagating light waves with orthogonal linear polarizations form a standing wave. This configuration is familiarly called lin-perp-lin. Fig. 43.5 illustrates the change of polarization every period of $\lambda/8$ from linear to circular to linear again, but rotated by 90°, and so on [323]. Along the same distance, the light-atom coupling produces a periodic energy shift (light-shift) of the ground state Zeeman levels. To illustrate the cooling mechanism, we assume the simplest case, a transition $J_g = \frac{1}{2} \longrightarrow J_e = \frac{3}{2}$. As shown in Fig. 43.5 an atom moving through

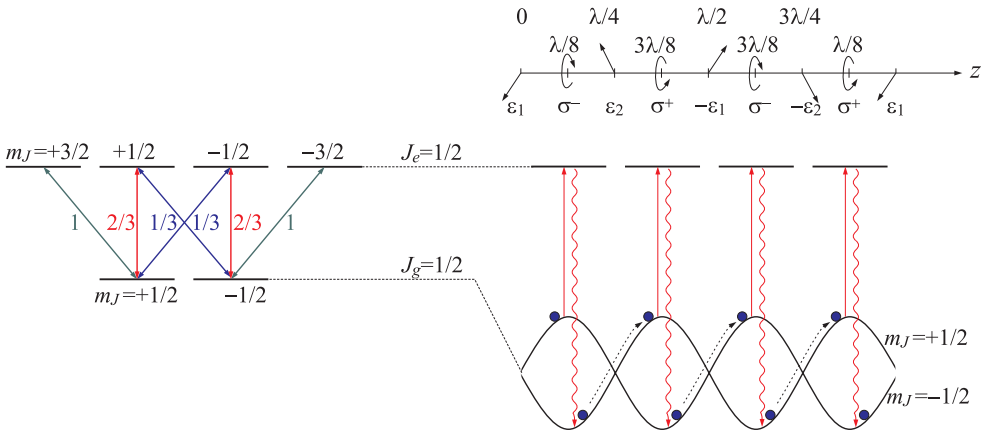

Figure 43.5: The upper line shows, how the polarization changes as a function of position (in units of a wavelength) for the 'lin-perp-lin' standing wave configuration. The figure below shows a simplified picture of the Sisyphus cooling mechanism for an atom with two levels, $J_g \leftrightarrow J_e$.

the region $z \simeq \lambda/8$, where the polarization is σ_-, will see its population pumped to $J_g = -\frac{1}{2}$. In addition, the Clebsch-Gordan coefficients that control the dipolar coupling of the $J_e = \frac{3}{2}$ require that the $J_g = -\frac{1}{2}$ couples to σ_- with a force three times larger than the $J_g = +\frac{1}{2}$ does. The difference of the coupling forces leads to the light-shift between the two fundamental states shown in Fig. 43.5. As the atom continues to move toward $+z$, the relative coupling forces are reversed near $3\lambda/8$, where the polarization is essentially σ_+. Thus, the relative energy levels of the two hyperfine fundamental states oscillate 'out of phase' when the atom moves through the standing wave.

The fundamental idea is that the optical pumping rate, which always redistributes population to the lower hyperfine level, delays the light-shift of the atom moving through the field. The result is a 'Sisyphus effect', where the atom spends most of its time in sub-levels climbing a potential hill and thus converting kinetic energy into potential energy. This accumulated potential energy is subsequently dissipated by spontaneous emission to the electromagnetic modes of the vacuum. Simultaneously, the spontaneous emission transfers the population back to the lower one of two ground state levels. The lower diagram of Fig. 43.5 illustrates the phase delay of optical pumping. For this cooling mechanism to work, the optical pumping time, which is controlled by the intensity of the light, must be sufficiently slow to give the atom enough time to climb a noticeable part of the light-shift potential. This time essentially depends on the speed of the atom. As the atom is moving slowly, having previously been cooled by the Doppler mechanism, the light field must be weak in order to decrease the optical pumping rate. Interestingly, this physical picture combines the conservative dipole optical force, whose spatial integral gives rise to the mounts and valleys of the potential on which the atom moves, and the irreversible dissipation of energy by spontaneous emission, which is necessary for any type of cooling.

We can obtain simple expressions for the friction coefficient and the capture ve-

locity after some definitions. As in the Doppler cooling model we define the friction coefficient α_{lpl} as the proportionality constant between the force F and the atomic velocity v,

$$F = -\alpha_{lpl} v \ . \tag{43.30}$$

We assume that the light field is tuned to the red of the transition J_g - J_e,

$$\Delta = \omega - \omega_0 \ , \tag{43.31}$$

and we denote the light-shifts of the levels $J_g = \pm\frac{1}{2}$ as $\Delta_\pm$, respectively. At the position $z = \lambda/8$, we find $\Delta_- = 3\Delta_+$ and at $z = 3\lambda/8$, $\Delta_+ = 3\Delta_-$. As the applied field is tuned to red, all $\Delta_\pm$ have negative values. Now, for the cooling mechanism to be efficient, the optical pumping time τ_p should be similar to the time needed for an atom with velocity v to move from the bottom to the top of the potential, $\frac{\lambda/4}{v}$,

$$\tau_p = \frac{\lambda/4}{v} \tag{43.32}$$

or

$$\Gamma' \simeq kv \ , \tag{43.33}$$

where $\Gamma' = 1/\tau_p$ and $\lambda/4 \simeq 1/k$. Now, the energy W dissipated during a cycle of escalation and spontaneous emission is essentially the average energy difference between the light-shifted ground states, $\Delta_{ls} \equiv \Delta_+ + \Delta_-$, that is $W \simeq -\hbar\Delta_{ls}$. Therefore, the rate for energy dissipation is,

$$\frac{dW}{dt} = \Gamma'\hbar\Delta_{ls} \ . \tag{43.34}$$

At the same time, every temporal energy change of a system can always be expressed as $\frac{dW}{dt} = \mathbf{F}\cdot\mathbf{v}$. Therefore, in this one-dimensional model, considering Eq. (43.31), we can write,

$$\frac{dW}{dt} = -\alpha_{lpl} v^2 = -\Gamma'\hbar\Delta_{ls} \ , \tag{43.35}$$

such that with (43.33),

$$\alpha_{lpl} = -\frac{\Gamma'\hbar\Delta_{ls}}{v^2} \simeq -kv\frac{\hbar\Delta_{ls}}{v^2} \simeq -\frac{\hbar k^2\Delta_{ls}}{\Gamma'} \ . \tag{43.36}$$

Note that since $\Delta < 0$, α_{lpl} is a positive quantity. Also note, that for large detunings, ($\Delta \gg \Gamma$) Eq. (38.24) gives,

$$\frac{U}{\hbar} = \frac{\Delta_{ls}}{4} = \frac{\Omega^2}{4\Delta} \ . \tag{43.37}$$

It is also true that for light-shifts, which are large compared to the natural width of ground state ($\Delta_{ls} \gg \Gamma'$), and for large red detunings ($\Delta \gtrsim 4\Gamma$),

$$\frac{\Gamma}{\Gamma'} \simeq \frac{\Delta^2}{4\Omega^2} \ . \tag{43.38}$$

Therefore, the sub-Doppler friction coefficient can also be written,

$$\alpha_{lpl} = -\frac{\hbar k^2\Delta}{4\Gamma} \tag{43.39}$$

Eq. (43.39) makes two remarkable predictions: Firstly, in the 'lin-perp-lin' configuration the sub-Doppler friction coefficient can be a large number in comparison to α_d. Note that from Eq. (43.28), with $I \lesssim I_{sat}$ and $\Delta \gg \Gamma$,

$$\alpha_d \simeq \hbar k^2 \left(\frac{\Gamma}{\Delta}\right)^3 , \tag{43.40}$$

and

$$\frac{\alpha_{lpl}}{\alpha_d} \simeq \left(\frac{\Delta}{\Gamma}\right)^4 . \tag{43.41}$$

Secondly, α_{lpl} is independent of the intensity of the applied field. This last result is different from the friction coefficient, which is proportional to the field intensity up to until saturation (see Eq. (43.28)). However, although α_{lpl} seems impressive, the range of atomic velocities where it can operate is constrained by the condition,

$$\Gamma' \simeq kv . \tag{43.42}$$

The ratio of the capture velocities for sub-Doppler versus Doppler cooling is therefore only,

$$\frac{v_{lpl}}{v_d} \simeq \frac{4\Delta_{ls}}{\Delta} . \tag{43.43}$$

Fig. 43.6 graphically illustrates the comparison between the Doppler and the 'lin-perp-lin' sub-Doppler cooling mechanisms. The dramatic difference of the capture ranges is evident. Note also that the slopes of the curves give the friction coefficients and that, within the capture range, the slope is much steeper for the sub-Doppler mechanism.

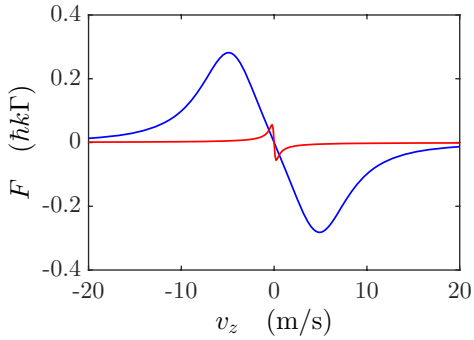

Figure 43.6: (code) Comparison of slopes, amplitudes, and capture ranges for Doppler and Sisyphus cooling.

43.2.2.2 σ^+-σ^- molasses

The second mechanism operates with two counterpropagating light beams, which are circularly polarized in opposite directions. When the two counterpropagating beams have the same amplitude, the resulting polarization is always linear and orthogonal

to the propagation axis, but the tip of the polarization vector traces a helix with a periodicity of λ [see Fig. 43.7(b)]. The physics of this sub-Doppler mechanism *does not involve hill-climbing nor spontaneous emission*, but an imbalance of the photon scattering rates by the two counterpropagating light waves as the atom moves along the z-axis. This imbalance leads to a velocity-dependent force counteracting the atomic displacement. The essential factor leading to the different scattering rates is the creation of a population orientation along the z-axis between the sub-levels of the atomic ground state. The more populated sub-levels scatter more photons. Now, considering the energy level diagram (see Fig. 43.5) and the symmetry of the Clebsch-Gordan coefficients, it is evident that transitions $J_g = \frac{1}{2} \leftrightarrow J_e = \frac{3}{2}$ coupled by linearly polarized light can not produce an orientation of the population in the ground state. In fact, the simplest system exhibiting this effect is $J_g = 1 \leftrightarrow J_e = 2$. A measure for this orientation is the magnitude of the matrix element $\langle J_z \rangle$ between the sublevels $J_{g_z} = \pm 1$. For an atom at rest at the position $z = 0$ interacting with the light polarized along the y-direction, the light-shifts Δ_0 and $\Delta_\pm$ of the three sub-levels of the ground state would be,

$$\Delta_{+1} = \Delta_{-1} = \tfrac{3}{4}\Delta_0 \ , \tag{43.44}$$

and the stationary populations would be 4/17, 4/17 e 9/17, respectively. Obviously, linearly polarized light does not produce a stationary orientation, $\langle J_z \rangle_s = 0$. But when the atom begins to move along the z-axis with velocity v, it sees a linear polarization precessing about the axis of propagation at an angle $\varphi = kz = -kvt$. This precession gives rise to a new term in the Hamiltonian, $V = kvJ_z$. Furthermore, when we transform to a rotating coordinate system, the eigenfunctions of the Hamiltonian of the atom moving in this new 'inertial' system become linear combinations of the basis functions of the resting atom. The expectation value of the stationary orientation operator J_z, is now zero in the inertial system [323],

$$\langle J_z \rangle = \frac{40}{17}\frac{\hbar k v}{\Delta_0} = \hbar(\Pi_+ - \Pi_-) \ . \tag{43.45}$$

Note that, as the expectation value of the orientation is nonzero only when the atom moves. In Eq. (43.45) we denote the populations of the sub-levels $|\pm>$ as $\Pi_\pm$, and we interpret nonzero matrix elements as a direct measure of the population difference between the ground state levels $|\pm>$. Note that, since Δ_0 is negative (red tuning), the Eq. (43.45) tells us, that the population Π_- is larger than Π_+. Now, when an atom traveling in $+z$ direction is exposed to two light waves with polarizations $\sigma_\mp$ propagating in the $\mp z$ directions, the preponderance of population in the state $|-\rangle$ will result in a higher scattering rate from the wave propagating in $-z$ direction. Therefore, the atom will be subject to a total force opposite to its movement and proportional to its velocity. The differential scattering rate is,

$$\frac{40}{17}\frac{kv}{\Delta_0}\Gamma' \ . \tag{43.46}$$

With a quantized momentum of $\hbar k$ transferred at each scattering event, the total force is,

$$F = \frac{40}{17}\frac{\hbar k^2 v \Gamma'}{\Delta_0} \ . \tag{43.47}$$

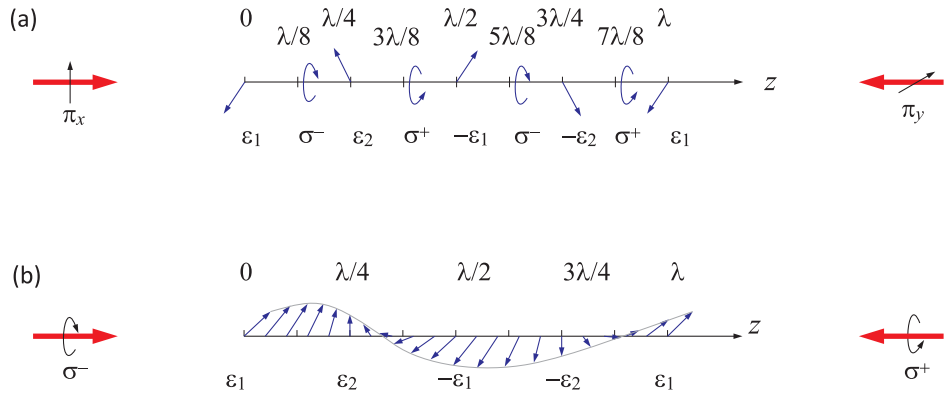

Figure 43.7: Polarization as a function of position (in units of a wavelength) for the σ^+-σ^- standing wave configuration.

The friction coefficient α_{cp} is,

$$\alpha_{cp} = -\frac{40}{17}\hbar k^2 \frac{\Gamma'}{\Delta_0} \ , \tag{43.48}$$

which is a positive quantity, since Δ_0 is negative for red detuning. Comparing α_{cp} with α_{lpl} we see, that α_{cp} must be much smaller, because we always assumed that the light shifts Δ are much larger than the linewidths Γ'. However, the heating rate due to fluctuations of the recoil is also much lower. Thus, the minimum temperatures that can be reached with the two sub-Doppler mechanisms are comparable.

Although the Doppler cooling mechanism also depends on an imbalance of scattering from counterpropagating light waves, in this case the imbalance comes from the fact that the Doppler shift experienced by the moving atoms leads to different probabilities for photon scattering. For the sub-Doppler mechanism the scattering probabilities from the two light waves are the same, but the ground state populations are not. The state with the largest population suffers the highest scattering rate.

43.2.3 Raman cooling

43.2.3.1 Optical cooling of confined particles

It is also possible to cool ions confined in a trap [1381]. The direction of their motion and their velocity change periodically with the secular frequencies ζ_r und ζ_z. For optical cooling it is sufficient to irradiate a single red-detuned running-wave light field: In a real ion trap the cylindrical symmetry cannot be realized with absolute precision so that we get different secular frequencies $\zeta_x \neq \zeta_y \neq \zeta_z$ and a coupling of the degrees of freedom for all directions of space. The cooling of the ionic motion in a single direction results in a cooling of the motion in the other directions.

In the rest system of an ion oscillating in a harmonic trap the Doppler-shift of the laser frequency changes periodically: $\mathbf{v}(t) = \mathbf{v}_0 \cos \zeta_{r,z} t$. The ion absorbs therefore in its rest system the light on a withb of sidebands whose distance and strength depend on the oscillation frequency and amplitude. The absorption profile of a transition

in such a harmonically vibrating ion follows as a convolution of the Lorentz profile $\mathcal{L}_\Gamma$, describing the naturally broadened resonance, with a function $\mathcal{S}$, describing the splitting of the absorption profile into sidebands [655]:

$$\mathcal{A}(\Delta) = (\mathcal{L}_\Gamma \star \mathcal{S})(\Delta) \quad , \quad \mathcal{S}(\Delta) = \sum_n \mathcal{J}_n(\mathbf{k}\cdot\mathbf{v}_0/\zeta_{r,z})^2 \delta(\Delta - n\zeta_{r,z}) \ . \tag{43.49}$$

$\mathcal{J}_n$ denotes the Bessel function of n^{th} order. In essence, the system is governed by three time-constants: The natural decay width of the cooling transition Γ is a measure for the inneratomic time scale, since it determines the average duration of absorption-emissions cycles. The secular frequencies $\zeta_{r,z}$ determine the time scales for changes in the external degrees of freedom, i.e. for changes of the ion's location and velocity. The Doppler-shift kv_0 of the resonance frequency in the return point of the ion motion finally, is a measure for the kinetic energy of the ion.

The relative importance of these three characteristic frequencies reveal the state of the ion in the trap. The modulation index $\mathbf{k}\mathbf{v}_0/\zeta_{r,z}$ decides on the height and the number of sidebands in the excitation spectrum. The better the ion has been cooled, the smaller the modulation index and the smaller the height and number of sidebands. The kinetic energy of the ion is,

$$E_{kin} = \frac{1}{2} m v_0^2 = \frac{1}{2} m \zeta_{r,z}^2 x_0^2 \ . \tag{43.50}$$

The modulation index $\mathbf{k}\mathbf{v}_0/\zeta_{r,z} = kx_0 = 2\pi x_0/\lambda$ is also called *Lamb-Dicke parameter*. By cooling the Lamb-Dicke parameter is so much reduced and the ion is so well localized that its motional sidebands are smaller than the wavelength of the exciting light. It then is in the so-called Lamb-Dicke regime $x_0 \ll \lambda$ [**?**] and has so small motional sidebands that they do not contribute to the line shape and do not influence the line width. Therefore the linear Doppler effect vanishes.

The quantity $\zeta_{r,z}/\Gamma$ defines the *resolution* of the sidebands. If the resolution is poor, we talk about weak confinement, else about strong confinement. Therefore the same ion can be weakly confined with respect to an allowed transition and strongly confined with respect to a forbidden transition. The cooling processes in the two cases of strong and weak trapping must be described differently. At weak confinement the oscillation frequency $\zeta_{r,z}$ is so slow that many absorption-emission cycles with the time constant Γ^{-1} can occur during one oscillation period. Cooling process and cooling limit are approximately the same as for free particles and are described by Doppler cooling.

43.2.3.2 Raman sideband cooling

In the case of strong confinement for the description of the cooling process we must consider the quantization of the motional energy in the harmonic potential. The two levels coupled by the narrow transition split into vibrational sublevels $|n_{r,z}\rangle$, which are populated in thermal equilibrium according to the Bose-Einstein distribution and have the kinetic energies E_{kin},

$$n_{r,z} = \frac{1}{e^{\hbar\zeta_{r,z}/k_B T} - 1} \quad \text{and} \quad E_{kin} = \hbar\zeta_{r,z}(n_{r,z} + \tfrac{1}{2}) \ . \tag{43.51}$$

To perform the so-called optical cooling *sideband cooling* [1381] the laser is tuned to the first lower sideband. The laser light is then scattered in a Raman-Anti-Stokes process at the excited electronic state with a vibrational quantumnumber lower by 1 $|e, n_{r,z} - 1\rangle$. The subsequent spontaneous decay occurs most probably to the same vibrational substate of the ground state $|g, n_{r,z} - 1\rangle$. The net effect of such a scattering process therefore is a transition to the next lower vibrational quantum number. The zero point energy of the ion in the trapping potential cannot be underscored by cooling, $E_{kin} > \frac{1}{2}\hbar\zeta_{r,z}$ (for the Yb^+ ion it is $E_{kin} > 2\,\mathrm{neV}$). However, the uncertainty of the kinetic energy, and the temperature T given by (43.51) have no lower limit [367].

At every absorption process, free particles carry away the momentum of the photons $\hbar k$. The recoil of a free Yb^+ ion corresponds to the frequency shift $\varepsilon/2\pi = 5.3\,\mathrm{kHz}$. On a narrow transition, it yields a resonance at the frequency ε. For trapped ions, this is not the case, because the momentum is absorbed by the whole trap (see analogy to the *Mößbauer effect*).

43.2.3.3 Stimulated Raman sideband cooling

We may use two lasers detuned far from resonance to couple two vibrational states. However, additional dissipation by optical pumping is still required.

Numerous schemes have been tested to cool neutral atoms in optical lattices. For the schemes to work, the ion should be already in the Lamb-Dicke regime. Otherwise, transitions with transfer of higher vibrational quantum numbers $n_{r,z}$ are possible during spontaneous emission. The Lamb-Dicke limit is set by $kr < 1$, or,

$$\langle n \rangle = \frac{m\omega_{trap}}{2\hbar k^2} \ . \tag{43.52}$$

This means that higher trap frequencies ease the required temperature at which sideband cooling can start to work.

43.2.4 Adiabatic cooling of an optical lattice

Adiabatic cooling by [701] in 1D. Defining the lattice constant Q_0, the Boltzmann factor $f_B \equiv e^{-\hbar\omega/k_B T}$, the initial thermal population $\pi_n = (1 - f_B) f_B^n$, the recoil energy $E_{rec} \equiv \frac{\hbar^2 k^2}{2m}$,

$$\frac{k_B T}{2} = \sum_n \frac{\pi_n}{\hbar Q_0} \int_{(n+1)^{th}\text{Bloch band}} \frac{p^2}{2m} dp = 2 \sum_n \frac{\pi_n}{\hbar Q_0} \int_{n\hbar Q_0/2}^{(n+1)\hbar Q_0/2} \frac{p^2}{2m} dp \tag{43.53}$$

$$= 2E_{rec} \left(\frac{Q_0}{k}\right)^2 \sum_{n=0}^{\infty} \pi_n \frac{3n^2 + 3n + 1}{24} = E_{rec} \left(\frac{Q_0}{k}\right)^2 \frac{1 + 4f_B + f_B^2}{12(1 - f_B)^2} \ . \tag{43.54}$$

Furthermore,

$$f_B = \frac{\bar{n}}{1 + \bar{n}} \qquad \Longleftrightarrow \qquad \bar{n} = \frac{f_B}{1 - f_B} \ .$$

43.2.5 Exercises

43.2.5.1 Ex: Optical molasses

Optical molasses are created (in one dimension) by two beams counterpropaganting lasers tuned to red of an atomic transition. Each of the laser beams exerts on the atoms the radiative pressure force $F_\pm = \hbar k \frac{\Gamma}{2} \frac{s}{[2(\Delta \pm kv)/\Gamma]^2+1+s}$. Δ is the detuning of the laser, ν is the velocity of an atom.
a. Show that for small velocities ($|kv| \ll \Gamma$ and $\Delta \leq \Gamma$) the optical molasses can be understood as a friction force and calculate the friction coefficient.
b. Heating processes caused by spontaneous emission limit the minimum temperature that can be reached in optical molasses. Calculate the laser tuning, where the temperature reaches its minimum value and specify the cooling limit.
Help: Suppose a one-dimensional molasses and assume, that the spontaneous emission only happens along this dimension. The heating rate follows from the scattering rate R through $\left(\frac{dE}{dt}\right)_{heat} = \frac{d}{dt}\frac{\langle p^2\rangle}{2m} = \frac{\hbar^2 k^2}{2m} 2R$, the cooling rate follows from $\left(\frac{dE}{dt}\right)_{cool} = Fv$.

Solution: *The force exerted on an atom is,*

$$\begin{aligned} F = F_+ - F_- &= \hbar k \Gamma s \left(\frac{1}{[2(\Delta + kv)/\Gamma]^2 + 1 + s} - \frac{1}{[2(\Delta - kv)/\Gamma]^2 + 1 + s} \right) \\ &= \hbar k \Gamma \frac{s}{2} \frac{-16 \Delta kv/\Gamma^2}{[(2\Delta/\Gamma)^2 + (2kv/\Gamma)^2 + 1 + s]^2 - (4\Delta kv/\Gamma)^2} \end{aligned}$$

A first order Taylor expansion gives,

$$\begin{aligned} F(\nu) &= F(0) + v \frac{\partial}{\partial \nu} F(0) \\ &= 0 + v \left[\hbar k \Gamma \frac{s}{2} \frac{-16 \frac{\Delta k}{\Gamma^2} \left[\left(2\frac{\Delta}{\Gamma} \right)^2 + \left(2\frac{kv}{\Gamma} \right)^2 + 1 + s \right)^2 - \left(4\frac{\delta kv}{\Gamma} \right)^2 \right] + 16 \frac{\Delta kv}{\Gamma^2} \frac{\partial}{\partial z} denominator(\nu)}{\left[\left(2\frac{\Delta}{\Gamma} \right)^2 + \left(2\frac{kv}{\Gamma} \right)^2 + 1 + s \right)^2 - \left(4\frac{\Delta kv}{\Gamma} \right)^2 \right]} \right] \\ &= -\alpha_d v \end{aligned}$$

when

$$\alpha_d = 4\hbar k^2 s \frac{2\Delta/\Gamma}{[(2\Delta/\Gamma)^2 + 1 + s]^2} \ .$$

We find the maximums of the coefficient of friction for $0 = d\alpha_d/d\Delta$ at the detunings $\Delta_m = \pm\Gamma\sqrt{\frac{1+s}{12}}$:

$$\alpha_d(\Delta_m) = \sqrt{3}\hbar k^2 s (1+s)^{-3/2} \overset{s \ll 1}{\longrightarrow} \sqrt{3}\hbar k^2 s \ .$$

b. The stationary temperature is reached when the cooling and heating rates are balanced $\left(\frac{dE}{dt}\right)_{heat} = -\left(\frac{dE}{dt}\right)_{cool}$. The cooling rate corresponds to the dissipated power,

$\left(\frac{dE}{dt}\right)_{cool} = Fv \approx -\alpha_d v^2$. *The heating rate is* $\left(\frac{dE}{dt}\right)_{heat} = \frac{d}{dt}\frac{\langle p^2\rangle}{2m} = \frac{\hbar^2k^2}{2m}2R$, *where* $R = \frac{F_+ + F_-}{\hbar k} = \Gamma\frac{I/I_s}{\left(2\frac{\Delta}{\Gamma}\right)^2+1+\frac{I}{I_s}}$ *is the scattering rate. Equalization gives,*

$$k_B T_{mi} = m v_{mi}^2 = \frac{m\left(\frac{dE}{dt}\right)_{cool}}{\alpha_d} = \frac{m\left(\frac{dE}{dt}\right)_{heat}}{\alpha_d} = \frac{m\frac{\hbar^2k^2}{2m}2R}{\alpha_d}$$
$$= \frac{m\frac{\hbar^2k^2}{2m}2\Gamma\frac{s}{[(2\Delta/\Gamma)^2+1+s]^2}}{4\hbar k^2 s\frac{2\Delta/\Gamma}{[(2\Delta/\Gamma)^2+1+s]^2}} = \hbar\Gamma\frac{(2\Delta/\Gamma)^2+1+s}{8\Delta/\Gamma} \approx \frac{\hbar\Gamma}{4}\left(\frac{2\Delta}{\Gamma}+\frac{\Gamma}{2\Delta}\right) .$$

This expression is minimized by $\Delta = \frac{1}{2}\Gamma$, *and we obtain* $k_B T_{mi} \approx \frac{1}{2}\hbar\Gamma$.

43.2.5.2 Ex: Atomic fountain

In atomic fountains atoms are accelerated upward by a 'moving optical molasses'. After the molasses has been switched off, they perform a ballistic flight in the Earth gravitational field. The moving molasses is generated by two pairs of counterpropagating laser beams intersecting at right angle and oriented both at an angle of 45° with respect to gravity. The upgoing beams are tuned to the blue, and the counterpropagating downgoing beams have the same detuning to the red side of the atomic resonance (λ = 780 nm). Supposing that the resonator is close to the position of the molasses and has with negligible length, what should be the detuning in order to achieve 1 s time period between the two passages of the atoms through the microwave resonator?

Solution: *The Doppler shift is* $\Delta = \mathbf{kv} = kv\cos 45° = \frac{2\pi\nu}{\lambda\sqrt{2}}$. *Ballistic flight is described by* $s(t) = -\frac{g}{2}t^2 + \nu(0)t$, *where* $s(t_1 = 1\ s) = 0$. *So we have...*

43.3 Optical and magneto-optical traps

43.3.1 The magneto-optical trap

An apparently fatal obstacle to the confinement of particles by optical forces is Earnshaw's optical theorem. This theorem states that, if a force is proportional to the light intensity, its divergence must be zero because the divergence of the Poynting vector expressing the directional flux of intensity is zero inside a volume without sources nor sinks of radiation. The absence of divergence precludes the possibility of a restoring force to the interior at all places of a closed surface [52]. However, Earnshaw's optical theorem can be bypassed by a clever trick. The internal degrees of freedom of the atom (i.e., its electronic energy levels) can change the proportionality between the force and the Poynting vector in a position-dependent manner, such that the optical Earnshaw's theorem does not apply. Spatial confinement is then possible using the radiative pressure force generated by counterpropagating light beams. The most common trap configuration is based on a radial magnetic field gradient produced by a quadrupolar field and three pairs of counterpropagating circularly polarized laser

beams tuned to the red of an atomic transition and intersecting at right angles at the point where the field is zero. This *magneto-optical trap* (*MOT*) uses the position-dependent Zeeman shift of the electronic levels as the atom moves in the radially increasing magnetic field. The use of circularly polarized light which is red-detuned by about Γ results in a spatially varying transition probability, whose effect is to produce a restoring force that pulls the atom back to the origin. To understand bet-

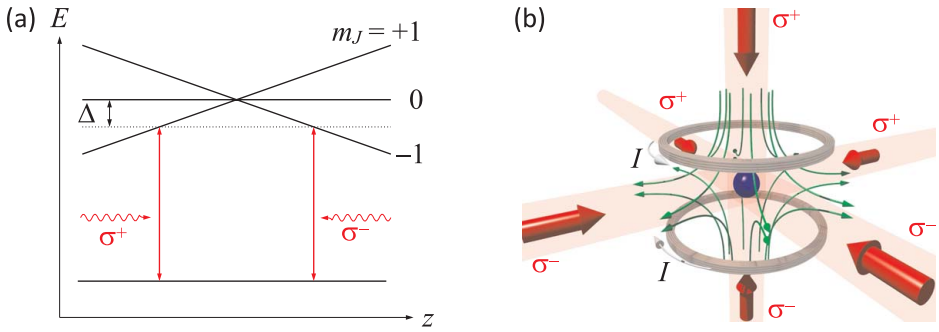

Figure 43.8: Left: Diagram of the energy level shift in an MOT, when an atom moves out of the center of the trap. A restoring force is observed around the indicated resonance positions. Right: Scheme of a typical MOT set up showing the six laser beams and the current-carrying coils in anti-Helmholtz configuration producing the quadrupolar magnetic field.

ter how the trapping scheme works, we consider a two-level atom with a transition $J = 0 \to J = 1$ moving along the z-direction. We apply a magnetic field $\mathcal{B}(z)$ growing linearly with the distance from the origin. The Zeeman shifts of the electronic levels depend on the position,

$$\Delta_{\mathcal{B}} = \frac{\mu_B g_F m_F}{\hbar} \frac{d\mathcal{B}}{dz} z \equiv \partial z \omega_{zeem} \ , \tag{43.55}$$

see Fig. 43.8. We also apply counterpropagating laser beams along the directions $\pm z$ with circular polarizations of opposite signs and tuned to the red of the atomic transition. It is clear from Fig. 43.8 that an atom moving in $\pm z$ direction will scatter $\sigma_{\mp}$ type photons at a faster rate than $\sigma_{\pm}$ type photons, because the Zeeman effect will pull the $\Delta m_J = \mp 1$ transition closer to the laser frequency. The expression for the radiation pressure force extends Eq. (43.26) to include the Doppler effect kv_z and the Zeeman effect,

$$F_{\pm z} = -\frac{\hbar k}{2} \Gamma \frac{2\Omega^2}{4(\Delta \pm k v_z \pm z \partial \omega_{zeem})^2 + 2\Omega^2 + \Gamma^2} \ . \tag{43.56}$$

The atom will, therefore, feel a restoring force which pushes it back to the origin. If the laser beams are red-detuned by an amount $\Delta = -\Gamma$, the Doppler shift of the atomic motion introduces velocity-depending term to the restoring force, such that for small displacements and velocities the total restoring force can be expressed by the sum of a term which is linear in the velocity and a term which is linear in the displacement,

$$F_{MOT} = F_{1z} + F_{2z} = -\alpha \dot{z} - \kappa z \ , \tag{43.57}$$

as we will study in Exc. 43.3.3.1. From Eq. (43.57) we can derive the equation of motion of a damped harmonic oscillator with mass m,

$$\ddot{z} + \frac{2\alpha}{m}\dot{z} + \frac{\kappa}{m}z = 0 \ . \tag{43.58}$$

The damping constant α and the spring constant κ can be written compactly in terms of atomic parameters and the field as,

$$\kappa = \frac{16\hbar k\Gamma\Omega^2\Delta\partial_z\omega_{zeem}}{4\Delta^2 + 2\cdot 6\Omega^2 + \Gamma^2} \ . \tag{43.59}$$

and

$$\alpha = \kappa\frac{k}{\partial_z\omega_{zeem}} \ . \tag{43.60}$$

Typical conditions for MOT are $\Omega = \Gamma/2$, $\Delta = -\Gamma$. For typical MOTs,

$$\alpha \simeq 2\cdot 10^{-22}\,\mathrm{Ns/m} \qquad \text{and} \qquad \kappa \simeq 3.7\cdot 10^{-19}\,\mathrm{N/m} \ . \tag{43.61}$$

We can also estimate the curvature of the MOT,

$$\omega = \sqrt{\frac{\kappa}{m}} \simeq (2\pi)\ 200\,\mathrm{Hz} \ . \tag{43.62}$$

Solve Exc. 43.3.3.2.

MOTs are realized with current-carrying coils in anti-Helmholtz configuration which generates a quadrupolar geometry potential. Near the center, the magnetic field and its absolute value are well approximated by,

$$\vec{\mathcal{B}} = q\begin{pmatrix} x \\ y \\ -2z \end{pmatrix} \qquad \text{and} \qquad |\vec{\mathcal{B}}| = q\mathcal{B}\sqrt{r^2 + 4z^2} \ , \tag{43.63}$$

with $r^2 = x^2 + y^2$ and the gradient $q \equiv \partial_r B$ is a constant, which depends only on the geometry of the coils and the current in them. Thus, the extension of the above results to three dimensions is simple if we consider the fact that the gradient of the quadrupolar field in the z-direction is twice the gradient in the radial directions x and y, such that $\kappa_z = 2\kappa_x = 2\kappa_y$.The damping term, which proportional to the velocity, implies that the kinetic energy E is dissipated from the atom (or a cloud of atoms) as,

$$E/E_0 = e^{-2\alpha t/m} \ , \tag{43.64}$$

where m is the atomic mass and E_0 the kinetic energy at the beginning of the cooling process. Therefore, the dissipative force term cools the atomic cloud and, at the same time, combines with the position-dependent term to confine it. The time constant for the damping,

$$\tau = \frac{m}{2\alpha} \tag{43.65}$$

is typically dozens of microseconds. It is important to keep in mind that a MOT is anisotropic, since the restoring force is proportional to the anisotropic field gradients.

Figure 43.9: Picture of a strontium MOT operated at 461 nm. The atomic cloud, which consists of about 10^6 atoms at 5 mK temperature is visible as a diffuse spot located inside a three-mirror ring cavity.

Because of its dissipative non-conservative nature, it is is more accurate to characterize a MOT by the maximum capture rate, rather than by a 'potential depth'.

In early experiments MOTs were loaded from a decelerated atomic beam. Later it was shown, that the low-velocity tail of the Maxwell-Boltzmann distribution provides a sufficient amount of atoms that can be captured by a MOT, so that it can be loaded directly from an atomic vapor at room temperature. Now many groups in the world use these assemblies for applications ranging from precision spectroscopy to the optical control of reactive collisions; the MOT has become the working horse of atom optics.

43.3.1.1 Density in a MOT

A typical MOT captures up to a billion atoms in a volume of a few $1\,\mathrm{mm}^3$ resulting in densities of $\sim 10^{10}\,\mathrm{cm}^{-3}$. Although a MOT works as a versatile and robust 'reaction cell' for many applications, the frequencies of the light beams must be tuned close to atomic transitions, which bears the disadvantage that a considerable fraction of atoms remains in excited states. This fact is at the origin of two processes limiting the density of a MOT: (1) losses of trapped atoms by collisions and (2) repulsive forces

between the atoms caused by reabsorption of photons scattered within the cloud. Collisional losses arise from two sources: (i) hot atoms of the residual gas inside the chamber can elastically collide with cold atoms and kick them out of the MOT, and (ii) cold atoms in excited states can undergo inelastic binary collisions. 'Photon-induced repulsion' or *radiation trapping* arises when a trapped atom spontaneously emits a photon, which is then reabsorbed by other atoms. If the optical density of the cloud is high, it can take a long time for the photon to find its way out [2]. Since any photon exchange between two atoms will increase their relative momentum by $2\hbar k$, this leads to a repulsive force, which is proportional to the absorption cross section for the incident light beam. When this repulsive force balances the confining force exerted by the MOT, any increase in the number of trapped atoms augments its size, but its density.

43.3.1.2 Dark SPOT

In order to overcome the 'radiation trapping' effect, the atoms can be optically pumped into a 'dark' hyperfine level of the ground state that does not interact with the MOT light. In a conventional MOT one usually employs an auxiliary light beam called 'repumper', copropagating with the MOT beams, but tuned to another transition between hyperfine levels of the ground and excited states. The repumper recycles the population leaking out of the (not perfectly) cyclic MOT transition. As an example, Fig. 43.10 shows the MOT and repumper transitions for sodium.

In contrast to this conventional MOT, the scheme known as the *dark spontaneous force optical trap* (dark SPOT), passes the repumping beam through a glass plate the center of which is obstructed by a small circular disk. The shadow of this disk is projected into the center of the trap in such a way that the atoms in the center are not repumped back into the cyclic transition, but spend most of their time ($\sim 99\%$) in 'dark' hyperfine levels. While the cooling and confinement force continue to operate on the periphery of MOT, its center does not feel any radiation pressure. Dark SPOTs are able to increase the density of a trapped cloud by almost *two orders* of magnitude.

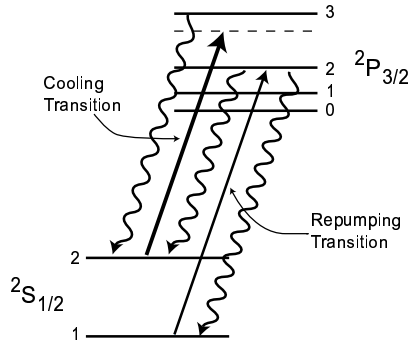

Figure 43.10: Hyperfine structure in sodium atoms showing the usual cooling, pumping, and repumping transitions.

[2] E.g. a photon at the center of the sun will take thousands of years to get out.

43.3.2 Optical dipole traps

When temporal variations are to be applied to a confinement potential, magnetic fields are not the best choice, because they are slow and of limited spatial resolution. On the other side, laser beams can be varied quickly and in localized well. The dipole force exerted by a far-detuned laser beam can be derived from the gradient of the Rabi frequency $\mathbf{F} = -\nabla(\mathbf{d}\cdot\vec{\mathcal{E}})$. Hence, it can be derived from an optical potential, which can be used for trapping. The force may be attractive (toward the intensity maximum) or repulsive.

Compared to MOTs, optical traps (*far off-resonance optical trap*, FORT) are tuned far away from resonances, where the population in excited states is insignificant and spontaneous forces are absent. Note from Eq. (38.22), that spontaneous forces fall off with the square of the detuning while the potential derived from the dipolar force only decreases linearly with the detuning. The off-resonant optical density is negligible, so that radiation trapping is not an issue. The most simple FORT consists of a single focussed, linearly polarized gaussian laser beam tuned far to the red of an atomic resonance. For large detunings and strong field gradients the Eqs. (38.24) and Eqs. (38.25) become [547],

$$\boxed{U(\mathbf{r}) \simeq \frac{\hbar\Omega(\mathbf{r})^2}{4\Delta} = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}I(\mathbf{r}) \quad \text{and} \quad \hbar\gamma_{sct}(\mathbf{r}) \simeq \sigma_a(\Delta)\frac{I(\mathbf{r})}{\omega} = \frac{3\pi c^2}{2\omega_0^3}\left(\frac{\Gamma}{\Delta}\right)^2 I(\mathbf{r})}\,, \tag{43.66}$$

using the Rabi frequency $\hbar\Omega = d_{12}\mathcal{E}$, the dipole moment $d_{12} = \sqrt{3\pi\varepsilon_0\hbar\Gamma/k^3}$, and the intensity $I = \frac{\varepsilon_0}{2}c|\mathcal{E}|^2$. This shows that the potential becomes directly proportional to the light intensity and inversely proportional to the detuning. Therefore, at large detuning but very high intensity, the depth of the FORT can be maintained, although the atoms do not absorb photons. Important advantages of FORTs as compared to MOTs are: (1) high densities ($\sim 10^{12}\,\mathrm{cm}^{-3}$) and (2) a well-defined polarization axis along which the atoms can be aligned or oriented (polarization of the spins).

Since lasers beams can easily be manipulated in position, intensity, and frequency, they can realize a large wide variety of possible geometries. For example, with a focused laser beam, one may influence the local density of a condensate and stir it around by moving the position of the laser beam. Strongly focused laser beams are often used for transporting or manipulating microscopic objects in arrangements called *optical tweezers*. And with standing light waves, it is possible to form periodic optical lattices in one, two or three dimensions (see Sec. 46.4.2).

43.3.2.1 Spin relaxation

When the atomic ground state has a hyperfine structure, another relaxation mechanism can be observed: Near-resonance Raman scattering can induce transitions between hyperfine states causing a population redistribution of between Zeeman substates called *spin relaxation*. In magnetic traps, this can lead to losses, because not all Zeeman substates are trapped.

The rate of an arbitrary scattering process starting from an initial state $|F, m\rangle$ through several possible excited states $|F'_j, m'_j\rangle$ to a final state $|F''m''\rangle$ is, according

to the formula of Kramers-Heisenberg [895],

$$\gamma_{Fm\to F'm'} \propto \left| \sum_j \frac{\alpha^{(F'_j m'_j)}_{Fm\to F'm'}}{\Delta_{F'_j m'_j}} \right|^2 . \tag{43.67}$$

Far from resonance the scattering decreases as Δ^2 for Rayleigh scattering, $Fm = F'm'$. Raman scattering, $Fm \neq F'm'$, is further suppressed by destructive interference of the different scattering paths.

In the case of rubidium, we calculate,

$$\gamma_{spin} = \frac{3c^2\omega^4}{8\pi}\frac{70}{81}\Gamma^2 \left| \left(\frac{1}{\omega_{D1}}\right)^3 \frac{1}{\Delta_{D1}} - \left(\frac{1}{\omega_{D2}}\right)^3 \frac{1}{\Delta_{D2}} \right|^2 \frac{I_0}{\hbar\omega} . \tag{43.68}$$

43.3.2.2 Potential of a Gaussian beam

The *far-off resonance optical trap* (FORT) is an example of an optical trap based on dipole forces [547]. The intensity distribution of a gaussian beam with a diameter of w_0 at its waist is [3],

$$I(\mathbf{r}) = \frac{2P}{\pi w_0^2} e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} , \tag{43.69}$$

where P is the total power of the beam and $z_R \equiv \pi w_0^2/\lambda$ the *Rayleigh length* at a given wavelength λ. The dipolar potential is given by (43.66). Using the potential depth,

$$\boxed{U_0 \equiv \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}\frac{2P}{\pi w_0^2}} , \tag{43.70}$$

which is $U_0 < 0$ for red-detuned light, we can approach the potential near its center, that is, near the optical axis, $r \ll \frac{1}{2}w_0$, and within the range of the Rayleigh length, $z \ll \pi w_0^2/\lambda$, by a harmonic potential [4],

$$\begin{aligned} U(\mathbf{r}) &\simeq U_0 e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} \simeq U_0 \left(1 - \frac{2x^2+2y^2}{w_0^2} - \frac{z^2}{z_R^2}\right) \\ &\equiv U_0 + \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 \equiv k_B T \left(\frac{U_0}{k_B T} + \frac{r^2}{2\bar{r}^2} + \frac{z^2}{2\bar{z}^2}\right) . \end{aligned} \tag{43.71}$$

This leads to the equivalences,

$$\boxed{\begin{array}{rclcrcl} \omega_r &=& \frac{2}{w_0}\sqrt{\frac{U_0}{m}} &,& \omega_z &=& \frac{1}{z_R}\sqrt{\frac{2U_0}{m}} \\ \bar{r} &=& \frac{w_0}{2}\sqrt{\frac{k_B T}{U_0}} &,& \bar{z} &=& z_R\sqrt{\frac{k_B T}{2U_0}} \end{array}} . \tag{43.72}$$

Solve Excs. 43.3.3.3 and 43.3.3.4.

[3] See script on *Electrodynamics* (2023).

[4] The diameter of a Gaussian beam can be characterized in several ways,

$$\bar{r}_{1/\sqrt{e}\text{-radius}} = \frac{\bar{r}_{1/e^2\text{-radius}}}{\sqrt{2}} = \sqrt{2}\,\bar{r}_{1/e^2\text{-radius}} = \frac{\bar{r}_{1/2\text{-radius}}}{2\ln 2} ,$$

and $\bar{r}_{\text{-rms}} \equiv \bar{r}_{1/\sqrt{e}\text{-diam}}$ and $\bar{r}_{\text{-hwhm}} \equiv \bar{r}_{1/2\text{-diam}}$ and $\bar{r}_{\text{-diam}} = 2\bar{r}_{\text{-radius}}$.

Example 277 (*Dipole trap for rubidium*): The formulas (43.66) hold for a two-level system. In case of the $D1$- and $D2$-lines of rubidium, we must consider all contributions weighted by the respective detunings,

$$U_0 \equiv \sigma_0 \frac{\hbar\Gamma}{4}\left(\frac{1}{\Delta_{D1}} + \frac{g_{D2}/g_{D1}}{\Delta_{D2}}\right)\frac{I_0}{\hbar\omega} \simeq \frac{3\hbar\pi c^2}{2\omega^2}\frac{\Gamma}{\Delta}\frac{I_0}{\hbar\omega} \ ,$$

where $g_{D2}/g_{D1} = 2$.
Similarly, the spontaneous emission rate is,

$$\gamma_{sct} \simeq \frac{\pi c^2\Gamma^2}{2\omega^2}\left(\frac{1}{\Delta_{D1}^2} + \frac{g_{D2}/g_{D1}}{\Delta_{D2}^2}\right)\frac{I_0}{\hbar\omega} \ .$$

The spontaneous emission rate decays faster with detuning than the potential depth. Thus, heating can be avoided by working at large detunings and providing higher laser intensities. Defining the recoil temperature by,

$$T_{rec} = \frac{\hbar^2 k^2}{k_B m} \ ,$$

the *heating rate* is [547],

$$\dot{T} = \frac{1}{3}T_{rec}\gamma_{sct} = \frac{\hbar^2 k^2}{3mk_B}\gamma_{sct} \ .$$

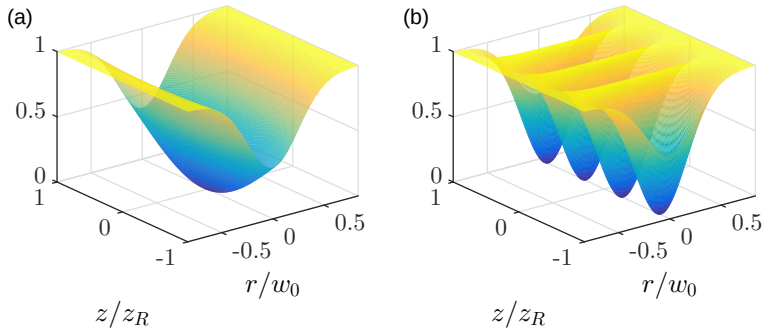

Figure 43.11: (code) (left) Dipole potential created by a Gaussian beam. (right) Dipole potential created by a stationary light wave.

43.3.2.3 Trapping in standing light waves

If both counterpropagating modes are pumped at different powers, $P_\pm$, the intensity distribution is,

$$I(\mathbf{r}) = \frac{2}{\pi w_0^2} e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2}\left|\sqrt{P_+}e^{\imath kz} + \sqrt{P_-}e^{-\imath kz}\right|^2 \ . \tag{43.73}$$

Defining the contrast of the standing wave as,

$$C_{sw} \equiv \frac{4\sqrt{P_+P_-}}{(\sqrt{P_+}+\sqrt{P_-})^2} \ , \tag{43.74}$$

we can express the potential depth by,

$$\boxed{U_0 = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}\frac{2(\sqrt{P_+}+\sqrt{P_-})^2}{\pi w_0^2} = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}\frac{8(\sqrt{P_+P_-})^2}{\pi w_0^2 C_{sw}}} \ . \tag{43.75}$$

Therefore, within the Rayleigh length, the potential is,

$$\begin{aligned} U(\mathbf{r}) &\simeq U_0 e^{(-2x^2-2y^2)/w_0^2} e^{-z^2/z_R^2} \frac{P_+ + P_- + 2\sqrt{P_+P_-}\cos kz}{P_+ + P_- + 2\sqrt{P_+P_-}} \\ &\simeq C_{sw} U_0 e^{-2\rho^2/w_0^2} \frac{P_+ + P_- + 2\sqrt{P_+P_-}\cos kz}{4\sqrt{P_+P_-}} \ . \end{aligned} \tag{43.76}$$

Neglecting terms containing higher powers of the coordinates than squared, we can also write,

$$U(\mathbf{r}) \simeq U_0 \left(1 - \frac{2x^2}{w_0^2} - \frac{2y^2}{w_0^2} - \frac{\sqrt{P_+P_-}}{(\sqrt{P_+}+\sqrt{P_-})^2}k^2z^2 + ...\right) \ . \tag{43.77}$$

This leads to the identities,

$$\boxed{\begin{array}{rclcrcrcl} \omega_r &=& \frac{2}{w_0}\sqrt{\frac{U_0}{m}} &,& \omega_z &=& \frac{1}{z_R}\sqrt{\frac{2U_0}{m}} &,& \omega_{lat} = k\sqrt{\frac{C_{sw}U_0}{2m}} \\ \bar{r} &=& \frac{w_0}{2}\sqrt{\frac{k_BT}{U_0}} &,& \bar{z} &=& \frac{\sqrt{2}}{k}\sqrt{\frac{k_BT}{U_0}} & & \end{array}} \ . \tag{43.78}$$

Solve the Excs. 43.3.3.5, 43.3.3.6, and 43.3.3.7.

43.3.3 Exercises

43.3.3.1 Ex: Linearization of the MOT

Derive the friction coefficient and the spring constant for a MOT.

Solution: *We use the following expressions,*

$$\sigma(\Delta) = \frac{\sigma_0\Gamma^2}{4\Delta^2+2\Omega^2+\Gamma^2} \quad \textit{and} \quad \sigma_0 = 3\frac{\lambda^2}{2\pi} \quad \textit{and} \quad \Omega^2 = \Gamma\sigma_0\frac{I}{\hbar\omega} \quad \textit{and} \quad \frac{I}{I_s} = \frac{2\Omega^2}{\Gamma^2} \ .$$

For strong/weak saturation,

$$\frac{I}{\hbar\omega}\sigma(\Delta) \begin{cases} \overset{\Omega\gg\Delta,\Gamma}{\longrightarrow} \frac{\Gamma}{2} \\ \overset{\Gamma\gg\Omega,\Gamma}{\longrightarrow} \frac{\Omega^2}{\Gamma} \end{cases} \ .$$

The scattering force is,

$$F = \frac{I}{\hbar\omega}\sigma(\Delta)\hbar k = \frac{\hbar k\Gamma\Omega^2}{4\Delta^2+2\Omega^2+\Gamma^2} \ .$$

The trapping force in a MOT in z-direction (and analogously in x and y-direction) is $F_s = F_z^+ + F_z^-$ *with,*

$$F_z^{\pm} \equiv \frac{\hbar k \Gamma \Omega^2 e^{-2\frac{x^2}{w^2}-2\frac{y^2}{w^2}}}{4[\Delta \pm k v_z \pm \frac{\mu_B g_F m_F}{\hbar}\ \partial_z B\ z]^2 + 2\Omega^2[2e^{-2\frac{y^2}{w^2}^2-2\frac{z^2}{w^2}} + 2e^{-2\frac{y^2}{w^2}-2\frac{z^2}{w^2}} + 2e^{-2\frac{x^2}{w^2}-2\frac{y^2}{w^2}^2}\ ] + \Gamma^2} \ .$$

In the trap center, $x = y = z = 0$*, defining* $\partial_z \omega_{zee} \equiv (\mu_B g_F m_F/\hbar)\ \partial_z B$*,*

$$F_z^{\pm} \equiv \frac{\hbar k \Gamma \Omega^2}{4[\Delta \pm k v_z \pm \partial_z \omega_{zee}\ z]^2 + 12\Omega^2 + \Gamma^2} \ .$$

Now, we linearize for small Ω*,*

$$\begin{aligned} F_z(z, v_z) &= F(0,0) + z\frac{\partial}{\partial z}F(0,0) + v_z\frac{\partial}{\partial v_z}F(0,0) + ... \\ &= 0 + z\frac{16\hbar k \Gamma \Omega^2 \Delta\ \partial_z \omega_{zee}}{(4\Delta^2 + 12\Omega^2 + \Gamma^2)^2} + v_z\frac{16\hbar k \Gamma \Omega^2 \Delta\ k}{(4\Delta^2 + 12\Omega^2 + \Gamma^2)^2} + o(z^3) \ , \end{aligned}$$

such that,

$$F_z(z, v_z) = -\kappa z - \alpha v_z$$

with

$$\kappa \equiv \frac{16\hbar k \Gamma \Omega^2 \Delta\ \partial_z \omega_{zee}}{(4\Delta^2 + 12\Omega^2 + \Gamma^2)^2} \qquad \textit{and} \qquad \alpha \equiv \kappa \frac{k}{\partial_z \omega_{zee}} \qquad \textit{and} \qquad \omega = \sqrt{\frac{\kappa}{m}} \ .$$

Using typical parameters for a Na MOT $\Gamma = (2\pi)\ 9.89\,\mathrm{MHz}$*,* $\lambda = 589\,\mathrm{nm}$*,* $w_0 = 0.64\,\mathrm{cm}$*,* $\partial_z B = 2\partial_x B = 20\,\mathrm{G/cm}$*,* $I_s = 6\,\mathrm{mW/cm^2}$*, and* $I = 60\,\mathrm{mW/cm^2}$*, we find,*

$$\begin{aligned} \kappa &= 3.7 \cdot 10^{-19}\,\mathrm{N/m} \\ \alpha &= 2.2 \cdot 10^{-22}\,\mathrm{Ns/m} \\ \omega &= (2\pi)\ 500\,\mathrm{Hz} \ . \end{aligned}$$

43.3.3.2 Ex: Design of a Zeeman slower

In this exercise we will design a 'decreasing field *Zeeman slower*' for strontium (see also Exc. 34.6.7.3).

a. Calculate the mean velocity of atoms in a strontium gas heated to 500° C. What is the Doppler shift for an atom moving at this velocity at the cooling transition at $\lambda = 461\,\mathrm{nm}$ (linewidth 30.5 MHz)?

b. Assuming you want to decelerate a fraction of 20% of the atoms flying in a particular direction, to what frequency should a counterpropagating laser (intensity $I = 20\,\mathrm{mW/cm^2}$) be tuned in order to slow down the atoms?

c. Suppose the strontium atoms were always in resonance with the counterpropagating laser light while being decelerated. What would be the evolution of their Doppler shift along their trajectory (supposed to be on a straight line antiparallel to the laser

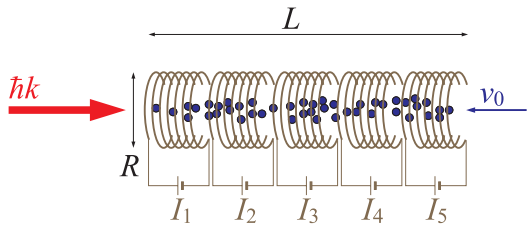

Figure 43.12: Design of a Zeeman slower.

beam).
d. In order to maintain the laser always in resonance we need to compensate for the diminishing Doppler shift along the atomic trajectory. This can be done exploiting the Zeeman shift induced by a magnetic field. We will now design a magnetic field generating an appropriate Zeeman shift. For simplicity, let us assume 5 identical radial solenoids distributed over $L = 30\,\text{cm}$ as sketched in Fig. 43.12, the only adjustable parameters being the currents in all solenoids, which need to be optimized such as to compensate the Doppler shift along the atom's trajectory.
e. Simulate the 1D trajectory of an atom cooled by the Zeeman slower.

Solution: *The results are shown in Fig. 43.13.*

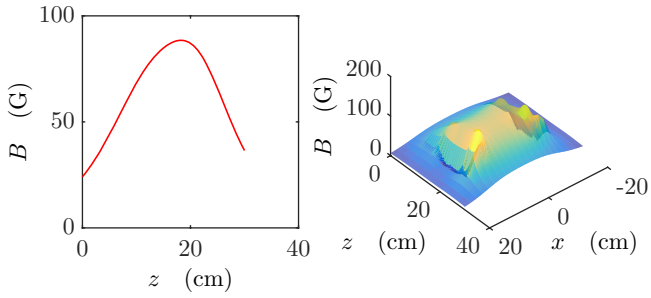

Figure 43.13: Magnetic field in a Zeeman slower.

43.3.3.3 Ex: Dipole trap near an intercombination line

a. Strontium has a strong transition ($\Gamma_{461} = (2\pi)\ 30.5\,\text{kHz}$) at 461 nm and a weak intercombination resonance ($\Gamma_{689} = (2\pi)\ 7.6\,\text{kHz}$) at 689 nm. A Gaussian laser beam with the power $P = 10\,\text{mW}$ focused to a waist of $w_0 = 100\,\mu\text{m}$ is tuned $\Delta_{689} = -(2\pi)\ 10\,\text{GHz}$ below the intercombination transition. Calculate the potential depth and the vibration frequencies for atoms trapped by this laser beam considering both resonances. What is the scattering rate on the two transitions.
b. Supposes that the trapped atomic cloud consists of $N = 10^8$ atoms at the temperature $T = 10\,\mu\text{K}$. Calculate the atomic density n_0 in the center of the cloud.

Solution: *a. Based on the formula (43.70) we find for the potential depth,*

$$U_{0,k} = \frac{3\pi c^2 \Gamma_k}{2\omega_0^3 \Delta_k} I_0 \ ,$$

with $k = 461$ *ou* $k = 689$*, such that,*

$$\frac{U_{0,461}}{U_{0,689}} = \frac{\Gamma_{461}\Delta_{689}}{\Gamma_{689}\Delta_{461}} \ .$$

The scattering rate is,

$$\gamma_{sct} = \left(\frac{\Gamma_{461}\Delta_{689}}{\Gamma_{689}\Delta_{461}}\right)^2 \ .$$

43.3.3.4 Ex: Dipole trap with a focused beam

a. Calculate the vibration frequencies of ^{87}Rb atoms confined in an optical trap consisting of a focused laser beam with the power $P = 10\,\mathrm{W}$ and the beam diameter $w_0 = 100\,\mu\mathrm{m}$. The laser beam is tuned 5 nm to the red side of the rubidium $D1$ resonance located at $\lambda = 795\,\mathrm{nm}$.
b. Assume that the trapped atomic cloud consists of $N = 10^8$ atoms at the temperature $T = 100\,\mu\mathrm{K}$. Calculate the atomic density n_0 in the center of the cloud.
c. The cross section for elastic collisions is $\sigma = 10^{-12}\,\mathrm{cm}^2$. How many times do atoms meet on average?

Solution: *a. The intensity of the beam is,*

$$I(r,z) = \frac{2P}{\pi w(z)^2} e^{-2r^2/w(z)^2} \quad with \quad w(z) = w_0\sqrt{1+\left(\frac{z}{z_R}\right)^2} \quad and \quad z_R = \frac{\pi w_0^2}{\lambda} \ ,$$

and $I_0 = \frac{2P}{\pi w_0^2} = 64000\,\mathrm{W/cm}^2$*. For rubidium we have* $\Gamma = (2\pi)\ 6\,\mathrm{MHz}$*. For* $\Delta = -2\pi\frac{c}{\lambda^2}\Delta\lambda = -2\pi \times 2300\,\mathrm{GHz}$ *we expect an optical potential of,*

$$U_0 = \frac{3\pi c^2 \Gamma}{2\omega_0^3 \Delta} I_0 = h \times 82\,\mathrm{MHz} = 4\,\mathrm{mK} \ .$$

If we approach the intensity profile harmonically, we obtain the secular radial frequency, $\omega_r = \sqrt{\frac{2U_0}{m}}\frac{\sqrt{2}}{w_0} = 2\pi \times 2$ *kHz, e axial,* $\omega_z = \sqrt{\frac{2U_0}{m}}\frac{1}{z_R} = 2\pi \times 35$ *Hz.*
b. At the specified temperature the cloud size is given by $k_B T = m\omega_r^2 r^2$*. Hence,*

$$\bar{r} = \sqrt{\frac{k_B T}{2U_0}}\frac{w_0}{\sqrt{2}} = 8\,\mu\mathrm{m} \qquad and \qquad \bar{z} = \sqrt{\frac{k_B T}{2U_0}} z_R = 2.8\,\mathrm{mm} \ .$$

The atomic density follows from the normalization condition,

$$n_0 = \frac{N}{(2\pi)^{3/2}\bar{r}^2\bar{z}} = 3.5 \times 10^{13}\,\mathrm{cm}^{-3} \ .$$

c. The collision rate is given by $\gamma_{coll} = \sigma\bar{v}n_0 = 3.5\,\mathrm{s}^{-1}$ *with* $\bar{v} = \sqrt{\frac{k_B T}{m}}$*.*

43.3.3.5 Ex: Optical lattice

A laser beam with wavelength $\lambda_{dip} = 1064\,\text{nm}$, power $P = 2\,\text{W}$, and diameter $w_0 = 50\,\mu\text{m}$ is subdivided into three retroreflected beams intersecting at right angles. With this configuration we form a cubic optical lattice for strontium atoms, whose relevant transition lies at $\lambda_{Sr} = 461\,\text{nm}$ and has a decay width of $\Gamma_{Sr} = (2\pi)\ 32\,\text{MHz}$. Calculate the potential depth and the secular frequencies.

Solution: *The dipolar potential is,*

$$U_d(\mathbf{r}) = \frac{3\pi c^2 \Gamma_{461}}{2\omega_{461}^3} \frac{1}{\omega_d - \omega_{461}} I(\mathbf{r}) \ ,$$

with a maximum intensity,

$$I_0 = \frac{2P}{\pi w_0^2} \ .$$

We expect a potential depth of,

$$U_0 = \frac{3\pi c^2 \Gamma_{461}}{2\omega_{461}^3} \frac{1}{\omega_d - \omega_{461}} I_0 \simeq k_B \cdot 20\ \mu K \ ,$$

for the given parameters and a single laser beam. For superposed laser beams, the effective intensity is the sum of all. Thus, as the laser is divided into three parts before being superposed and retroreflected, we have twice the effective intensity and twice the potential depth.
The secular frequencies depend on the geometry of the beam. Expanding the spatial distribution of a single focused beam,

$$I(r,z) = \frac{2P}{\pi w_0^2} e^{-2r^2/w(z)^2} \qquad with \qquad w(z) = \sqrt{1 - \left(\frac{z}{z_R}\right)^2} \ ,$$

near the position $r = z = 0$, we obtain,

$$\omega_r = \sqrt{\frac{2U_0}{m}} \frac{\sqrt{2}}{w_0} \simeq (2\pi)\ 276\,\text{Hz} \qquad and \qquad \omega_z = \sqrt{\frac{2U_0}{m}} \frac{1}{z_R} \simeq (2\pi)\ 0.57\,\text{Hz} \ ,$$

with $z_R = \pi w_0^2/\lambda$. For an optical lattice with lattice constant $\lambda/2$, we expand,

$$I(z) = \cos\frac{kz}{2} \ ,$$

and obtain,

$$\omega_z = \sqrt{2\frac{2U_0}{m}} k \simeq (2\pi)\ 188\,\text{kHz} \ .$$

43.3.3.6 Ex: Minimum optical lattice depth

Estimate the minimum required intensity of two counterpropagating laser beams tuned 7 GHz to the red of the strontium intercombination transition at 689 nm necessary to sustain an optical lattice exhibiting a single vibrational level.

Solution: *Approximating a lattice antinode by a harmonic potential, the condition for having a bound state is,*

$$U_0 > \frac{\hbar\omega_{lat}}{2}$$

using the results of Sec. 43.3.2,

$$U_0 = \frac{3\pi c^2}{2\omega_0^3}\frac{\Gamma}{\Delta}4I \qquad and \qquad \omega_{lat} = k\sqrt{\frac{U_0}{2m}} \ .$$

Hence,

$$U_0 > \frac{\hbar^2 k^2}{8m} = \frac{E_{rec}}{4} \ ,$$

that is,

$$I > \frac{\omega_0^3 E_{rec}}{24\pi c^2}\frac{\Delta}{\Gamma} \approx 1.6\,\mathrm{W/cm}^2 \ .$$

43.3.3.7 Ex: Ring shaped optical potential

An interesting system is the $1D$ array of annular optical potentials realized in a standing wave formed by red-detuned Gaussian beam and a counterpropagating blue-detuned doonat-mode. In general, the tight longitudinal confinement freezes out the axial motion by *quantum confinement*. It can be readily shown [1388] that in the far-off resonance case and if the potential is approximate by a harmonic potential around its minimum the eigenenergy spectrum is given by,

$$E_{pq} = U_0 + \hbar\omega(q + \tfrac{1}{2}) + \frac{\hbar^2 p^2}{2mR_0^2} \ .$$

It thus reproduces the ro-vibrational spectrum of a $2D$ artificial molecule and gives rise to two normal motions. In its ground state, we have the atom optical analog of a $2D$ rigid rotator. Gravity plays formally the same role as static electric fields for molecules. Such systems might be interesting for investigating the selection rules for transitions between ro-vibrational states involving conservation of total angular momentum of light and atoms and yield insight into the concept of orbital angular momentum of light fields.

Solution:

43.3.3.8 Ex: Time-averaged trap

For sufficiently fast periodic displacements of a far-detuned laser beam it is possible to engineer effective more complicated trapping potential. What are the conditions for modulation speed? Simulate the effective trapping potential generated by a vibrating laser beam.

Solution: *The result is shown in Fig. 43.14.*

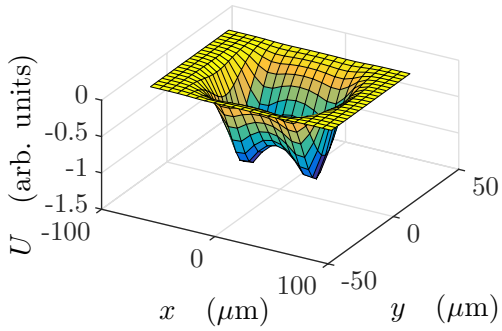

Figure 43.14: Effective potential in radial direction of a shaking dipole trap.

43.4 Magnetic traps

Purely magnetic traps are widely used in atom optics, where they served, e.g., for the first realizations of Bose-Einstein condensation (BEC). The most important feature that distinguishes magnetic traps is, that they do not need light to confine atoms. Hence, they are free of heating effects caused by photonic absorption, which turned out to be necessary condition for reaching BEC. Magnetic traps rely on the interaction of atomic spins with magnetic fields and gradients designed to contain the atoms. Depending on the sign of U and $\mathbf{F}$, atoms in states whose energy increases or decreases with the magnetic field are called 'low-field seekers' or 'high-field seekers', respectively. One might think, that it should be possible to trap atoms in any of these states, generating either a magnetic field minimum or a maximum. Unfortunately, only low-field seekers can be trapped in static magnetic fields, because in free space magnetic fields can not form maxima. Even though low-field seekers are not in the energetically lowest hyperfine levels, they can still be trapped because the rate of spontaneous emission through the magnetic dipole is $\sim 10^{-10}\,\mathrm{s}^{-1}$, and hence completely negligible. However, spin changing collisions can induce losses and limit the maximum densities. Solve Exc. 43.4.6.1.

The most basic static magnetic trap for neutral atoms is generated by a pair of current-carrying coils in anti-Helmholtz configuration (similar to the geometry used for a MOT), producing an axially symmetric qudrupolar magnetic field. Since this field configuration always has a central point, where the magnetic field disappears, non-adiabatic Majorana transitions can occur when the atom passes through the

zero point. The transitions transfers population from a low-field seeking state to a high-field seeker, which consecutively is expelled from the trap. This problem can be overcome by using a different magnetic field geometries. One example is the so-called *magnetic bottle* also called the *Ioffe-Pritchard trap*, where the minimum field amplitude has a finite value different from zero. Other methods to eliminate the zero-field point are time-varying potentials, such as the time-orbiting potential (TOP) trap, or the application of an 'optical plug', which consist in an intense dipolar optical laser beam, tuned to the blue of an atomic transition, focused into the center of a quadrupole trap where the magnetic field is zero, and repelling the atoms from this area.

43.4.1 Quadrupolar traps and Majorana spin-flips

The most basic static magnetic trap for neutral atoms is generated by a pair of current-carrying coils in anti-Helmholtz configuration producing an axially symmetric quadrupolar magnetic field, as shown in Fig. 43.15.

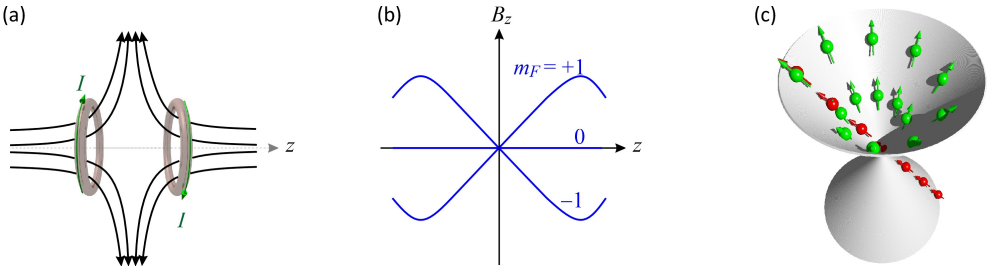

Figure 43.15: (a) Quadrupolar magnetic trap generated by a pair of current-carrying wires in anti-Helmholtz configuration. (b) Ground state energy levels of ^{23}Na, $^2S_{1/2}$, $F = 1$ as a function of axial distance from the trap center. (c) Illustration of Majorana spin-flips: The red atom passes through the hole, while the green one moves adiabatically avoiding the hole.

Close to the trap center an expansion of the magnetic field generated by anti-Helmholtz coils yields,

$$\vec{\mathcal{B}} = \begin{pmatrix} x \\ y \\ -2z \end{pmatrix} \partial_r \mathcal{B} \ , \tag{43.79}$$

where the field gradient $\partial_r B$ along radial direction $r^2 \equiv x^2 + y^2$ in the trap center depends on the applied current and the geometry of the coils. However, the 1:2 aspect ratio is generic for all quadrupolar potentials, as we will see in Exc. 43.4.6.2. We easily verify that,

$$\nabla \cdot \vec{\mathcal{B}} = 0 \qquad \text{but} \qquad \nabla |\vec{\mathcal{B}}| = \frac{\partial_r \mathcal{B}}{\sqrt{r^2 + 4z^2}} \begin{pmatrix} x \\ y \\ 4z \end{pmatrix} \ . \tag{43.80}$$

Thus, the quadrupolar magnetic potential is linear in the spatial coordinates,

$$\boxed{U(\mathbf{r}) = -|\vec{\mu}||\vec{\mathcal{B}}| = \mu_B g_J m_J \ \partial_r \mathcal{B} \ \sqrt{r^2 + 4z^2}} \ , \tag{43.81}$$

where $2\partial_r \mathcal{B} = \partial_z \mathcal{B}$.

To calculate the *rms*-radius $\bar{r}$ of a cloud of temperature T confined to this potential, we set,

$$k_B T \equiv U(\bar{r}, 0) = \mu_B \bar{r} \partial_r \mathcal{B} \ , \tag{43.82}$$

and obtain the density distribution,

$$n(\mathbf{r}) = n_0 e^{-U(\mathbf{r})/k_B T} = n_0 e^{-\sqrt{r^2+4z^2}/\bar{r}} \ . \tag{43.83}$$

Normalization requires,

$$\begin{aligned} N &= \int_{R^3} n(\mathbf{r}) \ d^3 r = n_0 \int_{-\infty}^{\infty} \int_0^{\infty} e^{-\sqrt{r^2+4z^2}/\bar{r}} 2\pi r \ dr dz \\ &= n_0 2\pi \bar{r}^2 \int_{-\infty}^{\infty} \int_{2|z|/\bar{r}}^{\infty} \xi e^{-\xi} d\xi dz = n_0 2\pi \bar{r}^2 \int_{-\infty}^{\infty} e^{-\frac{2|z|}{\bar{r}}} \left(1 + \tfrac{2|z|}{\bar{r}}\right) \ dz \\ &= n_0 2\pi \bar{r}^3 \int_0^{\infty} e^{-\zeta} (1+\zeta) \ d\zeta = n_0 4\pi \bar{r}^3 \ . \end{aligned} \tag{43.84}$$

Therefore, the effective volume is, $V_{eff} = 4\pi \bar{r}^3$. In application example is discussed in Exc. 43.4.6.3.

43.4.1.1 Majorana spin-flips

The quadrupolar trap is the simplest one that can be technically realized. Unfortunately, this trap is not stable because of the phenomenon of *Majorana spin-flips*, which expel atoms from the trapped cloud. Since this field configuration always has a central point, where the magnetic field disappears, non-adiabatic Majorana transitions can occur when the atom passes through the zero point [see Fig. 43.15(c)]. The disappearance of the field leaves the atoms disoriented, that is, ready to reorient their spins. The transitions transfer population from a low-field seeking state to a high-field seeker, which consecutively is expelled from the trap. This problem is particularly severe for hydrogen, where it can induce a so-called *relaxation explosion* [618].

From (43.82) we get the *rms*-radius,

$$\bar{r} = \frac{k_B T}{\mu_B \partial_r \mathcal{B}} \ . \tag{43.85}$$

The average velocity of an atom is,

$$\bar{v} = \sqrt{\frac{k_B T}{m}} \ . \tag{43.86}$$

In order for the atomic motion in the magnetic potential to be adiabatic [so that Eq. (43.81) applies], the *local Larmor frequency*,

$$\omega_{Larmor}(\mathbf{r}) = \frac{\mu_B}{\hbar} \sqrt{r^2 + 4z^2} \partial_r \mathcal{B} \tag{43.87}$$

must be faster, than any change the atom might experience due to its motion with velocity $\mathbf{v}$. I.e. we need [1018],

$$\omega_{Larmor}(\mathbf{r}) > \frac{\mathbf{v} \cdot \nabla |\vec{\mathcal{B}}|}{|\vec{\mathcal{B}}|} \ . \tag{43.88}$$

For a quadrupolar trap, this can not be satisfied within a certain volume located at the trap center, since the expression (43.88) divergence near the center. This ellipsoidal volume is delimited by $\mathbf{r}_{sf}$ given by the condition,

$$\omega_{Larmor}(\mathbf{r}_{sf}) \equiv \frac{\mathbf{v}\cdot\nabla|\vec{\mathcal{B}}|}{|\vec{\mathcal{B}}|} \ . \tag{43.89}$$

For our quadrupole trap,

$$\frac{\mathbf{v}\cdot\nabla|\vec{\mathcal{B}}|}{|\vec{\mathcal{B}}|} = \frac{\mathbf{v}\cdot\frac{\partial_r\mathcal{B}}{\sqrt{r_{sf}^2+4z_{sf}^2}}}{\partial_r\mathcal{B}\sqrt{r_{sf}^2+4z_{sf}^2}}\begin{pmatrix} x_{sf} \\ y_{sf} \\ 4z_{sf}\end{pmatrix} = \frac{x_{sf}v_x + y_{sf}v_y + 4z_{sf}v_z}{r_{sf}^2+4z_{sf}^2} \ . \tag{43.90}$$

Considering for simplicity only radial motion, $\mathbf{v} = v\hat{\mathbf{e}}_r$, then by equating (43.87) and (43.89),

$$\frac{\mu_B}{\hbar} r_{sf}\partial_r\mathcal{B} = \omega_{Larmor}(r_{sf}) = \frac{v}{r_{sf}} \ , \tag{43.91}$$

that is, the spin-flip volume is on the order of,

$$r_{sf} = \sqrt{\frac{\hbar v}{\mu_B\partial_r\mathcal{B}}} \ . \tag{43.92}$$

Let us now estimate the spin relaxation rate from the flow of atoms through the volume,

$$\frac{1}{\tau_{sf}} = N\frac{r_{sf}^3}{V_{eff}}\frac{\bar{v}}{r_{sf}} \ , \tag{43.93}$$

where r_{sf}^3/V_{eff} is simply the fraction of the cloud's volume overlapping with the spin-flip volume. Then,

$$\begin{aligned}\frac{1}{\tau_{sf}} &= \frac{N}{4\pi\bar{r}^3}r_{sf}^2\bar{v} = \frac{N}{4\pi\left(\frac{k_BT}{\mu_B\partial_r\mathcal{B}}\right)^3}\frac{\hbar\bar{v}}{\mu_B\partial_r\mathcal{B}}\bar{v} \\ &= \frac{N\hbar}{4\pi(k_BT)^3}(\mu_B\partial_r\mathcal{B})^2\frac{k_BT}{m} = \frac{N\hbar(\mu_B\partial_r\mathcal{B})^2}{4\pi m(k_BT)^2} \ .\end{aligned} \tag{43.94}$$

That is, the problem gets worse when the cloud is cooled to low temperatures.

43.4.2 Magnetic Ioffe-type traps

The spin-flip problem can be overcome by using a different magnetic field geometries. One example is the so-called *magnetic bottle*, also called the *Ioffe-Pritchard trap* illustrated in Fig. 43.16(a), where the minimum field amplitude has a finite value different from zero. Other methods to eliminate the zero-field point are time-varying potentials, such as the time-orbiting potential (TOP) trap illustrated in Fig. 43.16(b) and discussed in Exc. 43.4.6.4 [417, 580], or the application of an 'optical plug', which consist in an intense dipolar optical laser beam, tuned to the blue of an atomic transition, focused into the center of a quadrupole trap where the magnetic field is zero, and

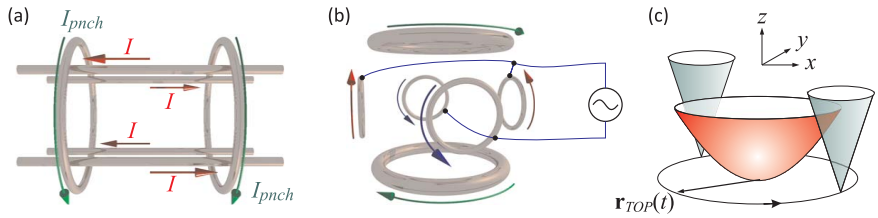

Figure 43.16: (a) Magnetic trap in Ioffe-Pritchard configuration. (b) Time-Orbiting Potential (TOP) trap. (c) Death-circle in a TOP trap.

repelling the atoms from this area (see Fig. 43.24). The advantage of Ioffe-Pritchard-type traps is that they are always harmonic sufficiently close to the trap center, which simplifies the theoretical treatment in many respects, as shown in Exc. 43.4.6.5.

Close to the trap center Ioffe-Pritchard-type traps are described by,

$$\boxed{U(\mathbf{r}) = \mu_B g_F m_F \sqrt{\mathcal{B}_0^2 + (r\partial_r \mathcal{B})^2 + (z\partial_z \mathcal{B})^2}} \,, \tag{43.95}$$

and this magnetic trapping potential can be harmonically approximated by,

$$\begin{aligned} U(\mathbf{r}) &\simeq \mu_B g_F m_F \left(\mathcal{B}_0 + \frac{(r\partial_r \mathcal{B})^2}{2B_0} + \frac{(z\partial_z \mathcal{B})^2}{2B_0} \right) \\ &\equiv const + \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 \equiv k_B T \left(const + \frac{r^2}{2\bar{r}^2} + \frac{z^2}{2\bar{z}^2} \right) \,, \end{aligned} \tag{43.96}$$

where the *rms*-radius $\bar{r} = \omega_r^{-1}\sqrt{k_B T/m}$ follow from the normalization of the density $n(\mathbf{r}) = n_0 e^{-U(\mathbf{r})/k_B T}$ to the number of atoms,

$$N = \int n(\mathbf{r}) d^3 r = n_0 \int_0^\infty e^{-r^2/2\bar{r}^2} 2\pi dr \int_{-\infty}^\infty e^{-z^2/2\bar{z}^2} dz = n_0 (2\pi)^{3/2} \bar{r}^2 \bar{z} \equiv n_0 V_{eff} \,. \tag{43.97}$$

The trap frequencies can be calculated as,

$$\omega_{r,z} = \sqrt{\frac{\mu_B (\partial_r \mathcal{B}_{r,z})^2}{m\mathcal{B}_0}} \,. \tag{43.98}$$

The Earth's gravitational field deforms the trapping potential and, in the case of a harmonic potential, causes a gravitational sag without changing the secular frequencies of the potential. Assuming the potential to be given by,

$$U = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2 - mgz = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 (z - g/\omega_z^2)^2 - \frac{m}{2} g^2/\omega_z^2 \,, \tag{43.99}$$

the atoms sag to a height of g/ω_z^2. In time-dependent traps, gravity causes a more complex behavior [573]. Important works have been done by [261, 1030, 421, 554, 5, 327, 776, 781, 357]. We study the impact of gravitation in Exc. 43.4.6.6.

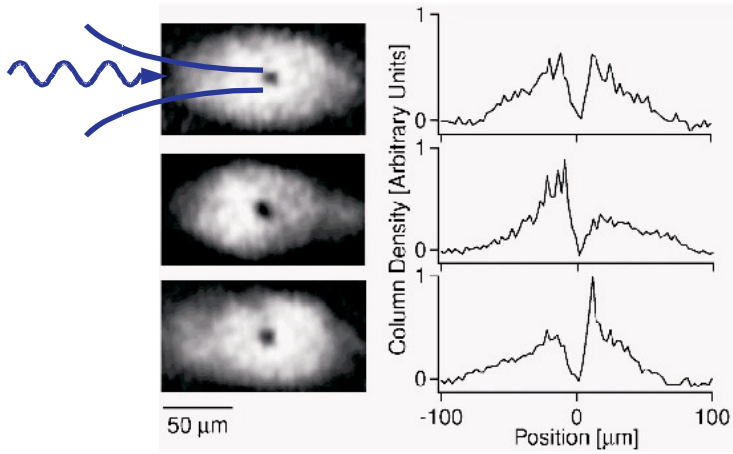

Figure 43.17: Creation of a repulsive hole by light tuned to the blue of an atomic transition.

43.4.2.1 Characterization of Ioffe-type traps

The 'time-of-flight' density distribution is,

$$r_{ToF} = \sqrt{\bar{r}^2 + \bar{v}^2 t_{ToF}^2} = \sqrt{\frac{k_B T}{m}} \sqrt{\frac{1}{\omega_r^2} + t_{ToF}^2} \simeq t_{ToF} \sqrt{\frac{k_B T}{m}} \ . \tag{43.100}$$

The *phase space density* is,

$$\rho = n_0 \lambda_{dB}^3 = \frac{N}{(2\pi)^{3/2} \bar{r}^2 \bar{z}} \left(\frac{2\pi\hbar^2}{m k_B T} \right)^{3/2} = N \omega_r^2 \omega_z \left(\frac{\hbar}{k_B T} \right)^3 = \zeta(3) \left(\frac{T_c}{T} \right)^3 \ . \tag{43.101}$$

where $\zeta(3) = 1.202$ is,

$$k_B T_c = \hbar \left(\frac{N \omega_r^2 \omega_z}{\zeta(3)} \right)^{1/3} \tag{43.102}$$

is the critical temperature. The *maximum collision rate* is,

$$\gamma_{coll} = n_0 \sigma \bar{v} = n_0 4\pi a_s^2 \sqrt{\frac{k_B T}{m}} \ . \tag{43.103}$$

The average collision rate can be obtained from,

$$\bar{\gamma}_{coll} N = \frac{1}{N} \int \gamma_{coll}(\mathbf{r}) n(\mathbf{r}) d^3 r = \frac{\int \sigma \bar{v} n^2(\mathbf{r}) d^3 \mathbf{r}}{\int n(\mathbf{r}) d^3 r} \ . \tag{43.104}$$

43.4.3 Radiative coupling and evaporative cooling

As we saw in the last section, optical cooling becomes ineffective when the density of the gas is high. Hence, we need another dissipation mechanism to cool trapped atoms. A method called *evaporation* has been proposed by Hess [616] for spin-polarized hydrogen (H↑) and was observed by Masuhara et al. [855]. Later, evaporation was used

Figure 43.18: The basic idea of evaporation consists in removing hot particles from the sample.

on alkali metals [5, 1018, 330]. A detailed review of the subject was published by Ketterle and van Druten [711].

Another collision-based cooling mechanism is *sympathetic cooling*. The technique was originally used in ion traps. Later it was applied to neutral atoms confined in magnetic traps. The idea is to get the cloud under study into thermal contact with a cold buffer gas. In some cases, the buffer gas may be optically or evaporatively cooled. Sympathetic cooling has been used in magnetic traps to create double condensates [939] and to cool fermions until the regime of quantum degeneracy [347].

43.4.4 Evaporative cooling

Evaporation always occurs when energetic particles abandon a system with finite bonding energy, removing more than their share of average energy per particle. Here, we consider the case of a finite-sized trapping potential, that is, the potential has an edge or a beak through which hot atoms, with sufficient kinetic energy to reach that region, may leave the trap. In the ideal case, this will lead to a complete truncation of the hot tail of the equilibrium Maxwell-Boltzmann velocity distribution. If the remaining system finds back to thermal equilibrium, it will do at a lower temperature. The redistribution of kinetic energy between atoms leading to *thermalization* occurs through elastic collisions.

43.4.4.1 Truncating the Boltzmann distribution

Let us first explain how the truncation leads to colder temperatures.

The objective is to calculate the Boltzmann distribution in a particular trap for a given atom number N and temperature T. The first step is to obtain the density-

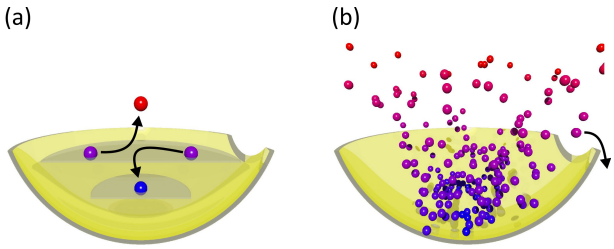

Figure 43.19: Principle of (a) rethermalization due to elastic collisions and (b) evaporation.

of-states. For an isotropic harmonic trap $\varepsilon = \frac{p^2}{2m} + V(r)$ with $V(r) = \frac{m}{2}\omega^2 r^2$, it is,

$$\eta(\varepsilon)d\varepsilon = \frac{1}{(2\pi)^3}\int_V d^3r d^3k = \frac{2\pi(2m)^{3/2}}{h^3}\int_V \sqrt{\varepsilon - V(r)}d^3r d\varepsilon = \frac{\varepsilon^2 d\varepsilon}{2(\hbar\omega)^3} \ . \quad (43.105)$$

The atom density is,

$$n(\varepsilon) = e^{(\mu-\varepsilon)/k_BT} = Ze^{-\varepsilon/k_BT} \ . \quad (43.106)$$

From these expression we obtain the atom number,

$$N = \int_0^\infty n(\varepsilon)\eta(\varepsilon)d\varepsilon = \int_0^\infty e^{(\mu-\varepsilon)/k_BT}\frac{\varepsilon^2}{2(\hbar\omega)^3}d\varepsilon = Z\frac{(k_BT)^3}{(\hbar\omega)^3} \ , \quad (43.107)$$

which we may now use to calibrate the fugacity via

$$Z = N\frac{(\hbar\omega)^3}{(k_BT)^3} \ , \quad (43.108)$$

which finally allows us to calculate the total energy,

$$E = \int_0^\infty \varepsilon n(\varepsilon)\eta(\varepsilon)d\varepsilon = \int_0^\infty \varepsilon e^{(\mu-\varepsilon)/k_BT}\frac{\varepsilon^2}{2(\hbar\omega)^3}d\varepsilon = 3Z\frac{(k_BT)^4}{(\hbar\omega)^3} = 3Nk_BT \ . \quad (43.109)$$

The evaporation consists in truncating the distribution function $n(\varepsilon)$ at some energy $\hbar\omega_{rf}$. We get with $\beta \equiv (k_BT)^{-1}$,

$$\tilde{N} = \int_0^{\hbar\omega_{rf}} n(\varepsilon)\eta(\varepsilon)d\varepsilon = N\left(1 - \frac{2 + 2\beta\hbar\omega_{rf} + (\beta\hbar\omega_{rf})^2}{2e^{\beta\hbar\omega_{rf}}}\right) \quad (43.110)$$

and

$$\tilde{E} = \int_0^{\hbar\omega_{rf}} \varepsilon n(\varepsilon)\eta(\varepsilon)d\varepsilon = E\left(1 - \frac{6 + 6\beta\hbar\omega_{rf} + 3(\beta\hbar\omega_{rf})^2 + (\beta\hbar\omega_{rf})^3}{6e^{\beta\hbar\omega_{rf}}}\right) \ . \quad (43.111)$$

As the truncation removes the hottest atoms from the cloud, we loose atom number and energy. Assuming the existence of some rethermalization mechanism, we may now use the new values for N and T to calculate the new equilibrium Boltzmann distribution starting all over from Eq. (43.106),

$$N \longleftarrow \tilde{N} \quad \text{and} \quad T \longleftarrow \frac{\tilde{E}}{3Nk_B} \quad (43.112)$$

Repeating this over and over the temperature will gradually reduce. The cooling process can be speed up by readjusting the truncation frequency to the actual temperature. This is called forced evaporation (see Fig. 43.20).

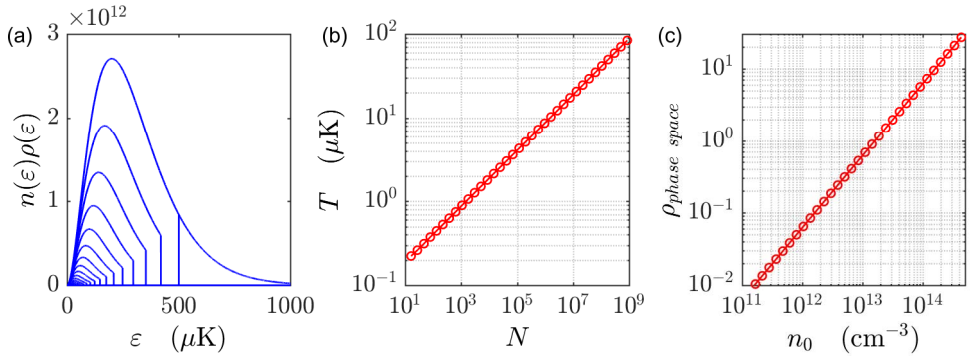

Figure 43.20: (code) (a) Forced evaporation by truncating the Boltzmann distribution over and over again. (b) Evolution of the temperature and (c) of the phase space density with number of remaining atoms.

43.4.4.2 Rethermalization

As already mentioned, rethermalization occurs due to elastic collisions. It needs more or less three collisions per atom to rethermalize a cloud [914, 1394], so that the collision rate determines the speed of the evaporation process. A large collision rate is desirable to keep the evaporation process faster than trap loss processes. Evaporation ramps between several seconds and a minute are typical.

The maximum rate of elastic collisions between trapped atoms (in the trap center) is,

$$\gamma_{coll} = n_0 \sigma_{el} \bar{v} \sqrt{2} \propto \rho^3 N^{2/3} \ , \tag{43.113}$$

where n_0 is the peak density,

$$\sigma_{el} = 8\pi a_s^2 \ , \tag{43.114}$$

is the cross-section for elastic collisions and, $\bar{v}$ being the average thermal velocity of the cloud, $\sqrt{2}\bar{v}$ is the average relative velocity between two of its atoms [710]. This formula gives the average collision rate at the *center of the cloud*, where the density is highest. To calculate the total collision rate, we need to integrate over the entire volume of the cloud,

$$\bar{\gamma}_{coll} = \tfrac{1}{N} \int \gamma_{coll}(\mathbf{r}) n(\mathbf{r}) d^3 r = \frac{\int \sigma_{el} \bar{v} n^2(\mathbf{r}) d^3 r}{\int n(\mathbf{r}) d^3 r} \ . \tag{43.115}$$

For harmonic potential we find an average rate reduced by $2\sqrt{2}$, for linear potentials by 8. We verify this in Exc. 43.4.6.7. Finally, the rate for collision events is two times smaller, as it involves two atoms at a time.

Obviously, the evaporation process slows down when the cloud cools more, unless the edge of the potential is lowered, such that the hotter atoms of the colder cloud can

be evaporated. By continually lowering the edge of the potential, while the atomic cloud keeps on rethermalizing (this procedure is called *forced evaporation*) very low temperatures in the nano-Kelvin regime can be achieved, and the phase space density can be increased by many orders of magnitude (between a MOT and a BEC there are 6 orders of magnitude) up to the threshold of Bose-Einstein condensation. Of course, this is only possible by sacrificing many hot atoms. Even with a well optimized evaporation ramp (i.e., a controlled lowering of the potential edge), usually only some 0.1% of the atoms reach the condensation phase after about 500 collisions per atom.

Two aspects should be mentioned regarding the optimization of the evaporation ramp. The first aspect is, that elastic collisions with atoms from the residual background vapor of the vacuum chamber limit the lifetime of the trap. Therefore, the evaporation must be sufficiently fast, which requires either a high rate of elastic collisions or a good vacuum. A compromise must be found between a slow but efficient evaporative cooling and a minimization of the losses, which come into play when the evaporation takes too long. The second aspect is, that the dimensionality of the evaporation surface determines the effectiveness of the cooling. In the first demonstration of evaporation, H↑ atoms of a hot cloud were ejected over a saddle point. The saddle was located a small region away from the trap center, and only atoms with sufficient kinetic energy *along a certain direction*, $E_z > U_{edge}$, could leave the trap. In such cases, evaporation is called one-dimensional. Even though ergodic redistribution due to anharmonicities of the potential will drive, sooner or later, all the atoms to this region, this effect becomes less pronounced when the cloud cools down, because the atoms accumulate at the bottom of the approximately harmonic (and therefore separable) potential. This fact has inhibited efficient evaporation of H↑ below 120 μK [466].

A second evaporative technique has been demonstrated in traps called *time-orbiting potential* (TOP) [1018]. It is a feature of TOP traps to display a spatial region called a 'death-circle', where passing atoms are ejected from the trap. This fatal circle can act as a 2-dimensional evaporation surface, provided the radius of the circle is large enough [580]. However, under the influence of gravity the dimensionality is further reduced to 1D [710].

The most successful evaporation technique implemented so far is based on a radiative coupling of confined and free states. We discuss this technique in the following sections. Publications on *evaporative cooling* are [819, 892, 1018, 1058, 127, 882, 914, 420, 425, 602, 948, 616, 855, 330, 711, 1393, 582, 848, 387, 618]. See ([297], Sec. 3.1.4) for an overview.

43.4.4.3 Adiabatic decompression

The condition for *adiabatic decompression* of a trapping potential is,

$$\frac{|\dot{\omega}_{trap}|}{\omega_{trap}} \ll \omega_{trap} \ . \tag{43.116}$$

The population of the quantized levels should not change under adiabatic decompression, $e^{\hbar\omega_i/k_BT_i} = e^{\hbar\omega_f/k_BT_f}$, and the phase space density remains unchanged,

$n_i \lambda_{dB,i} = n_f \lambda_{dB,f}$. If this is true, then the temperature and density change as,

$$\frac{\omega_f}{\omega_i} = \frac{T_f}{T_i} = \left(\frac{n_f}{n_i}\right)^{3/2} . \tag{43.117}$$

Solve Exc. 43.4.6.8.

43.4.4.4 Radiative coupling of internal state

The most successful evaporation technique implemented so far is based on a radiative coupling of confined and free states. We discuss this technique in the following sections. See ([297], Sec. 3.1.4) for an overview.

The radiative coupling technique originates from an idea proposed by Pritchard et al. [582], who have already had some experience with radiofrequency spectroscopy in magnetically trapped neutral atoms [848, 602]. The spatial dependence of the Zeeman splitting is an intrinsic feature of magnetic traps. Irradiation of a radio wave at a certain frequency couples trapped and untrapped Zeeman substates at a well-defined distance from the trap center. This gives rise to a 3D evaporation surface, where the passing atoms can undergo Landau-Zener transitions and be expelled from the trap. The technical advantages of this technique are substantial: The magnetic trapping potential does not have to be manipulated, for example, by the creation of a nozzle, and the potential edges can be easily controlled by the radiofrequency. If evaporation is forced via a continuous reduction of the radiofrequency and if the evaporation ramp is optimized, the density will increase as well as the collision rate. Rethermalization will accelerate and initiate a self-accelerated evaporation process (*run-away evaporation*). Rf-evaporation was first demonstrated by Ketterle and colleagues [330]. Solve Exc. 43.4.6.9.

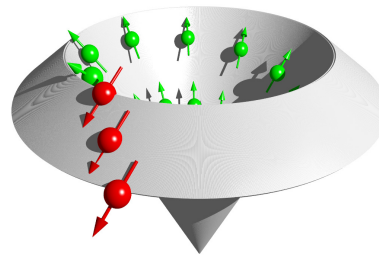

Figure 43.21: Illustration of evaporative truncation.

43.4.4.5 Adiabatic and diabatic limits of rf-induced evaporation

Rf-induced evaporation can be described within the formalism of the dressed atom [277], where the different states m_F of an atom with spin F are coupled to an rf-field [5], which we assume to be linearly polarized:

$$\mathcal{B}(t) = \mathcal{B}\hat{\mathbf{e}}_{rf} \cos \omega t \ . \tag{43.118}$$

The element of the coupling matrix between the levels, $|F, m_F\rangle$ and $|F, m_F \pm 1\rangle$ is,

$$\Omega = \frac{\mu_B g}{4\hbar} \left| \vec{\mathcal{B}}_{rf} \times \hat{\mathbf{e}}_B \right| \sqrt{F(F+1) - m_F(m_F+1)} \ , \tag{43.119}$$

where g is the atomic g-factor and $\hat{e}_B$ the orientation of the local static magnetic field.

[5] Alternatively, a *microwave* frequency may be used to couple *different hyperfine levels*.

The adiabatic potentials $U(r)$ are obtained through the eigenvalues of the atomic states dressed by the local magnetic field $\mathcal{B}(r)$. In the dressed atom picture, we consider the total energy of the atom plus the field of N radiofrequency photons. Without coupling, this simply means that $N\hbar\omega$ is added to the atomic Zeeman energies, resulting in a Zeeman pattern being vertically shifted by $N\hbar\omega$ for $N = 0, \pm 1, ...$ At positions where the rf-field is in resonance, curves with $\Delta N = 1$ intersect. Here, the coupling develops an *avoided crossing*, which determines the pattern of adiabatic energy levels [see Fig. 43.22(b)].

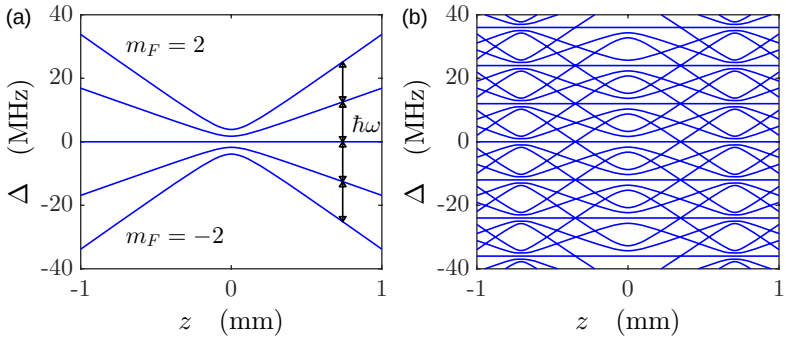

Figure 43.22: (code) (Left) Potentials due to the Zeeman structure of an atom in the ground state with $F = 1$. (Right) Adiabatic potentials resulting from the coupling of Zeeman levels via radiofrequency radiation being resonant with the difference of Zeeman levels at the position 0.7.

A slowly moving atom remains on the curve of an *adiabatic potential*. As an example, let us assume an atom in the hyperfine state $|F, F\rangle$ moving away from the center of the trap. When it comes close to resonance, the rf-field blends this state with other m_F-states, from the $|F, F-1\rangle$ down to the $|F, -F\rangle$ state, which changes the slope of the potential curve. Beyond the resonance point, the atomic state is adiabatically transformed into an untrapped high-field seeking state, and the atom is repelled from the trap. Thus, while passing the avoided crossing, the atom has emitted $2F$ rf-photons in a stimulated manner and inverted the orientation of both the electron and the nuclear spin.

In this way the radiofrequency generates an adiabatic potential surface with a depth of approximately $|m_F|\hbar(\omega - \omega_0)$, where ω_0 is the resonant rf-frequency at the center of the trap. The evaporation process corresponds, then, to the removal of the most energetic atoms out of the trap.

For this adiabatic picture to be valid, an adiabaticity condition must be fulfilled. This condition requires that the energy difference at the avoided crossover be larger than the energy uncertainty related to the limited time that an atom with velocity v spends in the resonance region. For a two-level system coupled by a matrix element V_{12} and an atom moving with velocity v along the z-axis, the transition probability P between the adiabatic curves is given by the *Landau-Zener formula* [1114],

$$P = 1 - e^{-\xi} \quad \text{with} \quad \xi = \frac{2\pi|V_{12}|^2}{\hbar g \mu_B \partial_z \mathcal{B} v} \,. \tag{43.120}$$

The Landau-Zener theory is strictly valid only for a two-level system, which we use here only for a qualitative discussion of two following limiting cases.

For a weak rf-field, $\xi \ll 1$, P is much smaller than 1, i.e., the atoms remain predominantly on the diabatic surface shown in Fig. 43.22(a). The probability for a *spin flip* transition is, $P \approx t$, which describes the diabatic limit of rf-induced evaporative cooling: The atomic energy levels are almost unperturbed, the atoms often spill across the resonance surface, and only after $1/P$ oscillations, they spin-flip from the hyperfine state $|F, F\rangle$ to the $|F, F-1\rangle$.

The adiabatic limit is clearly the ideal situation for evaporative cooling. However, the evaporation process in a trap (with oscillation time T_{osc}) saturates at a lower rf-power. The condition for saturation is $P \approx T_{osc}/\tau_{el}$, where τ_{el} is the average time between two collisions. This means that an energetic atom is evaporated before it collides again.

Only the component of the magnetic field of the rf-radiation which is *perpendicular* to the magnetic trapping field induces spin-flips. In certain geometries of the confinement potential, for example the quadrupole trap, the magnetic field covers the entire solid angle. Consequently, there are two points where the trapping field and the rf-field are parallel and the elements of the transition matrix consequently zero. Within an area around these points, the coupling is diabatic. In practice however, the rf-transition can be sufficiently saturated that this area is small and does not strongly affect the evaporation efficiency.

Note also that gravitation deforms the equipotential surfaces of the confinement potential, which can reduce the evaporation efficiency [710]. Solve Exc. 43.4.6.10.

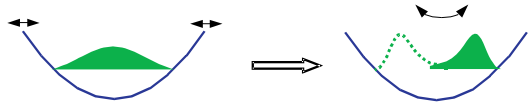

Figure 43.23: Effective potential due to a rapid modulation of the trap's location.

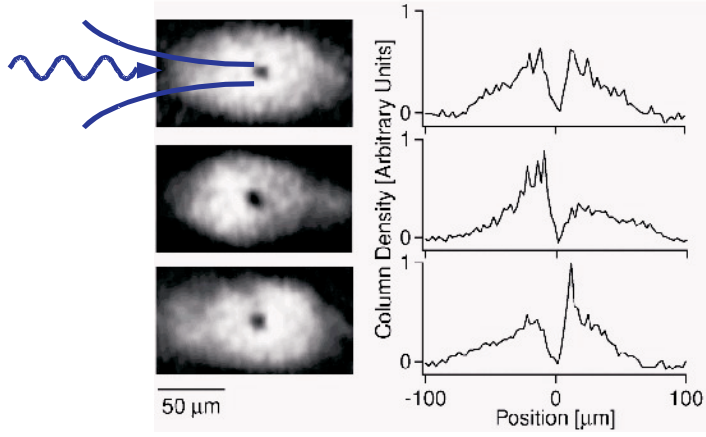

Figure 43.24: Creation of a repulsive hole by light tuned to the blue of an atomic transition.

43.4.5 Sympathetic cooling

The efficiency of evaporative cooling depends on the rate of interatomic collisions. However, there are atomic species with unfavorable, that is, small or even negative scattering lengths. Also, while at low temperatures only s-wave collisions occur (higher partial waves being frozen behind the centrifugal barrier), such collisions are prohibited for fermionic gases. Fermions or species with unfavorable scattering lengths can not be cooled by evaporation. There is, however, another technique called *sympathetic cooling* by thermal contact with another species. The additional species is, in general, actively cooled (e.g., by evaporation), while the species of interest is passively cooled via elastic collisions with atoms of the additional species. Of course, for this scheme to work the *interspecies scattering length* and the mass ratio must be adequate to ensure adequate thermal coupling.

Following [935] the transfer of kinetic energy between two colliding atoms is reduced by a factor depending on the their mass difference,

$$\xi = \frac{4m_1 m_2}{(m_1 + m_2)^2} \ . \tag{43.121}$$

Around $3/\xi$ collisions per atom on average are required for complete thermalization of a gas. For example, for the Rb-Li mixture, we have $3/\xi = 12.4$. The collision rate is,

$$\Gamma_{coll} = \sigma_{12}\bar{v} \int n_1(\mathbf{r}) n_2(\mathbf{r}) d^3r \ , \tag{43.122}$$

where the average thermal velocity is,

$$\bar{v} = \sqrt{\frac{8k_B}{\pi}\left(\frac{T_1}{m_1} + \frac{T_2}{m_2}\right)} \ . \tag{43.123}$$

The instantaneous temperature is calculated by,

$$\gamma_{therm} = -\frac{1}{\Delta T}\frac{d\Delta T}{dt} \ , \tag{43.124}$$

or via simulations: $\Delta T(t + dt) = \Delta T(t) - \Delta T(t)\gamma_{therm} dt$. Following [346] the rethermalization rate is connected to the collision rate via,

$$\boxed{\gamma_{therm} = \frac{\xi}{3}\left(\frac{\Delta E_{1\to 2}}{N_1 k_B \Delta T} + \frac{\Delta E_{2\to 1}}{N_2 k_B \Delta T}\right) = \frac{\xi}{3}\left(\frac{\Gamma_{coll}}{N_1} + \frac{\Gamma_{coll}}{N_2}\right)} \ . \tag{43.125}$$

Analytic solutions can be derived for harmonic traps. This will be studied in Excs. 43.4.6.11 and Exc. 43.4.6.12.

43.4.6 Exercises

43.4.6.1 Ex: Lack of trapping potentials for strong field seekers

Show that it is not possible to create magnetic trapping potentials for atoms in low-field seeking Zeeman states.

Solution: *Consider the potential,*

$$U(\mathbf{r}) = -\alpha|\vec{\mathcal{B}}|^2 = -\alpha(\mathcal{B}_x^2 + \mathcal{B}_y^2 + \mathcal{B}_z^2) \ .$$

Now we calculate,

$$\nabla^2|\vec{\mathcal{B}}|^2 = 2(|\nabla\mathcal{B}_x|^2 + |\nabla\mathcal{B}_y|^2 + |\nabla\mathcal{B}_z|^2 + \mathcal{B}_x\nabla^2\mathcal{B}_x + \mathcal{B}_y\nabla^2\mathcal{B}_y + \mathcal{B}_z\nabla^2\mathcal{B}_z) \ .$$

Using

$$\nabla^2\vec{\mathcal{B}} = \nabla(\nabla\cdot\vec{\mathcal{B}}) = \nabla\times(\nabla\times\vec{\mathcal{B}}) \ ,$$

and knowing, that in magnetostatics $\nabla\cdot\vec{\mathcal{B}} = 0 = \nabla\times\vec{\mathcal{B}}$*, we find,*

$$\nabla^2|\vec{\mathcal{B}}|^2 = 2(|\nabla\mathcal{B}_x|^2 + |\nabla\mathcal{B}_y|^2 + |\nabla\mathcal{B}_z|^2) > 0 \ .$$

The same argument holds for the trapping potential,

$$U(\mathbf{r}) = -\alpha|\vec{\mathcal{B}}| = -\alpha\sqrt{\mathcal{B}_x^2 + \mathcal{B}_y^2 + \mathcal{B}_z^2} \ .$$

43.4.6.2 Ex: Quadrupolar potential

Show that for a quadrupolar trap always holds $2\partial_r\mathcal{B}_{qua} = \partial_z\mathcal{B}_{qua}$.

Solution: *Maxwell's fourth equation gives,*

$$0 = \nabla\cdot\vec{\mathcal{B}} = \frac{\partial\vec{\mathcal{B}}}{\partial x} + \frac{\partial\vec{\mathcal{B}}}{\partial y} + \frac{\partial\vec{\mathcal{B}}}{\partial z} = 2\frac{\partial\vec{\mathcal{B}}}{\partial r} + \frac{\partial\vec{\mathcal{B}}}{\partial z} \ .$$

43.4.6.3 Ex: Magnetic quadrupole trap

a. Consider ^{87}Rb atoms confined in a magnetic trap with $\vec{\mathcal{B}}(x,y,z) = x \quad y \quad -2z \times 200\,\mathrm{G/cm}$. The atoms are in the state $|F=1, m_F=-1\rangle$ with the g-factor $g_F = 1/2$. Check whether it is reasonable to assume constant vibration frequencies for such traps.
b. Assume that the trapped atomic cloud consists of $N = 10^8$ atoms at temperature $T = 100\,\mathrm{K}$. Calculate the atomic density n_0 at the center of the cloud.
c. The cross section for elastic collisions is $\sigma = 10^{-12}\,\mathrm{cm}^2$. How many times do atoms meet in the middle of the trap?

Solution: *a. There are no oscillation frequencies in quadrupolar potentials.*
b. We showed in class that the maximum atomic density in a quadrupolar trap is,

$$n_0 = \frac{N}{(2\pi)^{3/2}\bar{r}^2\bar{z}} \ ,$$

hence, we find $n_0 = 3.5\times10^{13}\,\mathrm{cm}^{-3}$.
c. The collision rate is given by $\gamma_{coll} = \sigma\bar{v}n_0 = 3.5\,\mathrm{s}^{-1}$ *with* $\bar{v} = \sqrt{\frac{k_BT}{m}}$.

43.4.6.4 Ex: TOP trap

The TOP trap (time-orbiting potential) was the first design to allow for Bose-Einstein condensation in 1995. It consists of the superposition of a quadrupolar magnetic field, with the radial and axial gradients $2\partial_r \mathcal{B}_{qua} = \partial_z \mathcal{B}_{qua}$), and a homogeneous magnetic field $\mathcal{B}_{top}$ rotating in the symmetry plane of the quadrupole field. Atoms which oscillate with an amplitude beyond a given radius r_d, called the 'circle of death', undergo Majorana transitions and are expelled from the trap.
a. Calculate the radius of the death circle.
b. Plot the time-averaged 'effective' trapping potential.

Solution: *a. The death circle radius is,*

$$r_{death} = \frac{\mathcal{B}_{r,top}}{\partial_r \mathcal{B}_{r,qua}} \ .$$

The potential can be expressed as,

$$U(\mathbf{r}) = -\mu \cdot \mathcal{B}_{top} - \frac{\mu(\partial_r \mathcal{B}_{qua})^2}{4\mathcal{B}_{top}(r^2 + 8z^2)} \ ,$$

the density with,

$$n(\mathbf{r}) = n_0 e^{-(r^2+8z^2)/2\bar{r}} \ ,$$

and the actual volume as,

$$V_{eff} \equiv \frac{N}{n_0} = \pi^{3/2}\bar{r}^3 \ .$$

b. The result is shown in Fig. 43.25.

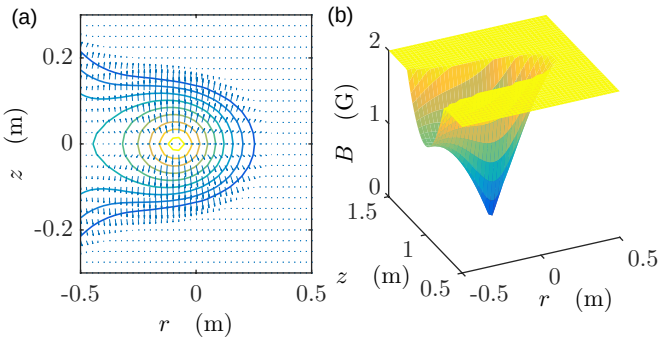

Figure 43.25: (code) Effective potential in radial direction of a shaking dipole trap.

43.4.6.5 Ex: Harmonic trap

Calculate the vibration frequencies of ^{87}Rb atoms trapped in a harmonic trap, when the atoms are in the $|F = 1, m_F = -1\rangle$ hyperfine level of the ground state.

Solution: *The potential is,*

$$U(\mathbf{r}) = -\mu_B g_F m_F |\vec{\mathcal{B}}| = \frac{m}{2}(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 z^2) = k_B T \left(\frac{x^2}{2\bar{x}^2} + \frac{y^2}{2\bar{y}^2} + \frac{z^2}{2\bar{z}^2} \right) ,$$

and the density,

$$n(\mathbf{r}) = n_0 e^{-U(\mathbf{r})/k_B T} .$$

Normalization requires,

$$N = \int n(\mathbf{r}) d^3 r = n_0 (2\pi)^{3/2} \bar{x}\bar{y}\bar{z} \equiv n_0 V_{eff} .$$

The expressions for the potential give,

$$\bar{x} = \sqrt{\frac{k_B T}{m\omega_x^2}} ,$$

etc.. If we know the magnetic field through its curvatures, B_j", that is, $|\vec{\mathcal{B}}| = \mathcal{B}"_x x^2 + \mathcal{B}"_y y^2 + \mathcal{B}"_z z^2$, we can calculate the frequencies:

$$\omega_x = \sqrt{\frac{2\mu_B g_F m_F}{m}} .$$

etc..

43.4.6.6 Ex: Gravitational sag in a trap

Consider (a) a quadrupolar trap and (b) an isotropic harmonic trap. What is the gradient, respectively the curvature of the trapping potential required to suspend a cloud of rubidium subject to gravitation? What is the sag of the cloud in the potential due to gravitation?

Solution: *a. The potential of a quadrupolar trap subject to gravitation can be written,*

$$U(r,z) = \mu \partial_r \mathcal{B} \sqrt{r^2 + 4z^2} + mgz .$$

We let $r = 0$,

$$U(0,z) = 2\mu \partial_r \mathcal{B} |z| + mgz .$$

The minimum of this potential stays at the same place $z = 0$, but the slope changes. For $2\mu\partial_r\mathcal{B} < mg$, the trap becomes unstable.
b. The potential of an isotropic harmonic trap subject to gravitation can be written,

$$U(r,z) = \tfrac{m}{2}\omega_r^2 r^2 + \tfrac{m}{2}\omega_z^2 z^2 + mgz .$$

We let $r = 0$. The position of the minimum is given by,

$$0 = \partial_z U(0,z) = m\omega_z^2 z + mg .$$

The minimum of this potential is lower by $z = g/\omega_z^2$, but for any ω_z, there is always a place, where the trap is stable. We can rewrite the potential as

$$U(r,z) = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2\left(z + \frac{g}{\omega_z^2}\right)^2 + const. \ .$$

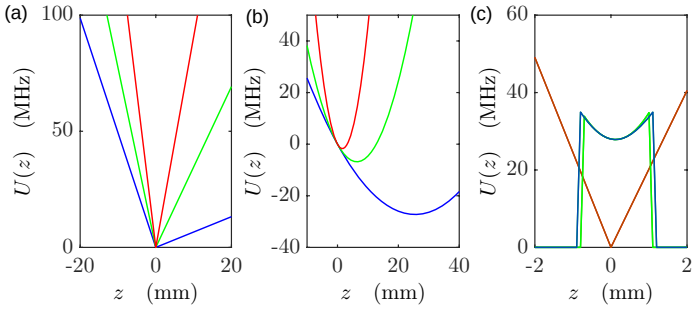

Figure 43.26: (code) Gravitational sag in a quadrupole and in a harmonic trap.

43.4.6.7 Ex: Mean collision rate

Assuming that the peak collision rate γ_{coll} is known, calculate the average collision rate (a) in a quadrupolar and (b) in a harmonic trap.

Solution: *a. As shown in Eq. (43.83) and (43.97) the density of an atomic cloud confined in a quadrupole trap is,*

$$n(\mathbf{r}) = n_0 e^{-\sqrt{r^2+4z^2}/\bar{r}}$$
$$with \qquad n_0 = \frac{N}{4\pi\bar{r}^3} \qquad and \qquad \bar{r} = \frac{k_B T}{\mu_B g_J m_J \partial_r \mathcal{B}} \qquad and \qquad N = \int n(\mathbf{r}) d^3 r \ .$$

Hence,

$$\bar{\gamma}_{coll} = \frac{1}{N}\int \sigma_{el}\bar{v} n^2(\mathbf{r}) d^3 r = \frac{\sigma_{el}\bar{v}}{N}\int \left[\frac{N}{4\pi\bar{r}^3} e^{-\sqrt{r^2+4z^2}/\bar{r}}\right]^2 d^3 r$$
$$= \frac{\sigma_{el}\bar{v}}{N}\frac{N}{4\pi\bar{r}^3}\frac{1}{8}\int \frac{N}{4\pi\bar{r}^3} e^{-\sqrt{(2r)^2+4(2z)^2}/\bar{r}} d^3(2r) = \frac{\sigma_{el}\bar{v}}{N}\frac{N}{4\pi\bar{r}^3}\frac{1}{8}N = \frac{\gamma_{coll}}{8} \ .$$

b. The density of an atomic cloud confined in a quadrupole trap is,

$$n(\mathbf{r}) = n_0 e^{-r^2/2\bar{r}^2}$$
$$with \qquad n_0 = \frac{N}{(2\pi)^{3/2}\bar{r}^3} \qquad and \qquad \bar{r} = \sqrt{\frac{k_B T}{2\mu_B g_J m_J}} \qquad and \qquad N = \int n(\mathbf{r}) d^3 r \ .$$

Hence,

$$\bar{\gamma}_{coll} = \frac{1}{N}\int \sigma_{el}\bar{v}n^2(\mathbf{r})d^3r = \frac{\sigma_{el}\bar{v}}{N}\int\left[\frac{N}{(2\pi)^{3/2}\bar{r}^3}e^{-r^2/2\bar{r}^2}\right]^2 d^3r$$
$$= \frac{\sigma_{el}\bar{v}}{N}\frac{N}{(2\pi)^{3/2}\bar{r}^3}\frac{1}{2^{3/2}}\int\frac{N}{(2\pi)^{3/2}\bar{r}^3}e^{-(\sqrt{2}r)^2/2\bar{r}^2}d^3(\sqrt{2}r) = \frac{\sigma_{el}\bar{v}}{N}\frac{N}{4\pi\bar{r}^3}\frac{1}{2^{3/2}}N = \frac{\gamma_{coll}}{2^{3/2}}\ .$$

43.4.6.8 Ex: Adiabatic compression

How does temperature change upon adiabatic compression of (a) a quadrupole trap and (b) a harmonic trap. How do density, phase space density, and elastic collision rate vary. **Help:** Define the compression for quadrupole trap as $\eta \equiv \partial_r\mathcal{B}_{r,final}/\partial_r\mathcal{B}_{r,initial}$ and for harmonic trap as $\eta \equiv \omega_{r,final}/\omega_{r,initial}$.

Solution: *a. We have already shown in a previous exercise that the e^{-1} radius $\bar{r}$ of a cloud in a quadrupole trap is,*

$$\bar{r} \equiv \frac{k_BT}{\mu_Bg_Fm_F\partial_r\mathcal{B}}$$

and the density,

$$n_0 = \frac{N}{(2\pi)^{3/2}\bar{r}^2\bar{z}}\ .$$

As the phase space density can not change when we make adiabatic variations, $\rho = n_0\lambda_{therm}^3 = const$, the density changes with the temperature as $n_0 \propto \lambda_{therm}^{-3} \propto T^{3/2}$. We also know $\bar{v} = \sqrt{k_BT/m}$, such that the collision rate is $\gamma = \sigma\bar{v}n_0 \propto \sqrt{T}T^{3/2}$. Thus, the density and temperature change with the pressure as,

$$\eta = \frac{\partial_r\mathcal{B}_{r,final}}{\partial_r\mathcal{B}_{r,initial}} = \frac{T_f\bar{r}_i}{T_i\bar{r}_f} = \frac{T_fn_f^{1/3}}{T_in_i^{1/3}} = \frac{T_f^{3/2}}{T_i^{3/2}} = \frac{n_f}{n_i} = \frac{\gamma_f^{3/4}}{\gamma_i^{3/4}}\ .$$

b. We have already shown in a previous exercise that the rms*-radius $\bar{r}$ of a harmonically trapped cloud is,*

$$\bar{r} \equiv \sqrt{\frac{k_BT}{m\omega^2}}\ ,$$

and the maximum density

$$n_0 = \frac{N}{(2\pi)^{3/2}\bar{x}\bar{y}\bar{z}}\ .$$

With the same argument of (a) we find now,

$$\eta = \frac{\omega_{r,final}}{\omega_{r,initial}} = \frac{T_f^{1/2}\bar{r}_i}{T_i^{1/2}\bar{r}_f} = \frac{T_f^{1/2}n_i^{1/3}}{T_i^{1/2}n_f^{1/3}} = \frac{T_f}{T_i} = \frac{n_f^{2/3}}{n_i^{2/3}} = \frac{\gamma_f^{1/2}}{\gamma_i^{1/2}}\ .$$

43.4.6.9 Ex: RF-antenna for radiative coupling

Calculate the Rabi frequency that can be generated by an rf-antenna consisting of a single square loop with side length $L = 2\,\mathrm{cm}$ on a cloud of trapped ^{87}Rb atoms located in the center of the loop on transitions between magnetic sublevels of the $F = 1$ ground state hyperfine structure. Assume the antenna to carry an ac-current with $I = 1\,\mathrm{A}$ amplitude.

Solution: *The first step is to calculate the magnetic field generated at the position of the cloud (assumed to be small). At rf-frequencies we can treat the magnetic field as being quasi static, i.e. we apply the the Biot-Savart law. The result of a numerical integration is shown in Fig. 43.27. We see that* $1\,\mathrm{A}$ *of current amplitude in the square loop generates a magnetic field of* $0.28\,\mathrm{G}$ *amplitude.*

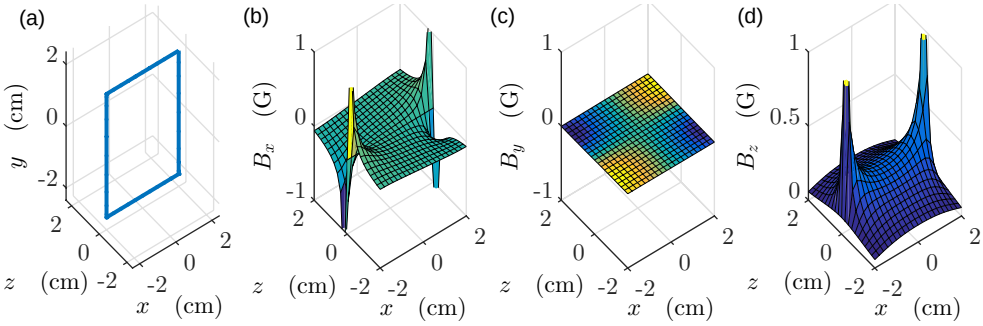

Figure 43.27: (code) RF-antenna for radiative coupling.

43.4.6.10 Ex: Landau-Zener transitions

Consider a rubidium-88 cloud in its ground state $^2S_{1/2}, F = 1, m_F = -1$ confined in an isotropic quadrupolar potential with the gradient $200\,\mathrm{G/cm}$. To initiate an efficient radiofrequency evaporation, you want atoms crossing the region where the radiofrequency couples the Zeeman states to make a transition to the untrapped Zeeman state $m_F = 0$ with 95% probability. What is the amplitude of the required magnetic field.

Solution: *When the sum of the kinetic and the potential energy of the atom is larger than* $\hbar\omega_{rf}$*, the atom can climb the potential up to the distance* R *from the center, where the Zeeman states suffer an avoided crossing. They follow the adiabatic path with the Landau-Zener transition probability,*

$$P_{LZ} = 1 - e^{-2\pi\Omega^2/\frac{\partial\Delta}{\partial R}v} \ ,$$

where the (co-rotating part of the) Rabi frequency is,

$$\Omega = \langle 1, 0|\mathbf{d}|1, -1\rangle \frac{\vec{\mathcal{B}}_{rf}}{2\hbar} \approx \frac{\mu_B \mathcal{B}_{rf}}{6\hbar} \ ,$$

and the energy splitting along the radial axis (here we have $\vec{\mathcal{B}}_{rf} \perp \vec{\mathcal{B}}_{trap}$) is,

$$\Delta = \frac{\mu_B \mathcal{B}_{trap}}{2\hbar} \ ,$$

with $\partial_r \mathcal{B}_{trap} = 200\,\mathrm{G/cm}$. The excess energy of atoms of $100\,\mu\mathrm{K}$ temperature is,

$$v = \sqrt{\frac{2E_{exc}}{m}} \ ,$$

with $E_{exc} = \frac{1}{2}k_B T$. Using these relationships we need, in order to obtain efficient cooling ($P_{LZ} > 95\%$), to fulfill,

$$\mathcal{B}_{rf} > \frac{6\hbar}{\mu_B}\sqrt{\frac{\partial_R \Delta v}{2\pi}\ln(1-P_{LZ})} \approx 0.052\,\mathrm{G} \ .$$

43.4.6.11 Ex: Damping in mixtures of species

From Eq. (43.125) derive the interspecies thermalization rate for harmonic potentials.

Solution: *With the potential $V_j(r) = \frac{1}{2}m_j\omega_{rj}^2 r^2 + \frac{1}{2}m_j\omega_{zj}^2 r^2 = k_B T_j \ \left(r^2/2\bar{r}_j^2 + z^2/2\bar{z}_j^2\right)$ the densities are $n_j(r) = n_{0j}e^{-r^2/2\bar{r}_j^2 - z^2/2\bar{z}_j^2}$, and the integral is [927],*

$$\begin{aligned}
\Gamma_{coll} &= \sigma_{12}\bar{v}n_{01}n_{02}\int e^{-r^2/2\bar{r}_1^2 - z^2/2\bar{z}_1^2 - r^2/2\bar{r}_2^2 - z^2/2\bar{z}_2^2}\ d^3\mathbf{r} \\
&= \frac{\sigma_{12}\bar{v}n_{01}n_{02}(2\pi)^{3/2}}{\sqrt{(\bar{x}_1^{-2}+\bar{x}_2^{-2})(\bar{y}_1^{-2}+\bar{y}_2^{-2})(\bar{z}_1^{-2}+\bar{z}_2^{-2})}} \\
&= \frac{\sigma_{12}\bar{v}N_1N_2}{(2\pi)^{3/2}\sqrt{(\bar{x}_1^2+\bar{x}_2^2)(\bar{y}_1^2+\bar{y}_2^2)(\bar{z}_1^2+\bar{z}_2^2)}} \ ,
\end{aligned}$$

letting $N = n_0(2\pi)^{3/2}\bar{x}\bar{y}\bar{z}$. Defining $m_2\omega_2^2 = \beta^2 m_1\omega_1^2$,

$$\Gamma_{coll} = \frac{(m_1\omega_1^2)^{3/2}\sigma_{12}\bar{v}N_1N_2}{(2\pi k_B)^{3/2}\,(T_1 + T_2\beta^{-2})^{3/2}} \ .$$

Once more, according to [346], the rethermalization rate is,

$$\gamma_{therm} = \frac{\xi(N_1+N_2)(m_1\omega_1^2)^{3/2}\sigma_{12}\sqrt{T_1/m_1 + T_2/m_2}}{3\pi^2 k_B(T_1 + T_2\beta^{-2})^{3/2}} \ .$$

For an anisotropic trap, we take the geometric mean of the trap frequencies, $\omega_1 = \sqrt{\omega_{1x}\omega_{1y}\omega_{1z}}$. The scattering length then follows from,

$$|a_{12}| = \sqrt{\sigma_{12}/4\pi} \ .$$

43.4.6.12 Ex: Damping in mixtures of species

Describe the damping in mixtures of species, and show how to use a measurement of the damping time for a determination of the interspecies the scattering length.

Solution: *The damping is described by two differential equations [439],*

$$\ddot{z}_1 = -\omega_1^2 z_1 - \frac{4}{3}\frac{m_2}{m}\frac{N_2}{N}\gamma_{therm}(\dot{z}_1 - \dot{z}_2)$$
$$\ddot{z}_2 = -\omega_2^2 z_2 - \frac{4}{3}\frac{m_1}{m}\frac{N_1}{N}\gamma_{therm}(\dot{z}_2 - \dot{z}_1) \ ,$$

or in matrix form,

$$\begin{pmatrix} \dot{y}_1 \\ \dot{z}_1 \\ \dot{y}_2 \\ \dot{z}_2 \end{pmatrix} = \begin{pmatrix} -\frac{4}{3}\frac{m_2}{m}\frac{N_2}{N}\Gamma & -\omega_1^2 & \frac{4}{3}\frac{m_2}{m}\frac{N_2}{N}\Gamma & 0 \\ 1 & 0 & 0 & 0 \\ \frac{4}{3}\frac{m_1}{m}\frac{N_1}{N} & 0 & -\frac{4}{3}\frac{m_1}{m}\frac{N_1}{N}\Gamma & -\omega_2^2 \\ 0 & 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} y_1 \\ z_1 \\ y_2 \\ z_2 \end{pmatrix} \ ,$$

where $\gamma_{therm} = n_{12}\sigma_{12}v$ *with* $n_{12} = \left(\frac{1}{N_1} + \frac{1}{N_2}\right)\int n_1 n_2 d^3\mathbf{r}$. *Hence,*

$$\gamma_{therm} = \left(\frac{1}{N_1} + \frac{1}{N_2}\right)\Gamma_{coll} \ .$$

43.5 Other traps

43.5.1 Ion traps

The electric charge of ions allow for their efficient manipulation and control by electric and magnetic fields exploiting the Coulomb-Lorentz force. In fact, the control is so good, that it is possible to isolate and store individual ions or even arrays of quantum entangled ions and to perform coherent operations on them, which qualifies them as quantum registers. Two different types of traps have been investigated. In *Penning trap*s [1014], electrically charged particles are subjected to a radially attractive quadrupolar electrostatic field superimposed to an axial magnetostatic field forcing the particles into closed circular orbitals [6]. In the so-called *radiofrequency trap* or *Paul trap* –*Wolfgang Paul* received the Nobel Prize in 1989 together with Hans Dehmelt and Norman Ramsey– charged particles subjected to an alternating electric field with quadrupolar symmetry. Hyperboloidal electrode configurations produce saddle-shaped potentials, as shown in Fig. 43.29, which are, at any instant of time, parabolically repulsive in the one direction (axial or radial) and parabolically attractive in the other (radial or axial). The alternating electric field causes a periodic reorientation of the Coulomb force, which leads to a time-averaged parabolic

[6] Note that purely electrostatic fields do not lend themselves to trapping, since the necessary condition for the existence of minima in a potential, $\partial_i\partial_j\phi < 0$, does not obey the Laplace equation.

quasi-potential $\Phi(\mathbf{r}, t)$. In this potential the particles perform harmonic oscillations at characteristic frequencies, which are independent of the oscillation amplitude [1001]:

$$\Phi(r, z) = \Phi_0(t)(r^2 - 2z^2) \quad , \quad r^2 = x^2 + y^2 \ , \tag{43.126}$$

where the polarity is alternated at a radiofrequency Ω_a,

$$\Phi_0(t) = \Phi_{dc} + \Phi_{ac} \cos(\Omega_a t) \ . \tag{43.127}$$

Φ_{dc} denotes the amplitude of the *dc* part of the voltage, Φ_{ac} the amplitude of the *ac* part. The potential $\Phi(r, z, t)$ exerts, in the temporal average, a central force on the ion, if the radiofrequency field satisfies specific conditions.

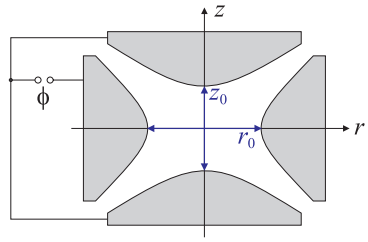

Figure 43.28: Geometry of the Paul trap.

43.5.1.1 Evaluation of the stability diagram

Paul traps do not have to have perfect quadrupolar geometry. To determine the secular frequencies of the pseudo-potential for an arbitrary geometry, we expand the potential around the position $\mathbf{r}_0$ of the potential minimum, which depends on the geometry of the electrodes and the applied voltages,

$$\begin{aligned} \Phi(\mathbf{r}) &= \Phi_a + (\mathbf{r} - \mathbf{r}_0)\nabla\Phi(\mathbf{r}_0) + \tfrac{1}{2}[(\mathbf{r} - \mathbf{r}_0)\nabla]^2\Phi(\mathbf{r}_0) + ... \\ &\equiv \Phi_a[1 + b_r(r - r_0)^2 + b_z(z - z_0)^2] \ . \end{aligned} \tag{43.128}$$

In the last step, we assume that the potential has an almost cylindrical shape. For a given geometry, the curvatures $b_{z,r}$ can be extracted from numerical simulations. From the continuity equation, we find $b_z = -2b_r$. The polarity of the electrodes is modulated with frequency Ω,

$$\Phi(\mathbf{r}, t) = \Phi(\mathbf{r})(\zeta - \cos \Omega t) \ . \tag{43.129}$$

The equations of motion are derived from $m\ddot{\mathbf{r}} = -e\nabla\phi(\mathbf{r}, t)$,

$$m\ddot{r}_j + 2e\Phi_a b_j(\zeta - \cos \Omega t) r_j = 0 \ . \tag{43.130}$$

Introducing the parameters a and q,

$$a_z = \frac{8e\phi_a b_z \zeta}{m\Omega^2} = -2a_r \quad \text{and} \quad q_z = \frac{4e\Phi_a b_z}{m\Omega^2} = -2q_r \ , \tag{43.131}$$

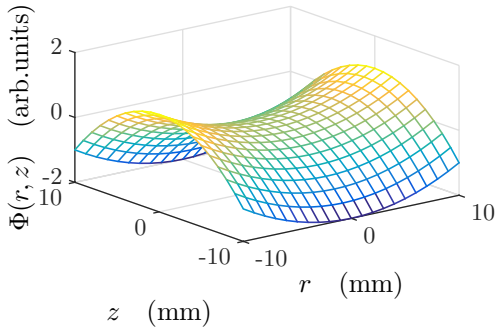

Figure 43.29: (code) Two-dimensional illustration of time-dependent potential: at each instant of time the potential has the form of a saddle. The potential rotates around the vertical axis at an appropriate pace.

we arrive at the so-called *Mathieu equation* [869, 446],

$$\ddot{r}_j + \tfrac{1}{4}\Omega^2(a_j - 2q_j\zeta\cos\Omega t)r_j = 0\ . \tag{43.132}$$

These equations predict stable orbits, provided that the parameters a and q are within the so-called stability diagram shown in Fig. 43.30.

According to these equations, the ion goes through oscillatory motions that are defined by the trap parameters a_i and q_i. For the motion of the ion to be finite, its oscillation amplitude may not exceed the boundaries defined by the electrodes. This condition imposes an allowed regime for the trap parameters called *stability diagram* [869].

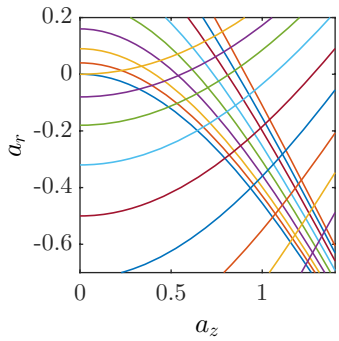

Figure 43.30: (code) Stability diagram.

In the limit $|a_i|, q_i \ll 1$ the ion travels only a short distance $s \ll r_0$ during one modulation period Ω_a. Then the ion undergoes a slow periodic motion called *macromotion* within the trapping potential with the secular frequency ζ_i. This motion is modulated by a rapid oscillation called *micromotion*, which is excited by the modulation field Ω_a. Without *dc* voltage applied between the ring and the endcaps, $a_i = 0$, the motion of the ion is described by the following simple equation:

$$r_i(t) = r_i^0\left(1 - \tfrac{1}{2}q_i\cos\Omega_a t\right)\cos\zeta_i t \quad , \quad \zeta_i = \tfrac{1}{\sqrt{8}}q_i\Omega_a \quad , \quad i = r, z\ . \tag{43.133}$$

The orbit of the ion is confined to the inner region of the trap, if its kinetic energy is less than $m\zeta_r^2 r_0^2 + M\zeta_z^2 z_0^2$. Since the trap is, at any instant of time, focusing in some directions and defocusing others, it is not a conservative potential. The oscillatory motion (disregarding micromotion) of the ion, however suggests a model, where the trap is described by a pseudo-potential [446, **?**] whose depth is,

$$D_z = \tfrac{q_z}{8} e V_{ac} = 2D_r \qquad \text{if} \qquad a_i = 0 \ . \tag{43.134}$$

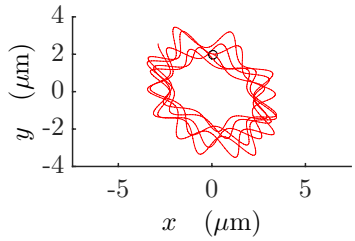

Figure 43.31: (code) Simulated micro- and macromotion of an ion.

Other geometries, deviating from the perfect quadrupole, are possible for the electrodes. These traps are also well described by equation (43.126), as long as the ion is near the trap center. For example, higher order multipolar traps have been used for trapping ion clouds [1357], as well as Paul-Straubl traps [1167] and storage rings [1350]. Particularly important for the storage of arrays of cooled ions with applications in quantum computing is the *linear Paul trap* [1055, 452, 1054], where immobilized ions are aligned on a linear chain. The advantage of the linear trap, as compared to other traps designed for many ions, is the easier optical access to individual ions by focused laser beams and the possibility of canceling the micromotion.

43.5.2 Micromotion

The motion of an ion in a Paul trap is a superposition of two vibrations with the respective oscillation frequencies Ω_a (modulation frequency) and $\zeta_{r,z}$ (secular frequencies for radial and axial direction vibrations). For an ion in thermal equilibrium (i.e., without active cooling), the mean kinetic energies of the micro- and macromotion are equal [150].

The macromotion can be reduced by cooling, in contrast to the micromotion, which is constantly excited by the modulation of the applied electric field [267]. On the other hand, the amplitude of the micromotion decreases with the distance of the ion from the trap center and, in the minimum of the pseudo potential, disappears completely. Therefore, to suppress the micromotion, it is imperative to cool the macromotion and push the ion to the trap center, if necessary, using additional static electric fields. Since the frequency of the micromotion is much higher than that of the macromotion, the dynamic sidebands can be resolved on a sufficiently narrow optical transition. When the modulation frequency Ω_a is very high, the secular frequencies of the macromotion are also high, so that even large optical transitions are able to resolve the macromotional sidebands. This is called the *strong coupling* regime.

Because of Coulomb repulsion, only a single atom can be at the center of a Paul trap, such that it is difficult to zero micromovement. One solution is to use a linear trap, where the center is smeared out over a straight line. Solve Exc. 43.5.4.1.

Example 278 (*Numerical calculation of the electric field created by a charged surface*): To calculate the trapping potential for a charged particle held on top of a planar microtrap structure, we proceed as follows. The energy of a charge in an electric field is $H = -e\Phi$. The electrostatic potential is given by Coulomb's law,

$$\Phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0}\sum_n \int_{V_n} \frac{\rho(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}dV' - \frac{1}{4\pi}\sum_n \int_{S_n} \Phi_n \frac{\mathbf{r}-\mathbf{r}'}{|\mathbf{r}-\mathbf{r}'|^3}d\mathbf{f}' + \frac{1}{4\pi}\sum_n \int_{S_n} \frac{\vec{\mathcal{E}}(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|}\cdot d\mathbf{f}' \ ,$$

where ϕ_n is the voltage applied to the n-th boundary. In practice, electric fields are generated by electrodes set to specific voltages. Using the Dirichlet boundary conditions, we only retain the second term. Furthermore, to account for the planar geometry of the chip electrodes, we only consider surface boundaries in the $y' = 0$ plane,

$$\Phi(\mathbf{r}) = -\frac{1}{4\pi}\sum_n \Phi_n \int_{S_n} \frac{y dx' dz'}{\sqrt{(x-x')^2 + y^2 + (z-z')^2}^3} \ .$$

This implies that the field lines cross the chip surface orthogonally, which in reality is only true if the chip electrodes cover the whole area. Therefore, we

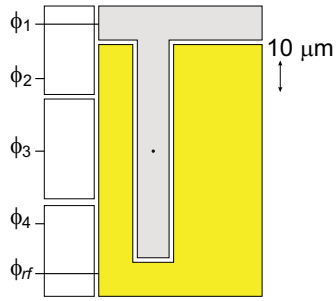

Figure 43.32: Possible design for a microchip ion trap. Φ_n are static potentials except for Φ_0, which is alternates sign with radio frequency.

only consider small gaps between the electrodes. We digitize the integral by dividing every electrode Φ_n into a number of identical surface elements Δf_m,

$$\Phi(\mathbf{r}) = -\frac{1}{4\pi}\sum_{n,m} \Phi_n \frac{y\Delta f_m}{\sqrt{(x-x_m)^2 + y^2 + (z-z_m)^2}^3} \ .$$

This formula can easily be evaluated numerically. A concrete example for a microchip ion trap is shown in Fig. 43.32.

Example 279 (*Numerical calculation of the magnetic field created by a current wire*): Current-carrying wires may exert Lorentz forces on the ions. The magnetostatic field is given by the Biot-Savart law,

$$\vec{\mathcal{B}}(\mathbf{r}) = \frac{\mu_0}{4\pi}\int_V \frac{(\mathbf{r}-\mathbf{r}')\times\mathbf{j}}{|\mathbf{r}-\mathbf{r}'|^3}dV' \ .$$

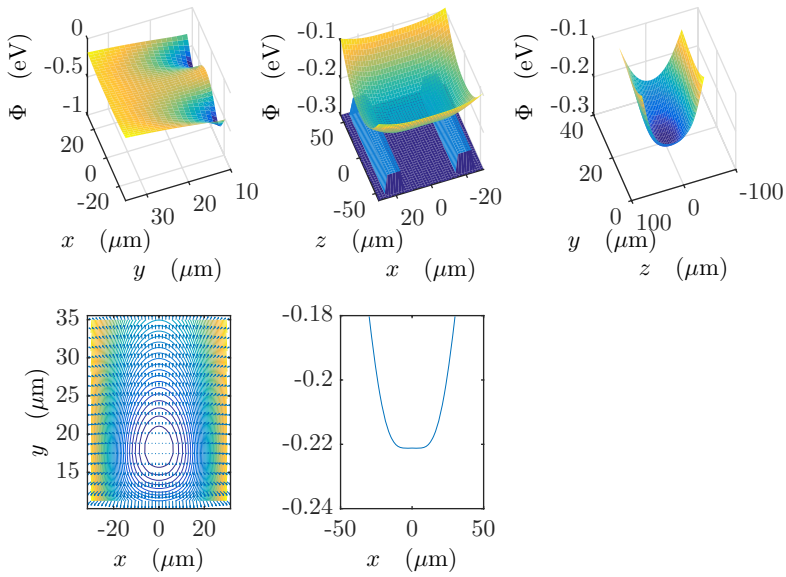

Figure 43.33: (code) Two-dimensional cuts through the electric potential generated by the microchip shown in Fig. 43.32 for $\Phi_{rf} = 100$ V and $\Phi_j = 0$.

In practice magnetic fields are created by current-carrying wires. Those can be parametrized by one-dimensional currents, $\mathbf{j} = I\delta^2 d\mathbf{s}$, so that,

$$\vec{\mathcal{B}}(\mathbf{r}) = \frac{\mu_0 I}{4\pi} \int_C \frac{d\mathbf{s}' \times (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3}$$

$$|\vec{\mathcal{B}}(\mathbf{r})| = \frac{\mu_0 I}{4\pi} \sum_n \frac{\sqrt{ds_{y,n}^2 (z - z_n)^2 + ds_{z,n}^2 (x - x_n)^2 + ds_{x,n}^2 (y - y_n)^2}}{\sqrt{(x - x_n)^2 + (y - y_n)^2 + (z - z_n)^2}^3} .$$

can immediately be numerically solved.

43.5.2.1 Electronic detection of ions

The presence of ions in the trap can be probed through the damping that they induce a coupled electronic resonance circuit [1356, 1362].

43.5.3 QUEST

Homonuclear atoms and dimers do not have a permanent electrical dipole moment, but they may have a permanent magnetic dipole moment. Therefore, homonuclear dimers must be confined by magnetic field gradients, or else an electric dipole moment must be *induced* by an oscillating electromagnetic field. In the optical regime, this was demonstrated with the quasi-electrostatic trap (*QUEST*).

In contrast, heteronuclear dimers are polar molecules with a permanent electric dipole moment, which can be quite large if the molecules are deeply bound. According to Earnshaw's theorem, there is no static magnetic field maximum in free space. Thus, no 'high-field seeking' state can be trapped. In principle, QUEST-type dipolar optical

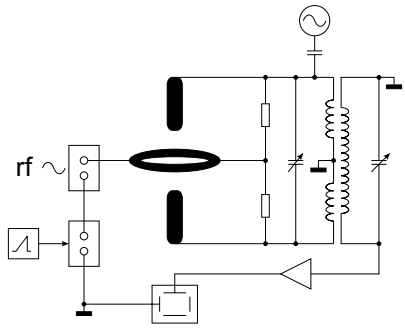

Figure 43.34: Resonance circuit for electronic ion detection. The trap is operated by a radiofrequency, while a DC voltage is scanned across the stability diagram. Simultaneously, an oscillating field is tuned near one of the trap's secular frequencies. When the stability point is such, that the secular frequency coincides with the frequency of the oscillating field, the motion of the ions is parametrically excited and the resonance circuit is damped. This damping is detected by a narrow-band amplifier.

traps can also be used for heteronuclear dimers. The problem is, however, that in contrast to homonuclear molecules, transitions between the vibrational ground state levels are possible. Thus, the light generating the QUEST also induces transitions leading to a redistribution of the population over all vibrational states.

Very far from resonance,

$$U_{dip}(\mathbf{r}) = -\alpha_{stat}\frac{I(\mathbf{r})}{2\varepsilon_0 c} \ . \tag{43.135}$$

Loosely bound homonuclear molecules are subject to the sum of the restoring forces exerted by magnetic traps on the individual atoms, $\mu_m = 2\mu_a$ and $d_m = 2d_a$. This is also true for heteronuclear molecules as long as the trapping potential is much weaker than the binding energy.

Example 280 (*Permanent electric dipole moment of LiRb*): The interaction energy of two dipoles is,

$$\hat{H}_{int} = \frac{1}{4\pi\varepsilon_0}\frac{\mathbf{p}_1\cdot\mathbf{p}_2 - 3(\mathbf{p}_1\cdot\hat{\mathbf{r}})(\mathbf{p}_2\cdot\hat{\mathbf{r}})}{r^3} \ .$$

Thus, two identical dipoles with 1 Debye $= 10^{-27}/2.998\,\mathrm{Cm} = 10^{-19}/c\,\mathrm{Cm}^2\,/\,\mathrm{s} =$ 39.36 ea_B parallel oriented at a distance $r = 1\,\mu\mathrm{m}$ have the energy,

$$\hat{H}_{int} = \frac{1}{4\pi\varepsilon_0}\frac{p^2}{r^3} \approx h \times 1.5\,\mathrm{MHz} \approx k_B \times 73\,\mu\mathrm{K} \ .$$

For example, LiRb has an electrical dipole moment of between -2 and -4.2 Debye depending on the vibrational state of the molecule.

43.5.4 Exercises

43.5.4.1 Ex: Coulomb repulsion in linear Paul trap

Coulombian repulsion prevents that two ions confined in a linear Paul trap be simultaneously in the ground state. Determine the spatial extent of the ground state

and the depth of the potential in the pseudo-potential approximation. What is the equilibrium distance of the ions?

Solution: *The size of the ground state is,*

$$a_{trap} = \sqrt{\frac{\hbar}{m\omega_{trap}}} \ .$$

The Coulomb repulsion balances the potential energy. For two ions the equilibrium distance is,

$$d_{Coul} = \sqrt{\frac{e^2}{\pi\varepsilon_0 m\omega_{trap}^2}} \ .$$

Therefore two ions can share the ground state if $a_{trap} > d_{Coul}$*. For this to happen, we find* $\omega_{trap} > 2\pi\times 10^{21}$ Hz*! Also we didn't account for micromotional heating which also will occur. Then how about linear ion traps? Obviously, in the experiments carried out thus far the ions settle down in chains and are well localized and distinguishable, i.e. not condensed in an ionic condensate. And the reason for that is certainly not fermionic statistics. The ions are apparently not in the longitudinal ground state of the linear trap, but just in the transversal.*

43.6 Analysing techniques

To analyze the kinetic state of an atomic gas and, for example, to identify the presence of a Bose-Einstein condensate, it is necessary to measure its spatial or momentum distributions. However, the only way to gather information from the atoms is to throw some kind of particles into them and to detect, where these particles are scattered. The most suitable particle to penetrate an ultra-high vacuum chamber surely is the *photon*. Therefore, apart from few exceptions where electron beams are used, all information on ultra-cold gases has been obtained so far through their reactions to incident laser beams [626, 238, 34, 670, 534].

43.6.1 Time-of-flight imaging

The most common imaging techniques measure the absorption of a laser beam by an atomic cloud after a *time-of-flight* or the dispersion of a laser beam induced by trapped cloud. The amplitude E_0 of a light wave traversing an atomic cloud of diameter L and characterized by the refractive index η is modified by a factor $e^{\imath\omega L\eta/c}$. For an inhomogeneous cloud, we have,

$$\mathcal{E} = \mathcal{E}_0 e^{\imath\omega L/c} \exp\left(\imath\frac{\omega}{c}\int_{-\infty}^{\infty}(\eta(\mathbf{r})-1)dz\right) . \tag{43.136}$$

We can approximate the refractive index by the atomic susceptibility,

$$\eta = \sqrt{1+\chi} \simeq 1+\frac{\chi}{2} \qquad \text{with} \qquad \chi = -\frac{4\pi n(\mathbf{r})}{k^3(2\Delta/\Gamma+\imath)} . \tag{43.137}$$

where $n(\mathbf{r})$ is the density distribution of the cloud. The imaginary part of the susceptibility is related to the *absorption coefficient* α and the real part to the *dispersion coefficient* δ,

$$\mathfrak{Im}\ \chi = \frac{\alpha}{\omega/c} \qquad \text{and} \qquad \mathfrak{Re}\ \chi = \frac{2\delta}{\omega/c} . \tag{43.138}$$

Now, the absorption and dispersion coefficients can be related to the optical cross-section $\sigma(\Delta)$ defined in (22.102) [816], where Δ is the detuning of light frequency from an atomic resonance, whose linewidth is Γ. This result is called the *optical theorem*,

$$\alpha = n\sigma(\Delta) \qquad \text{and} \qquad \delta = n\sigma(\Delta)\frac{\Delta}{\Gamma} , \tag{43.139}$$

Finally, we obtain the *Lambert-Beer law*,

$$\boxed{\mathcal{E} = \mathcal{E}_0 e^{\imath\omega L/c} \exp\left[\imath\sigma(\Delta)\left(\frac{\imath}{2}-\frac{\Delta}{\Gamma}\right)\int_{-\infty}^{\infty} n(\mathbf{r})dz\right] \equiv \mathcal{E}_0 e^{\imath\omega L/c} e^{-b/2} e^{\imath\varphi}} . \tag{43.140}$$

For the intensity, $I \propto |E|^2$, we get,

$$\frac{I}{I_0} = \exp\left[-\sigma(\Delta)\int_{-\infty}^{\infty} n(\mathbf{r})dz\right] \equiv e^{-b} . \tag{43.141}$$

The *absorption* b describes the loss of intensity for the laser beam due to scattering by the (disordered) atoms. It is strong near resonance, but diminished quadratically with the detuning Δ. The scattering is necessarily accompanied by radiation pressure accelerating and heating the atoms. The *dispersion* φ describes the refraction of the laser beam by the atomic density distribution (which for this purpose can be considered as continuous) [298, 458]. It disappears in resonance and diminishes slowly with increased detuning ($\propto \Delta$). It is connected to the dipole force and, thus, does not heat the atomic cloud. The coefficient φ describes the phase shift of the electromagnetic wave transmitted through the atomic cloud.

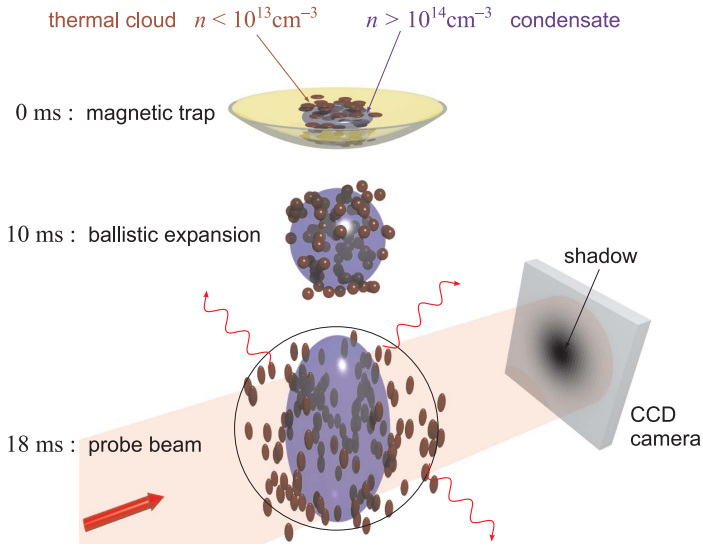

Figure 43.35: Sequence of a typical time-of-flight experiment: As soon as the trapping potential is suddenly switched off, the atomic cloud ballistically expands for 18 ms, before it is illuminated by a short resonant laser pulse. The shadow printed by the cloud onto the beam is photographed by a CCD camera.

43.6.2 Absorption imaging

Let us now detail the experimental process of *absorption imaging* (see Fig. 43.36): The trap confining the atomic cloud is suddenly turned off, thus letting the atoms, accelerated by the Earth's gravitation, fall for a flight time of a few ms. Then a pulse of a resonant laser light, whose diameter is much larger than the size of the cloud, is irradiated. The local attenuation of the beam intensity $I \sim |\mathcal{E}|^2$ can be related through the absorption b (also called *optical density* or *optical depth*) to the atomic density via,

$$-\ln \frac{I(x,y)}{I_0} = b(x,y) = \sigma(\Delta) \int n(\mathbf{r}) dz \ . \tag{43.142}$$

The shadow printed by the atomic cloud on the transverse profile of the laser beam is recorded by a CCD camera.

We have already noted that the absorption is accompanied by radiative pressure. After some scattering events, due to the photonic recoil, the atoms have accumulated a sufficiently large velocity, and therefore a sufficiently large Doppler shift, to be out of resonance with the laser beam. Subsequent photons are no longer scattered by the atoms and only contribute to increase the illumination of the CCD camera without carrying any information about the presence of atoms. Consequently, it is advantageous to use very short laser pulses. In addition, the intensity of the laser beam should not saturate the transition in order to guarantee an optical cross-section, which is independent of the intensity, and hence to guarantee the validity of the Lambert-Beer law. Finally, the laser frequency must be tuned perfectly to resonance, $\Delta = 0$. Otherwise, the interaction between the laser beam and the atomic cloud becomes

partially dispersive, which leads to a focusing or defocusing of the laser beam by refraction and a distortion of the image making it impossible to estimate the size of the cloud.

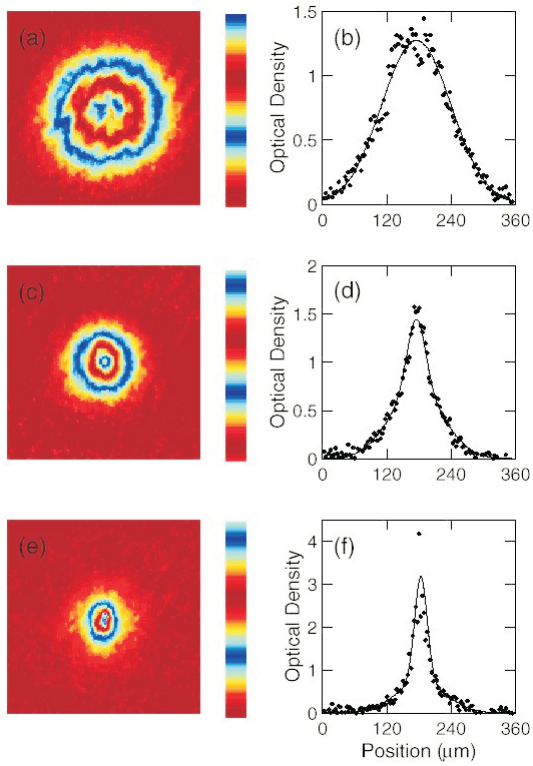

Figure 43.36: Absorption images after a time-of-flight allow to identify the presence of a Bose-condensate through its characteristic momentum distribution. Shown are images (a,b) above, (c,d) slightly below, and (e,f) well below the critical temperature for a Bose-Einstein phase transition (figures [580]).

Fig. 43.36 shows examples of absorption images of an atomic cloud taken at different stages of the evaporation process. Fig. 43.36(a,b) was taken at a temperature of 320 nK; the cloud is large and isotropic and therefore purely thermal. At 250 nK [see Fig. 43.36(c,d)] an elliptically shaped part appears in the center of the thermal cloud. And at 180 nK [see Fig. 43.36(e,f)] the thermal cloud almost completely disappeared for the benefit of the condensate. A quantitative evaluation of the condensed fraction is given in Sec. 44.1.4. Solve the Excs. 43.6.6.2 and 43.6.6.1.

43.6.3 Dispersive imaging

The absorption imaging technique is destructive, because of the involved ballistic expansion and also because of the radiative pressure exerted by the resonant imaging beam, which accelerates and heats the atomic cloud. That is, the measurement process messes up the distributions of the cloud, such that a second image taken after

the first one will give different results. However, there is a non-destructive imaging technique called *dispersive imaging* or *phase contrast imaging*. In this technique, the laser light is tuned sufficiently far from resonance, $|\Delta| \gg \Gamma$, for spontaneous emission and heating induced by random photonic recoil to be negligible [34]. This permits to take a series of consecutive images and create a *movie* of the temporal evolution of the cloud. Another advantage of this technique is the low off-resonant optical density, which allows to take pictures of very dense clouds *in situ*, that is, *while they are confined in a trap*.

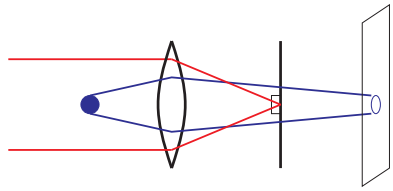

Figure 43.37: Scheme for dispersive images.

The physical quantity which is measured by this method is the local phase shift of the wavefront of the probe laser. Wavefront distortions are difficult to measure. To transform the phase profile into an intensity profile, a method known from classical optics called *Schlieren method* is used. It is based on the interference of the probe beam with its distorted wavefront and a reference plane wave. In practice, there are several possibilities. For *dark-ground imaging*, the part of the incident beam not having interacted with the atoms is blocked behind the interaction zone (see Fig. 43.37)

$$\bar{I}_{dg} = \tfrac{1}{2}|\mathcal{E} - \mathcal{E}_0|^2 = I_0 \left| e^{-b/2+\imath\varphi} - 1 \right|^2 \overset{b\to 0}{\longrightarrow} I_0 \varphi^2 = I_0 b \frac{\Delta^2}{\Gamma^2} \,. \tag{43.143}$$

The intensity signal $\bar{I}_{dg}$ is quadratic in optical density b.

For *phase contrast imaging*, the part of the beam not having interacted with the atoms receives a phase shift of $\lambda/4$ with respect to the part of the beam having interacted with the atoms:

$$\bar{I}_{pc} = \tfrac{1}{2}|\mathcal{E} - \mathcal{E}_0 + \mathcal{E}_0 e^{\pm\imath\pi/2}|^2 = I_0 \left| e^{-b/2+\imath\varphi} - 1 + e^{\pm\imath\pi/2} \right|^2 \overset{b\to 0}{\longrightarrow} I_0(\pm 1 + \varphi)^2 \simeq I_0 \left(1 \pm b\frac{\Delta}{\Gamma} \right) \,. \tag{43.144}$$

The intensity $\bar{I}_{pc}$ is linear in b and, consequently, more sensitive to weak signals. Finally, a third technique, called *polarization contrast imaging*, detects the local birefringence of the atomic cloud [188, 1125].

The imaging techniques shown so far only allow to visualize the instantaneous density distribution of the atomic cloud $n(\mathbf{r})$. If we are interested in other quantities, we have to conceive the experiment in such a way, that the desired information leaves its signatures in the density distribution. For example, to measure the excitation

frequencies of a condensate, which can perturb its shape and observe the subsequent time evolution of $n(\mathbf{r}, t)$ via dispersive imaging [674, 883, 35, 712].

43.6.4 Reconstruction of column-integrated absorption images

Assume cylindrical symmetry $n(\mathbf{r}) = n(r, z)$, with $r = \sqrt{x^2 + y^2}$. Absorption images are *column-integrated*, i.e. they are taken by integration along the x-axis,

$$\frac{I(y,z)}{I_0(y,z)} = e^{-\sigma \int n(r,z)dx} = e^{-\sigma f(y,z)} \ . \tag{43.145}$$

The radial density can be recovered by tomography [342, 389, 993],

$$n(r,z) = \frac{1}{(2\pi)^2} \int (\mathcal{F}_y f)(\kappa_y, z) J_0(\kappa_y r) d\kappa_y \ . \tag{43.146}$$

This is called *image reconstruction* or *Fourier reconstruction* or *inverse Abel transform* and will we studied in Exc. 43.6.6.3.

43.6.5 Condensable atomic species

Early work on BEC has been done by [1149, 93, 149, 248, 802]. Proposals for atomic gases withe from [592, 1275, 1269]. An appropriate BEC candidate must fulfill a few conditions: The transition wavelengths must be *accessible by laser light*, the level scheme should exhibit a *closed cycling transition* for laser cooling and have a reasonable pressure in gas phase. Furthermore, it is desirable to have a large HFS, metastable electronic state, no trapping state, large positive scattering length, Feshbach resonances. For sympathetic cooling it may be nice to have several isotopes of the same element.

The most common elements are alkalis, alkali earths and noble gases. The following gases have already been condensed ^{1}H, ^{1}He*, ^{7}Li, ^{23}Na, ^{85}Rb, and ^{87}Rb [31], [329], [189], [188], [1126], [301], [580], [585]. Investigations in ^{1}Ne*, ^{39}K, ^{133}Cs, ^{x}Sr, ^{x}Cr and ^{40}Ca are underway [1227], [556], [737], [1056], [1202], [113], [466].

43.6.6 Exercises

43.6.6.1 Ex: Lensing by cold clouds

The interaction of light with two-level atoms generates a susceptibility which gives rise to a refraction index,

$$\eta(\mathbf{r}) = \sqrt{1 - \frac{4\pi n(\mathbf{r})}{k^3(2\Delta/\Gamma + \imath)}} \ ,$$

where $n(\mathbf{r})$ is the cloud's density distribution and $\Gamma/2\pi = 30.5\,\mathrm{MHz}$ for strontium.
a. Calculate the phase-shift suffered by a light beam crossing an ultracold atomic cloud ($N = 10^5$, $T = 1\,\mu\mathrm{K}$) confined in an isotropic harmonic trap ($\omega_{trp} = (2\pi)\ 100\,\mathrm{Hz}$) as a function of detuning.
b. Estimate the focal distance of the cloud for $\Delta = -\Gamma$.

Solution: *a. The density distribution is,*

$$n(\mathbf{r}) = \frac{N}{(2\pi)^{3/2}\bar{r}^3} e^{-r^2/2\bar{r}^2} \qquad with \qquad \bar{r} = \sqrt{\frac{k_B T}{m\omega_{trp}^2}} \ .$$

The phase shift is then,

$$\varphi = \int_{-\infty}^{\infty} n(0,0,z)\sigma(\Delta)\frac{\Delta}{\Gamma}dz = \frac{3\lambda^2}{2\pi}\frac{\Gamma^2}{4\Delta^2+2\Omega^2+\Gamma^2}\frac{\Delta}{\Gamma}\frac{N}{(2\pi)^{3/2}\bar{r}^3}\int_{-\infty}^{\infty} e^{-z^2/2\bar{r}^2}dz$$
$$= \frac{3N\lambda^2}{(2\pi)^{5/2}}\frac{\Delta\Gamma}{4\Delta^2+2\Omega^2+\Gamma^2}\frac{m\omega_{trp}^2}{k_B T}\sqrt{2\pi} = \frac{3N}{k^2}\frac{\Delta\Gamma}{4\Delta^2+2\Omega^2+\Gamma^2}\frac{m\omega_{trp}^2}{k_B T} \ .$$

b. Let us assume that the phase shift is negligible for a beam passing at a distance $\bar{r}$

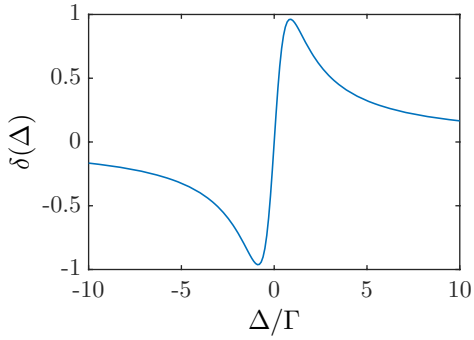

Figure 43.38: (code) Lensing.

from the cloud center. Then we estimate the focal distance f from,

$$\frac{\varphi\lambda/2}{\bar{r}} = \tan\theta \simeq \sin\theta = \frac{\bar{r}}{f}$$

as,

$$f \simeq \frac{2\bar{r}^2}{\varphi\lambda} \approx 1\,\text{mm} \ .$$

43.6.6.2 Ex: Optical density

A cloud of $N = 10^6$ ^{87}Rb atoms is prepared in a cylindrical harmonic trap characterized by the axial vibration frequencies $\omega_z = (2\pi)\ 50\,\text{Hz}$ and the radial one $\omega_r = (2\pi)\ 200\,\text{Hz}$. The experimenter takes the absorption image after 18 ms time-of-flight, as shown in Fig. 43.36(a). A pixel of the CCD camera corresponds to 5 µm in real space.
a. At what temperature is the phase transition to Bose-Einstein condensate to be expected?

b. Determine the temperature of the sample.
c. Evaluate its density distribution.
d. Evaluate the resonant optical density for the $D2$-transition at 780 nm along the symmetry axis of the trapped cloud.

Solution: *a. The critical temperature is* $T_c = \frac{\hbar(\omega_r^2\omega_z)^{1/3}}{k_B}\left(\frac{N}{1.202}\right)^{2/3}$, *giving* $T_c = 570\,\mathrm{nK}$.
b. The cloud is purely thermal, since the distribution after ballistic expansion is isotropic. From the image's rms*-diameter,* $\bar{\mathbf{r}}_{tof}$, *we calculate the* rms*-diameter of the velocity distribution,* $\bar{v} = \frac{\bar{r}_{tof}}{t_{tof}}$, *and therewith the temperature,* $T = \frac{m\bar{v}^2}{k_B}$. *This yields* $T = 17\,\mu\mathrm{K}$.
c. The thermal cloud is described by a Gaussian distribution, $n(\mathbf{r}) = n_0 e^{-U(\mathbf{r})/k_BT}$. *Normalization gives,*

$$N = \int n(\mathbf{r})d^3r = n_0 \iiint_{-\infty}^{\infty} e^{(-m\omega_r^2r^2 - m\omega_z^2z^2)/2k_BT}dxdydz = n_0\sqrt{\left(\frac{2\pi k_BT}{m}\right)^3\frac{1}{\omega_r^4\omega_z^2}}\,.$$

Or $n_0 = N\sqrt{\left(\frac{m}{2\pi k_BT}\right)^3\omega_r^4\omega_z^2}$. *This yields,* $n_0 = 4.8\cdot 10^{11}\,\mathrm{cm}^{-3}$.
d. The optical density is now,

$$b = 3\frac{\lambda^2}{2\pi}\int_{-\infty}^{\infty} n(\mathbf{r})dz = 3\frac{\lambda^2}{2\pi}n_0\int_{-\infty}^{\infty} e^{-m\omega_z^2z^2/2k_BT}dz = 3\frac{\lambda^2}{2\pi}n_0\sqrt{\frac{2\pi k_BT}{m\omega_z^2}}\,.$$

This gives $b = 44.8$.

43.6.6.3 Ex: Inverse Abel transformation

Calculate the inverse Abel transform using Bessel of an arbitrary function in 2D.

Solution: *MW_AbelTrafo1: Inverse Abel transform using Bessel of a real Fermi sphere. MW_AbelTrafo2: Inverse Abel transform using Bessel of an arbitrary function in 2D. MW_AbelTrafo3: Inverse Abel transform . MW_AbelTrafo4: Forward Abel transform, comparison with column integration and analytical formula. MW_AbelTrafo5: Forward Abel transform, comparison with column integration and analytical formula in 2D.*

Chapter 44

Thermodynamics of ideal quantum gases

The journey of the quest for Bose-Einstein condensation (BEC) begins with its prediction by Bose and Einstein in 1926. The first hint, that the condensation was more than just a theoretical fantasy came from London [812], who linked the newly discovered phenomenon of superfluidity in ^{4}He to BEC. However, the interpretation of the λ-point in terms of BEC was not obvious, because strong interactions between particles concealed the role of quantum statistics, and the thermodynamic potentials exhibited divergences at the critical temperature instead of discontinuities, as expected for an ideal gas BEC. These uncertainties triggered an intense search for other systems. In 1954, Schafroth pointed out that electron pairs can be seen as composite bosons and may form Bose-Einstein condensates at low temperatures [1149]. In 1957, Bardeen, Cooper and Schrieffer developed the microscopic theory of superconductivity [93], after other researchers, including Blutt, Schaffrot, Fröhlich and Bogolubov, had suggested a relationship of this phenomenon to Bose condensation of electron pairs (nowadays called Cooper pairs).

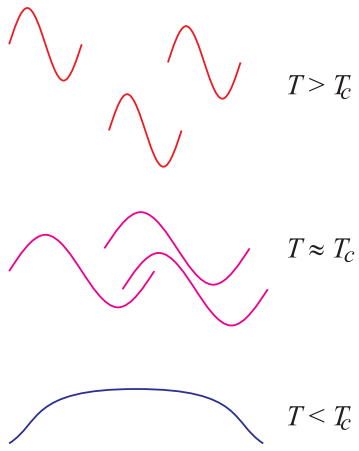

Figure 44.1: Illustration of atomic Broglie waves. From the top to the bottom the temperature of the atoms is decreasing.

Motivated by the need to test the concept of condensation of composite particles

in weakly interacting systems, in 1962 *Blatt et al.* proposed the investigation of the BEC in gases of *excitons* [149]. Excitons are bound electron-hole pairs that can form a weakly interacting gas in certain non-metallic crystals. They are interesting because their small mass allows BEC at high temperatures and gas density can be controlled over a wide range, by only modifying the intensity of the optical excitation. Being *quasi-particles*, excitons can be created and annihilated, that is their number is not conserved. Excitons were discovered in 1968, and the first evidence for Bose-Einstein of biexciton molecules in a CuCl crystal dates back to 1979 [248].

The laser as coherence phenomenon between photons shares many analogies with condensates. However, photons are quasi-particles as well, and again their number is not conserved [1]. Hence, there is no phase transition: When an optical cavity containing photonic modes is cooled, the photons prefer to disappear in the walls of the cavity instead of condensing.

Hecht [592] suggested in 1959, followed by Stwalley and Nosanow [1275] in 1976, that an atomic hydrogen gas with polarized spins would be an appropriate candidate for BEC. The advantage of this system is that interactions between atoms are weak and only give rise to a negligible quantum depletion below 1%. In 1978 Greytak and Kleppner started at the MIT intensive efforts to generate BECs in dilute hydrogen gases. In the 1990s, important advances in the cooling of atoms using laser light allowed to reach very low temperatures, and the invention of the magneto-optical trap (MOT) for neutral atoms permitted their spatial confinement and the compression of their density. These successes boosted efforts to try to create BEC in alkaline gases, which have electronic level schemes that lend themselves to optical cooling. Later, it was discovered that the phase space density in MOTs is limited by radiation trapping effects. As a solution to this problem, scientists had to learn how to trap atoms without the use of light in conservative traps, e.g. by their magnetic dipole moment, and to replace optical cooling with *evaporative cooling*. This was the crucial step that finally permitted to reach BEC in alkaline gases in 1995. Later, the hydrogen experiment, which initially stimulated the alkaline experiments, now taking advantage of their success, has been taken to BEC as well [466].

Why did it take so long to reach Bose-Einstein condensation, seven decades after its prediction by Bose and Einstein? How can we *see* when we have a condensate? What are the characteristics of a BEC accessible to observation and how to measure them? These are the answers that we will answer in the following sections. Solve

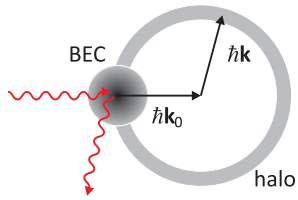

Figure 44.2: Scheme of the Broglie wave of cold atoms. From top to bottom the temperature decreases.

Exc. 44.1.5.1.

[1] The chemical potential of photons is $\mu = 0$.

44.1 Quantum statistics of an ideal Bose gas

The canonical approach to statistical mechanics begins with the probabilistic analysis of Boltzmann's velocity distribution of an ideal gas. For a gas consisting of particles of mass m at temperature T, the velocity distribution is given by the well-known *Maxwell-Boltzmann law* (MB) [641]

$$g(\mathbf{v}) = \left(\sqrt{\frac{m}{2\pi k_B T}}\right)^3 e^{-m\mathbf{v}^2/2k_B T} \ , \tag{44.1}$$

where k_B is the Boltzmann constant. Maxwell-Boltzmann's law was experimentally proven by Otto Stern in 1920, using a primitive atomic beam and a simple time-of-flight technique based on a rotating drum for selecting atomic velocities. With the advent of laser spectroscopy, the MB law and its limitations can be tested with highly improved accuracy. This law describes well the behavior of weakly interacting hot atoms. Deviations from this law are insignificant until, at low temperatures, quantum effects come into play. For this to happen the temperature must be so low that the atomic Broglie wavelengths become comparable to the average distance between particles. For a gas in thermal equilibrium the characteristic wavelength, called *thermal de Broglie wavelength*, is,

$$\boxed{\lambda_{therm} = \sqrt{\frac{2\pi\hbar^2}{mk_B T}}} \ , \tag{44.2}$$

where $\hbar = h/2\pi$ is Planck's constant. In a gas of density n, the mean distance between particles is $n^{-1/3}$. So, quantum effects are expected to emerge when $n^{-1/3} \sim \lambda_{dB}(T)$, such that the limit for this regime is defined by,

$$k_B T(n) = \frac{2\pi\hbar^2}{m} n^{2/3} \ . \tag{44.3}$$

For example, an atomic gas with density $n \sim 10^{16}\,\text{cm}^{-3}$ and temperature 900 K is certainly in the classical regime, since $n^{-1/3} \sim 10^6\,\text{cm} \gg \lambda_{dB} = 10^{-9}\,\text{cm}$. To observe quantum effects, we need relatively dense and cold clouds of atoms. In most gases, lowering the temperature or increasing the density promotes the system to liquidity before the quantum regime is reached. Well-known exceptions are spin-polarized hydrogen (H↑), which does not become liquid and helium, which exhibits quantum degeneracy effects in the liquid phase, although these effects are quite complex due to strong interparticle forces.

We have already seen that all particles in the quantum world are either *bosons* with integer spin or *fermions* with semi-integer spin. Fermions do not share a quantum state, because they must follow the *Pauli's exclusion principle*. They obey a quantum statistical distribution called *Fermi-Dirac distribution* (FD). In contrast, bosons enjoy to share a quantum state and even encourage other bosons to join them in a process called *bosonic stimulation*. Bosons obey a quantum statistical distribution called *Bose-Einstein distribution* (BE). The basic difference between the MB-statistics on one hand and the BE- or FD-quantum statistics on the other is that the former applies to identical particles which, however, are distinguishable from each other, while the

second describes identical indistinguishable particles. For the BE/FD statistics one can derive [726] the occupancy number for a non-degenerate quantum state having the energy ε when the system is kept at temperature T,

$$\boxed{w_{T,\mu} = \frac{1}{(2\pi)^3} \frac{1}{e^{\beta(\varepsilon-\mu)} \mp 1}} \,, \tag{44.4}$$

where we used the abbreviation $\beta \equiv 1/k_B T$. The upper sign refers to the BE statistics, the lower sign to the FD statistics. The chemical potential μ is an important system parameter, which helps to normalize the distribution (44.4) to the total number of particles,

$$N = \sum_{\varepsilon} w_{T,\mu}(\varepsilon) \,. \tag{44.5}$$

Similarly, the total energy of the system is given by,

$$E = \sum_{\varepsilon} \varepsilon w_{T,\mu}(\varepsilon) \,. \tag{44.6}$$

A very remarkable effect occurs in a bosonic gas at a certain characteristic *critical temperature* T_c: below this temperature a substantial fraction of the total number of particles occupies the lowest energy state, while all other states are occupied by a negligible number of particles. Above the transition temperature the macroscopic observables of the gas, such as pressure, heat capacity, etc., receive contributions of all states with a certain statistical weight, but without favoring the state of lower energy. Below the transition temperature, the observables are altered by a macroscopic occupation of the ground state, which results in dramatic changes of the thermodynamic properties. The phase transition is named after Shandrasekar Bose [181] and Albert Einstein [410] *Bose-Einstein condensation* (BEC).

44.1.1 Condensation of a free gas confined in a box potential

One of the keys to understanding BEC is the behavior of the chemical potential μ at very low temperatures. The chemical potential is responsible for the concentration of a large number of atoms in the ground state N_0. A system with a large number of non-interacting bosons condenses to the ground state when the temperature approaches zero, $N_0 \to N$. The Bose-Einstein distribution function (44.4) gives the population of the ground state, $\varepsilon = 0$, in the zero temperature limit, $N = \lim_{T\to 0}(e^{-\beta\mu} - 1)^{-1} = -1/\beta\mu$, or in terms of the *fugacity* defined by,

$$\boxed{Z \equiv e^{\beta\mu}} \,, \tag{44.7}$$

we may write, $Z \simeq 1 - 1/N$. It should be noted that the chemical potential in a bosonic system must always be less than the ground state energy in order to guarantee non-negative occupation $w_{T,\mu}(\varepsilon)$ of any state. $Z \simeq 1$ denotes macroscopic occupation of the ground state. We define the critical temperature for Bose-Einstein condensation via the occupation of the ground state. Above this temperature the occupancy of ground state is not macroscopic, below it is.

For a Bose gas of N non-interacting particles with mass m confined inside a box potential of volume $V = L^3$ the critical temperature for BEC can be calculated from equation (44.3). The boundary conditions require that the momenta satisfy $p_j = 2\pi\hbar l_j/L$, where $j = x, y$ or z and j are integers. Each state is labeled by a set of three integers (l_x, l_y, l_z). In the *thermodynamic limit*, the sum over all quantum states can be converted into an integral over a continuum of states,

$$\sum_{\mathbf{r},\mathbf{k}} \overset{N\to\infty}{\longrightarrow} \frac{1}{\hbar^3}\int d^3r d^3p = \int d^3r d^3k \ . \tag{44.8}$$

For a free gas with energy $\varepsilon = p^2/2m$ we can derive, simplifying the calculation using the *density of states* η defined by (43.19), which basically depends on the geometry of our system [2]. Using the occupation number $w_{T,\mu}(\varepsilon)$ for the Bose-Einstein distribution (44.4) in the thermodynamic limit and the density-of-states in a box potential (43.22), let us calculate the total number of particles,

$$\begin{aligned} N &= N_0 + \iint w_{T,\mu}(\varepsilon(\mathbf{r},\mathbf{k}))d^3r d^3k = N_0 + (2\pi)^3\int_0^\infty w_{T,\mu}(\varepsilon)\eta(\varepsilon)d\varepsilon \\ &= N_0 + \frac{\sqrt{2m}^3}{(2\pi)^2\hbar^3}V\int_0^\infty \frac{\varepsilon^{1/2}d\varepsilon}{e^{\beta(\varepsilon-\mu)}-1} \ , \end{aligned} \tag{44.9}$$

where the ground state population N_0 is maintained explicitly. In the process of converting the sum to an integral (44.8) the density of states disappears when we approach the ground state. This error is corrected by adding a contribution of an explicit term N_0 to the integral.

44.1.1.1 Riemann's zeta function

At this point, to help simplifying the notation, we introduce the *Bose function* and its integral representation,

$$g_\xi(Z) = \sum_{t=1}^\infty \frac{Z^t}{t^\xi} = \frac{1}{\Gamma(\xi)}\int_0^\infty \frac{x^{\xi-1}dx}{Z^{-1}e^x - 1} \ . \tag{44.10}$$

where $\Gamma(\eta)$ denotes the Gamma function. Analogically, we can define the *Fermi function* via,

$$f_\xi(Z) = \sum_{t=1}^\infty -\frac{(-Z)^t}{t^\xi} = \frac{1}{\Gamma(\xi)}\int_0^\infty \frac{x^{\xi-1}dx}{Z^{-1}e^x + 1} \ . \tag{44.11}$$

For classical particles,

$$c_\xi(Z) = \frac{1}{\Gamma(\xi)}\int_0^\infty \frac{x^{\xi-1}dx}{Z^{-1}e^x + 0} = Z \ . \tag{44.12}$$

A particular value is the *Riemann zeta-function*,

$$g_\xi(1) = \zeta(\xi) \ . \tag{44.13}$$

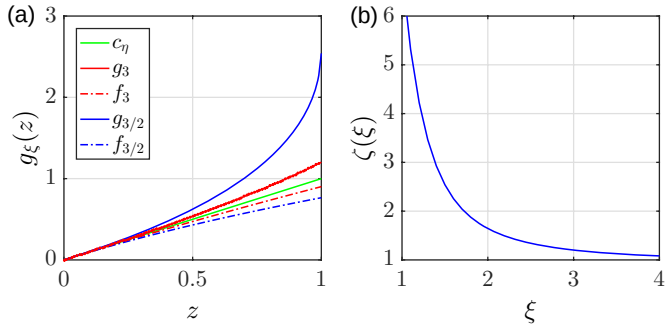

Figure 44.3: (code) (a) Bose and Fermi functions for box potentials (g_3 and f_3) and for harmonic potentials ($g_{3/2}$ and $f_{3/2}$). Also shown is the Boltzmann limit (44.12). (b) Riemann function.

With this definition and the definition of the thermal Broglie wavelength (44.2), Eq. (44.9) becomes,

$$N = N_0 + \frac{V}{\lambda_{th}^3(T)} g_{3/2}(e^{\beta\mu}) \ . \tag{44.14}$$

We can use Eq. (44.14) to calculate the critical temperature[3] $T_c^{(3/2)}$ defined for $N_0 \nearrow 0$ and $\mu \to 0$. Above the phase transition, $T > T_c^{(3/2)}$, the population is distributed over all states, each individual state being weakly populated. Below $T_c^{(3/2)}$ the chemical potential is fixed by $\mu = 0$ and the number of the particles occupying the excited states is,

$$N_{th} = \frac{V}{\lambda_{th}^3(T)} g_{3/2}(1) = N \left(\frac{T}{T_c^{(3/2)}} \right)^{3/2} \ , \tag{44.15}$$

with $g_{3/2}(1) = 2.612$. Since $N_0 + N_{th} = N$, the number of particles in the ground state is given by,

$$\boxed{\frac{N_0}{N} = 1 - \left(\frac{\min(T, T_c^{(3/2)})}{T_c^{(3/2)}} \right)^{3/2} \qquad \text{with} \qquad k_B T_c^{(3/2)} = \frac{2\pi\hbar^2}{m} \left(\frac{N}{V g_{3/2}(1)} \right)^{2/3}} \ , \tag{44.16}$$

N_0/N is the fraction of the atomic cloud which is condensed in the ground state. The abrupt occurrence of a finite occupation in a single quantum state at temperature below $T_c^{(3/2)}$ indicates a spontaneous change in the system and a thermodynamic phase transition. Solve Exc. 44.1.5.2.

[2]We must, however, keep in mind that the state density approach is an approximation not valid for experiments with a limited number of atoms.

[3]The superscript (3/2) denotes the box potential shape of the trapping potential. See 44.1.5.3 for an explanation of the notation.

44.1.2 Condensation of a harmonically confined gas

The critical temperature T_c^0 can be significantly altered, when the atoms are confined to a spatially inhomogeneous potential. The critical temperature depends on the general shape and the tightness of the potential. Let us consider N particles of an ideal Bose gas distributed over several quantum states of an arbitrary potential. The occupation number $w_{T,\mu}(\varepsilon)$ of particles at an energy level ε is still given by (44.4), the ground state energy is defined as zero. In the thermodynamic limit, the relation between the chemical potential and the total number of particles is still given by Eq. (44.9), with an adequate density of states $\eta(\varepsilon)$. The state density for an arbitrary confinement potential $U(\mathbf{r})$ can be found by generalizing the calculation to the free gas. The phase space volume between the energy surfaces ε and $\varepsilon + d\varepsilon$ is proportional to the number of states in this energy range. However, the external potential limits the space available for the gas. For a harmonic potential (43.18) with the mean secular frequency $\bar{\omega}$ the density-of-states $\eta(\varepsilon)$ has already been calculated in Eq. (43.21). With this, we can analogically to (44.9) calculate,

$$N = N_0 + \iint w_{T,\mu}(\varepsilon(\mathbf{r},\mathbf{k}))d^3r d^3k = N_0 + (2\pi)^3 \int_0^\infty w_{T,\mu}(\varepsilon)\eta(\varepsilon)d\varepsilon \tag{44.17}$$
$$= N_0 + \frac{1}{2(\hbar\bar{\omega})^3}\int_0^\infty \frac{\varepsilon^2 d\varepsilon}{e^{\beta(\varepsilon-\mu)}-1} = N_0 + \left(\frac{k_B T}{\hbar\bar{\omega}}\right)^3 g_3(Z)\ .$$

In the same way as for a potential well we find for a harmonic potential,

$$N_{th} = \left(\frac{k_B T}{\hbar\bar{\omega}}\right)^3 g_3(1) = N\left(\frac{T}{T_c^{(3)}}\right)^3\ , \tag{44.18}$$

with $g_3(1) = 1.202$. Since $N_0 + N_{th} = N$, the number of particles in the ground state is,

$$\boxed{\frac{N_0}{N} = 1 - \left(\frac{\min(T, T_c^{(3)})}{T_c^{(3)}}\right)^3 \qquad \text{with} \qquad k_B T_c^{(3)} = \hbar\bar{\omega}\left(\frac{N}{g_3(1)}\right)^{1/3}}\ . \tag{44.19}$$

The superscript (3) indicates the harmonic shape of the trap.

Fig. 44.4(left) traces the condensed fraction N_c/N measured as a function of the reduced temperature $T/T_c^{(3)}$. Experiments [580, 417] confirm Bose's ideal gas theory in the thermodynamic limit.

We note that smaller trapping volumes (or tighter potentials) increase the critical temperature T_c, thus allowing for quantum degeneracy at higher temperatures, which can be advantageous in experimentation. Also, at a given temperature, a strongly confining potential reduces the total minimum number of atoms required to reach condensation.

44.1.3 Energy and heat capacity

When the number of atoms is limited, $N < \infty$, we expect a slightly reduced critical temperature [551]. In addition, the interatomic interaction reduces the critical temperature [72]. The technical resolution of most experiments today is not sufficient to

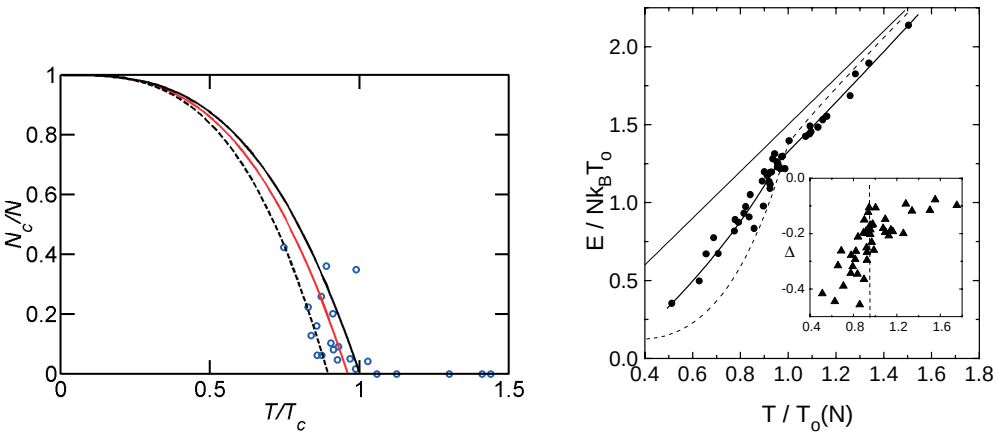

Figure 44.4: Left: Condensed fraction N_c/N as a function of reduced temperature $T/T_c^{(3)}$. The circles represent measured values. The upper solid line shows the theory for an ideal gas, the intermediate solid line shows a curve fitted to the measurements, and the lower part is a theoretical curve taking into account finite size effects and interatomic interactions. Right: Measurement of the release energy [417].

permit the study of these effects. However, measurements of other thermodynamic quantities such as energy and heat capacity [347, 417] showed significant deviations from the ideal gas behavior due to interaction effects. Therefore, although temperature being the most basic variable of the thermodynamic state, the system needs to be characterized by other quantities.

Heat is not a state variable because the amount of heat needed to raise the temperature of the system depends on how the heat is transferred. The *heat capacity* quantifies the system's ability to secure its energy. In conventional systems, the heat capacity is typically given either specified at constant volume or at constant pressure. Together with this specification, heat capacities are extensive state variables. When crossing a phase transition, the temperature-dependent heat capacity measures the degree of change in the system above and below the critical temperature and provides valuable information about the general type of phase transition.

The total energy $E/N \equiv N^{-1} \int \epsilon w d^3x d^3k$ per particle is given by,

$$\frac{E}{N} = \frac{\int \epsilon w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3x d^3k}{\int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3x d^3k} = \frac{\int \epsilon \eta(\epsilon)(e^{\beta(\epsilon-\mu)}-1)^{-1} d\varepsilon}{\int \eta(\epsilon)(e^{\beta(\epsilon-\mu)}-1)^{-1} d\varepsilon} = 3k_B T \frac{g_4(Z)}{g_3(Z)} \ . \qquad (44.20)$$

For a confined gas, volume and temperature are interdependent, and the concept of pressure is somewhat vague. In this case, we can not refer to the heat capacity at constant volume or pressure. However, one can define the heat capacity for a fixed number of particles,

$$C(T) = \frac{\partial E(T)}{\partial T} \ . \qquad (44.21)$$

Recalling the implicit dependencies of the thermodynamic variables on temperature,

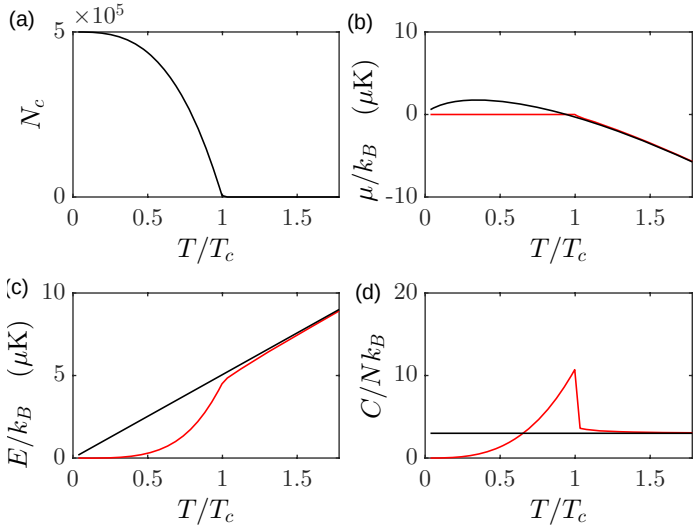

Figure 44.5: (code) Numerical calculation of thermodynamic potentials for a Bose gas as a function of temperature for a given trapping potential. (a) Chemical potential, (b) energy, (c) heat capacity per particle, and (d) total heat capacity.

we can evaluate (44.19):

$$C(T) = \beta \int_0^\infty \varepsilon f(\varepsilon)^2 \rho(\varepsilon) \left[\mu'(T) + \frac{\varepsilon - \mu}{T}\right] e^{\beta(\varepsilon-\mu)} d\varepsilon \ , \tag{44.22}$$

where the derivative of the chemical potential approaching the phase transition from above, $T \searrow T_c^0$, is

$$\mu'(T_c^+) = -\frac{1}{T} \frac{\int_0^\infty \varepsilon f(\varepsilon)^2 \rho(\varepsilon) e^{\beta\varepsilon} d\varepsilon}{\int_0^\infty f(\varepsilon)^2 \rho(\varepsilon) e^{\beta\varepsilon} d\varepsilon} \ . \tag{44.23}$$

Calculating the second moments of the distributions obtained for the same density by time-of-flight of absorption images, we obtain the kinetic energy,

$$U = \int \frac{p^2}{2m} n(\mathbf{p}) d^3\mathbf{p} \ . \tag{44.24}$$

For confined ideal gases, the virial theorem ensures $E_{kin} + E_{pot} = 2E_{kin}$. For real gases, the repulsive energy of the mean field adds to this energy, $E = E_{kin} + E_{pot} + E_{self}$. The sudden extinction of the trapping potential before time-of-flight takes away the potential energy E_{pot} non-adiabatically. The kinetic energy and the self-energy of the condensate are fully converted into kinetic energy during ballistic expansion. It is this energy, $p^2/2m = E_{kin} + E_{self}$, which is sometimes called *release energy*, which is measured after ballistic expansion [4]. Fig. 44.4(right) shows a measurement of the release energy. Solve the Exc. 44.1.5.3.

[4] It is interesting to measure the heat capacity of a partially condensed cloud near the critical point and analyze the discontinuity, because it contains important information about interatomic interactions and finite-size effects ([297], Seç. 3.4). In addition, the classification of Bose-Einstein condensation as a phase transition depends very much on the behavior of the thermodynamic potential near the critical point [772, 641].

44.1.4 Distribution functions for a Bose gas

Bose-Einstein condensates consist of atoms sharing a single quantum state. In inhomogeneous potentials, the condensate and the thermal fraction form spatially separated clouds, concentrated around the center of the potential and therefore very dense. For this reason, interatomic interaction effects generally dominate the density and momentum distribution of the condensed fraction. However, the non-condensed (or normal, or thermal) fraction is also subject to modifications due to the bosonic nature of the atoms. Since the density of the normal fraction is generally much smaller, these modifications are weak. In this section, we will only discuss these effects briefly, but we note that the calculations are analogous to the calculations for fermionic gases presented in Sec. 44.2.4.

For an ideal Bose gas the density and momentum distributions are expressed by Bose functions $g_{3/2}(z)$ [297]. For example, as will be derived in Exc. 44.1.5.4(a), the density and momentum distributions are,

$$\boxed{\begin{aligned} n(\mathbf{x}) &= \frac{1}{\lambda_{dB}^3}\, g_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) \\ n(\mathbf{k}) &= \frac{a_{trap}^6}{\lambda_{dB}^3}\, g_{3/2}(e^{\beta(\mu-\mathbf{p}^2/2m)}) \end{aligned}} \quad \text{bosonic distribution functions .} \tag{44.25}$$

In the classical limit, we can calibrate the chemical potential by Eq. (44.14) for a box potential or by (44.17) for a harmonic potential,

$$g_{3/2}(e^{\beta\mu}) \to c_{3/2}(e^{\beta\mu}) = e^{\beta\mu} = \begin{cases} \frac{N}{V}\lambda_{th}^3 & \text{for a box potential} \\ c_3(e^{\beta\mu}) = N\left(\frac{\hbar\bar{\omega}}{k_BT}\right)^3 & \text{for a harmonic potential} \end{cases} . \tag{44.26}$$

Hence, we obtain for the classical density distribution,

$$\begin{aligned} n(\mathbf{x}) &= \frac{1}{\lambda_{th}^3} c_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) = \frac{e^{\beta\mu}}{\lambda_{th}^3} e^{-\beta U(\mathbf{x})} \qquad (44.27) \\ &= \begin{cases} \frac{N}{V} e^{-\beta U(\mathbf{x})} & \text{for a box potential} \\ N\sqrt{\frac{m\bar{\omega}^2}{2\pi k_BT}}^3 e^{-\beta m\bar{\omega}^2 x^2/2} & \text{for a harmonic potential} \end{cases} . \end{aligned}$$

Similarly, the momentum density distribution is given by,

$$\begin{aligned} n(\mathbf{k}) &= \frac{a_{trp}^6}{\lambda_{th}^3} c_{3/2}(e^{\beta(\mu-p^2/2m)}) = \frac{a_{trp}^6 e^{\beta\mu}}{\lambda_{th}^3} e^{-\beta p^2/2m} \qquad (44.28) \\ &= \begin{cases} \frac{N}{V} a_{trp}^6 e^{-\beta U(\mathbf{x})} & \text{for a box potential} \\ N\hbar^3\sqrt{\frac{1}{2\pi m k_BT}}^3 e^{-\beta p^2/2m} & \text{for a harmonic potential} \end{cases} . \end{aligned}$$

We see that we recover the Maxwell-Boltzmann velocity distribution, as seen in Fig. 44.6,

$$n(\mathbf{v}) = n(\mathbf{k})\frac{m^3}{\hbar^3} = N\sqrt{\frac{m}{2\pi k_BT}}^3 e^{-\beta m v^2/2} . \tag{44.29}$$

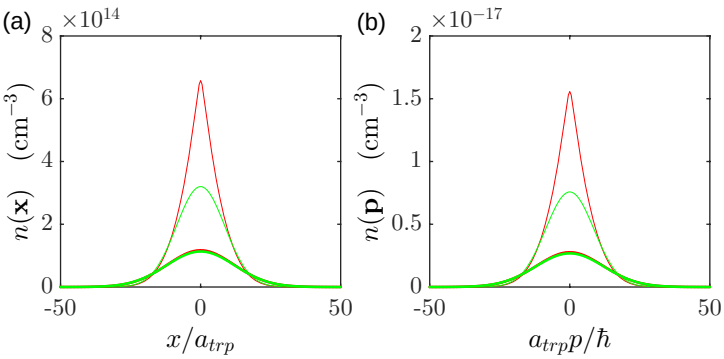

Figure 44.6: (code) (a) Density and (b) momentum distribution of a Bose gas (red) and a Boltzmann gas (green) at $T = 1.1T_c$ (solid line) and at $T = 2T_c$ (dotted line).

44.1.4.1 Ballistic expansion

To describe the density distribution of an ultracold Bose-gas after a time-of-flight we replace in the second Eq. (44.25): $\mathbf{k} = m\mathbf{r}/\hbar t_{tof}$. We obtain the density distribution,

$$n_{tof}(\mathbf{r}, t_{tof}) = \left(\frac{m}{\hbar t_{tof}}\right)^3 n(\mathbf{k} = m\mathbf{r}/\hbar t_{tof}) = \left(\frac{m}{\hbar t_{tof}}\right)^3 \frac{a_{trp}^6}{\lambda_{th}^3} g_{3/2}(e^{(\mu - mr^2/2t_{tof}^2)/k_BT})$$
$$\overset{T\to\infty}{\longrightarrow} \left(\frac{m}{\hbar t_{tof}}\right)^3 N\hbar^3 \sqrt{\frac{1}{2\pi m k_B T}}^3 e^{-mr^2/2t_{tof}^2 k_B T} = \frac{N}{(2\pi)^{3/2} r_{rms}^3} e^{-r^2/2r_{rms}^2} , \quad (44.30)$$

where we defined,

$$r_{rms} \equiv \sqrt{\frac{k_B T}{m}} t_{tof} . \quad (44.31)$$

This distribution does not directly depend on the potential $U(\mathbf{r})$, that is, the expansion is isotropic. However, the chemical potential does depend on the potential. For very long flight times (usually several 10 ms) the density resembles a Gaussian distribution [297]. In Exc. 44.1.5.4(b) we determine the time-of-flight density distribution of an ultracold Bose gas.

In a time-of-flight experiment, any deviation observed between the results (44.30) and (44.31) points towards an impact of quantum statistics. However, absorption images only record projections of the time-of-flight distribution on a plane.

44.1.4.2 Temperature and excitations

The *temperature of a Bose condensate* is given by the ratio of the numbers of condensed and thermal atoms. What about collective excitations in pure condensate? Can they be cooled? In fact, an oscillating BEC is not in thermal equilibrium. However, in the presence of some dissipation mechanism the excitations may thermalize evolving towards a steady state. Once the collective excitations have become thermal excitations, they simply increase the thermal fraction.

44.1.5 Exercises

44.1.5.1 Ex: Boson or fermion?

Whether an atom is a fermion or boson solely depends on its total spin. Half-integer spin particles are fermions, integer spin particles are bosons. For example, Rb atoms have in the ground state $J = 1/2, I = 7/2$ and F integer, and therefore are bosons. Ca^+ ions have $J = 1/2$ and no hyperfine structure, and thus are fermions. ^{6}Li has the half-integer F and is a boson.
Decide on the bosonic or fermionic nature of the following atoms/molecules:
^{85}Rb with $I = 3/2$ in the state $^2S_{1/2}$
^{88}Sr with $I = 0$ in the state $^1S_0$
^{88}Sr with $I = 0$ in the state $^3P_2$
^{87}Sr with $I = 9/2$ in the state $^1S_0$
$^{172}Yb^+$ with $I = 0$ in the state $^2S_{1/2}$
$^{171}Yb^+$ with $I = 1/2$ in the state $^2S_{1/2}$

Solution: *^{85}Rb in the state $^2S_{1/2}$ has the total spin $F = 1$ or $F = 2$ and is a boson*
^{88}Sr in the state $^1S_0$ has the total spin $F = 0$ and is a boson
^{88}Sr in the state $^3P_2$ has the total spin $F = 2$ and is a boson
^{87}Sr in the state $^1S_0$ has the total spin $F = 9/2$ and is a fermion
$^{172}Yb^+$ in the state $^2S_{1/2}$ has the total spin $F = 0$ and is a boson
$^{171}Yb^+$ in the state $^2S_{1/2}$ has the total spin $F = 0$ or $F = 1$ and is a boson

44.1.5.2 Ex: Monoatomic gas

Consider a classical monoatomic gas made up of N non-interacting atoms of mass m confined in a container of volume V, at temperature T. The Hamiltonian corresponding to an atom is given by $\hat{H} = (p_x^2 + p_y^2 + p_z^2)/2m$.
a. Show that the atomic canonical partition function is $\zeta = V/\lambda^3$, where $\lambda = h/\sqrt{2\pi m k_B T}$ is the thermal de Broglie wavelength.
b. Using ζ of the previous item, obtain the system's partition function Z and the Helmholtz free energy F. Also obtain the free energy per atom $f = F/N$ in the thermodynamic limit $N \longrightarrow \infty$, $V \longrightarrow \infty$, $v = N/V$ fixed.
c. Obtain internal energy U and the gas pressure p.
d. Calculate the chemical potential and entropy per atom in the thermodynamic limit.

Solution: *a. Be $\beta = 1/k_B T$. The atomic canonical partition function is,*

$$\zeta = \frac{1}{h^3}\int e^{-\beta H} dp_x dp_y dp_z dx dy dz = \frac{1}{h^3}\int e^{-\beta(p_x^2+p_y^2+p_z^2)/2m} dp_x dp_y dp_z dx dy dz$$
$$= \frac{V}{h^3}\left(\frac{2\pi m}{\beta}\right)^{3/2} = V\left(\frac{2\pi m k_B T}{h^2}\right)^{3/2} = \frac{V}{\lambda^3}\ .$$

b. For a sample of N atoms we have $Z = \frac{\zeta^N}{N!} = \frac{V^N}{N!\lambda^{3N}}$. With this,

$$F = -k_B T \ln Z = -k_B T \left(N \ln \frac{V}{\lambda^3} - N! \right) \ .$$

Using the Stirling formula,

$$F = -k_B T \left(N \ln \frac{V}{\lambda^3} - N \ln N + N \right) = -k_B T N \left(\ln \frac{V}{N\lambda^3} + 1 \right) \ ,$$

and

$$f = -k_B T \left(\ln \frac{v}{\lambda^3} + 1 \right) \ .$$

c. The internal energy is,

$$U = -\frac{\partial}{\partial \beta} \ln Z = -N \frac{\partial}{\partial \beta} \ln \zeta = \frac{3N}{2\beta} = \frac{3N}{2} k_B T \ .$$

The pressure is,

$$p = -\frac{\partial F}{\partial V} = k_B T \frac{\partial}{\partial V} \ln Z = k_B T \frac{N}{V} \ .$$

d. The chemical potential is,

$$\mu = \frac{\partial F}{\partial N} = -k_B T \left(\ln \frac{V}{\lambda^3} - \ln N \right) = -k_B T \ln \frac{v}{\lambda^3} \ .$$

The entropy is

$$s = \frac{\partial f}{\partial T} \ ,$$

or, using $f = u - Ts$, $u = U/N$,

$$s = \frac{u - f}{T} = k_B T \left(\ln \frac{v}{\lambda^3} + \frac{5}{2} \right) \ ,$$

which is the Sackur-Tetrode formula.

44.1.5.3 Ex: Generalization for arbitrary potentials in reduced dimensions

The calculation of the thermodynamic potentials can be generalized to arbitrary trapping potentials and dimensions [181, 410, 338, 73, 1405, 457, 74, 551, 615, 722, 711, 945, 772, 812, 417]. To do so, we consider a generic power law potential confining an ideal Bose gas in α dimensions,

$$U(\mathbf{r}) = \sum\nolimits_{i=1}^{\alpha} \left| \frac{x_i}{a_i} \right|^{t_i} \ ,$$

and define a parameter describing the confinement power of the potential,

$$\xi = \frac{\alpha}{2} + \sum\nolimits_{i=1}^{\alpha} \frac{1}{t_i} \ .$$

For example, for a three-dimensional potential, $\alpha = 3$. Now, for a 3D harmonic potential, $\xi = 3$, and for 3D box potential, $\xi = 3/2$.
a. Calculate the density of states η using the equation (43.19) employing Bose functions (44.10).
b. Prove the following expressions:

bosonic potentials

$$\begin{array}{rcl}
\frac{N_0}{N} & = & 1 - \left(\frac{\min(T,T_c)}{T_c}\right)^{\xi} \\
\frac{E}{Nk_BT} & = & \xi \frac{g_{\xi+1}(Z)}{g_\xi(Z)} \left(\frac{\min(T,T_c)}{T_c}\right)^{\xi} \\
\frac{S}{Nk_B} & = & 4\frac{g_{\xi+1}(Z)}{g_\xi(Z)} - \frac{2\mu}{k_BT} \\
\frac{C}{Nk_B} & = & \xi(\xi+1)\frac{g_{\xi+1}(Z)}{g_\xi(Z)} \left(\frac{\min(T,T_c)}{T_c}\right)^{\xi} - \xi^2 \frac{g_\xi(Z)}{g_{\eta-1}(Z)} \frac{\max(T-T_c,0)}{T-T_c} \\
\frac{C_{T>T_c}}{Nk_B} & = & \xi(\xi+1)\frac{g_{\xi+1}(Z)}{g_\xi(Z)} - \xi^2 \frac{g_\xi(Z)}{g_{\xi-1}(Z)} \quad , \quad \frac{C_{T<T_c}}{Nk_B} = \xi(\eta+1)\frac{g_{\xi+1}(1)}{g_\xi(1)} \\
\frac{\Delta C_{T_c}}{Nk_B} & = & \frac{C_{T_c^-} - C_{T_c^+}}{Nk_B} = \xi^2 \frac{g_\xi(1)}{g_{\xi-1}(1)}
\end{array} .$$

Solution: *a. The calculations are analogous to those performed for homogeneous Bose-gases, and we restrict ourselves here to give the general results for the thermodynamic quantities [72, 1405], e.g. the internal energy E and the heat capacity C. The expression for the critical temperature for N confined particles in a generic power law potential in α dimensions is,*

$$T_c^0 = k_B^{-1} \left[\frac{h^\alpha}{(2\pi m)^{\alpha/2}} \frac{N}{2^\alpha} \frac{1}{g_\eta(1) \prod_{i=1}^{\alpha} a_i \Gamma(t_i^{-1}+1)} \right]^{1/\eta} .$$

To evaluate the temperature dependence of the thermodynamic variables, we can calculate the fugacity $Z(T) = e^{\beta\mu}$ from the second of the above equations to E/Nk_BT [641]. For $T > T_c$ we derive fugacity as the root of $g_\eta(Z) = g_\eta(1)(T_c/T)^\eta$ and for $T < T_c$ the fugacity is simply $Z = 1$.
b. It is especially interesting to compare the discontinuity of the heat capacity and its a derivative $\partial C(T)/\partial T$ for several power law potentials and confinement dimensions, since this may clarify the nature of the phase transition. The thermodynamic quantities take a particularly simple form for power law potentials.
It is also interesting to note that the jump in the heat capacity at the phase transition is higher for any power law potential than for a potential well. This is due to the fact that the increase of the gas' energy requires work against the confinement potential. Steeper potentials (i.e., smaller coefficients t_i) give higher values for T_c^0. The critical temperature also depends on the confinement power of the potential,

$$\eta = -\frac{T_c^0}{N} \left(\frac{dN_0}{dT}\right)_{T=T_c^0} .$$

44.1.5.4 Ex: Time-of-flight distribution of a Bose-gas

a. Derive the formulae (44.25) describing the density and momentum distribution of an ultracold Bose-gas.
b. Calculate the time-of-flight distribution of a Bose-gas as a function of temperature (i) analytically for a harmonic potential and (ii) numerically for an arbitrary potential.

Solution: *a. To start with, we need to know the trap's geometry $V(\mathbf{r})$. Let us first assume a harmonic potential,*

$$V(\mathbf{r}) = \tfrac{m}{2}\omega_x^2 x^2 + \tfrac{m}{2}\omega_y^2 y^2 + \tfrac{m}{2}\omega_z^2 z^2 \ .$$

From the time-of-flight picture we can determine the number of atoms N. We also assume a given temperature T and proceed as follows. First we calculate the chemical potential from the normalization condition $N = \int n(e)\rho(e)de$.

44.2 Quantum statistics of an ideal Fermi gas

Atoms are fermions or bosons, or depending on their spin is integer or semi-integer. For example, ^{87}Rb atoms with their total integer spin of F are bosons, while ^{40}K atoms having a half-integer spin are fermions. At high phase space densities, atoms have to figure out how they will organize their coexistence. Bosons encourage each other to occupy the same phase space cell, in contrast to the reluctant fermions, which prefer to follow Pauli's exclusion principle. The different behavior is described by different quantum statistics that determine how the phase space (i.e., the available energy levels) has to be filled by the atoms. The Bose-Einstein distribution is valid for bosons, the distribution of Fermi-Dirac for fermions and both asymptotically approach the Boltzmann distribution at high temperatures. We have seen that bosons undergo a phase transition and condense in the ground state when the temperature is reduced below a critical threshold. On the other hand, the fermions organize their phase space, so that their energy levels are arranged like a ladder. The impact of fermionic quantum statistics on a cold cloud of atoms were observed experimentally by DeMarco and Jin [347, 966]. They cooled a two-components Fermi gas of 7×10^5 potassium atoms down to 300 nK, which corresponded to 60% of the atoms populating energy levels below the Fermi energy. The measured density distribution was found to deviate from the one expected for an ideal Boltzmann gas [5].

44.2.1 Chemical potential and Fermi radius for a harmonic trap

The phase space density for a *degenerate Fermi gas* has already been given in (44.4). In the same way as for a Bose gas, the chemical potential must satisfy the normalization

[5] We note that meanwhile ultracold two-components Fermi gas have been demonstrated to form bosonic Cooper-pairs, similarly to the phenomena known as superconductivity in some metals and as superfluidity of the fermionic ^{3}He.

condition,

$$N = \iint w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3k = (2\pi)^3 \int w_{T,\mu}(\varepsilon)\eta(\varepsilon) d\varepsilon \tag{44.32}$$
$$= \frac{1}{2(\hbar\bar{\omega})^3} \int_0^\infty \frac{\varepsilon^2 d\varepsilon}{e^{\beta(\varepsilon-\mu)}+1} = \left(\frac{k_B T}{\hbar\bar{\omega}}\right)^3 f_3(Z) \; .$$

In the last line, we inserted the density of the states into a harmonic potential (43.21) and used the definition of the Fermi functions (44.11).

For low temperatures, $x \equiv \mu \gg 1$, we can use the Sommerfeld expansion which in first order gives $f_\eta(e^x) \simeq x^\eta/\Gamma(\eta+1)$. From this we immediately obtain the energy, the Fermi radius and the momentum of free particles,

$$E_F = \mu(T=0) = \hbar\bar{\omega}(6N)^{1/3} \tag{44.33}$$
$$r_F = \sqrt{\frac{2E_F}{m\omega_r^2}} \quad \text{and} \quad z_F = \sqrt{\frac{2E_F}{m\omega_z^2}}$$
$$K_F = \sqrt{\frac{2mE_F}{\hbar^2}} \; .$$

Using the second order of the Sommerfeld expansion, $f_\xi(e^x) \simeq \frac{x^\xi}{\Gamma(\xi+1)}\left(1 + \frac{\pi^2\xi(\xi-1)}{6x^2} + ...\right)$, we obtain for the chemical potential the equation, $0 = \mu^3 + (\pi k_B T)^2 \mu - E_F^3$. The approximate solution of this equation, neglecting terms such as $4\pi^6 k_B^6 T^6 \ll 27 E_F^6$, is

$$\mu = E_F \left[1 - \frac{\pi^2}{3}\left(\frac{k_B T}{E_F}\right)^2\right] \; . \tag{44.34}$$

In the limit of high temperatures, $f_\eta(Z) \overset{Z\to 1}{\longrightarrow} Z$

$$N = \left(\frac{k_B T}{\hbar\bar{\omega}}\right)^3 e^{\beta\mu} = \left(\frac{k_B T}{\hbar\bar{\omega}}\right)^3 (1 + \beta\mu + ...) \; , \tag{44.35}$$
$$\mu \approx k_B T \ln N \left(\frac{\hbar\bar{\omega}}{k_B T}\right)^3 = k_B T \ln \frac{1}{6}\left(\frac{E_F}{k_B T}\right)^3 \; .$$

This means that we recover the *Boltzmann gas*, which satisfies an ideal gas equation similar to that of particles in a box potential,

$$N = \left(\frac{k_B T}{\hbar\bar{\omega}}\right)^3 \qquad \text{(Boltzmann)} \; . \tag{44.36}$$

For comparison, for bosons we have,

$$\frac{N_0}{N} = 1 - \left(\frac{T}{T_c}\right)^3 \frac{g_3(Z)}{g_3(1)} \qquad \text{(Bose)} \; . \tag{44.37}$$

The chemical potentials are calculated in Fig. 44.7(a).

44.2.2 Energy

The total energy $E_1 \equiv E/N \equiv N^{-1}\int \epsilon w d^3\mathbf{x} d^3k$ per particle is given by,

$$\begin{aligned} E_1 &= \frac{\int \epsilon w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3k}{\int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} d^3k} \\ &= \frac{\int \epsilon\eta(\epsilon)\left(e^{\beta(\epsilon-\mu)}+1\right)^{-1} d\varepsilon}{\int \eta(\epsilon)\left(e^{\beta(\epsilon-\mu)}+1\right)^{-1} d\varepsilon} = 3k_BT\frac{f_4(Z)}{f_3(Z)} \ . \end{aligned} \tag{44.38}$$

Again using the Sommerfeld approximation, we see that for $T \to 0$ the energy is limited by

$$\begin{aligned} E_1 &= \frac{3}{N\beta(\beta\hbar\bar{\omega})^3} f_4(e^{\beta\mu}) \\ &= \frac{3\mu^4}{4E_F^3}\left(1+\frac{2\pi^2}{(\beta\mu)^2}+...\right) \overset{T\to 0}{\longrightarrow} \frac{3}{4}E_F \qquad \text{(Fermi)} \ . \end{aligned} \tag{44.39}$$

because the atoms are forced to adopt a state of larger dynamics in the outermost regions of the trap. This implies, $E_1/E_F \overset{T\to 0}{\longrightarrow} 3/4$.

In the limit of high temperatures, $T \to \infty$, a classical gas has the energy per particle,

$$E_1 = \frac{3}{N\beta(\beta\hbar\bar{\omega})^3} f_4\left(f_3^{-1}\left(\frac{(\beta E_F)^3}{6}\right)\right) \approx 3k_BT \qquad \text{(Boltzmann)} \ , \tag{44.40}$$

which is seen by taking the high temperature limit $f_\eta(Z) \overset{Z\to 0}{\longrightarrow} Z$ and extrapolating to all Z. This implies, $E_1/E_F \overset{T\to\infty}{\longrightarrow} 3k_BT/E_F$.

Comparing with bosons,

$$E_1 = 3k_BT\frac{g_4(1)}{g_3(1)} \approx 2.7 \qquad \text{(Bose)} \ . \tag{44.41}$$

44.2.3 Entropy and heat capacity

The entropy $S = -k_B\int g(\epsilon)\left[w\ln w + (1-w)\ln(1-w)\right] d\epsilon$ per particle is,

$$S_1 = 4k_B\frac{f_4(Z)}{f_3(Z)} - \frac{\mu}{T} = \frac{4E_1}{3T} - \frac{\mu}{T} \ . \tag{44.42}$$

The heat capacity per particle $C_1 = \frac{\partial E_1}{\partial T}\big|_N$ is easily calculated using $Zf'_\eta(Z) = f_{\eta-1}(Z)$,

$$C_1 = 3k_B\frac{f_4(Z)}{f_3(Z)} - \frac{3\mu}{T}\left(1-\frac{f_4(Z)f_2(Z)}{f_3(Z)^2}\right) = \frac{E_1}{T} - \frac{3\mu}{T}\left(1-\frac{f_4(Z)f_2(Z)}{f_3(Z)^2}\right) \ . \tag{44.43}$$

For fermions well below the Fermi temperature, $T \to 0$, using the Sommerfeld approximation, we calculate,

$$C_1 \overset{T\to 0}{\longrightarrow} \frac{3\pi^2}{2}\frac{k_BT}{T_F} \qquad \text{(Fermi)} \ . \tag{44.44}$$

For high temperature T

$$C_1 \approx 3k_B \qquad \text{(Boltzmann)} \ . \tag{44.45}$$

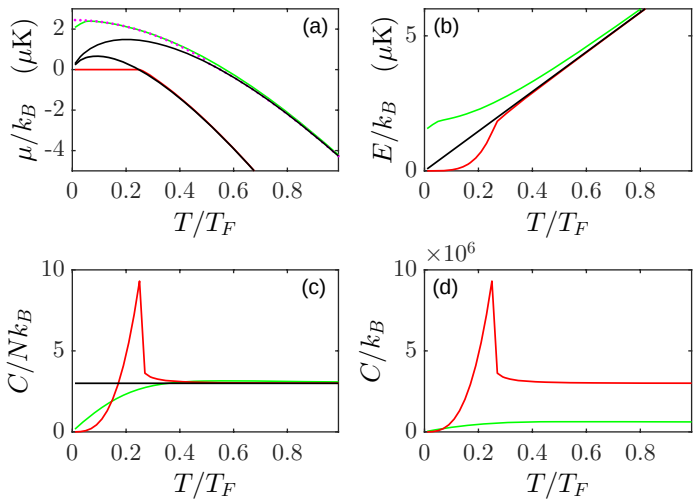

Figure 44.7: (code) Numerical calculation of thermodynamic potentials for Bose (red) and Fermi (green) gases as a function of temperature for a given harmonic trapping potential. (a) Chemical potential, (b) energy, (c) heat capacity per particle, and (d) total heat capacity. The dotted magenta line in (a) shows the chemical potential calculated from the Sommerfeld approximation.

44.2.4 Distributions of a Fermi gas

44.2.4.1 Spatial distribution

The density distribution is,

$$n(\mathbf{x}) = \int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{k} = \frac{1}{(2\pi)^2} \int \frac{2k^2 dk}{e^{\beta[\hbar^2 k^2/2m + U(\mathbf{x}) - \mu]} + 1} \tag{44.46}$$
$$= \frac{1}{(2\pi)^2} \left(\frac{2m}{\hbar^2}\right)^{3/2} \int \frac{\sqrt{\varepsilon} d\varepsilon}{e^{\beta[\varepsilon + U(\mathbf{x}) - \mu]} + 1} = \frac{1}{(2\pi)^2} \left(\frac{2m}{\beta\hbar^2}\right)^{3/2} \Gamma(3/2) f_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) \ ,$$

such that,

$$\boxed{n(\mathbf{x}) = \lambda_{dB}^{-3} f_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]})} \qquad \text{(Fermi)} \ . \tag{44.47}$$

At low temperatures, $T \to 0$, we can apply the Sommerfeld expansion [221], which to first order gives $\mu \to E_F$,

$$n(\mathbf{x}) \approx \frac{1}{(2\pi)^2}\frac{\Gamma(3/2)}{\Gamma(5/2)}\left(\frac{2m}{\hbar^2}\left[\mu - U(\mathbf{x})\right]\right)^{3/2} \tag{44.48}$$
$$= \frac{1}{(2\pi)^2}\frac{2}{3}\left(\frac{2m}{\hbar^2}\right)^{3/2}\left(E_F - \frac{m}{2}\omega_r^2\rho^2\right)^{3/2} = \frac{8\lambda}{\pi^2}\frac{N}{R_F^3}\left(1 - \frac{\rho^2}{R_F^2}\right)^{3/2} .$$

At high temperatures, $T \to \infty$, we should recover the Boltzmann gas situation,

$$n(\mathbf{x}) = \lambda_{dB}^{-3} f_{3/2}(e^{-\beta[U(\mathbf{x})-\mu]}) \tag{44.49}$$
$$\approx \lambda_{dB}^{-3} N\left(\beta\hbar\bar{\omega}\right)^3 e^{-\beta U(\mathbf{x})} = \left(\frac{m\beta\bar{\omega}^2}{2\pi}\right)^{3/2} N e^{-\beta m(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 z^2)/2} .$$

It's easy to check, $\int n(\mathbf{x}) d^3\mathbf{x} = N$. Introducing the peak density n_0, we obtain,

$$\boxed{n(\mathbf{x}) = n_0 e^{-m\omega^2\rho^2/2k_BT}} \quad \text{(Boltzmann)} . \tag{44.50}$$

The *rms*-radius of the distribution is $\sigma_j = \sqrt{k_BT/m\omega_j^2}$, which seems contrary to the above results, $\frac{m}{2}\omega_j^2\left\langle x_j^2\right\rangle = k_BT$. In comparison,

$$\boxed{n(\mathbf{x}) = \lambda_{dB}^{-3} g_{3/2}\left[e^{\beta(\mu - U(\mathbf{x}))}\right]} \quad \text{(Bose gas above } T_c\text{)} . \tag{44.51}$$

where $\lambda_{dB} = \sqrt{2\pi\hbar^2/mk_BT}$ e $a_{tr} = \sqrt{\hbar/m\bar{\omega}}$.

44.2.4.2 Momentum distribution

The momentum distribution is,

$$\tilde{n}(\mathbf{k}) = \int w_{T,\mu}(\mathbf{x},\mathbf{k}) d^3\mathbf{x} = \frac{1}{(2\pi)^2}\int \frac{rdrdz}{e^{\beta[\varepsilon(k) + m\omega_r^2\rho^2/2 - \mu]} + 1} \tag{44.52}$$
$$= \frac{1}{(2\pi)^3}\int \frac{4\pi\rho^2 d\rho}{e^{\beta[\varepsilon + m\omega_r^2\rho^2/2 - \mu]} + 1}$$
$$= \frac{1}{(2\pi)^2}\left(\frac{2}{\beta m\omega_r^2}\right)^{3/2}\int \frac{\sqrt{t}dt}{e^{\beta[\varepsilon + t - \mu]} + 1} = \frac{1}{(2\pi)^2}\left(\frac{2}{\beta m\omega_r^2}\right)^{3/2}\Gamma(3/2) f_{3/2}(e^{\beta(\mu-\varepsilon)}) ,$$

such that,

$$\boxed{\tilde{n}(\mathbf{k}) = \lambda_{dB}^{-3} a_{tr}^6 f_{3/2}(e^{\beta(\mu-\varepsilon)})} \quad \text{(Fermi)} . \tag{44.53}$$

At low temperatures, $T \to 0$,

$$\tilde{n}(\mathbf{k}) \approx \frac{1}{(2\pi)^2}\left(\frac{2}{\beta m\omega_r^2}\right)^{3/2}\frac{\Gamma(3/2)}{\Gamma(5/2)}\left(\beta\left[\mu - \varepsilon\right]\right)^{3/2} \tag{44.54}$$
$$\approx \frac{1}{(2\pi)^2}\left(\frac{2}{m\omega_r^2}\right)^{3/2}\frac{2}{3}\left(E_F - \frac{\hbar^2k^2}{2m}\right)^{3/2} = \frac{8}{\pi^2}\frac{N}{K_F^3}\left(1 - \frac{k^2}{K_F^2}\right)^{3/2} .$$

This can easily be integrated by dimensions,

$$\tilde{n}_{T\to 0}(k_z) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \tilde{n}_{cl}(\mathbf{k})dk_x dk_y = \frac{8}{\pi^2}\frac{N}{K_F^3}\int\int_{|k|\le K_F}\left(1-\frac{k^2}{K_F^2}\right)^{3/2} dk_x dk_y \tag{44.55}$$

$$= \frac{8}{\pi^2}\frac{N}{K_F^3}\int_0^{2\pi}\int_0^{\sqrt{K_F^2-k_z^2}}\left(1-\frac{k_z^2}{K_F^2}-\frac{k_\rho^2}{K_F^2}\right)^{3/2} k_\rho dk_\rho d\phi = \frac{16}{5\pi}\frac{N}{K_F}\left(1-\frac{k_z^2}{K_F^2}\right)^{5/2} .$$

It is easy to check $\int_{-\infty}^{\infty}\tilde{n}_{T\to 0}dk_z = N$, with Maple.

At high temperatures, $T\to\infty$, we should recover the Boltzmann gas situation,

$$\boxed{\tilde{n}(\mathbf{k}) \approx \left(\frac{\hbar^2\bar{\omega}^2}{2\pi m\omega_r^2}\right)^{3/2} N e^{-\beta\varepsilon}} \quad \text{(Boltzmann)} . \tag{44.56}$$

Since ε is the kinetic energy, the *rms*-radius $\sqrt{k^2}$ of this distribution is $\beta\hbar^2\langle k^2\rangle = m$. In comparison,

$$\boxed{\tilde{n}_B(\mathbf{k}) = \lambda_{dB}^{-3}a_{tr}^6\ g_{3/2}\left[e^{\beta\left(\mu-\mathbf{p}^2/2m\right)}\right]} \quad \text{(Bose gas above } T_c\text{)} . \tag{44.57}$$

Example 281 (*Integrated momentum distribution of a Fermi gas*): To integrate the momentum distribution of finite temperature Fermi gas by dimensions,

$$\tilde{n}(k_z) = \frac{1}{(2\pi)^3}\left(\frac{2}{\beta m\tilde{\omega}_{tr}^2}\right)^{3/2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_0^{\infty}\frac{4\pi\tilde{r}^2 d\tilde{r}}{e^{\beta\varepsilon-\beta\mu+\tilde{r}^2}+1}dk_y dk_x \tag{44.58}$$

$$= \frac{1}{(2\pi)^3}\left(\frac{2}{\beta m\tilde{\omega}_{tr}^2}\right)^{3/2} 2\pi\int_0^{\infty}\int_0^{\infty}\frac{4\pi\tilde{r}^2 d\tilde{r}}{e^{\beta\hbar^2k_z^2/2m+\beta\hbar^2k_\rho^2/2m-\beta\mu+\tilde{r}^2}+1}k_\rho dk_\rho$$

$$= \frac{1}{\pi}\left(\frac{2}{\beta m\tilde{\omega}_{tr}^2}\right)^{3/2}\frac{2m}{\beta\hbar^2}\int_0^{\infty}\int_0^{\infty}\frac{\tilde{k}_\rho d\tilde{k}_\rho}{e^{\beta\hbar^2k_z^2/2m-\beta\mu+\tilde{r}^2+\tilde{k}_\rho^2}+1}\tilde{r}^2 d\tilde{r}$$

$$= \frac{1}{\pi}\left(\frac{2}{\beta m\tilde{\omega}_{tr}^2}\right)^{3/2}\frac{2m}{\beta\hbar^2}\frac{1}{2}\int_0^{\infty}\tilde{r}^2\ln\frac{1}{1+e^{-\beta\hbar^2k_z^2/2m+\beta\mu-\tilde{r}^2-k_\rho^2}}\Bigg|_0^{\infty}d\tilde{r}$$

$$= \frac{2}{\pi\left(\beta\hbar\tilde{\omega}_{tr}\right)^2}\left(\frac{2}{\beta m\tilde{\omega}_{tr}^2}\right)^{1/2}\int_0^{\infty}\tilde{r}^2\ln\left(1+e^{\beta\mu-\beta\hbar^2k_z^2/2m-\tilde{r}^2}\right)d\tilde{r} .$$

44.2.4.3 Time-of-flight distribution

To describe time-of-flight images we substitute $\mathbf{k} = m\mathbf{r}/\hbar t$. We obtain the density distribution from a convolution,

$$n_{ToF}(\mathbf{x},t) = \frac{1}{(2\pi)^3}\int d^3\mathbf{x}_0 d^3\mathbf{k}\frac{\delta^3(\mathbf{x}-\mathbf{x}_0-\mathbf{p}t/m)}{e^{\beta(H(\mathbf{x}_0,\mathbf{p})-\mu)}+1} \tag{44.59}$$

$$= \frac{1}{(2\pi)^3}\int\frac{d^3\mathbf{k}}{e^{\beta(H(\mathbf{x}+\mathbf{p}t/m,\mathbf{p})-\mu)}+1}$$

$$= \frac{1}{(2\pi)^3}\int\frac{dk_x dk_y dk_z}{e^{\beta\Sigma_j\left[\hbar^2k_j^2/2m+\frac{1}{2}m\omega_j^2(x_j+\hbar k_j t/m)^2\right]}/Z+1} .$$

We rewrite the exponent,

$$\hbar^2 k_j^2/2m + \tfrac{1}{2}m\omega_j^2\left(x_j + \hbar k_j t/m\right)^2 = \hbar^2 k_j^2/2m(1+\omega_j^2 t^2) + \omega_j^2 t x_j \hbar k_j + \tfrac{1}{2}m\omega_j^2 x_j^2$$

$$= \left(\sqrt{\frac{\hbar^2 k_j^2}{2m}(1+\omega_j^2 t^2)} + \frac{\omega_j^2 t x_j \sqrt{2m}}{2\sqrt{1+\omega_j^2 t^2}}\right)^2 + \frac{m\omega_j^2 x_j^2}{2(1+\omega_j^2 t^2)} \tag{44.60}$$

$$= \xi_j + \frac{m}{2}\breve{\omega}_j^2 x_j^2 \ .$$

where we define $\breve{\omega}_i \equiv \omega_i \left(1+\omega_i^2 t^2\right)^{-1/2}$. With the substitution $d\xi_j = dk_j \sqrt{\frac{2\hbar^2}{m}\xi_j \left(1+\omega_j^2 t^2\right)}$ we obtain

$$n_{ToF}(\mathbf{x},t) = \frac{1}{(2\pi)^3}\left(\frac{mk_BT}{2\hbar^2}\right)^{3/2}\frac{1}{\prod_i\left(1+\omega_i^2 t^2\right)}\int \frac{\beta^{3/2}\left(\xi_x\xi_y\xi_z\right)^{-1/2}d\xi_x d\xi_y d\xi_z}{e^{\beta\Sigma_j\left[\xi_j+\frac{m}{2}\breve{\omega}_j^2 x_j^2\right]}/Z+1} \tag{44.61}$$

$$= \frac{1}{2^3\pi^{3/2}}\frac{1}{\lambda_{dB}^3}\frac{\tilde{\omega}^3}{\bar{\omega}^3}\int \frac{\beta^{3/2}\xi^{-3/2}4\pi\xi^2 d\xi}{e^{\beta\Sigma_j\left[\xi+\frac{m}{2}\breve{\omega}_j^2 x_j^2\right]}/Z+1} \ ,$$

where $\bar{\omega} \equiv (\omega_x\omega_y\omega_z)^{1/3}$ and $\breve{\omega} \equiv (\breve{\omega}_x\breve{\omega}_y\breve{\omega}_z)^{1/3}$.

$$\boxed{n_{ToF}(\mathbf{x},t) = \frac{1}{\lambda_{dB}^3}\frac{\breve{\omega}^3}{\bar{\omega}^3} f_{3/2}\left(e^{\beta\mu - \frac{1}{2}\beta m\Sigma_j\breve{\omega}_j^2 x_j^2}\right)} \ . \tag{44.62}$$

For long times-of-flight $t \gg \omega^{-1}$,

$$n_{ToF}(\mathbf{x},t) = \frac{1}{\lambda_{dB}^3}\frac{1}{\bar{\omega}^2 t^2} f_{3/2}\left(e^{\beta\left(\mu - m\mathbf{x}^2/2t^2\right)}\right) = \left(\frac{m}{\hbar t}\right)^3 \tilde{n}(m\mathbf{x}/t) \ . \tag{44.63}$$

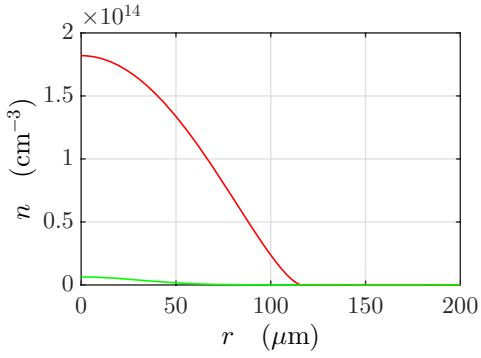

Figure 44.8: (code) Time-of-flight velocity distribution of (red) a Li Fermi gas at $T = 0$ with vanishing initial spatial distribution [221] and (green) a thermal gas at $T = T_F$.

At low temperatures,

$$n_{ToF}(\mathbf{x},t) = \left(\frac{m}{\hbar t}\right)^3 \frac{N}{K_F^3}\frac{8}{\pi^2}\left(1-\frac{(m\mathbf{x}/\hbar t)^2}{K_F^2}\right)^{3/2} = \left(\frac{m}{\hbar t}\right)^3 \frac{R_F^3}{6\pi^2\lambda}\left[1-\left(\frac{R_F m\mathbf{x}/\hbar t}{(48N\lambda)^{1/3}}\right)^2\right]^{3/2} \tag{44.64}$$

At high temperatures,

$$\begin{aligned} n_{ToF}(\mathbf{x},t) &= \frac{1}{\lambda_{dB}^3}\frac{1}{\bar{\omega}^2 t^2} f_{3/2}(e^{\beta(\mu - m\mathbf{x}^2/2t^2)}) \\ &\approx \frac{1}{\lambda_{dB}^3}\frac{1}{\bar{\omega}^2 t^2} e^{\beta(\mu - m\mathbf{x}^2/2t^2)} \\ &\approx \left(\frac{mk_BT}{2\pi\hbar^2}\right)^{3/2}\frac{1}{\bar{\omega}^2t^2}N\left(\frac{\hbar\bar{\omega}}{k_BT}\right)^3 e^{-\beta m\mathbf{x}^2/2t^2} \approx N\frac{\bar{\omega}}{t^2}\left(\frac{m}{2\pi k_BT}\right)^{3/2} e^{-\beta m\mathbf{x}^2/2t^2}\,. \end{aligned} \tag{44.65}$$

A *rms*-width is,

$$\begin{aligned} \langle r_{ToF}^2\rangle &= \int r^2 n_{ToF}(\mathbf{x},t)d^3\mathbf{x} \\ &= \frac{1}{\lambda_{dB}^3}\frac{\check{\omega}^3}{\bar{\omega}^3}\int r^2 f_{3/2}\left(e^{\beta\mu - \frac{1}{2}\beta m\Sigma_j \check{\omega}_j^2 x_j^2}\right)d^3\mathbf{x} \\ &= \frac{2}{m\check{\omega}_r^2 N}\int \frac{\varepsilon g(\varepsilon)d\varepsilon}{e^{\beta(\varepsilon-\mu)}+1} = \frac{k_BT}{m\check{\omega}_r^2}\frac{g_4(Z)}{g_3(Z)}\,. \end{aligned} \tag{44.66}$$

This shows that the width of the flight-of-time distribution can simply be obtained from the spatial distribution by substituting $\omega \to \omega/\sqrt{1+\omega^2t^2}$. Of course this does not hold for condensed gases Bose.

44.2.5 Equipartition theorem

We find for harmonic traps,

$$\begin{aligned} E_{pot,1} &= \frac{\int U(\mathbf{x})w_{T,\mu}(\mathbf{x},\mathbf{k})d^3\mathbf{x}d^3\mathbf{k}}{\int w_{T,\mu}(\mathbf{x},\mathbf{k})d^3\mathbf{x}d^3\mathbf{k}} = \frac{1}{(2\pi)^3N2}\int \frac{m\omega^2r^2d^3\mathbf{x}d^3\mathbf{k}}{e^{\beta[\hbar^2k^2/2m+m\omega^2r^2/2-\mu]}+1} \\ &= \frac{16}{\pi N\beta^4(\hbar\omega)^3}\int \frac{u^4v^2dudv}{e^{u^2+v^2}/Z+1} \\ &= \frac{1}{(2\pi)^3N2m}\int \frac{\hbar^2k^2d^3\mathbf{x}d^3\mathbf{k}}{e^{\beta[\hbar^2k^2/2m+m\omega^2r^2/2-\mu]}+1} = \frac{\int \hbar^2k^2w_{T,\mu}(\mathbf{x},\mathbf{k})d^3\mathbf{x}d^3\mathbf{k}}{2m\int w_{T,\mu}(\mathbf{x},\mathbf{k})d^3\mathbf{x}d^3\mathbf{k}} = E_{kin,1}\,. \end{aligned} \tag{44.67}$$

This confirms the *equipartition theorem* for confined particles, which postulates,

$$E = E_{kin} + E_{pot} = 2E_{kin}\,. \tag{44.68}$$

In flight time, however, E_{pot} suddenly vanishes.

44.2.5.1 Calibrating the number of atoms

Experimentally, to calibrate N, we can use either the measured value of $\langle k^2 \rangle$ at $T = 0$, which gives $\mu = E_F = 4E/3$ and consequently,

$$N = \frac{32}{3} \left(\frac{\hbar^2 \langle k^2 \rangle}{6m\hbar\bar{\omega}} \right)^3 . \tag{44.69}$$

Or we determine the temperature T_g where the Boltzmann gas turns into a Fermi gas $3\mu/4 = 3k_B T_g$,

$$N = \frac{32}{3} \left(\frac{k_B T_g}{\hbar\bar{\omega}} \right)^3 . \tag{44.70}$$

44.2.6 Density and momentum distribution for anharmonic potentials

44.2.6.1 Width of momentum distribution for anharmonic potentials

If the potential is non-harmonic, the widths of Fermi distributions must in general be calculated numerically. I.e. first $g(\epsilon)$ is determined by integrating for every value of ϵ the root $\sqrt{\epsilon - U(\mathbf{x})}$ over the entire volume, where $U(\mathbf{x}) < \epsilon$, i.e. in the case of cylindrical symmetry,

$$g(\epsilon) = \frac{(2m)^{3/2}}{2\pi\hbar^3} \int \sqrt{\epsilon - U(r,z)} r dr dz . \tag{44.71}$$

Second the chemical potential must also be calculated numerically from $N = \int g(\epsilon) \left(e^{\beta(\epsilon-\mu)} + 1 \right)^{-1} d\epsilon$ by minimizing the function,

$$o(Z) = \left| \beta N - \int \frac{g(x/\beta) dx}{e^x/Z + 1} \right| . \tag{44.72}$$

Finally, the *rms*-momentum width of a degenerate Fermi-gas is calculated from,

$$\frac{\langle k^2 \rangle}{k_F^2} = \frac{E_1}{E_F} = \frac{1}{NE_F} \int \frac{\epsilon g(\epsilon) d\epsilon}{e^{\beta(\epsilon-\mu)} + 1} . \tag{44.73}$$

It is important to note that the temperature cannot be obtained from $\hbar^2 \langle k^2 \rangle / 2m = 3Nk_B T$ any more. Rather for a given $\langle k^2 \rangle$ the parameter β in the integral (44.71) must be fitted to satisfy the equation.

Alternatively, we may assume a polynomial potential for which the density of states can be described by $g(\epsilon) \propto \epsilon^n$. Then,

$$\frac{\langle k^2 \rangle}{k_F^2} = \frac{1}{E_F} \frac{\int \epsilon g(\epsilon) \left(e^{\beta(\epsilon-\mu)} + 1 \right)^{-1} d\epsilon}{\int g(\epsilon) \left(e^{\beta(\epsilon-\mu)} + 1 \right)^{-1} d\epsilon} = \frac{T}{T_F} \frac{(n+1) f_{n+2}(Z)}{f_{n+1}(Z)} , \tag{44.74}$$

For a harmonic potential we recover the energy formula,

$$\frac{\langle k^2 \rangle}{k_F^2} = \frac{3T}{T_F} \frac{f_4(Z)}{f_3(Z)} , \tag{44.75}$$

and for hot clouds the classical limit holds,

$$\frac{\langle k^2\rangle}{k_F^2} = \frac{n+1}{\beta E_F} \ . \tag{44.76}$$

Must for a single dimension the value be divided by three? $\hbar^2\langle k_j^2\rangle = 2mk_BTf_4(Z)/f_3(Z)$ setting $\epsilon = \hbar^2k^2/m$.

For a harmonic potential $g(\epsilon) \propto \epsilon^2$ and for a linear potential $g(\epsilon) \propto \epsilon^{7/2}$. Intermediate values are possible for non isotropic traps, which are linear in some directions and harmonic in others, e.g. for a radially quadrupolar and axially harmonic trap, we expect $g(\epsilon) \propto \epsilon^3$ and thus $E = 4Nk_BT$. In general, we may have more complicated situations, where the trap becomes non-harmonic beyond a certain distance from the origin. In those cases, the density of states may be approximated by series,

$$g(\epsilon) \propto \epsilon^2 + \eta\epsilon^3 \ , \tag{44.77}$$

where η is a small parameter, so that,

$$\frac{\langle k^2\rangle}{k_F^2} = \frac{1}{E_F}\frac{\int(\epsilon^3+\eta\epsilon^4)(e^{\beta(\epsilon-\mu)}+1)^{-1}d\epsilon}{\int(\epsilon^2+\eta\epsilon^3)(e^{\beta(\epsilon-\mu)}+1)^{-1}d\epsilon} = \frac{T}{T_F}\frac{3f_4(Z)+12\eta f_5(Z)}{f_3(Z)+3\eta f_4(Z)} \ , \tag{44.78}$$

which in the classical limit gives rise to energies $E = 3..4Nk_BT$ depending on the value of η.

Such effects must be considered when the time-of-flight method is used for temperatures measurements. For example, if we underestimate $g(\varepsilon)$ by assuming a harmonic potential at all ε, although the potential is quadrupolar at large $\varepsilon \gg k_BT$, we get a wrong estimate for the temperature $T_{wrng} = E/3Nk_B$ instead of $T_{corr} = E/4Nk_B$.

44.2.6.2 Width of the density distribution for anharmonic potentials

The result also permits to calculate the *rms* spatial width,

$$\sum\nolimits_{j=1}^{3}\frac{m}{2}\omega_j^2\langle x_j^2\rangle = 3k_BT\frac{f_4(Z)}{f_3(Z)} \ . \tag{44.79}$$

Let us for simplicity assume $\omega_i = \omega_j$. So in the classical limit,

$$\frac{\langle x_j^2\rangle}{R_F^2} = \frac{\langle \mathbf{x}^2\rangle}{3R_F^2} = \frac{E_1}{3E_F} = \frac{1..1.3T}{T_F} \ . \tag{44.80}$$

If the potential is non-harmonic, the widths of Fermi distributions must in general be calculated numerically. We may use the same results for the density of states and the chemical potential as for the momentum width calculations. Then,

$$\frac{\langle x_j^2\rangle}{R_F^2} = \frac{E_1}{3E_F} = \frac{1}{3E_F}\frac{\int \epsilon g(\epsilon)\left(e^{\beta(\epsilon-\mu)}+1\right)^{-1}d\epsilon}{\int g(\epsilon)\left(e^{\beta(\epsilon-\mu)}+1\right)^{-1}d\epsilon} \ . \tag{44.81}$$

44.2.7 Classical gas

For a harmonic potential [330] the fraction of particles with energy smaller than $\eta k_B T$ is,

$$N(\eta) = \frac{1}{2N(\hbar\bar{\omega})^3}\int_0^{\eta k_B T}\frac{d\epsilon}{e^{\beta\epsilon}/Z-0} \approx 1-\frac{2+2\eta+\eta^2}{2e^\eta} \tag{44.82}$$
$$E(\eta) = \frac{1}{2N(\hbar\bar{\omega})^3}\int_0^{\eta k_B T}\frac{\epsilon^2 d\epsilon}{e^{\beta\epsilon}/Z-0} \approx 3-\frac{6+6\eta+3\eta^2+\eta^3}{6e^\eta}\ ,$$

while for a quadrupole potential,

$$N(\eta) \approx -2\sqrt{z}\frac{105+70\eta+28\eta^2+8\eta^3}{\sqrt{\pi}105e^\eta}+\mathrm{erf}(\sqrt{\eta}) \tag{44.83}$$
$$E(\eta) \approx -\frac{2}{9}\sqrt{z}\frac{945+630\eta+252\eta^2+72\eta^3+16\eta^4}{\sqrt{\pi}105e^\eta}+\frac{9}{2}\mathrm{erf}(\sqrt{\eta})\ .$$

44.2.7.1 Momentum distribution for a classical gas

For high temperatures, $T\to\infty$, we should recover the ideal Boltzmann gas situation, $f_{3/2}\to id$,

$$\tilde{n}_{T\to\infty}(\mathbf{k}) = \frac{1}{(2\pi)^3}\int\frac{4\pi\rho^2 d\rho}{e^{\beta[\varepsilon+m\omega_{tr}^2\rho^2/2-\mu]}} = \frac{1}{2\pi^2}e^{-\beta(\varepsilon-\mu)}\int e^{-\beta m\omega_{tr}^2\rho^2/2}\rho^2 d\rho \tag{44.84}$$
$$= \left(\frac{1}{2\pi\beta m\omega_{tr}^2}\right)^{3/2} e^{-\beta(\varepsilon-\mu)} = \lambda_{dB}^{-3}a_{tr}^6\ e^{\beta(\mu-\varepsilon)}\ .$$

Since the chemical potential satisfies the normalization, $\int\tilde{n}_{T\to\infty}(\mathbf{k})d^3\mathbf{k}=1$,

$$\tilde{n}_{T\to\infty}(\mathbf{k}) = \left(\frac{1}{2\pi\beta m\omega_{tr}^2}\right)^{3/2} N\left(\frac{\hbar\omega_{tr}}{k_B T}\right)^3 e^{-\beta\varepsilon} = N\sqrt{\frac{\hbar^2}{2\pi m k_B T}}^3\ e^{-\hbar^2k^2/2mk_BT}\ . \tag{44.85}$$

This is easy to integrate by dimensions, so that,

$$\tilde{n}_{T\to\infty}(k_z) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\tilde{n}_{T\to\infty}(\mathbf{k})dk_x dk_y = N\sqrt{\frac{\hbar^2}{2\pi m k_B T}}e^{-\hbar^2k_z^2/2mk_BT}\ . \tag{44.86}$$

The rms-width of this distribution is,

$$\Delta k_z = \frac{\sqrt{mk_BT}}{\hbar}\ . \tag{44.87}$$

44.2.7.2 Correlating fluctuations in the number of atoms

Experimentally the atom number will fluctuate. To minimize this problem we can renormalize it to a norm number N_{norm} by multiplying the measured time-of-flight

variance $\langle x_{tof}^2 \rangle$ with,

$$C_T(N) = \frac{\langle \tilde{x}_{tof}^2 \rangle}{\langle x_{tof}^2 \rangle} = \frac{N}{N_{norm}} \frac{f_4(\tilde{Z})}{f_4(Z)} \tag{44.88}$$
$$= \frac{N}{N_{norm}} \frac{f_4\left[f_3^{-1}(N_{norm}(\beta\hbar\bar{\omega})^3)\right]}{f_4\left[f_3^{-1}(N(\beta\hbar\bar{\omega})^3)\right]} \ .$$

44.2.8 Intensive and extensive parameters

The distinction between an *intensive parameter* and an *extensive parameter* is based on the concept that the system under investigation can be subdivided into smaller, identical and non-interconnected entities within which the parameter in question has the same properties, such that this parameter does not change, when the system is divided or subentities are combined [6] An intensive property is a global property, meaning that it is a physical property of a system that does not depend on the system size or the amount of material in the system. Examples of intensive properties are the temperature and the hardness of an object. No matter how small a diamond is cut, it maintains its intrinsic hardness.

By contrast, an extensive property is one that is additive for independent, non-interacting subsystems. The property is proportional to the amount of material in the system. For example, both the mass and the volume of a diamond are directly proportional to the amount that is left after cutting it from the raw mineral. Mass and volume are extensive properties, but hardness is intensive.

The ratio of two extensive properties, such as mass and volume, is scale-invariant, and this ratio, the density, is hence an intensive property.

Intensive parameter are: chemical potential, concentration, density (or specific gravity), ductility, elasticity, electrical resistivity, hardness, magnetic field, magnetization, malleability, melting point and boiling point, molar absorptivity, pressure, specific energy.

Extensive parameter are: energy, entropy, Gibbs energy, length, mass, particle number, momentum, number of moles, volume, magnetic moment, electrical charge, weight.

44.2.9 Signatures for quantum degeneracy of a Fermi gas

Whether an atom is a *fermion* or a *boson* uniquely depends on its total spin. Halfinteger spin particles are fermions, integer spin particles are bosons. E.g. Rb atoms have in the ground state $J = 1/2, I = 7/2$, integer F, and are therefore bosons. Ca^+ ions have $J = 1/2$ and no hyperfine structure so that F is halfinteger, and are therefore fermions. ^{6}Li has half-integer F and is a boson.

For a *composite particle* the quantum statistical nature may depend on the interaction strength of the partners. For weak interaction, e.g. Feshbach the total spins of the partners will couple to a total total spin, which determines the nature of the composite particle. A fermion pairing with a fermion or a boson pairing with a boson will

[6] How to derive the thermodynamic potentials from the macrocanonical partition function? How to calculate pressure and volume? [check thermodynamic derivations from Romero-Rochin [see Freddy's thesis].

be bosons. A fermion pairing with a boson will be a fermion. Composite trimers may be either bosonic or fermionic depending on the coupling scheme. Can the quantum nature change with the tightness of the binding? What is the total spin of a deeply bound molecule? [1084, 183, 513], [**?**, 622, 1020, **?**]

44.2.9.1 Optical density of a Fermi gas

With the local density of a Fermi gas,

$$n_{loc} = \frac{k_F^3}{3\pi^2} \tag{44.89}$$

the *optical density* is at $T = 0$,

$$\begin{aligned} \int \sigma n dy &= \frac{8\sigma}{\pi^2}\frac{N}{R_F^3}\int_{-R_F}^{R_F}\left(1-\frac{x^2+y^2}{R_F^2}-\frac{z^2}{Z_F^2}\right)^{3/2}dy \\ &= \frac{8\sigma}{\pi^2}\frac{N}{R_F^3}\left(1-\frac{x^2}{R_F^2}-\frac{z^2}{Z_F^2}\right)^{3/2}\int_{-R_F}^{R_F}\left(1-\frac{y^2}{R_F^2-x^2-R_F^2z^2/Z_F^2}\right)^{3/2}dy\ . \end{aligned} \tag{44.90}$$

Writing $a = R_F/\sqrt{R_F^2 - x^2 - R_F^2 z^2/Z_F^2}$,

$$\begin{aligned} \int \sigma n dy &= \frac{8\sigma}{\pi^2}\frac{N}{R_F^2 a^4}\int_{-a}^{a}(1-\tilde{y}^2)^{3/2}d\tilde{y} \\ &= \frac{2\sigma}{\pi^2}\frac{N}{R_F^2 a^4}\left(9a\sqrt{1-a^2}-2a^3\sqrt{1-a^2}+3\arcsin a\right)\ . \end{aligned} \tag{44.91}$$

In the center, $a = 1$,

$$\int \sigma n dy = \frac{3N\sigma}{\pi R_F^2} = \frac{9m\omega_r^2 N}{k_L^2 E_F}\ , \tag{44.92}$$

such that for $E_F \simeq 1\mu$K we expect $n_{loc} \simeq 4\times 10^{12}$ cm^{-3}.

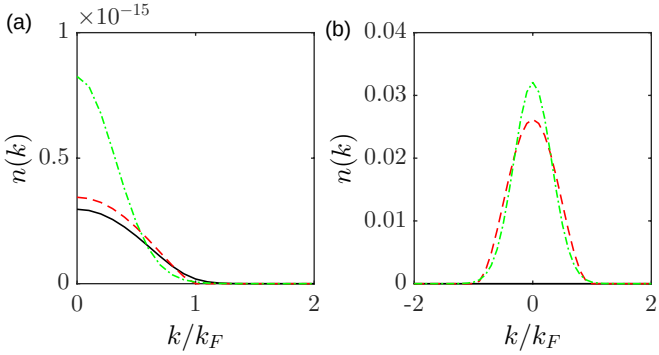

Figure 44.9: (code) (a) Radial momentum distribution and (b) distribution of momentum classes in the direction of k_z for a Fermi gas at $T/T_F = 0.2$ μK (solid), a classical gas (dash-dotted), and a Fermi gas at $T = 0$ (dashed).

44.2.9.2 'Pauli blocking' of sympathetic cooling

For a harmonic trap $U = \mu B = m\omega^2 r^2$ the *rms*-radius of a thermal cloud,

$$r_{rms} = \sqrt{\frac{2k_B T}{m\omega_r^2}} = \sqrt{\frac{k_B T}{\mu \partial_r^2 B}} \,, \tag{44.93}$$

is independent on the atomic mass. This means that a Li and a Rb cloud in the same harmonic trap at the same temperature have the same radius. This ensures good overlap. E.g. at $T = 10$ μK assuming the Rb secular frequencies $\omega_r \simeq 2\pi \times 300$ Hz and $\omega_z \simeq 2\pi \times 30$ Hz, we expect $r_{rms} = 16$ μm and $z_{rms} = 160$ μm. However below the temperature $0.5T_F$, which is $T_F \simeq 1$ μK for $N_F = 10^4$, the quantum pressure stops the reduction of the fermion cloud while cooling. This evtl. reduces the overlap with the boson cloud, disconnects the two clouds and stops the evaporative cooling. On the other hand, the interaction energy of the boson cloud also increases its size, when the Rb cloud approaches the critical temperature $T_c \simeq 0.6$ μK for $N_B = 10^6$.

The *Pauli blocking* of sympathetic cooling is a signature for the advent of quantum statistics [348, 540, 967]. It is due to a reduced mobility (or better reduced available phase space at collisions) of the atoms and not to be confused with the prohibition of s-wave collisions due to the *Pauli exlusion principle*. Furthermore, elastic collisions are suppressed [347], because atoms cannot be scattered into occupied trap levels [637, 1319, 562, 567].

44.2.9.3 Superfluid suppression of sympathetic cooling

The fermions inside the bosonic cloud can be regarded as impurities. If they travel too slow, $v < c$, and if the condensed fraction is too large, the motion will be frictionless and thermalization stops. If they travel fast, quasiparticles are excited, which can be removed by evaporation. With the typical velocity of sound in the BEC $c = \hbar\sqrt{16\pi na}/2m_B \approx 2$ mm/s, or $\frac{m}{2}c^2 \approx k_B \times 20$ nK, we see that this is no real danger.

44.2.9.4 Component separation

If the interspecies interaction h is stronger than the inter-bosonic interaction, the components may separate [965]. Otherwise a small fermionic cloud stays inside the BEC.

44.2.9.5 Excess energy modifies 2^{nd} moment

Independent on any model, just look deviation from Gaussian (interaction energy plays no role for the fermions). Also calculate the 2^{nd} moment $U = \int E_{kin}(k)n(k)dk$, where $n(k)$ is measured in time-of-flight and $E_{kin} = \hbar^2 k^2/2m$.

44.2.9.6 Modification of light scattering

The unavailability of final momentum states inhibits scattering in a similar way as the Lamb-Dicke effect. Forward scattering is suppressed, because all small momentum states are occupied. Furthermore, spontaneous emission is suppressed like in photonic

band gaps. However, here it is rather an atomic momentum band gap. Could it be that because scattering is suppressed, in-situ images of fermions are hampered?

A condition for this effect to play a role is $k_{rec} \ll k_F$. For Li the temperature must be $k_B T_F = \hbar^2 k_F^2/2m = \hbar\bar{\omega}(6N)^{1/3} \gg \hbar^2 k_L^2/2m \approx k_B \times 3\ \mu$K. I.e. we need quite large Fermi gases.

44.2.9.7 Hole heating

Loss processes that remove particles from an atom trap leave holes behind in the single particle distribution if the trapped gas is a degenerate fermion system. The appearance of holes increases the temperature, because of an increase in the energy share per particle if cold particles are removed. Heating is significant if the initial temperature is well below the Fermi temperature. Heating increases the temperature to $T > T_F/4$ after half of the systems lifetime, regardless of the initial temperature. The *hole heating* has important consequences for the prospect of observing Cooper pairing in atom traps.

44.2.10 Fermi gas in reduced dimensions

In n dimensions with the energy $\varepsilon = ap^s + br^t$ [**?**] we have to generalize the results of the last chapter,

$$N = g\frac{\Gamma\left(\frac{n}{s}+1\right)\Gamma\left(\frac{n}{t}+1\right)}{(2\hbar)^n a^{n/s} b^{n/t}\Gamma\left(\frac{n}{2}+1\right)^2}(k_B T)^{n/s+n/t} f_{n/s+n/t}(z)\ . \tag{44.94}$$

This gives for a harmonic trap where $\varepsilon = \frac{1}{2m}p^2 + \frac{m}{2}\omega^2 r^2$ and with the spin degeneracy factor $g = 1$,

$$N = \left(\frac{k_B T}{\hbar\omega}\right)^n f_n(z)\ . \tag{44.95}$$

The Fermi energy again follows from Sommerfeld's expansion,

$$E_F = (n!N)^{1/n}\hbar\omega\ . \tag{44.96}$$

We now assume a $1D$ potential $V = \frac{m}{2}\omega_z^2 r^2$ embedded in a $3D$ trap. A true $1D$ situation arises when the atoms occupy all low-lying axial levels with the lowest radial vibrational quantum number, i.e. $E_F \ll \hbar\omega_r$ which gives,

$$N \ll \frac{\omega_r}{\omega_z}\ . \tag{44.97}$$

Such quantum degenerate $1D$ fermion gases realize the so-called *Luttinger liquid*. One of the hallmarks of Luttinger liquids is *spin-charge separation*.

Example 282 (*Estimations for 1D*): Let us consider a Fermi gas in a very elongated microtrap: $\omega_r = \sqrt{\frac{87}{7}}2\pi \times 1.4$ kHz and $\omega_z = \sqrt{\frac{87}{7}}2\pi \times 15$ Hz for Rb. With $N_{Li} = 10^5$ the Fermi temperature is as high as $T_F \simeq 5\ \mu$K. However we

need $N \ll 100$ to see $1D$ features.
Assume $\varepsilon = \frac{1}{2m}p^2 + \frac{m^2}{4}b^4r^4$,

$$N = \frac{1}{(\hbar b)^n}\frac{\Gamma\left(\frac{n}{4}+1\right)}{\Gamma\left(\frac{n}{2}+1\right)}(k_BT)^{3n/4}f_{3n/4}(z)$$
$$E_F \approx (\hbar b)^{4/3}\left(N\frac{\Gamma\left(\frac{n}{2}+1\right)\Gamma(\frac{3n}{4}+1)}{\Gamma\left(\frac{n}{4}+1\right)}\right)^{4/3n} .$$

In $1D$,

$$N = \frac{1.02}{\hbar b}(k_BT)^{3/4}f_{3/4}(z)$$
$$E_F \approx 0.87(N\hbar b)^{4/3} .$$

44.2.11 Exercises

44.2.11.1 Ex: Li Fermi gas

Programs on Li Fermi gases.

Solution: *FermiBlocking1: Density distribution of a Li Fermi gas.*
FermiBlocking2: Momentum distribution of a Li Fermi gas.
FermiBlocking3: Time-of-flight distribution of a Li Fermi gas.
FermiBlocking4: Temperature dependence of the rms-size of a Li Fermi gas [221].
FermiBlocking4a: Temperature dependence of the rms-size of a Li Fermi gas [221], in the Sommerfeld approximation.
FermiBlocking4b: Temperature dependence of the rms-size of a Li Fermi gas [221], numerical integration of density of states.

Chapter 45

Bose-Einstein condensation

The experimental verification of Bose and Einstein's prediction was for a long time a cherished dream of many physicists. On the one hand, several phenomena have been related to BEC in the past, for example, the phenomenon of superfluidity in liquid helium and superconductivity. On the other hand, these strongly interacting systems are not pure enough to clearly identify the role of BEC. In 1995, however, Bose-Einstein condensation of weakly interacting confined atomic gases was achieved in several laboratories [31, 331, 189, 580]. This success gave rise to a revolution in atom optics documented in an enormous amount of theoretical and experimental work. While initial work focused on the equilibrium thermodynamics of condensates near the phase transition, very soon the dynamic response of condensates to perturbations was the subject of in-depth investigations, followed by the study of superfluid characteristics, quantum transport phenomena, the interaction of condensates with light, of condensed gas mixtures [939, 1261], and the behavior of condensates in periodic potentials. To name only a few landmarks, we mention the creation of vortices [856, 833] and quantum turbulence [609], the realization of various types of atom lasers [881, 30, 154, 570] and atom interferometers with condensates [574, 746], the coherent amplification of matter waves [649, 749, 651, 354], the creation of the Mott insulating states in optical lattices [537], the study of condensates in reduced dimensions [924], the Anderson localization of atomic matter waves [245, 1101], the observation of Feshbach type collision resonances [300, 648, 1349] and Efimov states [750, 100], the creation of homonuclear molecular [538, 677, 311, 1443, 1402, 612] and heteronuclear condensates [986] and degenerate Fermi gases [347], the observation of BCS type pairing [623, 539], the observation of matter wave superradiance [649] and the interaction of condensates with optical cavities [1217, 223] and with surfaces [119].

It is clearly unthinkable to discuss all matters in this course. Let us, however, give a basic and practical introduction to atomic optics with condensates.

45.1 Bose-Einstein condensation of dilute gases

The challenge of the experimental realization of Bose-Einstein condensation is the preparation of a very dense sample of very cold atoms. In practice, the first step consists in providing an atomic gas, for example, of an alkali metal. This is done by heating the metal in an oven (or sometimes in a dispenser). The atoms being ejected from the metal and forming a hot gas are then forced through a nozzle out of the oven, where they form a hot atomic beam. Some experiments employ a *Zeeman*

slower, which is a device that decelerates the fast atoms of the beam by means of a counterpropagating laser exerting a radiative pressure force. A position-dependent magnetic field applied along the trajectory of the atoms is calculated in order to compensate for the Doppler decreasing shift of the decelerated atoms and to ensure that the laser always stays in resonance with an atomic transition (see Exc. 34.6.7.3). Velocities around 30 m/s are realistic and low enough to allow the capture of the atoms by a magneto-optical (MOT) trap. Usually, some 10^9 atoms are captured in a few seconds.

MOTs do not only trap atoms, but simultaneously cool them down to the Doppler limit of typically some 10 μK. Quasi-resonant optical traps, such as MOT, are afflicted by the problem of radiation trapping (see Sec. 43.3.1), which limits the densities of atomic clouds to typically $10^{11}\,\mathrm{cm}^3$. This corresponds (at temperatures close to the Doppler limit) to phase space densities several orders of magnitude away from the threshold to Bose-Einstein condensation. For this reason, the atoms are transferred from the MOT to a potential exempt of radiative pressure force, for example, an optical dipole potential or a magnetic trap.

Once the atoms are confined in such a conservative potential, all the light beams are turned off, and the technique of evaporative cooling is activated (see Sec. 43.4.3). That is, the effective potential is deformed (for example, by an irradiated radiofrequency) in a way to skim out hot atoms and leave behind a cooler sample. This however supposes that the atomic cloud finds back to thermal equilibrium afterwards. As the rethermalization happens by elastic collisions, a high atomic density is necessary, which is often achieved via a compression of the trapping potential. In general, 99.9% of the atoms must be sacrificed to condense the rest. Finally, the momentum distribution is imaged after a time of free expansion. This is done by irradiation of a probe laser pulse (see Fig. 43.36). The entire process of producing a condensed cloud usually takes between 10 s and 60 s.

45.1.1 Condensate of alkaline gases

The first experimental observation of Bose-Einstein condensation was done with a dilute rubidium gas by Cornell and Wieman at the Joint Institute for Laboratory Astrophysics (JILA) [31]. A group from the University of Texas [580, 301] used rubidium as well. A group led by Ketterle from the Massachusetts Institute of Technology (MIT) created the first sodium condensate. And a group led by Hulet from Rice University opted for lithium [189, 187], which has a slightly negative scattering length, $a = -27.3a_B$. In this situation, only small condensates are expected to be stable [1122, 1270], which explains the observation of a limited number of about 1400 condensed lithium atoms. Meanwhile, Bose-Einstein condensation has been achieved with many other species, such as ^{1}H [466], ^{85}Rb [293], ^{4}He* [1107], ^{133}Cs [1227], ^{39}K [1056], ^{4}Ne [113], ^{88}Sr [1257], or even molecules [1396].

45.1.2 Condensation of hydrogen

Hydrogen is a very interesting element to study condensation, because its short scattering length, $a \approx 1.23a_B$, makes it an almost ideal gas. Consequently, the three-body collision rate causing losses is weak, even at very high densities. Since the mass of

hydrogen is small, the critical temperature is high. The simplicity of its electronic structure allows precise calculations of the interaction potentials based on fundamental principles, which can thus be tested experimentally.

Twenty years after having started the project of condensing dilute hydrogen gases, Greytak and Kleppner [466] crossed the phase transition at a temperature of 50 μK with an atomic density of $5 \times 10^{15}\,\mathrm{cm}^{-3}$. The number of condensed atoms was 10^9, which corresponds to a condensed fraction below 10% [1]. The condensed cloud had a needle-like shape of 15 μm diameter and 5 mm length. It was detected by an *in situ* measurement technique of the atomic velocity distribution.

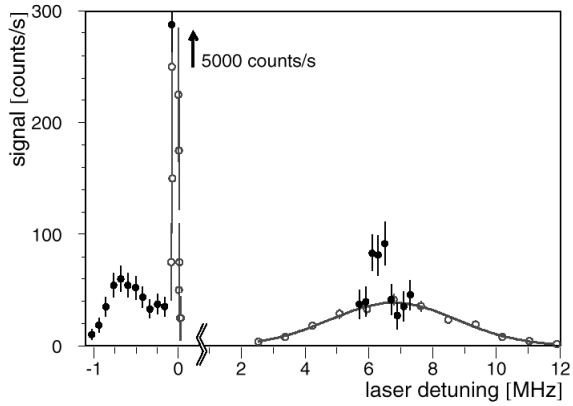

Figure 45.1: Spectrum of condensed hydrogen.

45.1.3 Recognizing Bose-Einstein condensates

'How to recognize the presence of a condensate, what are its signatures?' We have already seen in Sec. 44.1.4 that, trapped inside a confinement potential, an ultracold ideal Bose-gas has a modified density distribution when Bose-Einstein statistics come into play. Below the critical temperature the density distribution is well described by a superposition of a condensed cloud concentrated in the trap's ground state and a thermal cloud distributed over several vibrationally excited states. We thus expect distinct distribution functions for both clouds, and the same is true for the momentum distribution. The splitting of the distribution functions in two fractions occurs abruptly during the phase transition to quantum degeneracy. In a real gas, however, the interatomic collisions have a drastic influence on the distribution functions and the behavior of the gas at the phase transition, and we are obliged to develop a more general theory in order to quantitatively understand the thermodynamic properties (temperature, critical point, heat capacity, ...) through the measured static quantities (density, number of atoms, condensed fraction, ...).

'What observables can be measured in the laboratory?' In fact, with few exceptions, the only accessible quantity is the *spatial density distribution* of the atomic cloud

[1] When the condensed fraction and the density are too high, losses induced by dipolar spin-flip processes predominate over the gain due to evaporative cooling of the thermal cloud [618].

$n(\mathbf{r})$ measured after a time of ballistic expansion. Information on non-trivial properties of the condensate, for example, its dynamic behavior (excitations, superfluidity, turbulence, ...) or its coherent features (phase, correlations, ...), can only be gathered through an observation of the condensate's response to applied perturbations. Solve the Excs. 45.1.5.1 and 45.1.5.2.

45.1.4 Photon condensation

An interesting question is that of the possibility of *photon condensation* and its relationship to the laser. The relationship is not that obvious because, on one hand atomic condensates are produced by evaporating a ensemble in constant thermal equilibrium, while on the other hand the photonic laser requires inversion, which is a highly non-equilibrium situation. And under the constraint of having to reduce its energy, a photon gas trapped in an optical cavity has the simpler alternative to let photons escape into the void by annihilating them on the cavity walls, as it happens for black-body radiation. Since the number of photons in a cavity is not conserved, the chemical potential disappears, $\mu = 0$. The density of states can be written,

$$u(\nu) = \frac{8\pi V}{c^3} \frac{E^2 dE}{h^2} \ . \tag{45.1}$$

It is the same as in the Debye model. Planck's formula now follows from,

$$u(\epsilon)d\epsilon = \frac{1}{V}\epsilon f_{BE}(\epsilon)\rho(\epsilon)d\epsilon \ , \tag{45.2}$$

where f_{BE} is the Bose-Einstein distribution. Hence, the treatment of the photons as indistinguishable particles following the Bose-Einstein distribution is equivalent to assuming a Boltzmann distribution for waves with quantized energies.

Nevertheless, one can imagine a photonic gas in thermal equilibrium with an atomic gas through Compton scattering [712]. In fact, photon condensation was observed experimentally [727]. Also, there are theories about superfluid photon gases [254] [2].

[2] *Bose-Einstein condensation occurs in thermal equilibrium when entropy is maximized by putting a macroscopic population of atoms into the ground state of the system. It might appear counter-intuitive that an apparently highly ordered state as the Bose condensate maximizes entropy. However, only the particles in excited states contribute to the entropy. Their contribution is maximized at a given total energy by forming a Bose condensate in the ground state and distributing the remaining atoms among higher energy states. A macroscopic population of atoms in the ground state of the system is achieved simply by lowering the temperature of the sample. This is in contrast to the optical laser where a non-equilibrium process is necessary to place a macroscopic population of photons in a single mode of the electromagnetic field. This is due to the fact that, unlike photons, the number of atoms is conserved. For bosonic atoms, the lowest entropy state below a certain temperature includes a macroscopic population of the ground state. In contrast, when one cools down a blackbody cavity, the cavity empties. Photons do not Bose condense into the ground state of the cavity, but are absorbed by the walls. The absorbed energy leads to a larger entropy than forming a Bose condensate. The laser phenomenon requires inversion of the active medium characterized by a 'negative' temperature. In that sense, 'lasing' of atoms is a simpler phenomenon than lasing of light –all you need to do is cool a gas! However, if a photon gas would thermalize while the number of photons is conserved, it would be described by a Bose-Einstein distribution with non-zero chemical potential and could form a Bose condensate. Thermalization with number conservation is possible, for example, by Compton scattering with a thermal electron gas [712].*

45.1.5 Exercises

45.1.5.1 Ex: Condensation of ions

Discuss the possibility of creating Bose-Einstein condensates from ionic clouds.

Solution: *Assuming that we can cool the ions to the ground state of a tight trap, they will still have μm distances because of Coulomb repulsion. The de Broglie wavelength then needs to be ...*

45.1.5.2 Ex: Isobaric impurities

Discuss the possibility of creating Bose-Einstein condensates with isobaric species.

Solution:

45.2 Quantum theory

As detailed above, interatomic interactions strongly influence the properties of Bose-Einstein condensates, even their density and momentum distributions. For a correct interpretation of the experimental measurements a theoretical many-body treatment taking care of these interactions is compulsory. This is done through a description of the atomic distribution as a *scalar field of matter* called *second quantization*, where the atoms are treated as delocalized Broglie waves. However, we will leave a thorough introduction of this formalism to Chp. 50.3 or referto [1355].

45.2.1 Description of the atom as a scalar field

In position space a state with n particles can be described in a canonically quantized way by a *field operator*,

$$\hat{\Psi}(\mathbf{r}_1, ..., \mathbf{r}_n, t) = \hat{\psi}^\dagger(\mathbf{r}_1, t) \cdot ... \cdot \hat{\psi}^\dagger(\mathbf{r}_n, t)\hat{\Psi}_0 \quad , \quad \hat{\psi}(\mathbf{r})\hat{\Psi}_0 = 0 \ , \tag{45.3}$$

where Ψ_0 is the vacuum state. The field operators $\hat{\psi}(\mathbf{r}, t)$ and $\hat{\psi}^\dagger(\mathbf{r}, t)$ annihilate, respectively create, an atom at position $\mathbf{r}$ and time t. This state represents a bosonic Fock state and can be generated from the empty state by a sequence of individual particle creation operators. Applying the notions and rules developed for the harmonic oscillator in Sec. 24.6.1, we can define a coherent state of bosonic matter as,

$$|\hat{\Phi}(t)\rangle = \sum_{n=0}^{\infty} \frac{N^{n/2}}{\sqrt{n!}} |\hat{\Psi}(\mathbf{r}_1, ..., \mathbf{r}_n, t)\rangle \ . \tag{45.4}$$

The field operators for particle creation and annihilation are normalized to the number of atoms and satisfy the following commutation rules,

$$\begin{array}{llcl}
\text{(i)} & [\hat{\psi}(\mathbf{r}),\hat{\psi}(\mathbf{r}')]_- & = & 0 \\
\text{(ii)} & [\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r}')]_- & = & \delta^3(\mathbf{r}-\mathbf{r}') \quad , \quad \hat{\psi}^\dagger(\mathbf{r}) = \int d^3r'\hat{\psi}^\dagger(\mathbf{r}')\delta^3(\mathbf{r}-\mathbf{r}') \\
\text{(iii)} & [\hat{\psi}(\mathbf{r}),\hat{N}]_- & = & \hat{\psi}(\mathbf{r}) \quad , \quad \hat{N} = \int d^3r'\hat{\psi}^\dagger(\mathbf{r}')\hat{\psi}(\mathbf{r}') \\
\text{(iv)} & [\hat{\psi}(\mathbf{r}),\hat{\mathbf{p}}]_- & = & \frac{\hbar}{\imath}\nabla\hat{\psi}(\mathbf{r}) \quad , \quad \hat{\mathbf{p}} = \int d^3r'\hat{\psi}^\dagger(\mathbf{r}')(\frac{\hbar}{\imath}\nabla')\hat{\psi}(\mathbf{r}') \\
\text{(v)} & [\hat{\psi}(\mathbf{r}),\mathcal{H}]_- & = & \imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r})
\end{array} \tag{45.5}$$

The last equation is the Heisenberg equation of motion and describes the dynamics of a system whose *many-body Hamiltonian* $\mathcal{H} \equiv \mathcal{H}_{cm} + \mathcal{H}_{self}$ for N bosons interacting within an external potential V_{trap} in second quantization is defined by [3],

$$\begin{aligned}
\mathcal{H}_{cm} &\equiv \int d^3r\hat{\psi}^\dagger(\mathbf{r})\left(-\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r},t)\right)\hat{\psi}(\mathbf{r}) \\
\mathcal{H}_{self} &\equiv \int d^3r\int d^3r'\hat{\psi}^\dagger(\mathbf{r})\hat{\psi}^\dagger(\mathbf{r}')V_{coll}(\mathbf{r}-\mathbf{r}')\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r})
\end{aligned} \quad . \tag{45.6}$$

The equations (45.5) and (45.6) represent the foundation of the theory of ultracold bosonic gases. However, to solve the equations, we will need to apply some simplifications, which will be discussed in the following sections. For example, we will generally assume that the temperature of the sample is $T = 0$, and that all atoms are condensed. Also, in a first time, we will neglect quantum fluctuations, replacing field operators with complex numbers. And finally, we will need to handle the nonlinear term appearing in $\mathcal{H}_{self}$ and which signs responsible for collisions between atoms.

45.2.2 Quantum scattering at low temperatures

To simplify the term $\mathcal{H}_{self}$, we have to go back to Secs. 33.2.5 (and following) and study the phenomenon of the elastic collisions in the ultracold regime. For simplicity, we consider two particles without internal degrees of freedom with masses m_1 and m_2 approaching each other along the z-axis [276, 1363]. Neglecting spin-spin and spin-orbit interactions, the Schrödinger equation in the inertial center-of-mass system is given by (33.115),

$$\left(-\frac{\hbar^2}{2m^*}\nabla^2 + V_{coll}(r)\right)\hat{\psi}(\mathbf{r}) = E\hat{\psi}(\mathbf{r}) \ , \tag{45.7}$$

where $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$ is the momentary interatomic separation, $r = |\mathbf{r}|$, and $m_r \equiv m_1m_2/(m_1+m_2)$ is the reduced mass of atomic collision partners. We assume that the interatomic potential, $V_{coll}(r)$, is spherically symmetrical. In the asymptotic limit of large separations [4], and in the Born-approximation (33.135), the solution of

[3] Sometimes the *Kamiltonian* is used for canonical and macrocanonic ensembles. It defined by, $\mathcal{K} = \mathcal{H}_{cm} + \mathcal{H}_{self} - \int d^3\mathbf{r}\hat{\psi}^\dagger(\mathbf{r})\mu\hat{\psi}(\mathbf{r})$, where μ is the chemical potential.

[4] This means, $r \gg r_0$, where r_0 is the range of potential $V(r)$.

Eq. (45.7) can be seen as the sum of an incident plane wave and a scattered spherical wave modulated with a certain amplitude $f(\theta)$,

$$\psi(\mathbf{r}) = e^{\imath kz} + f(\theta)\frac{e^{\imath kr}}{r} \ , \tag{45.8}$$

where $k = \sqrt{2m_r E/\hbar^2}$ is the amplitude of the wavevector of the incident and scattered waves and θ the angle between r and z. The function $f(\theta)$ is called *scattering amplitude* and determines the scattering cross-section for s-wave collision through the expression [see (33.123)],

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2 \ . \tag{45.9}$$

where $d\Omega = \sin\theta d\theta d\phi$ is an element of the solid angle. To calculate the scattering amplitude, we expand the wavefunction (45.8) into spherical partial waves of orders ℓ of the angular momentum, as done in (33.136),

$$f_k(\theta) = \frac{1}{k}\sum_{\ell=0}^{\infty}(2\ell+1)P_\ell(\cos\theta)e^{\imath\delta_\ell}\sin\delta_\ell \ . \tag{45.10}$$

The collision cross section has been shown in (33.148) to be given by,

$$\sigma = \frac{4\pi}{k^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\delta_\ell \ . \tag{45.11}$$

For a potential with finite range, that is, a potential falling faster than r^{-3} with the distance (interatomic potentials usually fall as r^{-6} or r^{-7}), the phase shift satisfies,

$$\delta_\ell \propto k^{2\ell+1} \tag{45.12}$$

for small k. In ultra-cold gases, the collision energy is very low and $k \to 0$. Thus the scattering will be dominated by terms with $\ell = 0$. This is the so-called limit of *s-wave scattering*. In this limit the Eqs. (45.10) can be approximated as,

$$f_k(\theta) = \frac{1}{k}e^{\imath\delta_0}\sin\delta_0 \ . \tag{45.13}$$

45.2.3 Scattering length

For $\ell = 0$, taking the limit $k \to 0$, we define the *scattering length* a_s via,

$$\frac{\mathfrak{Im}\ f_k(\theta)}{\mathfrak{Re}\ f_k(\theta)} = \tan\delta_0 \equiv -\tan ka_s \ . \tag{45.14}$$

Therefore, the scattering length and cross section are given at very low temperatures at the asymptotic boundary by,

$$\boxed{a_s = -\frac{\delta_0}{k} \qquad \text{and} \qquad \sigma = 4\pi a_s^2} \ . \tag{45.15}$$

The scattering process can be interpreted as follows: During a collision, the system's wavefunction undergoes a phase shift, δ_0, which may be positive or negative, depending on the sign of a_s. If $a_s < 0$, the phase is 'delayed' by the collision. This corresponds to an attractive interaction. In contrast, if $a_s > 0$, the phase is 'advanced' and the interaction is repulsive. Of course, the intensity of the interaction is proportional to the value of $|a_s|$. The expression for σ in Eq. (45.15) indicates, that the atoms behave like *hard spheres* with radius $|a_s|$. The specific value of a_s will depend on the interaction potential, however, the details of the potential are unimportant, as all information about the collision is already contained in a_s. Consequently, in the low-energy limit, we can assume that the collision is mediated by an effective potential $V_{coll}(\mathbf{r})$, which has the particularity,

$$\int V_{coll}(\mathbf{r}) d^3r = \frac{4\pi\hbar^2}{m} a_s \equiv g \ . \tag{45.16}$$

This has been shown in Sec. 33.1.2. Consequently, the effective interaction between two particles at positions $\mathbf{r}$ and $\mathbf{r}'$ can be considered as contact interaction given by [5],

$$V_{coll}(\mathbf{r}, \mathbf{r}') = \frac{g}{2} \delta(\mathbf{r} - \mathbf{r}') \ . \tag{45.17}$$

The interatomic interaction potential decides on the value of the scattering length a_s: A repulsive potential corresponds to a positive a_s. For a purely attractive potential that does not support bound states a_s is negative, and for an attractive potential that supports bound states a_s may be positive or negative depending on the proximity of the last bound vibrational state of the interaction potential below the dissociation limit.

45.2.4 The mean field approximation

The *mean-field theory* (MFT) or *local density approximation* (LDA) is based on the assumption of *hard sphere collision*s between atoms (as described by the potential (45.17)) propagating through a locally homogeneous mean-field potential, $\frac{g}{2}|\hat{\psi}(\mathbf{r})|^2$. The procedure is also called *regularization of the interaction*.

Thus, the mean-field energy of a condensate is proportional to the density of the gas n and to a single atomic constant, which is the scattering length a_s. Its presence in the Gross-Pitaevskii equation emphasizes its impact on shape, dynamic stability and many other properties of the condensate. For example, the mean-field interaction contributes to the broadening of a condensed wavepacket, and consequently contracts its momentum distribution in comparison with an ideal gas. Homogeneous condensates with a negative scattering length are unstable, because the attempt of such a condensate to lower its self-energy by increasing its density also increases the rate of inelastic three-body collisions until the condensate collapses.

[5] The *Hartree-Fock-Bogolubov method* (HFB) for the mean-field theory disregards corrections of higher orders, for example, due to the renormalization of the scattering length. It also neglects quantum depletion due to the correlation effects of the order of $N_{out}/N = \frac{5}{8}\sqrt{\pi}\sqrt{a^3 n_0}$. The theory mean-field supposes the validity of the *Born approximation*, that is, two-body correlations are neglected, $\hat{\psi}(\mathbf{r}') \approx \hat{\psi}(\mathbf{r})$ and $\int d^3R V_{coll}(\mathbf{R}) = \frac{g}{2}$.

45.2.5 Gross-Pitaevskii equation

The Heisenberg equation [last line of (45.5)] is equivalent to the *variational principle*, as stated by the Ehrenfest theorem,

$$\imath\hbar\frac{d\hat{\psi}}{dt} = \frac{\delta\mathcal{H}}{\delta\hat{\psi}^\dagger} \ . \tag{45.18}$$

This facilitates the derivation of the equation of motion for the atomic field. With the Hamiltonian (45.6) in the mean-field approximation,

$$\mathcal{H}_{atom} \equiv \mathcal{H}_{cm} + \mathcal{H}_{mf} \qquad \text{with} \qquad \mathcal{H}_{mf} \equiv \int d^3r\hat{\psi}^\dagger(\mathbf{r},t)\frac{g}{2}|\hat{\psi}(\mathbf{r},t)|^2\hat{\psi}(\mathbf{r},t) \ , \tag{45.19}$$

we find the *non-linear Schrödinger equation*,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r},t) + g|\hat{\psi}(\mathbf{r},t)|^2\right]\hat{\psi}(\mathbf{r},t) = \imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r},t) \ . \tag{45.20}$$

Remember that, despite their symbol $\hat{\psi}$, which usually is associated to wavefunctions, and the fact that they satisfy a non-linear Schrödinger equation the field operators are represented by matrices acting of many-body states. That is, Eq. (45.20) also represents a Heisenberg equation for the field operators.

A common approximation is the *Bogolubov prescription*, where the field operators describing the condensate and its fluctuations are decomposed into a complex function, $\psi_0(\mathbf{r}) \equiv \langle\hat{\psi}(\mathbf{r})\rangle$ called *condensed wavefunction*, which can be chosen as the *order parameter* of the system, and a small perturbation, $\delta\hat{\psi}(\mathbf{r}) \equiv \hat{\psi}(\mathbf{r}) - \psi_0(\mathbf{r})$ describing *thermal excitations*. At zero temperature, we can neglect the excitations [108], and our system is completely described by a single wavefunction, $\psi_0(\mathbf{r},t)$, obeying the famous *Gross-Pitaevskii equation* (*GPE*),

$$\boxed{\left[\frac{-\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r},t) + g|\psi_0(\mathbf{r},t)|^2\right]\psi_0(\mathbf{r},t) = \imath\hbar\frac{\partial}{\partial t}\psi_0(\mathbf{r},t)} \ . \tag{45.21}$$

45.2.5.1 Spontaneous breaking of gauge symmetry

The description of a condensate by a single macroscopic wavefunction means that we attribute a well-defined phase to it. However, the GPE does not allow us to predict, which phase between 0 and 2π this will be, and we have to assume, that the BEC chooses its phase spontaneously when it undergoes the phase transition to quantum degeneracy. This principle is called *spontaneous breaking of gauge symmetry* [6]. In Exc. 45.2.6.2 we study the relation between the fact of having exactly N atoms in a condensate and a well-defined phase φ, knowing that these two quantities are conjugate variables having to satisfy a Heisenberg uncertainty relation.

[6] An alternative way of modeling the development of a BEC phase is based on measurement theory. See also (35.72) for an analogy to the correct state of a laser.

45.2.6 Exercises

45.2.6.1 Ex: Derivation of the non-linear Schrödinger equation

Derive the non-linear Schrödinger equation using (a) the commutator relation (45.5)(v) and (b) the variational expression (45.18).

Solution: *From the commutator relation,*

$$\imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r}) = [\hat{\psi}(\mathbf{r}),\mathcal{H}]_- = \left[\hat{\psi}(\mathbf{r}),\int d^3r'\hat{\psi}^\dagger(\mathbf{r}')\left(-\frac{\hbar^2}{2m}\nabla'^2 + V_{trap}(\mathbf{r}',t) + \frac{g}{2}\hat{\psi}^\dagger(\mathbf{r}')\hat{\psi}(\mathbf{r}')\right)\hat{\psi}(\mathbf{r}')\right]_-$$

$$= -\frac{\hbar^2}{2m}\int d^3r[\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r}')]_-\nabla'^2\hat{\psi}(\mathbf{r}') + \int d^3r[\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r}')]_- V_{trap}(\mathbf{r}',t)\hat{\psi}(\mathbf{r}')$$

$$+ \frac{g}{2}\int d^3r[\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r}')\hat{\psi}^\dagger(\mathbf{r}')]_-\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r}')$$

$$= -\frac{\hbar^2}{2m}\nabla^2\hat{\psi}(\mathbf{r}) + V_{trap}(\mathbf{r},t)\hat{\psi}(\mathbf{r}) + \frac{g}{2}\int d^3r\left\{[\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r}')]_-\hat{\psi}^\dagger(\mathbf{r}') + \hat{\psi}^\dagger(\mathbf{r}')[\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r}')]_-\right\}\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r}')$$

$$= \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r},t) + g|\hat{\psi}(\mathbf{r})|^2\right)\hat{\psi}(\mathbf{r}) \ ,$$

using the commutation relation $[\hat{\psi}(\mathbf{r}),\hat{\psi}^\dagger(\mathbf{r})]_- = \delta(\mathbf{r}-\mathbf{r}')$.
b. From the variational expression,

$$\imath\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r}) = \frac{\delta\mathcal{H}}{\delta\hat{\psi}^\dagger} = \frac{\delta}{\delta\hat{\psi}^\dagger}\int d^3r'\hat{\psi}^\dagger(\mathbf{r}')\left(-\frac{\hbar^2}{2m}\nabla'^2 + V_{trap}(\mathbf{r}',t) + \frac{g}{2}\hat{\psi}^\dagger(\mathbf{r}')\hat{\psi}(\mathbf{r}')\right)\hat{\psi}(\mathbf{r}')$$

$$= \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r},t) + g|\hat{\psi}(\mathbf{r})|^2\right)\hat{\psi}(\mathbf{r}) \ .$$

45.2.6.2 Ex: Spontaneous breaking of gauge symmetry

One of the primary characteristics of a condensate is its phase coherence. Now, consider a condensate with exactly N atoms. The exact knowledge of the atom number implies a totally uncertain phase of the condensate, according to Heisenberg's uncertainty relation. Explain this contradiction!

Solution: *Following Yukalov [297], the existence of a single phase is* not essential *for BECs. The question of symmetry breaking as a concept of quantum field theory only arises for homogeneous systems. If, in a phase transition, the two phases have different symmetries, the transition is accompanied by a symmetry breaking. Only continuous phase transitions may exhibit symmetry breaking. Therefore, spontaneous symmetry breaking is not expected for homogeneous condensates, but only in confined, finite or interacting systems. Gauge symmetry breaking leads to collapse and revivals due to particle number fluctuations. It was demonstrated [1115], that the theory of BEC can also be formulated without the concept of symmetry breaking. The existence of off-diagonal long-range order (ODLRO) in the density operator, which is an indicator for long-range correlations between particles, is equivalent to the presence of a condensed phase in a sample.*

45.3 Approximate solutions of the Gross-Pitaevskii equation

45.3.1 Stationary GPE

In cases where the external potential is stationary, $V_{trap}(\mathbf{r},t) = V_{trap}(\mathbf{r})$, the temporal dependency of the GPE can be removed by the ansatz,

$$\psi_0(\mathbf{r},t) = \psi_0(\mathbf{r})e^{-\imath\mu t/\hbar} \ . \tag{45.22}$$

This gives the stationary Gross-Pitaevskii equation,

$$\boxed{\left[\frac{-\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r}) + g|\psi_0(\mathbf{r})|^2\right]\psi_0(\mathbf{r}) = \mu\psi_0(\mathbf{r})} \ , \tag{45.23}$$

where μ is called the *chemical potential*. Solve Exc. 45.3.4.1.

45.3.2 Trapped condensates and the Thomas-Fermi limit

45.3.2.1 Free particles

The wavefunction of free particles, $V(\mathbf{r}) = 0$, can be described by a plane wave,

$$\psi(\mathbf{r}) = \sqrt{n}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{45.24}$$

also called the Hartree solution. Inserted it into the equation of Gross-Pitaevskii equation,

$$E(k) = \frac{\hbar^2k^2}{2m} + gn \ , \tag{45.25}$$

we observe a *gap* in the energy spectrum due to the interaction.

45.3.2.2 Ideal gas in a harmonic potential

Most experiments apply non-isotropic (often cylindrical) potentials, which are additionally distorted by the mean-field. Hence, the non-linear term of the GPE is important, and the spatial coordinates can not be separated. However, assuming an ideal gas and a harmonic potential, the dimensions could be separated, as demonstrated in Sec. 24.5.5, even when the potential is not isotropic. It is then sufficient to consider one-dimensional problems with $g = 0$,

$$\left[-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + \frac{m}{2}\omega_x^2\hat{x}^2\right]\psi_n = \mu_n\psi_n \ . \tag{45.26}$$

In this limit, the GPE is nothing more than the usual Schrödinger equation, which has the well-known spectrum (24.110) and the solutions (24.109).

45.3.2.3 Ideal gas in an isotropic potential

In the case of an ideal gas trapped in a spherically symmetric potential, as shown in (25.34), the Schrödinger equation can be reduced to its radial component,

$$\left[\frac{\partial^2}{\partial r^2} + \frac{2}{r}\frac{\partial}{\partial r} - \frac{l(l+1)}{r^2} + V_{trap}(r)\right] f_{nlm}(r) = \mu_{nl} f_{nlm}(r) \ , \tag{45.27}$$

with the solution (25.18),

$$\psi_n(r,\vartheta,\varphi) = \sum_{l,m} f_{nlm}(r) Y_{lm}(\vartheta,\varphi) \tag{45.28}$$

The differential equation (45.27) can be solved numerically by Runge-Kutta type methods,

$$\begin{pmatrix} f'' \\ f' \end{pmatrix} = \begin{pmatrix} \frac{2}{r} & \mu + \frac{l(l+1)}{r^2} - V_{trap}(r) \\ 1 & 0 \end{pmatrix} \begin{pmatrix} f' \\ f \end{pmatrix} \ . \tag{45.29}$$

45.3.2.4 Thomas-Fermi limit for strong interactions

In the case of strong interactions, the kinetic energy term can be neglected, at least in the center of the cloud, where the mean-field energy is stronger. For this case, called *Thomas-Fermi limit*, the GPE solution is easy,

$$|\psi_0(\mathbf{r})|^2 = \frac{\mu - V_{trap}}{g} \ . \tag{45.30}$$

The chemical potential follows from the normalization condition,

$$N = \int_{n(\mathbf{r})>0} n(\mathbf{r}) d^3\mathbf{r} \ . \tag{45.31}$$

In the case of an cylindrical harmonic oscillator potential, $V_{trap}(r,z) = \frac{m}{2}(\omega_r^2 r^2 + \omega_z^2 z^2)$, the chemical potential is,

$$\mu = \left(\frac{15Ng}{8\pi}\right)^{2/5} \left(\frac{m}{2}(\omega_r^2\omega_z)^{2/3}\right)^{3/5} \ . \tag{45.32}$$

The radial size σ of the condensate follows from $n(r_{hw},0) = \frac{n(0,0)}{2}$,

$$r_{hw} = \sqrt{\frac{\mu}{m\omega_r^2}} \ . \tag{45.33}$$

Solve the Excs. 45.3.4.2 and 45.3.4.3.

45.3.3 Variational treatment of the GPE

The many-body Hamiltonian (45.19) can be used as an *energy functional*,

$$E[\psi_0] \equiv \langle \mathcal{H}[\psi_0] \rangle = \int d^3r \left[\frac{\hbar^2}{2m}|\nabla\psi_0|^2 + V_{trap}(\mathbf{r})|\psi_0|^2 + \frac{g}{2}|\psi_0|^4\right] \ , \tag{45.34}$$

from which, using the variational condition (45.18), we have derived the Gross-Pitaevskii equation (45.21). Hence, the wavefunction ψ_0 minimizes the functional [378]. By inserting an ansatz for the wavefunction with adjustable parameters, the functional provides conditions to optimize these parameters.

The *variational method* is useful e.g. for finding the ground state wavefunction of a condensate in an arbitrarily shaped trap or to perform a stability analysis of a condensate with attractive interatomic forces.

45.3.3.1 Finding the fundamental state of the GPE

This problem of finding the ground state wavefunction of a condensate consists in finding the ψ for which the energy $\mathcal{H}[\psi]$ goes to a minimum. In general, the functional has the form $\mathcal{H}[\psi] = \int f[\psi, \nabla\psi] d^3r$. The fastest way to the minimum is to reduce the energy by varying ψ in that direction, where the gradient $\delta\mathcal{H}/\delta\psi^*$ is largest, that is,

$$\begin{aligned} \mathcal{H} &\to \mathcal{H}[\psi + \tau \, \tfrac{\delta\mathcal{H}}{\delta\psi^*}] \\ \psi &\to \psi + \tau \tfrac{\delta\mathcal{H}}{\delta\psi^*} \ , \end{aligned} \tag{45.35}$$

with the boundary condition, that the normalization must be preserved. Formally, this problem is similar to a time-dependent Gross-Pitaevskii equation, but with *imaginary time*. Physically, the procedure, called the *steepest descent method*, can be interpreted as applying a heavily 'overdamped' friction force,

$$\frac{\partial\psi}{\partial\tau} = \frac{\delta\mathcal{H}}{\delta\psi^*} \ . \tag{45.36}$$

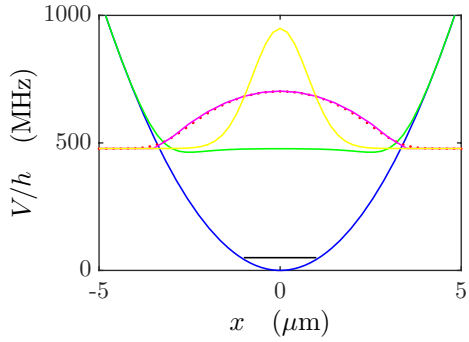

Figure 45.2: (code) Calculation of the BEC wavefunction by the steepest descent method (red dots). Also shown are the ideal gas approximation (yellow line) and the Thomas-Fermi approximation (magenta line), as well as the ground state energy (black line) and the chemical potential (green line).

In practice, the procedure is as follows: we start with a trial wavefunction, for example, the exact solution of the interaction-free case. This function is now propagated in imaginary time, using the complete Hamiltonian including the non-linear term, and then renormalized:

$$\hbar\frac{\partial}{\partial t}\psi(\mathbf{r}, t) = \mathcal{H}(\mathbf{r})\psi(\mathbf{r}, t) \ . \tag{45.37}$$

Substituting the imaginary unit i in the time-dependent Gross-Pitaevskii equation (45.21) by -1, we obtain,

$$\psi(\mathbf{r}, t + dt) = [1 - \hbar^{-1}\mathcal{H}(\mathbf{r})dt]\psi(\mathbf{r}, t) \tag{45.38}$$
$$\psi'(\mathbf{r}, t) \equiv \frac{\psi(\mathbf{r}, t + dt)}{|\psi(\mathbf{r}, t + dt)|} \to \psi(\mathbf{r}, t) \ .$$

This procedure is repeated until the function converges. Since this method is derived from a variational principle, it only serves to find the ground state of the trapping potential. It can not be used for excited states (with the exception of vortex states, where in cylindrical coordinates the Hamiltonian differs by an additional centrifugal term).

45.3.3.2 Collapse and stabilization of condensates with attractive interactions

Attractive interactions destabilize a Bose-Einstein condensate. Since the interaction energy, $4\pi\hbar^2 a_s n/m$, of a condensate with negative scattering length decreased with increasing density n, the condensate attempts to lower its interaction energy by increasing its density until it succumbs to inelastic two-body spin-changing collisions of to three-body collisions leading to the formation of molecules [1270]. Strictly speaking, this only holds true for homogeneous condensates. In the presence of a trapping potential, however, the zero-point energy exerts a kinetic pressure, which counteracts the *condensate collapse* to a certain extent, such that small condensates are stabilized. This can be verified by inserting a Gaussian wavefunction $\psi_0 \propto e^{-r^2/2\bar{r}^2}$ into the energy functional (45.34). Varying the radius $\bar{r}$ of the condensate, we find a local minimum where the condensate is stable. Calculations for spherical traps predict [1122, 319],

$$N_{min} \simeq 0.575 \frac{a_{trp}}{|a_s|} \ , \tag{45.39}$$

where $a_{trp} = \sqrt{\hbar/m\omega_{trp}}$.

The atomic species ^{7}Li has a slightly negative scattering length $a_s = -27.3a_B$. As can be seen in Fig. 45.3, small condensates can survive in a confining trap, since the energy functional has a local minimum [189, 187, 1124]. Solve Exc. 45.3.4.4.

45.3.4 Exercises

45.3.4.1 Ex: GPE in dimensionless units

Use the following abbreviations to rewrite the Gross-Pitaevskii equation and its solution for a harmonic isotropic potential in dimensionless units,

$$\begin{array}{llll} V_1 & \equiv V_{trap}/\hbar\omega_{trp} & V_{trap} & = \frac{m}{2}\omega_{trp}^2 r^2 \\ \mathbf{r}_1 & \equiv \mathbf{r}/a_{trp} & a_{trp} & = \sqrt{\hbar/m\omega_{trp}} \\ \mu_1 & \equiv \mu/\hbar\omega_{trp} & T_1 & \equiv k_B T/\hbar\omega_{trp} \\ \psi_1 & \equiv \psi/a_{trp}^{3/2} & p_1 & \equiv a_{trp}p/\hbar \\ g & \equiv 4\pi\hbar^2 a/m & g_1 & \equiv 8\pi N_0 a/a_{trp} \end{array}$$

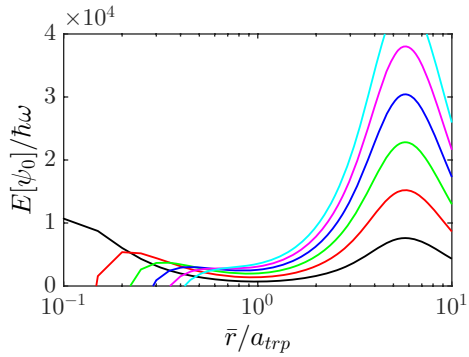

Figure 45.3: (code) Energy of a ^{7}Li condensate in a harmonic isotropic potential with $\omega_{trp} = (2\pi)$ 50 Hz with $N = 500$ atoms (linha inferior) up to $N = 3000$ (linha superior) when the radius $\bar{r}$ of the condensate is varied.

Solution: *In* 3 *dimensions the GPE becomes,*

$$\left(\nabla_1^2 + r_1^2 + g_1|\psi_1|^2\right)\psi_1 = \mu\psi_1 \ .$$

45.3.4.2 Ex: Interacting gas in an isotropic potential

Consider the potential $V(\mathbf{r}) = V(r)$, such that the wavefunction will have radial symmetry, $\psi(\mathbf{r}) = \frac{\phi(r)}{r}$. Rewrite the Gross-Pitaevskii equation for the function ϕ [626].

Solution: *The Gross-Pitaevskii equation is,*

$$\imath\hbar\frac{\partial\psi(\mathbf{r})}{\partial t} = \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(r) + g|\psi(\mathbf{r})|^2\right)\psi(\mathbf{r})$$

or [626],

$$\mu\frac{\phi(r)}{r} = \left(-\frac{\hbar^2}{2m}\left[\frac{1}{r}\frac{\partial^2}{\partial r^2}r + \frac{1}{r^2\sin\vartheta}\frac{\partial}{\partial\vartheta}\left(\sin\vartheta\frac{\partial}{\partial\vartheta}\right) + \frac{1}{r^2\sin^2\vartheta}\frac{\partial^2}{\partial\varphi^2}\right] + V_{trap}(r) + g\left|\frac{\phi(r)}{r}\right|^2\right)\frac{\phi(r)}{r}$$

$$\mu\phi(r) = \left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial r^2} + V_{trap}(r) + g\frac{|\phi(r)|^2}{r^2}\right)\phi(r) \ ,$$

with

$$\int|\psi(\mathbf{r})|^2 d^3r = 4\pi\int_0^\infty|\psi(\mathbf{r})|^2 r^2 dr = 4\pi\int_0^\infty|\phi(\rho,z)|^2 dr = 1 \ .$$

45.3.4.3 Ex: Interacting gas in a cylindrical potential

Consider the potential $V(\mathbf{r}) = V(\rho, z)$, such that the wavefunction will have rotational symmetry, $\psi(\rho, z, \varphi) = \frac{\phi(\rho,z)}{\rho}$. Rewrite the Gross-Pitaevskii equation for the function ϕ [626].

Solution: *The Gross-Pitaevskii equation is,*

$$i\hbar\frac{\partial}{\partial t}\frac{\phi(\rho,z)}{\rho} = \left(-\frac{\hbar^2}{2m}\left[\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial}{\partial\rho}\right) + \frac{1}{\rho^2}\frac{\partial^2}{\partial\varphi^2} + \frac{\partial^2}{\partial z^2}\right] + V_{trap}(\rho,z) + g\left|\frac{\phi(\rho,z)}{\rho}\right|^2\right)\frac{\phi(\rho,z)}{\rho}$$

$$i\hbar\frac{\partial\phi(\rho,z)}{\partial t} = -\frac{\hbar^2}{2m}\left[\frac{\partial^2}{\partial\rho^2} - \frac{1}{\rho}\frac{\partial}{\partial\rho} + \frac{1}{\rho^2} + \frac{\partial^2}{\partial z^2}\right]\phi(\rho,z) + V_{trap}(\rho,z)\phi(\rho,z) + g\frac{|\phi(\rho,z)|^2}{\rho^2}\phi(\rho,z) \ .$$

Often we have a harmonic trap at least in the radial direction, $\rho_1 \equiv \rho/a_\rho$. An appropriate scale is then,

$$\imath\frac{\partial\phi(\rho,z)}{\partial\omega_\rho t} = -\frac{1}{2}\left[\frac{\partial^2}{\partial\rho_1^2} - \frac{1}{\rho_1}\frac{\partial}{\partial\rho_1} + \frac{1}{\rho_1^2} + \frac{\partial^2}{\partial(z/a_\rho)^2}\right]\phi(\rho,z) + \frac{V_{trap}(\rho,z)}{\hbar\omega_\rho}\phi(\rho,z) + \frac{4\pi\hbar a_s|\phi(\rho,z)|^2}{\rho_1^2}\phi(\rho,z) \ ,$$

with

$$\int|\psi(\mathbf{r})|^2 d^3r = 2\pi\int_{-\infty}^{\infty}\int_0^{\infty}|\psi(\mathbf{r})|^2\rho d\rho dz = 2\pi\int_{-\infty}^{\infty}\int_0^{\infty}\frac{|\phi(\rho,z)|^2}{\rho}d\rho dz = 1 \ .$$

45.3.4.4 Ex: Collapse of condensate with attractive interactions

A Bose-Einstein condensate of ^{7}Li may become unstable due to attractive interatomic forces, the scattering length being $a_s = -27.3a_B$. Consider the radial Gross-Pitaevskii Hamiltonian with an external harmonic potential with the oscillation frequency $\omega_{trp}/(2\pi) = 50$ Hz. Using the variational method, determine the maximum number of atoms allowing for a stable condensate. (Note that the derived minimization condition must be evaluated numerically.)

Solution: *We want to minimize the radial Gross-Pitaevskii Hamiltonian,*

$$\hat{H}_\alpha = -\frac{\hbar^2}{2m}\frac{d^2}{dr^2} + \frac{m}{2}\omega^2 r^2 + \frac{g|\phi_\alpha(r)|^2}{r^2} \ ,$$

with $\psi_\alpha(\mathbf{r}) = \frac{\phi_\alpha(r)}{r}$ e $g = N\frac{4\pi\hbar^2 a_s}{m}$ making the ansatz $\psi_\alpha(\mathbf{r}) = Ae^{-\alpha r^2}$. Normalization requires,

$$1 = \langle\psi_\alpha|\psi_\alpha\rangle = 4\pi\int_0^{\infty}|\psi_\alpha(\mathbf{r})|^2 r^2 dr = 4\pi\int_0^{\infty}|\phi_\alpha(r)|^2 dr = 4\pi\int_0^{\infty}A^2 e^{-2\alpha r^2}r^2 dr = A^2\sqrt{\frac{\pi}{2\alpha}}^3 \ .$$

Hence, $A^2 = \sqrt{2\alpha/\pi}^3$. The ground state energy is now,

$$\begin{aligned}
\mu_\alpha &= \langle\phi_\alpha|\hat{H}_\alpha|\phi_\alpha\rangle = 4\pi\int_0^\infty \phi_\alpha(r)\hat{H}_\alpha\phi_\alpha(r)dr \\
&= 4\pi A^2\int_0^\infty re^{-\alpha r^2}\left[-\tfrac{\hbar^2}{2m}(-6\alpha+4r^2\alpha^2)+\tfrac{m}{2}\omega^2r^2+gA^2e^{-2\alpha r^2}\right]re^{-\alpha r^2}dr \\
&= \tfrac{4\pi A^2}{\alpha\sqrt{\alpha}}\tfrac{6\hbar^2\alpha}{2m}\int_0^\infty\zeta^2e^{-2\zeta^2}d\zeta+\tfrac{4\pi A^2}{\alpha^2\sqrt{\alpha}}\left(-\tfrac{4\hbar^2\alpha^2}{2m}+\tfrac{m\omega^2}{2}\right)\int_0^\infty\zeta^4e^{-2\zeta^2}d\zeta+\tfrac{4\pi A^2}{\alpha\sqrt{\alpha}}gA^2\int_0^\infty\zeta^2e^{-4\zeta^2}d\zeta \\
&= \tfrac{4\pi A^2}{\alpha\sqrt{\alpha}}\tfrac{6\hbar^2\alpha}{2m}\tfrac{1}{8}\sqrt{\tfrac{\pi}{2}}+\tfrac{4\pi A^2}{\alpha^2\sqrt{\alpha}}\left(-\tfrac{4\hbar^2\alpha^2}{2m}+\tfrac{m\omega^2}{2}\right)\tfrac{3}{32}\sqrt{\tfrac{\pi}{2}}+\tfrac{4\pi A^2}{\alpha\sqrt{\alpha}}gA^2\tfrac{\sqrt{\pi}}{32} = \tfrac{3\hbar^2\alpha}{2m}+\tfrac{m\omega^2}{2\alpha}+g\left(\tfrac{\alpha}{\pi}\right)^{3/2} .
\end{aligned}$$

Minimizing,

$$0 = \frac{\partial\mu_\alpha}{\partial\alpha} = \frac{\partial}{\partial\alpha}\left[\frac{3\hbar^2\alpha}{2m}+\frac{m\omega^2}{2\alpha}+g\left(\frac{\alpha}{\pi}\right)^{3/2}\right] = \frac{3\hbar^2\alpha^2-m^2\omega^2+3\pi^{-3/2}g\alpha^{\frac{5}{2}}m}{2m\alpha^2}$$

we obtain,

$$0 = 3\hbar^2\alpha^2-m^2\omega^2+3\pi^{-3/2}g\alpha^{\frac{5}{2}}m \ .$$

This equation must be evaluated numerically.

45.4 Elementary excitations

The dynamics of Bose-Einstein condensates is usually studied by observing the change of their shape in response to temporal variations in the trapping potential. The simplest variation surely consists in suddenly removing the trapping potential altogether. Consequently, the first experiment performed with a BEC was the study of its ballistic expansion [31, 420, 238] (see Sec. 45.7.1).

On the other hand, the temporal variation of the potential can also be a small oscillatory or pulsed perturbation, for example, a small modification of the amplitude of the trapping field, a displacement or a local anisotropy induced by the dipole force of a laser beam tuned far away from resonance. It is even conceivable to manipulate the self-energy of the condensate or to irradiate electromagnetic waves, which couples internal atomic excitation levels or states of the atomic motion [108, 33, 1241, 674, 883, 1210, 406, 1271, 675, 976, 1240, 501]. The response of the condensate to such small perturbations can be understood by a linearized model of the Gross-Pitaevskii equation, which we will present in the following sections.

45.4.1 Bogolubov spectrum of excitations

To analyze the spectrum of a condensate's response to small perturbations, let us follow Bogolubov's treatment of the time-dependent Gross-Pitaevskii equation [1238]. We start by substituting Eq. (45.20) [405],

$$\hat{\psi}(\mathbf{r},t) \longrightarrow \hat{\psi}(\mathbf{r},t)e^{-\imath\mu t/\hbar} \ , \tag{45.40}$$

which gives us,

$$\left[-\frac{\hbar^2}{2m}\nabla^2+V_{trap}(\mathbf{r})+g|\hat{\psi}(\mathbf{r},t)|^2\right]\hat{\psi}(\mathbf{r},t) = \left[\mu+i\hbar\frac{\partial}{\partial t}\right]\hat{\psi}(\mathbf{r},t) \ . \tag{45.41}$$

The *Bogolubov prescription* now consists in approximating the field operators of the condensate by a sum of the equilibrium wavefunction, which is interpreted as a complex number, and a small perturbation, which conserves its operator character,

$$\hat{\psi}(\mathbf{r},t) \simeq \psi_0(\mathbf{r}) + \delta\hat{\psi}(\mathbf{r},t) \ . \tag{45.42}$$

This treatment assumes that most atoms are condensed, $N - N_0 \ll N_0$, and only a few thermal atoms are left out.

Applying the *Bogolubov transform*,

$$\boxed{\delta\hat{\psi}(\mathbf{r},t) \equiv \sum_{\mathbf{k}} u_{\mathbf{k}}(\mathbf{r})\hat{a}_{\mathbf{k}}(t) + v^*_{\mathbf{k}}(\mathbf{r})\hat{a}_{\mathbf{k}}(t)^\dagger} \ , \tag{45.43}$$

the perturbation is expressed as a superposition of amplitudes for annihilation and creation of non-interacting *quasi-particles*. By inserting this ansatz into the Gross-Pitaevskii equation, we obtain a linear system of equations called *Bogolubov-de Gennes equations*.

45.4.1.1 Semi-classical approximation

To simplify the equations, let us neglect the operator character of the quasi-particle by doing the substitutions,

$$\hat{a}_{\mathbf{k}} \to e^{-\imath\omega_{\mathbf{k}}t} \qquad \text{and} \qquad \hat{a}^\dagger_{\mathbf{k}} \to e^{\imath\omega_{\mathbf{k}}t} \ . \tag{45.44}$$

That is, we insert the ansatz (45.42) with,

$$\delta\hat{\psi}(\mathbf{r},t) \equiv u_{\mathbf{k}}(\mathbf{r})e^{-\imath\omega_{\mathbf{k}}t} + v^*_{\mathbf{k}}(\mathbf{r})e^{\imath\omega_{\mathbf{k}}t} \ , \tag{45.45}$$

into the Gross-Pitaevskii equation (45.41), we look for the lowest order,

$$\left(-\frac{\hbar^2}{2m}\nabla^2 + V_{trap} + g|\psi_0|^2\right)\psi_0 = \mu\psi_0 \ , \tag{45.46}$$

and we collect the terms of first order in $e^{\pm i\omega_{\mathbf{k}}t}$, neglecting terms of order $u^2_{\mathbf{k}}, v^{*2}_{\mathbf{k}}$ or higher,

$$\begin{aligned} -\frac{\hbar^2}{2m}\nabla^2 u_{\mathbf{k}} + V_{trap}u_{\mathbf{k}} + 2g\psi_0^2 u_{\mathbf{k}} - g\psi_0^2 v^*_{\mathbf{k}} &= \mu u_{\mathbf{k}} + \hbar\omega_{\mathbf{k}}u_{\mathbf{k}} \\ \frac{\hbar^2}{2m}\nabla^2 v_{\mathbf{k}} - V_{trap}v_{\mathbf{k}} - 2g\psi_0^2 v_{\mathbf{k}} + g\psi_0^2 u^*_{\mathbf{k}} &= -\mu v_{\mathbf{k}} + \hbar\omega_{\mathbf{k}}v_{\mathbf{k}} \ . \end{aligned} \tag{45.47}$$

Introducing the abbreviations $n = \psi_0^2$ and,

$$\mathcal{L} \equiv \frac{-\hbar^2\nabla^2}{2m} + V_{trap} + 2gn - \mu \ , \tag{45.48}$$

we can write

$$\begin{pmatrix} \mathcal{L} - \hbar\omega_{\mathbf{k}} & gn \\ gn & \mathcal{L} + \hbar\omega_{\mathbf{k}} \end{pmatrix} \begin{pmatrix} u_{\mathbf{k}} \\ v_{\mathbf{k}} \end{pmatrix} = \left[\begin{pmatrix} \mathcal{L} & gn \\ gn & \mathcal{L} \end{pmatrix} - \hbar\omega_{\mathbf{k}}\hat{\sigma}_z \right] \phi_k = 0 \ , \tag{45.49}$$

with $\hat{\sigma}_z$ being the third Pauli matrix. The solution of Eq. (45.49) is given by the requirement, that the determinant of the matrix be 0,

$$\hbar\omega_{\mathbf{k}} = \sqrt{\mathcal{L}^2 - (gn)^2} \ . \tag{45.50}$$

The object

$$\phi_{\mathbf{k}} \equiv \begin{pmatrix} u_k(\mathbf{r}) \\ v_k(\mathbf{r}) \end{pmatrix} \tag{45.51}$$

is called a *normal mode* of the condensate. The normal modes (45.50) are orthonormal,

$$\langle \phi_{\mathbf{k}} | \phi_{\mathbf{k}'} \rangle = \int d\mathbf{r} \phi^\dagger_{\mathbf{k}}(\mathbf{r}) \hat{\sigma}_z \phi_{\mathbf{k}'}(\mathbf{r}) = \delta_{\mathbf{k},\mathbf{k}'} \ , \tag{45.52}$$

which means that *the modes do not interact*, that is, the quasi-particles *do not collide*.

For homogeneous systems or at the interior of a large condensate with strong interactions, we can assume that the potential is approximately constant, $V_{trap} \to 0$, and kinetic energy negligible compared to the self-energy, and Eq. (45.41) shows us, $\mu \to gn$. Assuming plane waves,

$$u_{\mathbf{k}}(\mathbf{r}) \equiv u e^{\imath \mathbf{k}\cdot\mathbf{r}} \qquad \text{and} \qquad v_{\mathbf{k}}(\mathbf{r}) \equiv v e^{\imath \mathbf{k}\cdot\mathbf{r}} \ , \tag{45.53}$$

we obtain the *Bogolubov spectrum* of elementary excitations,

$$\boxed{\hbar\omega_{\mathbf{k}} = \sqrt{\frac{\hbar^2\mathbf{k}^2}{2m}\left(\frac{\hbar^2\mathbf{k}^2}{2m} + 2\mu\right)}} \ . \tag{45.54}$$

which corresponds to a *dispersion relation* for Bose-Einstein condensates. For an interacting gas, the collective modes are distortions of the condensate, caused by restoring forces originating in the finite compressibility of the gas.

45.4.1.2 Phonon- and particle-like excitations

The coefficients u and v describe the annihilation and u^* and v^* the creation of *quasi-particle*s called *fonon*s or *elementary excitation*s. Two limits are interesting. In the low energy limit, $\frac{\hbar^2\mathbf{k}^2}{2m} \ll gn(\mathbf{r})$, we create *phonon-like excitation*s. The Bogolubov spectrum becomes,

$$\hbar\omega^{ph}_{\mathbf{k}} \simeq c_s \hbar k \qquad \text{with} \qquad c_s \equiv \sqrt{\frac{ng}{m}} \ . \tag{45.55}$$

Here is c_s the *sound velocity* inside the condensate. The fact that, comparing (45.54) and (45.55), we find,

$$\hbar\omega_{\mathbf{k}} > \hbar\omega^{ph}_{\mathbf{k}} \tag{45.56}$$

for all $\mathbf{k}$ is the *Landau criterion* for the superfluidity of the condensate. It means that, for an object being dragged through the condensate with a velocity less than c_s, it does not become energetically favorable to produce excitations, see Fig. 45.4. Therefore, the object will move without dissipation, which is an important characteristic of superfluids. Experiments demonstrated this manifestation of superfluidity by slowly

stirring a strongly focused blue-detuned laser through a condensate. We will come back to this in Sec. 46.1.1.

In the high energy limit, $\frac{\hbar^2\mathbf{k}^2}{2m} \gg gn(\mathbf{r})$, we create *particle-like excitations*. The Bogolubov spectrum becomes,

$$\hbar\omega_{\mathbf{k}}^{pa} = \frac{\hbar^2\mathbf{k}^2}{2m} \ . \tag{45.57}$$

In this limit, we recover the quadratic dispersion relation of free particles, as seen in Fig. 45.4.

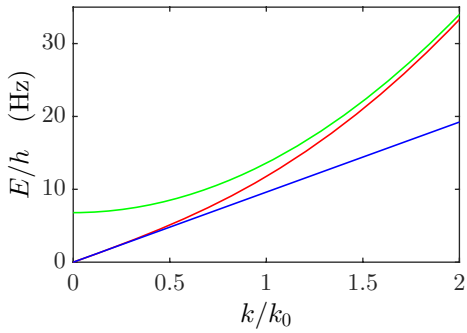

Figure 45.4: (code) Bogolubov spectrum (red), phonon limit (blue line) and particle limit (green line).

Experimentally, the complete Bogolubov spectrum (45.54) can be measured by Bragg spectroscopy [1260, 1239] (see Sec. 47.2). Solve Exc. 45.4.3.1.

45.4.2 Excitation of normal modes

In the simplest case, we generate a perturbation as a weak additional potential in the Gross-Pitaevskii equation (45.41),

$$\left[\mathcal{L} - gn + f_+(\mathbf{r})e^{-\imath\omega_p t} + f_-(\mathbf{r})e^{\imath\omega_p t}\right]\hat{\psi} = i\hbar\frac{\partial}{\partial t}\hat{\psi}(\mathbf{r},t) \ . \tag{45.58}$$

After the Bogolubov transform (45.45) we now have,

$$\left[\begin{pmatrix}\mathcal{L} & gn\\ gn & \mathcal{L}\end{pmatrix} - \hbar\omega_{\mathbf{k}}\sigma_3\right]\begin{pmatrix}u(\mathbf{r})\\ v(\mathbf{r})\end{pmatrix} = -\begin{pmatrix}f_+(\mathbf{r})\psi_0(\mathbf{r})\\ f_-^*(\mathbf{r})\psi_0^*(\mathbf{r})\end{pmatrix} \ . \tag{45.59}$$

The solution of this equation is found by expanding the amplitudes $u(\mathbf{r})$ and $v(\mathbf{r})$ into normal modes,

$$\begin{pmatrix}u(\mathbf{r})\\ v(\mathbf{r})\end{pmatrix} = \sum_{\mathbf{k}} c_{\mathbf{k}}\phi_{\mathbf{k}}(\mathbf{r}) \qquad \text{and} \qquad \begin{pmatrix}f_+(\mathbf{r})\psi_0(\mathbf{r})\\ f_-^*(\mathbf{r})\psi_0^*(\mathbf{r})\end{pmatrix} = \sum_{\mathbf{k}} g_{\mathbf{k}}\phi_{\mathbf{k}}(\mathbf{r}) \ , \tag{45.60}$$

where $g_{\mathbf{k}}$ is given by the overlap integral,

$$g_{\mathbf{k}} = \int d\mathbf{r}\phi_{\mathbf{k}}^\dagger(\mathbf{r})\sigma_3\begin{pmatrix}f_+(\mathbf{r})\psi_0(\mathbf{r})\\ f_-^*(\mathbf{r})\psi_0^*(\mathbf{r})\end{pmatrix} \ . \tag{45.61}$$

To calculate the response of the condensate to a given perturbation $f_{\pm}(\mathbf{r})$, we must first calculate the normal mode spectrum $\phi_{\mathbf{k}}(\mathbf{r})$ from the Bogolubov equation (45.49). After that, we can calculate the coefficients (45.61). Inserting the expansions into the Eq. (45.59), we obtain the response of the condensate,

$$\begin{pmatrix} u(\mathbf{r}) \\ v(\mathbf{r}) \end{pmatrix} = -\sum_{\mathbf{k}} \frac{g_{\mathbf{k}}/\hbar}{\omega_{\mathbf{k}} - \omega} \phi_{\mathbf{k}} \ . \tag{45.62}$$

The deviation, which is observed for resonant excitation, is due to the neglected losses and non-linear effects.

45.4.2.1 Classification of normal modes

BECs often have cylindrical symmetry, $\psi(\mathbf{r}) = \psi_0(r, z)$. In this case, similar calculations to those shown above, result in analytical expressions for the frequencies of the elementary excitations. These frequencies were derived by [318] [7]. The modes can be classified by their main quantum numbers n_r and by their multipolar moment ℓ. Examples are the *surface excitation* or *shape oscillation* ($n_r = 0$) and the *compression oscillation* ($n_r \neq 0$). Special cases are called *shaking mode*, *breathing mode* ($n_r = 1, \ell = 0$), and *swirling mode*. In the case of cylindrical symmetry, the projection of the angular momentum onto the symmetry axis m is the relevant quantum number. The dispersion relations are,

$$\begin{aligned}
&\omega(\ell, \mp m = \ell) = |m|\omega_r^2 \\
&\omega(\ell, \mp m = \ell - 1) = |m|\omega_r^2 + \omega_z^2 \\
&\omega(\ell, \mp m = \ell - 2) = \omega_r^2 \left[2|m| + 2 + \tfrac{3}{2}\lambda^2 \mp \sqrt{(|m| + 2 - \tfrac{3}{2}\lambda^2)^2 + 2\lambda^2(|m| + 1)} \right] \\
&\omega(\ell, \mp m = \ell - 3) = \omega_r^2 \left[2|m| + 2 + \tfrac{7}{2}\lambda^2 \mp \sqrt{(|m| + 2 - \tfrac{5}{2}\lambda^2)^2 + 6\lambda^2(|m| + 1)} \right] \ ,
\end{aligned} \tag{45.63}$$

where λ is the aspect ratio $\lambda = \omega_z/\omega_r$. Obviously, higher excitation orders depend on the trap geometry. Moreover, we can easily see, that occasional degeneracies must arise for specific aspect ratios. For example, when $\omega_+(2,0) = 2\omega(2,2)$, we derive from (45.63) the condition $\lambda = \sqrt{16/7}$, and when $\omega_+(2,0) = 2\omega_-(2,0)$, we derive $\lambda = \frac{1}{6}\sqrt{77 + 5\sqrt{145}}$.

45.4.2.2 Quantum depletion

Following Bogolubov's theory the *quantum depletion* is given by,

$$\frac{\delta N}{N} = \frac{1}{N} \sum_{\mathbf{k}} \int d^3r |v_{\mathbf{k}}(\mathbf{r})|^2 \ . \tag{45.64}$$

[7] It is worth mentioning that the linearized theory applies to *small perturbations*. Strong disturbances render the dynamics chaotic, since the energy is coupled to many modes of excitation.

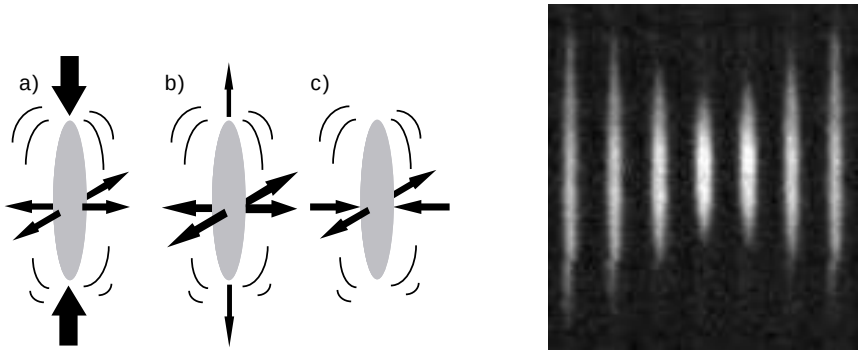

Figure 45.5: Normal modes of a BEC. (a) Shape oscillation, (b) breathing oscillation, and (c) quadrupole oscillation. (d) Non-destructive measurements of quadrupolar vibrations of a BEC [1240].

45.4.2.3 Fluctuations in BECs

Fluctuations in condensates are reduced as compared to thermal ensembles. Non-linearities are always very sensitive to fluctuations (see the laser). Therefore, we have to look at closer at collisions. For 3-body decay in a thermal source, $\langle\rho(\mathbf{r})^3\rangle \sim 6\langle\rho(\mathbf{r})\rangle^3$, and in a coherent source: $\langle\rho(\mathbf{r})^3\rangle \sim \langle\rho(\mathbf{r})\rangle^3$ [217, 1227].

45.4.3 Exercises

45.4.3.1 Ex: Sound velocity in the Thomas-Fermi regime

Consider a condensate of $N = 10^5$ ^{87}Rb atoms confined to an isotropic harmonic potential with secular frequency $\omega_{trp} = (2\pi)\ 50$ Hz. Remember $a_s = 110a_B$ and use the Thomas-Fermi approximation.
a. Evaluate the chemical potential.
b. Calculate the sound velocity at the center of the condensate.

Solution: *a. In the Thomas-Fermi limit the density distribution is given by,*

$$n(\mathbf{r}) = \tfrac{1}{g}\left(\mu - \tfrac{m}{2}\omega_{trp}^2 r^2\right) .$$

Normalization gives,

$$N = \int n(\mathbf{r})d^3r = \tfrac{1}{g}\int_0^{\sqrt{2\mu/m\omega_{trp}^2}} \left(\mu - \tfrac{m}{2}\omega_{trp}^2 r^2\right) 4\pi r^2 dr = \frac{8\pi\mu}{15g}\sqrt{\frac{2\mu}{m\omega_{trp}}} .$$

Hence,

$$\mu = \left(\frac{15Ng}{8\pi}\right)^{2/5}\left(\frac{m}{2}\omega_{trp}^2\right)^{3/5} .$$

This gives $\mu = h \cdot 796$ Hz.
b. The density at the center of the condensate now is,

$$n_0 = \frac{\mu}{g} .$$

The velocity of sound at the center is given by,

$$c_s = \sqrt{\frac{gn_0}{m}} = \sqrt{\frac{\mu}{m}} \ .$$

Hence, we find $c_s = 1.9$ *mm/s.*

45.5 Hydrodynamics and the propagation of sound

The question arises how the elementary excitations relate to the phenomenon of *sound*, well known from the hydrodynamic theory of superfluid ^{4}He proposed by Landau [772]. The *hydrodynamic regime* is characterized by the dominance of collisions [8]. On the other hand, Bogolubov's theory describes elementary excitations in the *collisionless regime*, where *quasi-particles* do not interact [9]. There is, therefore, a great motivation to study excitations with condensates in a very dense regime, where one can expect to recover predictions of hydrodynamic theory.

The hydrodynamic regime is reached, when the *free path* of the particles is smaller than the wavelength of the sound, that is [10],

$$l_{mfp} < \lambda/2\pi \ . \tag{45.65}$$

45.5.1 Zero, first and second sound

The occurrence of several types of sound was related by Tisza and London to the existence of superfluid and normal components in ^{4}He [954]. The *second sound* is a quantum phenomenon, where the heat transfer occurs as an *wave-like motion* instead of being diffusive. Heat takes the place of pressure in normal sound waves called *first sound*. This induces a very high thermal conductivity. At temperatures below the λ-point, ^{4}He has the highest known conductivity of all materials (a few hundred times higher than copper).

The *zero sound* was introduced by Landau to name quantum vibrations in Fermi quantum liquids. This sound can not be seen as a simple wave of compression and rarefaction. In gaseous condensates, the zero sound corresponds to the elementary excitation called *phonon-like*.

Finally, the excitation called *particle-like* or *ballistic*, observed in gaseous condensates has no correspondence in dense superfluids, since the mean free path there is too short. The various regimes accessible in condensed gasses are listed in the following table [33, 35, 544, 704, 1198, 1241, 1240, 456]:

[8] Collisions prevent condensation, because they localize the particles. This is the reason for the large quantum depletion, which in ^{4}He is of the order of 10% and hides effects of quantum statistics. Quantum depletion prevents any form of long-range order, as this requires delocalization.

[9] Bogolubov's theory assumes that the only impact of collisions is to deform the dispersion relationship, keeping the collective modes orthogonal.

[10] Note the similarity to the Ioffe-Regel criterion.

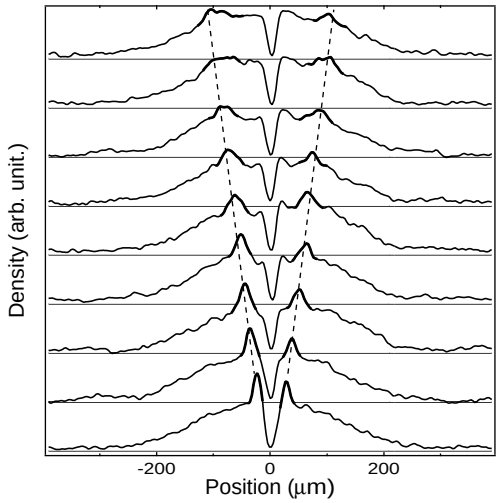

Figure 45.6: (code) Consecutive measurements of the BEC density profile showing the propagation of zero sound. The sound was excited by a blue-detuned laser tuned focused into the middle of the BEC (lower curve). The other curves show how the perturbation propagates towards the edges of the BEC.

regime	range scale	energy range	condensate	thermal cloud
collision-less	$k^{-1} < \xi < l_{mfp}$	$\frac{\hbar^2}{2ml^2_{mfp}} < gn_0 < \frac{\hbar^2 k^2}{2m}$	ballistic	ballistic
collision-less	$\xi < k^{-1} < l_{mfp}$	$\frac{\hbar^2}{2ml^2_{mfp}} < \frac{\hbar^2 k^2}{2m} < gn_0$	zero sound	ballistic
hydrodynamic	$\xi < l_{mfp} < k^{-1}$	$\frac{\hbar^2 k^2}{2m} < \frac{\hbar^2}{2ml^2_{mfp}} < gn_0$	second sound	first sound

(45.66)

normal modes			$qR \ll 1$
macroscopic			$qa \ll 1$
beyond Bogolubov			$qa > 1$
superfluid (TF limit, LDA)	$E_{self} \gg E_{kin}$	$8\pi Na \gg a_{ho}$	$a_{ho} \gg \xi$
???	$E_{self} \ll E_{kin}$	$8\pi Na \ll a_{ho}$	$a_{ho} \ll \xi$
collision-less	$\gamma_{coll} \ll \frac{\hbar q^2}{2m}$		$ql_{mfp} \ll 1$
hydrodynamic	$\gamma_{coll} > \frac{\hbar q^2}{2m}$		$ql_{mfp} > 1$

(45.67)

With $l_{mfp} \simeq 1/n_{th}\sigma$. Typical values are,

$$\begin{array}{ll} a = 0..1000 a_B & = 0..50\,\text{nm} \\ n^{-1/3} & = 20..200\,\mu\text{m} \\ 2\pi/q & = 0.2..\infty\,\mu\text{m} \\ \xi = \sqrt{8\pi n a}^{-1} & = 0.03..30\,\mu\text{m} \\ a_{ho} = \sqrt{\hbar/m\omega_{tr}} & = 0.1..3\,\mu\text{m} \\ 2\pi/k_F = 2\pi a_{ho}(48N)^{-1/6} & = 30..70\,\mu\text{m} \end{array} \tag{45.68}$$

The various regimes of sound are distinguished by frequency shifts and damping rates of the collective modes, which depend on the density (determining the mean-field energy and the mean free path) and the temperature (controlling the ratio between condensed and normal fraction). The quantity

$$\xi \equiv \frac{1}{\sqrt{8\pi a_s n}} \,, \tag{45.69}$$

is called *healing length*.

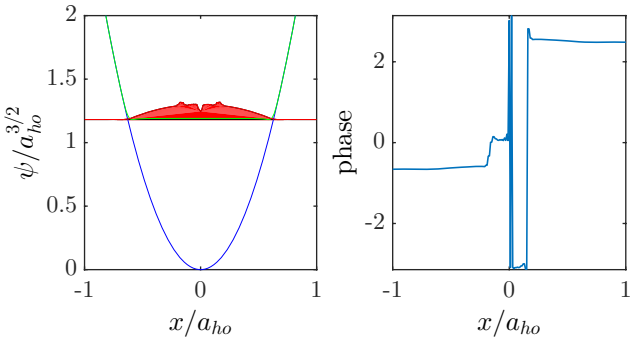

Figure 45.7: Simulation of the propagation of sound toward the edges of the condensate.

45.6 Momentum representation

We showed in Sec. 23.3.7, that the wavefunctions can be represented in the spatial or the momentum domain. These notions can be extended to the second quantization procedure by generalizing the equations (23.104),

$$\boxed{\hat{a}_{\mathbf{k}} \equiv \frac{1}{\sqrt{(2\pi)^3 V}} \int \hat{\psi}(\mathbf{r}) e^{-\imath \mathbf{k}\cdot\mathbf{r}} d^3 r \quad , \quad \hat{\psi}(\mathbf{r}) \equiv \sqrt{\frac{V}{(2\pi)^3}} \int \hat{a}_{\mathbf{k}} e^{\imath \mathbf{k}\cdot\mathbf{r}} d^3 k} \,. \tag{45.70}$$

Differently from (23.104) we chose here a normalization, which leaves the field operators $a_{\mathbf{k}}$ without unit.

45.6.1 Confined particles

In the case of confined atoms, $\mathcal{H} = \mathcal{H}_{cm} + V_{trap}(\mathbf{r}) + \mathcal{H}_{self}$, we get sharp eigenvalues,

$$\hat{a}_{\mathbf{k}} = \frac{1}{V} \sum_{\mathbf{k}'} \hat{a}_{\mathbf{k}'} \delta^{(3)}(\mathbf{k} - \mathbf{k}') \ . \tag{45.71}$$

We insert this in equation (45.70),

$$\begin{aligned} \hat{\psi}(\mathbf{r}) &= \sqrt{\tfrac{1}{(2\pi)^3 V}} \sum_{\mathbf{k}'} \hat{a}_{\mathbf{k}'} \int \delta^{(3)}(\mathbf{k} - \mathbf{k}') e^{\imath \mathbf{k}\cdot\mathbf{r}} d^3k \\ &= \sqrt{\tfrac{1}{(2\pi)^3 V}} \sum_{\mathbf{k}'} \hat{a}_{\mathbf{k}} e^{\imath \mathbf{k}\cdot\mathbf{r}} = \sum_{\mathbf{k}} u_{\mathbf{k}}(\mathbf{r}) \hat{a}_{\mathbf{k}} \ , \end{aligned} \tag{45.72}$$

thus making an expansion of the condensate into plane waves,

$$u_{\mathbf{k}}(\mathbf{r}) = \tfrac{1}{\sqrt{(2\pi)^3 V}} e^{\imath \mathbf{k}\cdot\mathbf{r}} \ , \tag{45.73}$$

which is particularly adapted to the 3D box potential, $V_{trap}(\mathbf{r}) \equiv \infty$ se $r > R$. Also, we calculate,

$$\hat{a}_{\mathbf{k}} = \sqrt{\tfrac{1}{(2\pi)^3 V}} \int \hat{\psi}(\mathbf{r}) e^{-\imath \mathbf{k}\cdot\mathbf{r}} d^3r = \int \hat{\psi}(\mathbf{r}) u^*_{\mathbf{k}}(\mathbf{r}) d^3\mathbf{r} \ . \tag{45.74}$$

We obtain the observable commutation rules from (45.5),

$$[\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = \delta_{\mathbf{k}\mathbf{k}'} \quad , \quad [\hat{a}_{\mathbf{k}}, \hat{a}_{\mathbf{k}'}] = 0 \quad , \quad \hat{N} = \sum_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}} \hat{a}_{\mathbf{k}} \ . \tag{45.75}$$

Using the following mathematical relationships,

$$\tfrac{1}{(2\pi)^3 V} \sum_{\mathbf{k}} e^{-\imath \mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')} = \delta^3(\mathbf{r} - \mathbf{r}') \quad \text{and} \quad \tfrac{1}{(2\pi)^3 V} \int d^3\mathbf{r} e^{\imath(\mathbf{k}'-\mathbf{k})\cdot\mathbf{r}} = \delta_{\mathbf{k},\mathbf{k}'} \ , \tag{45.76}$$

and easy to show for plane waves,

$$\sum_{\mathbf{k}} u^*_{\mathbf{k}}(\mathbf{r}) u_{\mathbf{k}}(\mathbf{r}') = \delta^3(\mathbf{r} - \mathbf{r}') \quad \text{and} \quad \int u^*_{\mathbf{k}}(\mathbf{r}) u_{\mathbf{k}'}(\mathbf{r}) d^3\mathbf{r} = \delta_{\mathbf{k}\mathbf{k}'} \ . \tag{45.77}$$

In Exc. 45.6.4.1 we will check the validity of the commutation rules (45.75), and in Exc. 45.6.4.2 we derive the following representation of the Hamiltonian:

$$\boxed{\begin{aligned} \mathcal{H} &= \int d^3r \hat{\psi}^\dagger(\mathbf{r}) \left(-\frac{\hbar^2}{2m} \nabla^2 + V_{trap}(\mathbf{r}) \right) \hat{\psi}(\mathbf{r}) \\ &\quad + \frac{g}{2} \int d^3r \int d^3r' \hat{\psi}^\dagger(\mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}') \delta(\mathbf{r} - \mathbf{r}') \hat{\psi}(\mathbf{r}') \hat{\psi}(\mathbf{r}) \\ &= \sum_{\mathbf{k}} \frac{\hbar^2 \mathbf{k}^2}{2m} \hat{a}^\dagger_{\mathbf{k}} \hat{a}_{\mathbf{k}} + \sum_{\mathbf{k},\mathbf{k}'} \hat{a}^\dagger_{\mathbf{k}} V_{\mathbf{k},\mathbf{k}'} \hat{a}_{\mathbf{k}'} + \frac{g}{2} \sum_{\mathbf{k},\mathbf{k}',\mathbf{k}''} \hat{a}^\dagger_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}''} \hat{a}_{\mathbf{k}+\mathbf{k}'-\mathbf{k}''} \end{aligned}} \ , \tag{45.78}$$

with the abbreviation,

$$V_{\mathbf{k},\mathbf{k}'} = \int u^*_{\mathbf{k}}(\mathbf{r}) V_{trap}(\mathbf{r}) u_{\mathbf{k}'}(\mathbf{r}) d^3\mathbf{r} = \tfrac{1}{(2\pi)^3} \int V_{trap}(\mathbf{r}) e^{\imath(\mathbf{k}'-\mathbf{k})\mathbf{r}} d^3\mathbf{r} \ . \tag{45.79}$$

The equation of motion for the momentum wavefunction now becomes,

$$\imath\hbar \frac{\partial}{\partial t} \hat{a}_{\mathbf{k}} = [\hat{a}_{\mathbf{k}}, \mathcal{H}] = \frac{\hbar^2 \mathbf{k}^2}{2m} \hat{a}_{\mathbf{k}} + \sum_{\mathbf{k}'} V_{\mathbf{k},\mathbf{k}'} \hat{a}_{\mathbf{k}'} + g \sum_{\mathbf{k}',\mathbf{k}''} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}''} \hat{a}_{\mathbf{k}+\mathbf{k}'-\mathbf{k}''} \ . \tag{45.80}$$

45.6.1.1 Harmonically confined particles

In harmonic traps, $V_{trap}(r) = \frac{m}{2}\omega^2_{trp} r^2$, the motion can be canonically quantized,

$$\hat{a} = \frac{1}{\sqrt{2}} \left(\frac{\hat{r}}{a_{trp}} \mp i a_{trp} \hat{p} \right) \qquad , \qquad \mathcal{H}_{cm} = \sum_{\mathbf{k}} \hbar\omega_{trp} \hat{a}^\dagger_{\mathbf{k}} \hat{a}_{\mathbf{k}} \ , \tag{45.81}$$

with the size of the ground state,

$$a_{trp} \equiv \sqrt{\frac{\hbar}{m\omega_{trp}}} \ . \tag{45.82}$$

As an alternative notation we could introduce,

$$|\mathbf{r}\rangle \equiv \hat{\psi}^\dagger(\mathbf{r}) \qquad \text{and} \qquad |\mathbf{k}\rangle \equiv \hat{a}^\dagger_{\mathbf{k}} \ . \tag{45.83}$$

Hence, just considering the ground state of the trap, that is, assuming that the atomic motion be frozen, our Hamiltonian becomes:

$$\mathcal{H}_{cm} + \mathcal{H}_{self} = \hbar\omega_{trp} \hat{a}^\dagger \hat{a} + \frac{g}{2} \hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a} \ . \tag{45.84}$$

45.6.2 Thomas-Fermi limit

In the limit of negligible kinetic energy (that is, in the middle of a large condensate) with the analytical form of the condensate wavefunction,

$$\hat{\psi}(\mathbf{r}) \propto \sqrt{n_0} \left(1 - \frac{\mathbf{r}^2}{\mathbf{r}_0^2} \right) \ , \tag{45.85}$$

the transformation (45.70) allows us to derive an expression for the momentum distribution,

$$|a(\mathbf{k})| \propto \frac{J_1(\mathbf{k} \cdot \mathbf{r}_0)}{(\mathbf{k} \cdot \mathbf{r}_0)^2} \ . \tag{45.86}$$

45.6.2.1 Width of the momentum distribution

It is interesting to compare the size of an ideal gas condensate with the size of an interacting condensate. We can express the Thomas-Fermi radius as,

$$\Delta r_{TF} = a_{trp} \sqrt{\frac{\mu}{\hbar\omega_{trp}}} \ . \tag{45.87}$$

The Heisenberg limit requires,

$$\Delta p_{TF} = \frac{\hbar}{\Delta r_{TF}} \ . \tag{45.88}$$

Since $\sqrt{\mu/\hbar\omega_{trp}} > 1$, the interaction increases the volume of the condensate, but restricts the distribution of its velocities. For a hypothetical thermal Boltzmann gas having the same temperature,

$$\Delta r_{th} = a_{trp}\sqrt{\frac{k_B T}{\hbar\omega_{trp}}} \qquad \text{and} \qquad \Delta p_{th} = \frac{\hbar}{a_{trp}}\sqrt{\frac{k_B T}{\hbar\omega_{trp}}} \ . \tag{45.89}$$

The thermal cloud *is not at the Heisenberg limit*, because $\sqrt{k_B T/\hbar\omega_{trp}} > 1$.

These relationships were experimentally confirmed [1260] by measurements of the velocity distributions of condensates using a Bragg spectroscopy technique (see Sec. 47.2). It is interesting to note that the measured widths of velocity distributions were *lower than the photonic recoil limit*, $\hbar k/m \simeq 30$ mm/s for ^{87}Rb.

45.6.3 Master equation approach

The Hamiltonian that describes a BEC in second quantization in an orthonormal set of energy eigenfunctions reads:

$$\begin{aligned} \mathcal{H} &= \sum\nolimits_{i,j} \mathcal{H}^{(ij)}_{atom} \hat{a}^\dagger_i \hat{a}_j + \sum_{i,j,k,l} \tfrac{1}{2} W^{(ijkl)} \hat{a}^\dagger_i \hat{a}^\dagger_j \hat{a}_k \hat{a}_l \\ \mathcal{H}^{(ij)}_{atom} &= \langle \phi_i | \tfrac{1}{2m}\mathbf{p}^2 + V_{trap}(\mathbf{r}) | \phi_j \rangle \\ W^{(ijkl)} &= g \int \phi_i(\mathbf{r})\phi_j(\mathbf{r})\phi_k(\mathbf{r})\phi_l(\mathbf{r}) d^3 r \ . \end{aligned} \tag{45.90}$$

The inclusion of spontaneous processes (one-body-loss, dephasing) requires a master equation including a *Lindblad term* within a density matrix formalism. The von Neumann equation for the density operator reads:

$$\begin{aligned} \frac{d}{dt}\hat{\rho} &= -\imath[V, \hat{\rho}] + \mathcal{L}\hat{\rho} \\ \mathcal{L}_{one-body\ loss} &\equiv \kappa(2\hat{a}\hat{\rho}\hat{a}^\dagger - \hat{a}^\dagger\hat{a}\hat{\rho} - \hat{\rho}\hat{a}^\dagger\hat{a}) \\ \mathcal{L}_{one-body\ feeding} &\equiv \kappa(2 + 2\hat{a}^\dagger\hat{\rho}\hat{a} - \hat{a}\hat{a}^\dagger\hat{\rho} - \hat{\rho}\hat{a}\hat{a}^\dagger) \\ \mathcal{L}_{two-body\ loss} &\equiv \kappa\left(2\hat{a}^2\hat{\rho}\hat{a}^{\dagger 2} - \hat{a}^{\dagger 2}\hat{a}^2\hat{\rho} - \hat{\rho}\hat{a}^{\dagger 2}\hat{a}^2\right) \ . \end{aligned} \tag{45.91}$$

45.6.4 Exercises

45.6.4.1 Ex: Commutators in momentum space

Demonstrate the validity of the commutation rules (45.75).

Solution: *It holds,*

$$\delta^3(\mathbf{r}-\mathbf{r}') = [\hat{\psi}(\mathbf{r}), \hat{\psi}^\dagger(\mathbf{r}')] = \tfrac{1}{(2\pi)^3 V} \sum_{\mathbf{k},\mathbf{k}'} e^{-\imath\mathbf{k}\cdot\mathbf{r}+\imath\mathbf{k}'\cdot\mathbf{r}'} [\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = \tfrac{1}{(2\pi)^3 V} \sum_{\mathbf{k},\mathbf{k}'} e^{-\imath\mathbf{k}\cdot\mathbf{r}+i\mathbf{k}'\cdot\mathbf{r}'} [\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] \ .$$

This is valid when $[\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = \delta_{\mathbf{k},\mathbf{k}'}$. *Also holds,*

$$0 = [\hat{\psi}(\mathbf{r}), \hat{\psi}(\mathbf{r}')] = \tfrac{1}{(2\pi)^3 V} \sum_{\mathbf{k},\mathbf{k}'} e^{\imath \mathbf{k}\cdot\mathbf{r} + \imath \mathbf{k}'\cdot\mathbf{r}'} [\hat{a}_{\mathbf{k}}, \hat{a}_{\mathbf{k}'}] = \tfrac{1}{(2\pi)^3 V} \sum_{\mathbf{k},\mathbf{k}'} e^{\imath \mathbf{k}\cdot\mathbf{r} + \imath \mathbf{k}'\cdot\mathbf{r}'} [\hat{a}_{\mathbf{k}}, \hat{a}_{\mathbf{k}'}] \ ,$$

This is valid when $[\hat{a}_{\mathbf{k}}, \hat{a}^\dagger_{\mathbf{k}'}] = 0$. *We can also express,*

$$\hat{N} = \int d^3\mathbf{r} \hat{\psi}^\dagger(\mathbf{r}) \hat{\psi}(\mathbf{r}) = \tfrac{1}{(2\pi)^3 V} \sum_{\mathbf{k},\mathbf{k}'} \int d^3\mathbf{r} e^{\imath(\mathbf{k}-\mathbf{k}')\cdot\mathbf{r}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}} = \sum_{\mathbf{k},\mathbf{k}'} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}} \delta_{\mathbf{k},\mathbf{k}'} = \sum_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}} \hat{a}_{\mathbf{k}} \ .$$

45.6.4.2 Ex: Commutators in momentum space

Derive the representation (45.78) of the Hamiltonian.

Solution: *The energy can also be calculated by,*

$$\begin{aligned}
\mathcal{H} &= \int d^3\mathbf{r} \hat{\psi}^\dagger(\mathbf{r}) \left(-\frac{\hbar^2}{2m} \nabla^2 + V_{trap}(\mathbf{r}) \right) \hat{\psi}(\mathbf{r}) + \tfrac{g}{2} \int d^3\mathbf{r} \int d^3\mathbf{r}' \hat{\psi}^\dagger(\mathbf{r}) \hat{\psi}^\dagger(\mathbf{r}') \delta(\mathbf{r}-\mathbf{r}') \hat{\psi}(\mathbf{r}') \hat{\psi}(\mathbf{r}) \\
&= ... + \tfrac{g}{2} \int d^3\mathbf{r} \int d^3\mathbf{r}' \sum_{\mathbf{k}} u^*_{\mathbf{k}}(\mathbf{r}) \hat{a}^\dagger_{\mathbf{k}} \sum_{\mathbf{k}} u^*_{\mathbf{k}}(\mathbf{r}') \hat{a}^\dagger_{\mathbf{k}} \delta(\mathbf{r}-\mathbf{r}') \sum_{\mathbf{k}} u_{\mathbf{k}}(\mathbf{r}') \hat{a}_{\mathbf{k}} \sum_{\mathbf{k}} u_{\mathbf{k}}(\mathbf{r}) \hat{a}_{\mathbf{k}} \\
&= ... + \tfrac{g}{2} \sum_{\mathbf{k},\mathbf{k}',\mathbf{k}'',\mathbf{k}'''} \hat{a}^\dagger_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}''} \hat{a}_{\mathbf{k}'''} (2\pi)^{-6} \int d^3\mathbf{r} \int d^3\mathbf{r}' e^{-\imath \mathbf{k}\cdot\mathbf{r}} e^{-\imath \mathbf{k}'\mathbf{r}'} \delta(\mathbf{r}-\mathbf{r}') e^{\imath \mathbf{k}''\mathbf{r}'} e^{\imath \mathbf{k}'''\mathbf{r}} \\
&= ... + \tfrac{g}{2} \sum_{\mathbf{k},\mathbf{k}',\mathbf{k}'',\mathbf{k}'''} \hat{a}^\dagger_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}''} \hat{a}_{\mathbf{k}'''} (2\pi)^{-6} \int d^3\mathbf{r} e^{-\imath \mathbf{k}\cdot\mathbf{r}} e^{-\imath \mathbf{k}'\mathbf{r}} e^{\imath \mathbf{k}''\mathbf{r}} e^{\imath \mathbf{k}'''\mathbf{r}} \\
&= \sum_{\mathbf{k}} \frac{\hbar^2 \mathbf{k}^2}{2m} \hat{a}^\dagger_{\mathbf{k}} \hat{a}_{\mathbf{k}} + \sum_{\mathbf{k},\mathbf{k}'} \hat{a}^\dagger_{\mathbf{k}} V_{\mathbf{k},\mathbf{k}'} \hat{a}_{\mathbf{k}'} + \frac{g}{2} \sum_{\mathbf{k},\mathbf{k}',\mathbf{k}''} \hat{a}^\dagger_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}''} \hat{a}_{\mathbf{k}+\mathbf{k}'-\mathbf{k}''} \ ,
\end{aligned}$$

where we defined,

$$V_{\mathbf{k},\mathbf{k}'} = \int u^*_{\mathbf{k}}(\mathbf{r}) V_{trap}(\mathbf{r}) u_{\mathbf{k}'}(\mathbf{r}) d^3\mathbf{r} = \tfrac{1}{(2\pi)^3} \int V_{trap}(\mathbf{r}) e^{\imath(\mathbf{k}'-\mathbf{k})\mathbf{r}} d^3\mathbf{r} \ .$$

45.7 Condensates at finite temperature

45.7.1 Ballistic expansion of a bosonic gas

As discussed in Sec. 43.6, the atomic density distributions are revealed through their interaction with a laser beam. The problem with imaging a confined condensate is, on the one hand, its very high optical density, which inhibits the penetration of resonant light and, on the other hand, its very small size, which is often below the diffraction limit and prevents its optical resolution. As discussed in Sec. 43.6, both

problems can be avoided by the time-of-flight imaging technique, which consists in quickly switching off the trap and dropping the atomic cloud (see Fig. 43.35). If the switching-off process is fast enough, the potential energy is lost, but in the course of ballistic expansion, the self-energy is transformed into kinetic energy. Both the self-energy transformed to kinetic energy and the inherent initial kinetic energy contribute to blow up the size of the atomic cloud, so that the density rapidly decreases. After a few 10 ms, when the optical density is sufficiently low (on the order of 1), the cloud can be imaged via its absorption of a resonant laser beam. The condensate, which is about 10 times denser than the thermal cloud, has a much larger repulsive self-energy. When the condensate is suddenly released from its trap, its explosion is accelerated by this self-energy, and the acceleration is faster in those directions, where the confining potential was stronger [626, 238]. Therefore, the aspect ratio of the condensate's shape is inverted during the flight time [712, 238]. In contrast, the self-energy of the thermal cloud is relatively insignificant. Therefore, its spatial density after a time of free expansion reflects the pure velocity distribution of the atomic cloud while it was trapped. This allows the interpretation of the spatial distribution of the expanded cloud in terms of a *temperature* of the trapped cloud.

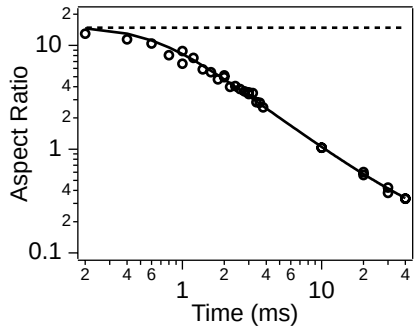

Figure 45.8: Inversion of aspect ratio during time-of-flight. The frequencies of the harmonic trap were $\omega_r = (2\pi) \cdot 248$ Hz and $\omega_r = (2\pi) \cdot 16$ Hz [712].

45.7.1.1 Popov approximation

The Popov decomposition separates the condensed part, described by a c-number $\phi \equiv \langle \hat{\psi} \rangle$ and normalized to the number of condensed atoms N_0 from the thermal part

$\tilde{\psi} \equiv \hat{\psi} - \phi$, which keeps track of the quantum nature of the Bose-gas [380],

$$\begin{aligned}
\mathcal{K} &= \mathcal{K}_0 + \mathcal{K}_1 + \mathcal{K}_1^\dagger + \mathcal{K}_2 \qquad (45.92)\\
\mathcal{K}_0 &= \int d^3\mathbf{r}\phi^*(\mathbf{r}) \left(-\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r}) + \frac{g}{2}|\phi|^2 - \mu \right) \phi(\mathbf{r})\\
\mathcal{K}_1 &= 0 \quad \text{if} \quad [\mathcal{L} - gn_0(\mathbf{r})]\phi(\mathbf{r}) = 0\\
\mathcal{K}_2 &= \int d^3r \left[\tilde{\psi}^+(\mathbf{r})\mathcal{L}\tilde{\psi}(\mathbf{r}) + \frac{g}{2}\left(\phi(\mathbf{r})^2\tilde{\psi}^+(\mathbf{r})\tilde{\psi}^+(\mathbf{r}) + \phi^*(\mathbf{r})^2\tilde{\psi} + (\mathbf{r})\tilde{\psi}(\mathbf{r}) \right) \right]\\
\mathcal{L} &\equiv -\frac{\hbar^2}{2m}\nabla^2 + V_{trap}(\mathbf{r}) - \mu + 2gn(\mathbf{r})\\
n(\mathbf{r}) &= n_0(\mathbf{r}) + n_T(\mathbf{r}) = |\phi(\mathbf{r})|^2 + \langle \tilde{\psi}^\dagger(\mathbf{r})\tilde{\psi}(\mathbf{r}) \rangle \ .
\end{aligned}$$

We perform the Bogolubov transform to the diagonalized Hamiltonian,

$$\begin{aligned}
\mathcal{K}_{Popov} &= \mathcal{K}_0 + \sum\nolimits_j \varepsilon_j \hat{b}_j^+ \hat{b}_j \qquad (45.93)\\
\tilde{\psi}(\mathbf{r}) &= \sum\nolimits_j u_j(\mathbf{r})\hat{b}_j - v_j^*(\mathbf{r})\hat{b}_j^+\\
\delta_{jk} &= \int d^3r \left(u_j u_k^* - v_j v_k^* \right)\\
\delta_{jk} &= [\hat{b}_j, \hat{b}_k^+] \ .
\end{aligned}$$

This yields a set of equations for elementary excitations (quasi-particle excitations in a diagonalized energy space),

$$\begin{aligned}
N_j &= \left[\exp(\varepsilon_j/k_BT) - 1 \right]^{-1} \qquad (45.94)\\
n_T(\mathbf{r}) &= \sum\nolimits_j \left[\left(|u_j|^2 + |v_j|^2 \right) N_j + |v_j|^2 \right]\\
\mathcal{L}u_j(\mathbf{r}) - gn_0(\mathbf{r})v_j(\mathbf{r}) &= \varepsilon_j u_j(\mathbf{r}) \ ,\\
\mathcal{L}v_j(\mathbf{r}) - gn_0(\mathbf{r})u_j(\mathbf{r}) &= -\varepsilon_j v_j(\mathbf{r}) \ .
\end{aligned}$$

The quantum depletion at $T = 0$ [last term in the density $n(\mathbf{r})$] may be neglected. In this zero-temperature limit, the equations simplify to yield the Gross-Pitaevskii equation. We may separate these equations using auxiliary functions [645],

$$\begin{aligned}
\tilde{\psi}_j^{(\pm)}(\mathbf{r}) &\equiv u_j(\mathbf{r}) \pm v_j(\mathbf{r}) \qquad (45.95)\\
\hat{h}_0 &\equiv \mathcal{L} - gn_0(\mathbf{r})\\
\hat{h}_0\tilde{\psi}_j^{(+)}(\mathbf{r}) &= E_j\tilde{\psi}_j^{(-)}(\mathbf{r}) \ .
\end{aligned}$$

The eigenvalue equations that one gets after substituting (III.2.5) into (III.2.4) may be solved by expanding in a set of eigenfunctions of $\hat{h}_0$:

$$\begin{aligned}
\tilde{\psi}_j^{(\pm)}(\mathbf{r}) &\equiv \sum\nolimits_\alpha c_\alpha^{(j)}\phi_\alpha(\mathbf{r}) \qquad (45.96)\\
\hat{h}_0\phi_\alpha(\mathbf{r}) &\equiv \varepsilon_\alpha\phi_\alpha(\mathbf{r})\\
\sum\nolimits_\beta (M_{\alpha\beta} + \varepsilon_\alpha\delta_{\alpha\beta})\varepsilon_\beta c_\alpha^{(j)} &= E_j^2 c_\alpha^{(j)}\\
M_{\alpha\beta} &= 2g\int \phi_\alpha^*(\mathbf{r})n_0(\mathbf{r})\phi_\beta(\mathbf{r})d^3r \ .
\end{aligned}$$

45.7.2 Hartree-Fock approach

45.7.2.1 Two-gas model for $T > 0$

The two phases of a condensate above $T = 0$ have a specific interdependence, which makes it possible to treat the problem with an approximation, where only the condensed part influences the non-condensed and not vice versa [379]. The HFB equation (III.2.11) is solved for the condensed part alone, assuming $n_{th} = 0$. The condensate wavefunction and the chemical potential are derived from that, *f.e.* using numerical methods like the method of steepest descent. The effective potential for the thermal cloud in the presence of a condensate is:

$$V_{1,eff}(\mathbf{r}_1) = V_{1,trap}(\mathbf{r}_1) + g_1|\psi_1(\mathbf{r}_1)|^2 \ . \tag{45.97}$$

Next, we diagonalize the Schrödinger equation:

$$[-\nabla_1^2 + V_{1,eff}(\mathbf{r}_1)]\psi_{1,j}(\mathbf{r}_1) = 2E_{1,j}\psi_{1,j}(\mathbf{r}_1) \ , \tag{45.98}$$

maintaining the normalization,

$$1 = \int |\psi_{1,j}(\mathbf{r}_1)|^2 d^3\mathbf{r}_1 \ . \tag{45.99}$$

This provides us with the energy eigenvalues of the excited trap states and their eigenfunctions. One can f.e. guess an eigenvalue and numerically solve the Schrödinger equation using Runge-Kutta integration routines. The eigenfunction will probably diverge. In this case, we vary the eigenvalue until the solution converges.

Finally, we can calculate the thermal density distribution:,

$$\begin{aligned} N_j &\equiv [\exp((E_{1,j} - \mu_1)/k_B T_1) - 1]^{-1} \\ n_{th}(\mathbf{r}_1) &= \sum\nolimits_j N_j |\psi_{1,j}(\mathbf{r}_1)|^2 \ , \end{aligned} \tag{45.100}$$

and all thermodynamic potentials, as shown in Sec. 44.1.2.

A more sophisticated method uses self-consistent recursion [645]. Here, the thermal density is plugged back into the HFB equation, and the whole procedure is repeated until it converges.

45.7.2.2 Hartree-Fock approximation

We have already seen that, inside a trap the condensate occupies the lowest vibrational level, whereas the atoms of the thermal gas are distributed among all levels. The trapping potential is often harmonic, $U_{trp}(\mathbf{r}) = \frac{m}{2}\omega_r^2 r^2$, with secular frequencies ω_r typically on the order of several tens or hundreds of Hz. The spatial (radial) extent of the vibration levels varies a lot with their quantum number, $r_j = \sqrt{(2j+1)\hbar/m\omega_r}$. This naturally produces a *separation of the thermal (or normal) and condensate fractions* at $T > 0$, which does not exist for a homogeneous gas and which allows (up to a certain degree) an individual treatment of the two fractions. The details of the interaction between the two fractions are very complicated and are still under intense theoretical investigation. However, to understand the shape of a trapped atomic cloud and other characteristics, we can use a simple approximate model [**?**, 645], assuming

that the condensate is only weakly disturbed by the thermal cloud. In contrast, the presence of the condensate dramatically modifies the potential for the thermal atoms. Therefore, we must *first* calculate the density of the condensate $n_0(\mathbf{r})$, *before* calculating that of the thermal cloud. If this procedure is applied iteratively, it is called *Hartree-Fock method*:

i. We start with $n_{th}(\mathbf{r}) = 0$;

ii. we solve the GPE $\left(-\frac{\hbar^2}{2m}\Delta + V_{trap}(\mathbf{r}) - \mu + g\left[|\psi(\mathbf{r})|^2 + n_{th}(\mathbf{r})\right]\right)\psi(\mathbf{r})$ numerically with the steepest descent method, we derive μ and ψ, and also $n(\mathbf{r}) = |\psi(\mathbf{r})|^2 + n_{th}(\mathbf{r})$;

iii. assuming that collisions between atoms of the thermal cloud, the density of which is weak, can be neglected, we can view the cloud as an ideal gas in a potential modified by the strongly anharmonic mean field of the condensate, $V_{trap}(\mathbf{r}) + 2gn(\mathbf{r})$, we calculate the thermal density $n'_{th}(\mathbf{r}) = \lambda_{dB}^{-3} g_{3/2}\left(\exp\frac{V_{trap}(\mathbf{r})-\mu+2gn(\mathbf{r})}{k_B T}\right)$;

iv. we start over at (ii) using the new thermal density.

We can now calculate the total energy,

$$U = \int d^3r \left(\psi(\mathbf{r})\frac{-\hbar^2\nabla^2}{2m}\psi(\mathbf{r}) + V_{trap}(\mathbf{r})n(\mathbf{r}) + \frac{g}{2}[2n(\mathbf{r})^2 - n_0(\mathbf{r})] + h^{-3}\int d^3k \frac{-\hbar^2k^2}{2m} n(\mathbf{r},\mathbf{k})\right) \tag{45.101}$$

$$= \int d^3\mathbf{r} \left(\psi(\mathbf{r})\frac{-\hbar^2\nabla^2}{2m}\psi(\mathbf{r}) + V_{trap}(\mathbf{r})n(\mathbf{r}) + \frac{g}{2}[2n(\mathbf{r})^2 - n_0(\mathbf{r})] + \frac{3k_BT}{2\lambda_{dB}^3} g_{3/2}\left[\exp\frac{V_{trap}(\mathbf{r})-\mu+2gn(\mathbf{r})}{k_BT}\right]\right)$$

and other thermodynamic quantities.

45.7.3 Ideal gas limit

Consider the ideal gas in an isotropic harmonic potential. The excitation spectrum then takes the form:

$$f(\mathbf{k},\mathbf{r}) = n(\mathbf{k},\mathbf{r}) \tag{45.102}$$
$$\varepsilon_{HF}(\mathbf{k},\mathbf{r}) = \mathcal{L}(\mathbf{k},\mathbf{r}) = \frac{\hbar^2\mathbf{k}^2}{2m} + V(\mathbf{r}) - \mu \ .$$

We can immediately calculate:

$$
\begin{aligned}
g &\longrightarrow 0 \\
\mu &\overset{g\to 0}{\longrightarrow} \tfrac{3}{2}\hbar\omega \\
\phi(\mathbf{r}) &\overset{g\to 0}{\longrightarrow} \tfrac{\sqrt{N_0}}{\pi^{3/4}a_{trap}^{3/2}} \exp(-\frac{\mathbf{r}^2}{2a_{trap}^2}) \\
E_{kin} &= \int \phi(\mathbf{r}) \frac{-\hbar^2\Delta}{2m} \phi(\mathbf{r}) d^3r = -\tfrac{9}{4} N_0 \hbar\omega \\
n_{th}(\mathbf{r}) \overset{g\to 0}{\longrightarrow} \int f(\mathbf{r}\cdot\mathbf{k}) d^3\mathbf{k} &= \frac{1}{\lambda_{dB}^3} g_{3/2}\left[\exp\left(\tfrac{V_{trap}(\mathbf{r})-\mu}{k_B T}\right)\right] \\
N_{th} \overset{g\to 0}{\longrightarrow} \int n_{th}(\mathbf{r}) d^3\mathbf{r} &= \left(\frac{k_B T}{\hbar\omega}\right)^3 g_3\left[\exp\left(\tfrac{\mu}{k_B T}\right)\right] \\
U \overset{g\to 0}{\longrightarrow} \int \varepsilon_{HF} f(\mathbf{r}\cdot\mathbf{k}) d^3\mathbf{r}\cdot\mathbf{d}^3k &= 3k_B T \left(\frac{k_B T}{\hbar\omega}\right)^3 g_4\left[\exp\left(\tfrac{\mu}{k_B T}\right)\right] \ .
\end{aligned}
\tag{45.103}
$$

45.7.4 Exercises

45.7.4.1 Ex: Ballistic expansion of a condensate

Calculate the ballistic expansion of a ^{87}Rb BEC initially confined in a cylindrically symmetric trap with secular frequencies $\omega_z = 20\,\text{Hz}$ and $\omega_r = 100\,\text{Hz}$.

Solution: *The result is shown in Fig. 45.9.*

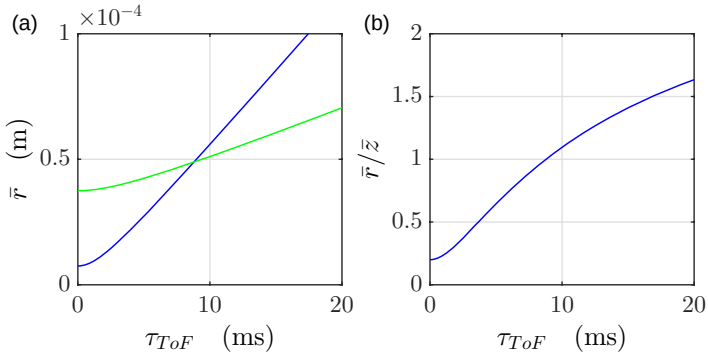

Figure 45.9: (code) Ballistic expansion of a condensate.

45.8 Numerical simulations of the Gross-Pitaevskii equation

To simulate the one-dimensional evolution of a wavepacket following the Gross-Pitaevskii equation,

$$\imath\hbar\frac{\partial}{\partial t}\psi(z,t) = \left[\frac{-\hbar^2}{2m}\frac{d^2}{dz^2} + V_{trap}(z) + |\psi(z,t)|^2\right]\psi(z,t) \ . \tag{45.104}$$

we solve iteratively [1046],

$$\psi(z,t+dt) = \psi(z,t) + dt\dot{\psi}(z,t) \ . \tag{45.105}$$

As initial state we choose, $\psi(z,0) = e^{-z^2/2\bar{z}^2}e^{\imath kz}$, where $k \equiv \sqrt{2mE}/\hbar$ is the wavevector.

The numerical propagation is conveniently performed using the *time-splitting spectral algorithm* [85, 84, 83, 486], which can be easily extended to two dimensions.

45.8.1 Crank-Nicholson-Crout algorithm

45.8.1.1 Crank-Nicholson-Crout algorithm for the time-dependent Schrödinger equation

The *Crank-Nicholson algorithm* goes as follows. The time-dependent Schrödinger equation in one dimension,

$$\frac{\partial}{\partial t}\psi(x,t) = \frac{\imath\hbar}{2m}\frac{\partial^2}{\partial x^2}\psi(x,t) - \frac{\imath V(x)}{\hbar}\psi(x,t) \tag{45.106}$$

is a parabolic partial differential equation. We usually seek a solution on an interval $x \in [a,b]$ and $t > 0$. The solution is uniquely determined from boundary conditions: $\psi(a,t) = \psi(b,t) = 0$ and $\psi(x,0) = g(x)$. One method for numerical solution solves for the values of the wavefunction on a regular grid of dimension $h = (b-a)/N_x$ in x and τ in t:,

$$\psi_j^k = \psi(a+jh, k\tau) \ . \tag{45.107}$$

The derivatives are replaced by simple finite differences. The r.h.s. of the equation at the grid point (i,j) is then,

$$\frac{\imath\hbar}{2mh^2}\left(\psi_{j+1}^k - 2\psi_j^k + \psi_{j-1}^k\right) - \frac{iV(a+jh)}{\hbar}\psi_j^k = \sum_{m=0}^{N} iH_{jm}\psi_j^k \ , \tag{45.108}$$

where H is a real symmetric tridiagonal matrix (provided $V(x)$ is real). The l.h.s. of the equation can be replaced either by a forward or backward difference,

$$\frac{\psi_j^{k+1} - \psi_j^k}{\tau} \quad \text{or} \quad \frac{\psi_j^k - \psi_j^{k-1}}{\tau} \ , \tag{45.109}$$

which, when combined with the r.h.s. gives the explicit algorithm,

$$\psi^{k+1} = (1 + iH\tau)\psi^k \quad \text{or} \quad \psi^k = (1 - \imath H\tau)\psi^{k+1} \ . \tag{45.110}$$

The Crank Nicholson Algorithm averages both,

$$(1 - \imath H\tau/2)\psi^{k+1} = (1 + \imath H\tau/2)\psi^k \ . \tag{45.111}$$

This method is a second order algorithm in t, i.e. the discretization error decreases as τ^2. The finite difference representation of the second derivative d^2/dx^2 is also good to second order in h^2. The Crank-Nicholson Algorithm also gives a unitary evolution in time. That is especially useful for quantum mechanics where unitarity assures that the normalization of the wavefunction is unchanged over time. The algorithm steps the solution forward in time by one time unit, starting from the initial wavefunction at $t = 0$. According to the Crank-Nicholson scheme, the time stepping process is half explicit and half implicit. The implicit part involves solving a tridiagonal system. That solution is accomplished by Crout reduction, a direct method related to Gaussian elimination and LU decomposition.

To simplify the algorithm we have chosen units in which the Planck constant $\hbar = 1$, time step $\tau = 1$ and the spatial separation $h = 1$. This can always be arranged by an appropriate redefinition of mass and potential: $m = m_{SI}\ h^2/\tau\hbar$ and $V = V_{SI}\ \tau/h$.

45.8.1.2 Crank-Nicholson algorithm for the time-dependent Gross-Pitaevskii equation

The Crank-Nicholson algorithm [7],

$$\begin{aligned}\frac{\imath\left(\varphi_j^{n+1} - \varphi_j^n\right)}{\Delta} &= -\frac{\varphi_{j+1}^{n+1} - 2\varphi_j^{n+1} + \varphi_{j-1}^{n+1} + \varphi_{j+1}^n - 2\varphi_j^n + \varphi_{j-1}^n}{2h^2} \\ &+ \frac{1}{2}\left(\frac{c(x_j)^2}{4} + n\frac{|\varphi_j^n|^2}{(x_j)^2}\right)\left(\varphi_j^{n+1} + \varphi_j^n\right) \ .\end{aligned} \tag{45.112}$$

Introducing abbreviations,

$$B(\varphi_j^{n+1} - \varphi_j^n) = -A\left(\varphi_{j+1}^{n+1} - 2\varphi_j^{n+1} + \varphi_{j-1}^{n+1} + \varphi_{j+1}^n - 2\varphi_j^n + \varphi_{j-1}^n\right) + C_j^n\left(\varphi_j^{n+1} + \varphi_j^n\right) \ . \tag{45.113}$$

Can be rewritten as,

$$A\varphi_{j+1}^{n+1} + \left(-2A + B - C_j^n\right)\varphi_j^{n+1} + A\varphi_{j-1}^{n+1} = -A\varphi_{j+1}^n + \left(2A + B + C_j^n\right)\varphi_j^n - A\varphi_{j-1}^n = X_j^n \ . \tag{45.114}$$

The set of equations,

$$\begin{pmatrix} -2A - B - C_1^n & A & 0 & \cdots & 0 \\ A & -2A - B - C_2^n & A & \cdots & 0 \\ 0 & A & -2A - B - C_3^n & \ddots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & A & -2A - B - C_j^n \end{pmatrix} \begin{pmatrix} \varphi_1^{n+1} \\ \varphi_2^{n+1} \\ \varphi_3^{n+1} \\ \vdots \\ \varphi_j^{n+1} \end{pmatrix} = \begin{pmatrix} X_1^n \\ X_2^n \\ X_3^n \\ \vdots \\ X_j^n \end{pmatrix} \tag{45.115}$$

can be solved by inverting tridiagonal matrix. Set $\varphi_0^{n+1} = \varphi_{J+1}^{n+1} = 0$. Run a loop $j = 1, .., J$. Assume given $\varphi_1^{n+1} = \varphi_j^{n+1}$,

$$\varphi_{j+1}^{n+1} = \frac{X_j^n}{A} + \frac{2A - B + C_j^n}{A}\varphi_j^{n+1} - \varphi_{j-1}^{n+1} \ . \tag{45.116}$$

45.8.2 Time-splitting spectral algorithm: Coherent propagation

We write the one-dimensional GPE in the form,

$$\imath\hbar\frac{\partial\psi(x,t)}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2\psi(x,t) + V(x)\psi(x,t) + \frac{4\pi\hbar^2 a_s}{m(2r_h)^2}|\psi(x,t)|^2\psi(x,t) \qquad (45.117)$$

for $a < x < b$. Choose periodic boundary conditions, $\psi(a,t) = \psi(b,t)$ and $\psi_x(a,t) = \psi_x(b,t)$. Various methods are known to solve the GPE numerically, such as the *Crank-Nicholson algorithm*. The *time-splitting spectral algorithm* (TSSA) consists in solving the first and the second of the following equations in two distinct steps [85, 84, 83, 486],

$$\frac{\partial\psi(x,t)}{\partial t} = -\imath\frac{V(x)}{\hbar}\psi(x,t) - \imath\frac{g_{1D}}{\hbar}|\psi(x,t)|^2\psi(x,t) \qquad (45.118)$$
$$\frac{\partial\psi(x,t)}{\partial t} = i\frac{\hbar}{2m}\psi_{xx}(x,t)\ ,$$

i.e. we discretize in space using $x = a + j(b-a)/M$ and $k = 2\pi l/(b-a)$ such that $k\,(x-a) = 2\pi lj/M$. We propagate half the way, $\Delta t/2$, in time,

$$\varphi_x \equiv e^{-\frac{\imath}{\hbar}(V(x)+g_{1D}|\psi(x,t)|^2)\frac{\Delta t}{2}}\psi(x,t) \qquad (45.119)$$

for $j = 0, .., M-1$. Now we propagate the spectral components, $(\mathcal{F}\varphi)_k \equiv \sum_{j=0}^{M-1}\varphi_x e^{-2\pi ilj/M}$, in momentum space and transform back, $(\mathcal{F}^{-1}\varphi)_x \equiv M^{-1}\sum_{l=-M/2}^{M/2-1}\varphi_k e^{2\pi ilj/M}$,

$$\phi_x \equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi)_k\right]\ . \qquad (45.120)$$

for $l = -M/2, .., M/2-1$. Finally, we propagate the remaining time, $\Delta t/2$,

$$\psi(x,t+dt) = e^{-\frac{\imath}{\hbar}(V(x)+g_{1D}|\phi_x|^2)\frac{\Delta t}{2}}\phi_x\ . \qquad (45.121)$$

Compared to the Crank-Nicholson algorithm time-splitting spectral algorithm has several advantages:

- TSSA is much much faster, especially, for large arrays;
- No divergence, perfect reversibility;
- Imaginary version yields same density shape as steepest descent.

But there are problems:

- The coherent version changes shape, maybe it's due to ifft(fft(x))!=x;
- The imaginary version mixes up real and imag parts;
- Don't know how to generalize to coupled GPEs.

45.8.2.1 Time-splitting spectral algorithm for coupled GPEs

Write the one-dimensional GPE in the form,

$$\begin{aligned} \imath\hbar\frac{\partial\psi_1(x,t)}{\partial t} &= -\frac{\hbar^2}{2m}\nabla^2\psi_1(x,t) + V(x)\psi_1(x,t) + \frac{4\pi\hbar^2 a_s}{m(2r_h)^2}|\psi_1(x,t)|^2\psi_1(x,t) \\ &+ \frac{\hbar}{2}\Omega_{mw}\psi_2(x,t) + \hbar\Delta_{mw}\psi_1(x,t) \\ \imath\hbar\frac{\partial\psi_2(x,t)}{\partial t} &= -\frac{\hbar^2}{2m}\nabla^2\psi_2(x,t) + V(x)\psi_2(x,t) + \frac{4\pi\hbar^2 a_s}{m(2r_h)^2}|\psi_2(x,t)|^2\psi_2(x,t) \\ &+ \frac{\hbar}{2}\Omega_{mw}\psi_1(x,t) \end{aligned} \tag{45.122}$$

for $a < x < b$. Choose periodic boundary conditions, $\psi(a,t) = \psi(b,t)$ and $\psi_x(a,t) = \psi_x(b,t)$. We generalize the *time-splitting spectral algorithm*,

$$\begin{aligned} \frac{\partial\psi_1(x,t)}{\partial t} &= -\frac{\imath}{\hbar}V(x)\psi_1(x,t) - \frac{\imath}{\hbar}g_{1D}|\psi_1(x,t)|^2\psi_1(x,t) - \imath\Delta_{mw}\psi_1(x,t) - \frac{\imath}{2}\Omega_{mw}\psi_2(x,t) \\ \frac{\partial\psi_2(x,t)}{\partial t} &= -\frac{\imath}{\hbar}V(x)\psi_2(x,t) - \frac{\imath}{\hbar}g_{1D}|\psi_2(x,t)|^2\psi_2(x,t) - \frac{\imath}{2}\Omega_{mw}\psi_1(x,t) \\ \frac{\partial\psi_1(x,t)}{\partial t} &= i\frac{\hbar}{2m}\psi_{xx1}(x,t) \\ \frac{\partial\psi_2(x,t)}{\partial t} &= i\frac{\hbar}{2m}\psi_{xx2}(x,t)\ , \end{aligned} \tag{45.123}$$

i.e. we discretize in space and propagate half the way, $\Delta t/2$, in time,

$$\begin{aligned} \varphi_{x1} &\equiv \psi_1(x,t) - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\psi_1(x,t)|^2 + i\Delta_{mw}\right)\psi_1(x,t) - \frac{\imath}{2}\Omega_{mw}\psi_2(x,t)\right]\frac{\Delta t}{2} \\ \varphi_{x2} &\equiv \psi_1(x,t) - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\psi_2(x,t)|^2\right)\psi_2(x,t) - \frac{\imath}{2}\Omega_{mw}\psi_1(x,t)\right]\frac{\Delta t}{2}\ . \end{aligned} \tag{45.124}$$

Since we here use the first order Taylor expansion of the exponential function, we introduce an error that we have to keep low by renormalizing the wavefunction after each step. Now we propagate the spectral components in momentum space and transform back,

$$\begin{aligned} \phi_{x1} &\equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi_{x1})_k\right] \\ \phi_{x2} &\equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi_{x2})_k\right]\ , \end{aligned} \tag{45.125}$$

for $l = -M/2, .., M/2-1$. Finally, we propagate the remaining time, $\Delta t/2$,

$$\begin{aligned} \psi_1(x,t+dt) &= \phi_{x1} - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\phi_{x1}|^2 + \frac{\imath}{2}\Delta_{mw}\right)\phi_{x1} - \frac{\imath}{2}\Omega_{mw}\phi_{x2}\right]\frac{\Delta t}{2} \\ \psi_2(x,t+dt) &= \phi_{x1} - \left[\left(\frac{\imath}{\hbar}V(x) + \frac{\imath}{\hbar}g_{1D}|\phi_{x2}|^2\right)\phi_{x2} - \frac{\imath}{2}\Omega_{mw}\phi_{x1}\right]\frac{\Delta t}{2}\ . \end{aligned} \tag{45.126}$$

45.8.2.2 Spinor notation

It may be possible to simplify the notation by writing the wavefunction as a spinor, $\vec{\psi} \equiv \begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix}$. Now the non-kinetic part of the coupled GPE can be written,

$$\frac{\partial \vec{\psi}(x,t)}{\partial t} = M\vec{\psi}(x,t) \ , \tag{45.127}$$

with the matrix,

$$M = \begin{pmatrix} -\frac{\imath}{\hbar}V(x) - \frac{\imath}{\hbar}g_{1D}|\psi_1(x,t)|^2 - \imath\Delta_{mw} & -\frac{\imath}{2}\Omega_{mw} \\ -\frac{\imath}{2}\Omega_{mw} & -\frac{\imath}{\hbar}V(x) - \frac{\imath}{\hbar}g_{1D}|\psi_2(x,t)|^2 \end{pmatrix} \ , \tag{45.128}$$

and the solution,

$$\vec{\psi}(x,t) = e^{Mt}\vec{\psi}(x,0) \ . \tag{45.129}$$

Let us now abbreviate the matrix by,

$$M = \begin{pmatrix} A & B \\ B & D \end{pmatrix} \ . \tag{45.130}$$

The matrix is diagonalized with the unitary transforms,

$$U = \frac{1}{\sqrt{2\Delta}} \begin{pmatrix} \frac{A-D}{2B} + \Delta & \frac{A-D}{2B} - \Delta \\ 1 & 1 \end{pmatrix} \quad \text{and} \quad U^{-1} = \frac{1}{\sqrt{2\Delta}} \begin{pmatrix} 1 & -\frac{A-D}{2B} + \Delta \\ -1 & \frac{A-D}{2B} + \Delta \end{pmatrix} \ . \tag{45.131}$$

The eigenvalue matrix is,

$$U^{-1}MU = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \tag{45.132}$$

with $E_{1,2} = \frac{1}{2}A + \frac{1}{2}D \pm B\Delta$. Here we used the abbreviation $\Delta = \sqrt{\left(\frac{D-A}{2B}\right)^2 + 1}$. The formal solution now reads,

$$\vec{\psi}(x,t) = \exp\left[U \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} U^{-1} t\right] \vec{\psi} = U \begin{pmatrix} e^{E_1 t} & 0 \\ 0 & e^{E_2 t} \end{pmatrix} U^{-1}\vec{\psi}(x,0) \ . \tag{45.133}$$

This formula can easily be computed, because the block matrices of transform U are diagonal in x.

45.8.3 Wavepacket propagation

45.8.3.1 1D simulations

We want to describe the one-dimensional evolution of an atomic wavepacket according to the Schrödinger equation. The problem is fully described by [1046],

$$\imath\hbar\frac{\partial}{\partial t}\psi(z,t) = \frac{-\hbar^2}{2m}\frac{d^2}{dz^2}\psi(z,t) + V(z)\psi(z,t) \ . \tag{45.134}$$

Numerically the Schrödinger equation is integrated via,

$$\psi(z,t+dt) = \psi(z,t) + dt\dot{\psi}(z,t) \ . \tag{45.135}$$

The initial state of the wavepacket is set to $\psi(z,0) = e^{-z^2/2\bar{z}^2} e^{\imath kz}$, where $k \equiv \sqrt{2mE}/\hbar$ is its wavevector.

The numerical propagation is conveniently done with the time-splitting spectral algorithm [85, 84, 83, 486].

The flux is,

$$\psi \nabla \psi = 0 \ . \tag{45.136}$$

45.8.3.2 2D simulations

We want to describe the two-dimensional evolution of an atomic wavepacket according to the Schrödinger equation. The problem is fully described by,

$$\frac{-\hbar^2}{2m}\left(\frac{d^2}{dx^2} + \frac{d^2}{dz^2}\right)\Psi(x,z,t) + V(x,z)\Psi(x,z,t) = i\hbar\frac{\partial}{\partial t}\Psi(x,z,t) \ . \tag{45.137}$$

Since the potential is conservative, we separate the time-evolution,

$$\Psi(x,z,t) = \psi(x,z)e^{-\imath Et/\hbar} \tag{45.138}$$

The initial shape of the wavefunction moving along the y coordinate could be a Gaussian,

$$\psi(x,z) = \psi_x(x,0)\psi_z(0,z) = (2\pi\sigma_x\sigma_z)^{-1/2}\, e^{-x^2/4\sigma_x^2 - z^2/4\sigma_y^2} \ . \tag{45.139}$$

We can assume $\sigma_z \gg \sigma_x$ and obtain an effectively one-dimensional model, $E = E_{kz}$. Set,

$$\psi(x,z,0) = \phi(x,z)e^{-\imath k_z z} \tag{45.140}$$

and,

$$-\frac{d^2}{dz^2}\phi(x,z) + 2\imath k_z \frac{d}{dz}\phi(x,z) = \frac{d^2}{dx^2}\phi(x,z) + \left[\frac{2m}{\hbar^2}E_{kz} - \frac{2m}{\hbar^2}V(x,z) - k_z^2\right]\phi(x,z) \ , \tag{45.141}$$

and,

$$\begin{aligned}
\frac{d}{dz}\phi(x,z) &= \frac{d^2}{dx^2}\phi(x,z) - \frac{2m}{\hbar^2}V(x,z)\phi(x,z) \qquad (45.142)\\
\frac{d}{dz}\phi(x,z) &= \frac{1}{2\imath k_z}\frac{1}{dx^2}[\phi(x-dx,z) - 2\phi(x,z) + \phi(x+dx,z)] - \frac{m}{\imath k_z \hbar^2}V(x,z)\phi(x,z) \ .
\end{aligned}$$

Discretize in steps dz.

45.8.3.3 Reflection from a potential barrier

Now we allow for a change of direction. We assume that a matter wave with wavevector $\mathbf{k}_0 = k_{0x}\hat{\mathbf{e}}_x + k_{0y}\hat{\mathbf{e}}_y = k_0\hat{\mathbf{e}}_x \sin\alpha + k_{0y}\hat{\mathbf{e}}_y \cos\alpha$, runs towards a potential step. If

the step is sharp, $V(x) = V_1\theta(-x) + V_2\theta(x)$, the following ansatz is reasonable,

$$\begin{aligned}\psi_0(x,y) &= e^{\imath x k_x + \imath y k_y} \\ \psi_1(x,y) &= re^{-\imath x k_x + \imath y k_y} \\ \psi_2(x,y) &= te^{\imath x k'_x + \imath y k_y}\end{aligned} \tag{45.143}$$

and we have to solve the equations,

$$\begin{aligned}\frac{-\hbar^2}{2m}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)(\psi_0+\psi_1) &= (E-V_1)(\psi_0+\psi_1) \\ \frac{-\hbar^2}{2m}\left(\frac{d^2}{dx^2}+\frac{d^2}{dy^2}\right)\psi_2 &= (E-V_2)\psi_2\ .\end{aligned} \tag{45.144}$$

In the step is smooth, $V(x\to-\infty) = V_1 < V_2 = V(x\to\infty)$, the situation is more complicated. Let us set $V(x) = (V_1 - V_2)\frac{1}{\pi}\arctan x + \frac{1}{2}(V_1+V_2)$.

Superfluid and coherent properties of Bose-Einstein condensates

Superfluid liquids or gases are distinguished by their ability to sustain flow without dissipation, i.e. flow which is free of viscous damping. The phenomenon of superfluidity is a well-known property of liquid ^{4}He, but the relationship between superfluidity and Bose-Einstein condensation in this strongly interacting system is not trivial. The situation is much simpler in weakly interacting Bose gases, where the superfluid fraction is almost identical with the condensed fraction and the normal phase of the fluid with the thermal fraction. The availability of dilute gas Bose-Einstein condensates now offers the unique opportunity to study the complicated interdependence between superfluidity and condensation.

46.1 Superfluidity in quantum gases

The *superfluidity* of a gaseous condensate, which is one of its most apparent properties, is intrinsically linked to interatomic collisions. To characterize this phenomenon, it is useful to define some parameters. In the local-density approximation, the *homogeneity* of a gas of N atoms with the thermal de Broglie wavelength (43.9) confined inside a harmonic trap with the ground state size defined by (24.85), is characterized by,

$$\frac{k_B T}{\hbar \omega_{trp}} = \frac{2\pi a_{trp}^2}{\lambda_{therm}^2} \ . \tag{46.1}$$

For a typical experimental situation, $k_B T/\hbar\omega_{trp} \approx N^{1/3} \approx 100$. This shows that the assumption of a locally homogeneous gas is generally a good approximation. With the definition of the *healing length* (45.69), the degree of superfluidity of a condensate with density n can be cast into the form,

$$\frac{gn}{\hbar \omega_{trp}} = \frac{a_{trp}^2}{\xi^2} \ . \tag{46.2}$$

For a typical experimental situation, $a_{trp}^2/\xi^2 \approx 100$. A parameter that well characterizes the importance of interatomic forces within a condensate is the gas *dilution*,

$$na_s^3 = \frac{a_s^2}{8\pi\xi^2} \ . \tag{46.3}$$

The typical numerical value $na_s^3 \approx 10^{-5}$ shows, that atomic gases are usually very dilute, although interatomic forces play an important role in the dynamics of condensates. In contrast, three-body collisions can be totally neglected, because the probability to have three atoms close to each other is even lower than the probability for two atoms.

There are several manifestations of phenomena linked to superfluidity, such as the behavior of collective elementary excitations, superfluid flow of non-circulating topological modes, quantized flux in vortices and matter wave solitons, which will be discussed in the following sections.

46.1.1 Landau's criterion for superfluidity

According to Landau, the phenomenon of superfluidity is rooted in the particular character of the Bogolubov spectrum of elementary excitations (45.54). Let us consider a bosonic fluid at a given temperature moving with velocity v. A macroscopic obstacle in the path of the superfluid can generate elementary excitations. That is, a fraction of the kinetic energy of the fluid is transferred to these excitations, thereby decelerating the fluid and causing *viscosity*. With the excitation energy $\mathcal{E}(p)$ and the momentum $\mathbf{p}$, the total energy of the fluid interacting with the obstacle is,

$$E = \mathcal{E}(p) + \frac{(\mathbf{p}+M\mathbf{v})^2}{2M} = \mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v} + \tfrac{1}{2}Mv^2 + \frac{p^2}{2M} \simeq \mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v} + \tfrac{1}{2}Mv^2 \ , \tag{46.4}$$

where M is the total mass of the superfluid. Since the term $Mv^2/2$ is the initial kinetic energy of the fluid, $\mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v}$ represents the excitation energy. And since the kinetic energy of the superfluid can only be diminished by the excitation, we need $\mathcal{E}(p) + \mathbf{p}\cdot\mathbf{v} < 0$. Finally, as $\mathcal{E}(p)$ must be positive, the condition for generating elementary excitations is,

$$\mathcal{E}(p) \leq pv \ , \tag{46.5}$$

where $\mathbf{p}$ and $\mathbf{v}$ are antiparallel.

Therefore, there is a relative *minimum velocity* between the fluid and the obstacle, called *critical Landau velocity*, for creating excitations,

$$v_c = \min\left(\frac{\mathcal{E}(p)}{p}\right) \ . \tag{46.6}$$

For velocities below v_c, it is impossible to generate excitations, and there is no mechanism to decrease the kinetic energy of the fluid. As a result, the system becomes superfluid [772].

The spectrum of elementary excitations for a weakly interacting condensate, is the Bogolubov spectrum (45.54). The graph Fig. 46.1 shows, that for velocities below the sound velocity given by (45.56), $v < c_s$, the curve representing the propagation of the

perturbation does not cross the Bogolubov spectrum. That is, the perturbation can not be converted into excitations, which is only possible when $v > c_s$.

In an ideal condensate without interactions, $a_s = 0$, the Bogolubov spectrum reduces to the quadratic dispersion relation of free particles, which means that there is no critical velocity, $v_c = c_s$. Consequently, it is always possible to excite the condensate, that is, an ideal condensate can not be superfluid, and, as first pointed out by Landau: *superfluidity and Bose-Einstein condensation are different phenomena.*

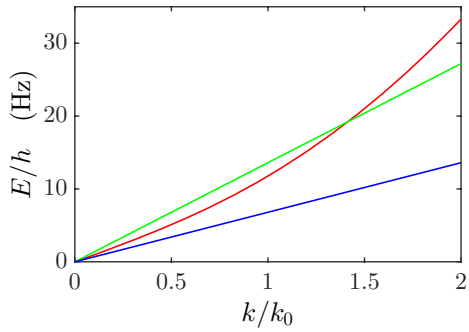

Figure 46.1: (code) Landau's criterion for superfluidity. Slow perturbations (blue line) do not cross the Bogolubov spectrum (red line) and do not generate excitations. Rapid perturbations (green line) cross the spectrum and can be dissipated.

46.1.2 Impurity scattering

A first hint for the superfluid nature of Bose-Einstein condensates is the fact that the hydrodynamic theory of superfluidity describes well the collective excitations (see Sec. 45.5). Moreover, several experiments provided direct evidence for the superfluid nature of condensates. For example, via a calorimetric measurement [1071]: A condensate, stirred around by a rotating far blue-detuned laser beam, dissipated atoms to the thermal fraction of the atomic cloud, provided the stirring velocity exceed a certain *critical velocity* v_c: At lower velocities, the perturbation did not lead to dissipation. At higher velocities, phonons were excited and the cloud was heated. In a subsequent experiment, perturbation-induced density fluctuations were observed *in vivo* and *in situ* [978]. When the stirring speed was below the critical velocity, the density was almost homogeneous, thus indicating superfluid flow. When, however, the stirring speed exceeded v_c, atoms piled up in front of the stirring beam, and the resulting pressure gradients led to a turbulent flow around the perturbation and to dissipation.

The critical velocity v_c found in the stirring experiments was about ten times smaller than the local sound velocity c_s,

$$c_s \equiv \sqrt{\frac{gn}{m}} = \frac{\hbar}{\sqrt{2}m\xi} \ . \tag{46.7}$$

In fact, while the onset of dissipation is accelerated by turbulence around the *macroscopic object* traversing the superfluid, the local sound velocity (46.8) is derived for

a *microscopic object*. Puzzled by this discrepancy, Chikkatur *et al.* [255] studied the motion of microscopic atomic impurities through a condensate. The *impurity* was created by transferring a few atoms out of the original BEC from the trapped state $|F = 1, m_F = -1\rangle$ to the free state $|F = 1, m_F = 0\rangle$ via induced Raman transitions. The initial velocity was adjusted by the laser beams exciting the Raman transition (polarization, incident angle and relative detuning) to satisfy the Bragg condition (see Sec. 47.2). After the free impurity passed through the BEC, the trap was switched off, a Stern-Gerlach magnetic field gradient was pulsed to separate atoms in different Zeeman states, and finally the atoms were detected via time-of-flight imaging (see Sec. 43.6.1). When the initial velocity of the impurity was well above a critical value given by the local velocity of sound, ultracold s-wave collisions between impurity atoms and the stationary condensate distributed the momenta of the collision partners uniformly. In TOF images this appeared as a *circular halo* centered around the center-of-mass momentum of the collision partners (see Fig. 46.2). When, however, the initial velocity of the impurity was reduced, its collision rate with the stationary condensate was suppressed and the trajectory became superfluid.

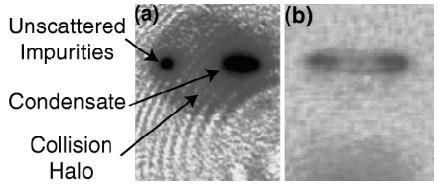

Figure 46.2: (a) Scattering of impurities at velocities above the critical velocity. The presence of a halo indicates the occurrence of collisions between the impurity and the condensate dissipating the relative kinetic energy. (b) For velocities below the critical velocity the halo disappears.

46.1.3 Hydrodynamic theory of superfluidity

For the description of superfluidity a hydrodynamic theory is adequate. Therefore, we will rewrite the time-dependent Gross-Pitaevskii equation (45.21). We consider the general case, in which the external potential $V_{trp}(\mathbf{r}, t)$ depends on time. The wavefunction can be written by defining the density and the velocity fields,

$$\phi(\mathbf{r}, t) = \sqrt{n_0(\mathbf{r}, t)} e^{i\theta(\mathbf{r},t)} \tag{46.8}$$

$$\mathbf{v}_s(\mathbf{r}, t) = \frac{\mathbf{j}(\mathbf{r}, t)}{n_0(\mathbf{r}, t)} = \frac{1}{2im} \frac{1}{n(\mathbf{r}, t)} \left[\phi^*(\mathbf{r}, t)\nabla\phi(\mathbf{r}, t) - \nabla\phi^*(\mathbf{r}, t)\phi(\mathbf{r}, t)\right] .$$

This gives,

$$\mathbf{v}_s(\mathbf{r}, t) = \tfrac{\hbar}{m}\nabla\theta(\mathbf{r}, t) . \tag{46.9}$$

From the GPE we derive the continuity and the Navier-Stokes equations:

$$\frac{\partial n}{\partial t} + \nabla(\mathbf{v}_s n) = 0 \tag{46.10}$$

$$m\frac{\partial \mathbf{v}_s}{\partial t} + \nabla\left(V_{trp} + gn - \frac{\hbar^2 a}{2m\sqrt{n}}\nabla^2\sqrt{n} - \mu + \frac{m}{2}\mathbf{v}_s^2\right) = 0 .$$

We can see that the hydrodynamic behavior of a BEC depends greatly on the quantum phase θ. When the kinetic pressure is small compared to the mean-field energy,

$$m\frac{\partial \mathbf{v}_s}{\partial t} + \nabla\left(V_{trp} + gn + \frac{m}{2}\mathbf{v}_s^2\right) = 0 \ . \tag{46.11}$$

This is the *Euler equation* for a fluid with a potential flow. This equation and the *continuity equation* have the typical structure of equations describing superfluids at $T = 0$. This is due 1. to the presence of a Bose-Einstein condensate allowing us to formulate an equation for a complex *order parameter*, and 2. to the presence of interactions, included via the pressure term in the Euler equation, which are necessary condition for superfluidity.

At zero temperature, the entire fluid is superfluid. Moreover, in the Gross-Pitaevskii approximation, the whole fluid is condensed. Therefore, $\mathbf{v}_s(\mathbf{r}, t)$ is the velocity flow of the superfluid [1].

46.2 Topological modes

Significant manifestations of superfluidity are associated with rotational phenomena. An example is the occurrence of *scissor mode*s [557], which are excited, when an angular momentum is suddenly applied to a condensate confined in an anisotropic trap. This can be done via a sudden reorientation of the symmetry axis of the trap [843, 842]. The condensate responds to this perturbation by an oscillation of its inclination implemented by an *irrotational superfluid flow*. The excitation spectrum reflects the strong reduction of the inertial momentum for superfluids.

The most rigorous manifestation of superfluidity, however, is the occurrence of a quantized and persistent current, called *quantized vortex*. In contrast to the elementary excitations, which must be created by perturbations, the vortex is a *stationary* (or *topological mode*) solution of the Gross-Pitaevskii equation Eq. (45.21).

Work on vortices has been done by [857, 833, 1071, 978, 255, 557, 843, 834, 253, 29, 1113, 377, 658, 222, 1420].

46.2.1 Vortices

From Eq. (46.9) it is easy to see, that the superfluid is non-rotational, that is,

$$\nabla \times \mathbf{v}_s(\mathbf{r}, t) = 0 \ . \tag{46.12}$$

This raises the question, how vortices are possible. The solution to this apparent contradiction is, that Eq. (46.12) does not apply, when the phase exhibits a singularity. Consider, for example, a closed loop C around the singularity. In a vortex, the superfluid current is pulled by the phase gradient, $\mathbf{v} = \frac{\hbar}{m}\nabla\theta$. For the condensate wavefunction to be well defined, the phase variation $\Delta\theta$ around the loop must be a multiple of 2π, that is,

$$\Delta\theta = \oint_C \nabla\theta \cdot d\mathbf{l} = 2\pi\ell \ . \tag{46.13}$$

[1] This is not the case for strongly interacting superfluids, such as superfluid helium, where the normal fluid fraction is considerable.

where ℓ is an integer. Therefore, we can calculate the *circulation* Γ around the closed loop, that is,

$$\Gamma = \oint_C \mathbf{v}_s(\mathbf{r},t)\cdot d\mathbf{l} = \frac{h}{m}\ell \ . \tag{46.14}$$

Apparently, the superfluid circulation is quantized in units of $\hbar/m$. The parameter ℓ is called *charge of the vortex* and measures, in unit of h, the quantized angular momentum of the vortex.

In addition, the flow must be persistent, because its circulation can only be changed in a discontinuous way, by overcoming a discrete energy barrier, which requires energy coming e.g. from thermal excitations. Clearly, the normal (thermal) fraction of a gas can also have a circular flow. However, the disordered microscopic motion of each individual particle causes a viscous drag that prevents the persistence of the flow in the absence of a torque. This is in contrast to superfluid flow, which persists even without external torque. The issues of vortex stability, formation, and topology were addressed in recent experiments [856, 833, 834, 253, 29]. Solve the Excs. 46.2.6.1 and 46.2.6.2.

The kinetic energy per unit vortex length can be estimated from a semi-classical approach. First, we define as the mass density ρ_m of the superfluid. If n is the particle density, $\rho_m = nm$. The kinetic energy of a flux line at the radius r is,

$$\mathcal{E}_{kin} = \tfrac{1}{2}\rho_m v_s^2 = \frac{\hbar^2\ell^2}{2m}\frac{n}{r^2} \ . \tag{46.15}$$

To obtain the kinetic energy per unit length, we integrate the expression (46.21) over a plane perpendicular to the vortex axis. Note, however, that the velocity field is $v_s \propto r^{-1}$ and, therefore, can not be integrated from zero. Instead, we begin the integration at a radius given by the *healing length* ξ, which represents a measure of the vortex core size. Now, the kinetic energy per unit length is,

$$E_{semi} = \int_0^{2\pi}\int_\xi^R \mathcal{E}_{kin}(\mathbf{r}) r dr d\theta = \pi n \frac{\hbar^2\ell^2}{m}\ln\frac{R}{\xi} \ . \tag{46.16}$$

Note, that a multiply charged vortex carrying the entire angular momentum $\ell = \ell_0$ of the superfluid is energetically less favorable than an ensemble of ℓ_0 vortices with unit charge $\ell = 1$. Therefore, a multiply charged vortex is unstable and may decay to several single charge vortices.

To calculate exactly the energy of a vortex, we do the following ansatz,

$$\Phi_0(\mathbf{r}) = \phi(r,z)e^{i\ell\vartheta} \ , \tag{46.17}$$

we then solve the Gross-Piatevskii equation (45.21) numerically, and calculate the expectation value of the energy of the vortex through the expression,

$$\langle\Phi_0|\hat{H}|\Phi_0\rangle = \int d^3\mathbf{r}\left[\tfrac{\hbar^2}{2m}|\nabla\Phi_0(r,z)|^2 + V_{trp}|\phi(r,z)|^2 + g|\phi(r,z)|^4\right] \ , \tag{46.18}$$

where $\hat{H}$ is the Gross-Pitaevskii Hamiltonian.

The calculation yields for energy per unit length of a single charge vortex in a uniform cylindrical condensate [1017],

$$E_{unif} = \pi n\tfrac{\hbar^2}{m}\ln\left(1.464\tfrac{R}{\xi}\right) \ , \tag{46.19}$$

which is very close to our semi-classical prediction. Although the wavefunction $|\phi(r,z)|$ has no analytic form, it can be shown by a variational approach, that the trial wavefunction,

$$|\phi(r,z)| = \frac{nr}{\sqrt{2\ell^2\xi^2 + r^2}} \tag{46.20}$$

is a good approximation [1017]. Note that the healing length ξ characterizes the size of the vortex. For a superfluid, we can calculate the total energy of the vortex exactly, because the fluid is confined in all directions,

$$E_{tot} = \frac{4\pi n_0}{3}\frac{\hbar}{m}\ln\left(0.671\frac{R_r}{\xi_0}\right) \ , \tag{46.21}$$

where n_0 and ξ_0 are, respectively, the density and healing length at the center of the fluid. R_z and R_r are, respectively, the extensions of the cloud along the axial and radial directions within the Thomas-Fermi approximation.

46.2.1.1 Creation and detection of vortices

The first superfluid vortex was observed 1979 in ^{4}He [1409]. For gaseous condensates, two approaches have been employed to produce vortices. Either one stirs the atomic cloud in order to impart an angular momentum to it. This can be done by rotating the (anisotropic) trap during the process of forced evaporation with time-orbiting magnetic fields or with an optical spoon. The vortex state is formed when the critical temperature for condensation is crossed. An alternative method is to imprint a 2π circular phase gradient into a previously created condensate. Indeed, the local phase of a matter wave can be manipulated via a local modification of the potential depth, which can be achieved by a Stark shift induced by a far-detuned laser beam [377]. Focused into a tiny spot which is moved across the condensate, the laser beam will create a phase gradient, which in turn will cause a velocity flow. It is important to force the local density at the center of the vortex to zero, which can be achieved via a proper design of the trapping potential (e.g., a Mexican hat-shaped potential), and let the BEC then relax to the vortex state.

A variation of this method [1378] avoids the need for relaxation processes. In this configuration the phase gradient is created through a *local* Raman coupling between two internal atomic states (for example, in ^{87}Rb the two trappable Zeeman states $|F, m_F\rangle = |1,-1\rangle$ to $|2,1\rangle$). At the spots, where the focused Raman beams hit the condensate, atoms were dynamically converted from the ground state to the excited state. The circular trajectory of the spots and the rotation speed were calculated such as to generate a toroidal topology for the adiabatic population transfer. The process was coherent and allowed to directly construct and shape the vortex wave function. We study this experiment in more detail in the Exc. 46.2.6.3.

In confined single-species condensates the diameter of the vortex core is on the order of the healing length, 2ξ. With typical values of $2\xi \approx 0.4$ μm it is thus way too small to be imaged *in situ*, and ballistic expansion times of several 10 ms are necessary. On the other hand, in double condensates formed by two repelling species (e.g. the two states $|2,1\rangle$ and $|1,-1\rangle$ in ^{87}Rb), one of the species can form a vortex around the second. In this case, the diameter of the vortex core, is determined by the diameter of the condensate of the second species and, hence, much larger. When

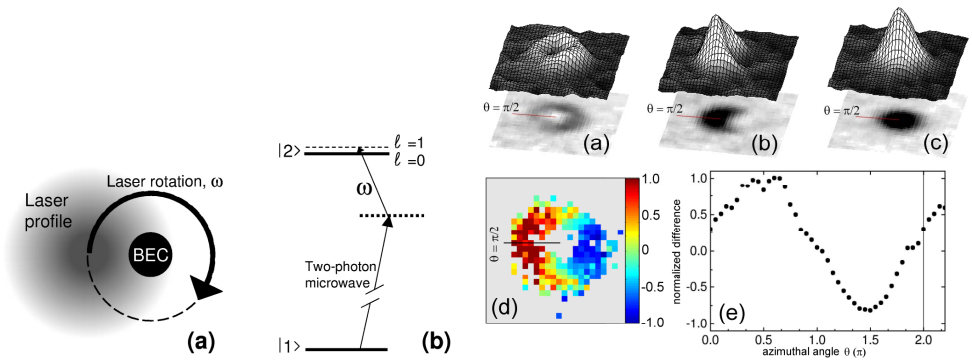

Figure 46.3: (Left) Scheme of the experiment [856]. (Medium) Level system used. (Right) Density distribution of a vortex state: (a) (the visible atoms are in the upper hyperfine state), (b) after a $\pi/2$-pulse and (c) after a π-pulse (the visible atoms are in the lower hyperfine state). The images (d) and (e) visualize the phase slip around the vortex.

the second species is selectively removed (e.g. by the radiative pressure exerted by a resonant laser), and the vortex in the first species can be studied by *in situ* imaging of the confined density distribution [857].

A particularly smart detection method for vortices is based on matter wave interferometry (see Sec. 46.3.3). Here, two matter waves, that is, the vortex state in $|2,1\rangle$ and a (reference) ground state BEC in $|1,-1\rangle$ are coherent mixed via a resonant two-photon radiofrequency $\pi/2$-pulse. The resulting matter wave interference patterns reveals the phase profile of the vortex (see Fig. 46.3).

46.2.1.2 Stability

In a topologically 'singly-connected' trap, for example a potential harmonic, vortices do not represent the lowest energy eigenstate, and they must decay to the ground state. If the mean-field energy of the condensate is weak compared to the kinetic energy, $gn_0/\hbar\omega_z \ll 1$, the healing length will exceed the size of the BEC, $\xi \gg a_{trp}$, and the vortex rapidly decays by dissipating its excess energy to thermal excitation. Such BECs can not be considered superfluid. If the mean-field interaction is strong, the vortex spontaneously breaks azimuthal symmetry, moves away from the center and exits the condensate on a spiral-shaped trajectory [1113]. Nevertheless, the decay time may be quite long.

On the other hand, a vortex can be the ground state of a 'multiply-connected' trap (for example, a toroidal potential). Such a potential can be realized as the temporal average of a harmonic potential with a small rotating anisotropy [833]. In such geometries vortices are extremely stable.

46.2.1.3 Vortex precession

A radial force acting on a vortex results in a radial displacement and a precession about the symmetry axis. The effect, known as *Magnus effect* [658], is due to pressure

imbalances on the vortex surface. A radial force naturally arises, when the core is displaced from the center, because local pressure gradients will force the vortex out of the center toward regions with lower densities. Experimentally, a slow precession ($\sim$ 1 Hz) spiraling the vortex toward the rim of the condensate has been observed [29] by taking a succession of nondestructive images.

46.2.2 Vortex lattices

Superfluid ^{4}He in a rotating bucket spontaneously develops symmetrically organized vortex patterns. Similar phenomena can be observed, when a dilute gas Bose-Einstein condensate is forced to rotate [222] at a given frequency Ω. The energy in the rotating system receives an additional contribution from the centrifugal term, $U_{rot}(\mathbf{r}) = U_{trp}(\mathbf{r}) - \Omega L_z$, where $L_z = \hbar N l_z$, and $l_z = i(y\partial_x - x\partial_y)$ is the angular momentum of the individual atoms. If the rotation is slow, the energy ΩL_z is too small to force the condensed wavefunction to rotate. If the rotation frequency is beyond a critical value Ω_c, the *time-averaged* potential, $U_{rot}(\mathbf{r})$ eventually develops a local minimum in the center, thus adopting the toroidal shape. For non-interacting gases, the critical frequency coincides with the radial secular frequency, $\Omega_c = \omega_r$. Then the radial restoring force of the trap does not balance the centrifugal force, such that atoms can escape from the trap. However, for superfluid gases the critical frequency is reduced, $\Omega_c < \omega_r$. Between the rotation frequencies $\Omega = \Omega_c$ and $\Omega = \omega_r$, the state with the lowest energy in the toroidal potential is the vortex, whose filament is pinned to the symmetry axis. For even higher rotation frequencies, we could expect a single vortex with a larger winding number (more than the phase winding of 2π for a single turn). However, individual multiple-order vortices in harmonic traps are unstable. Instead, vortex lattices [222] called *Abricosov lattice*s will form. For a given trapping potential and mean-field energy, the symmetry of the lattice and the number of vortices depend on the rotation frequency Ω. Counter-intuitively, the angular momentum of individual particles l_z *is not quantized*. When we vary Ω, regimes of forbidden l_z (i.e. when no vortex pattern is formed) alternate with allowed regimes. The discontinuous transition from one vortex pattern to another is a first-order phase transition, which spontaneously breaks one symmetry to form another. An upper limit for the rotation speed is given by the equilibrium between the centrifugal force and the radial restoring force of the trapping potential at $\Omega = \omega_r$.

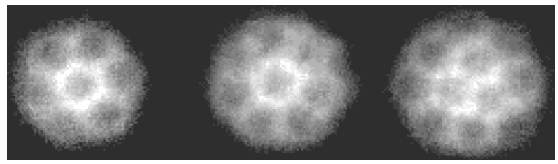

Figure 46.4: Abricosov vortex lattice.

These patterns of vortex lattices were observed in experiments using the *stirring method*, which consists in brushing a far-detuned focused laser ('optical spoon') around the rim of a condensate [833] at a certain frequency Ω. In this experiment, the ratio of the mean-field energy to the kinetic energy was $gn_0/\hbar\omega_z = a_{trp}^2/2\xi^2 > 100$. Beyond a certain critical rotation frequency, $\Omega_c \approx 2\pi \times 150$ Hz, a single central vortex

was formed. At even higher frequency, a symmetrical vortex lattice appeared in a transverse plane (see Fig. 46.4). Finally, at rotation frequencies near the radial trap frequency ω_r, the condensate wavefunction became turbulent and finally disappeared. As soon as the optical spoon was removed, the vortex lattice gradually decayed losing the vortices one by one.

46.2.3 Solitons

Work on solitons has been done by [1416, 1377, 856, 1378, 921, 1089, 657, 938, 218, 69, 397, 212, 356].

46.2.3.1 Dark solitons

Solitons are non-singular solutions of any equation satisfying,

$$|\psi(\mathbf{r},t)| = |\psi(\mathbf{r}-\mathbf{v}t)| \ . \tag{46.22}$$

Solitons are well known to occur in non-linear optical media, for example in optical fibers, when dispersion is counterbalanced by self-phase modulation, such that optical signals propagate without spreading. The Gross-Pitaevskii equation is another example for a nonlinear wave equation supporting soliton-like solutions. States called *dark soliton* or *twisted state* with a dynamically stable density dip are expected in condensates with repulsive interactions [921, 1089, 657, 938]. In contrast to topologically stable states, for example, vortices, dark solitons are pseudo-defects, the decay of which, even though it may be slow, is topologically trivial. Due of the greater freedom of movement of their wavefunctions, solitons can be distorted by complex deformations [218]. Soliton-like matter wave states were initially observed in superfluid ^{3}He-B [69]. In dilute gases, the size of the solitons is of the order of healing length.

The first dark solitons in dilute gases were created by applying an inhomogeneous phase shift to a condensate [212, 356]. One half of the condensate was irradiated by a far-detuned laser pulse (detuning Δ, Rabi frequency Ω, duration $\tau \ll \hbar/gn_0$) in order to advance the phase of this part of the condensate by $\varphi = \Omega^2\tau/4\Delta$. When the phase shift was set to π, an abrupt phase gradient developed at the boundary delimiting the two halves. The condensate reacted to the phase gradient by developing a deep density minimum all along the boundary corresponding to a soliton (see Fig. 46.5). The phase distribution can also be imaged by interferometric techniques based on Bragg diffraction (see Sec. 47.2). In one dimension, the density dip of the soliton corresponds to a node of the dipolar topological mode [1378, 921, 938].

The abrupt phase gradient at the boundary plane exerts a force trying to increase the gap, while repulsive interactions work to heal it. At zero temperature, this balance ensures the dynamic stability of the soliton. While a perfect dark soliton should be stationary, experiments [212, 356] revealed that solitons with finite contrast propagate along the direction of the plane's normal vector with a velocity, which must always be less than the local sound velocity,

$$v_{sol} = c_s\sqrt{\frac{n_{sol}}{n}} \ , \tag{46.23}$$

where n is the peak density of the condensate and n_{sol} the density at the bottom of the dark soliton [1089, 657]. Fig. 46.5 shows that the soliton develops a curvature

when it propagates. One reason for this is a slower sound velocity, $c_s = \sqrt{gn_0/m}$, on the edges of the condensate, where the density is lower. The second reason is, that the density in the dip, n_{sol}, goes to zero at the edges. In the presence of a thermal cloud, dissipation reduces the contrast of the density dip and accelerates the soliton, until it reaches the sound velocity c_s and finally disappears.

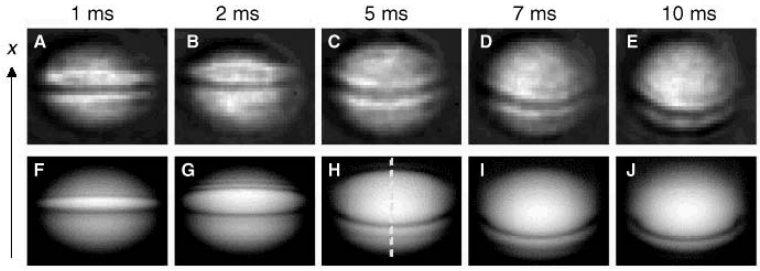

Figure 46.5: Solitons.

46.2.3.2 Bright solitons

In condensates with attractive interactions *bright solitons* have been observed, as well [715, 695].

46.2.4 Description of general topological modes

A coherent *topological mode* is a stationary solution of the *Gross-Pitaevskii equation*,

$$\left[-\frac{\hbar^2}{2m}\nabla^2 + U_{tr}(\mathbf{r}) + \frac{4\pi\hbar^2 a_s}{m}N|\phi_n|^2\right]\phi_n(\mathbf{r}) = E_n\Phi(\mathbf{r}) \ . \tag{46.24}$$

These modes can be calculated using an *optimized perturbation theory* [297]. We separate the Hamiltonian into an unperturbed part and a perturbed part, $\hat{H} = \hat{H}_0 + \Delta\hat{H}$, where the unperturbed part now depends on variational parameters,

$$\hat{H} = \hat{H}_0(u, v, ..) + \Delta H \ . \tag{46.25}$$

As usual, the first-order energy correction is,

$$E_n^{(1)}(u, v, ..) = E_n^{(0)}(u, v, ..) + \langle\Phi_n^{(0)}|\Delta\hat{H}|\Phi_n^{(0)}\rangle \ , \tag{46.26}$$

where the $\Phi_n^{(0)} = \Phi_n^{(0)}(u, v, ..)$ are the solutions of the unperturbed Hamiltonian $\hat{H}_0$. Once the energies are found, we must minimize them in terms of the variational parameters,

$$\frac{\partial E_n}{\partial u} = 0 \quad , \quad \frac{\partial E_n}{\partial v} = 0... \ . \tag{46.27}$$

With these parameters, we obtain the energies and the wavefunctions [2].

[2] Excited modes can be understood stationary matter waves with the trap serving as a cavity.

46.2.4.1 Creation of topological modes

One possibility of creating topological modes is to apply a temporal modulation to the trapping potential [1416]. The modulation frequency must be resonant with the energy difference between the excited mode and the ground state. Another possibility is to vary the interaction energy via a modulation of the scattering length in the vicinity of a *Feshbach resonance* [301].

The steady-state situation of a cloud in a stationary trap is *thermal equilibrium*, that is, inversion is not possible. At a time-dependent (e.g. shaking) potential however, for example, transitions to excited vibrational levels can be driven. These can generate inversion, provided collision-induced relaxation is not too fast [3].

46.2.5 Turbulence

The issue of turbulence is one of the most important problems of classical physics yet to be solved [442]. In superfluids, restrictions imposed by quantum mechanics constrain the emergence of turbulence, which is then called *quantum turbulence*. On the other hand, the study of quantum turbulence can improve our understanding of *classical turbulence* [384]. Recently, the study of the dynamics of a ensemble of vortices in a Bose-Einstein condensate allowed the identification of signatures of quantum turbulence [609, 584].

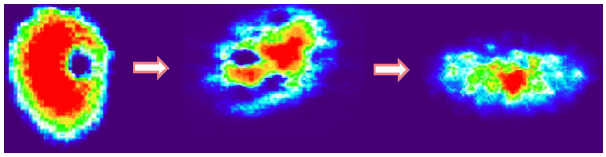

Figure 46.6: Turbulence.

46.2.6 Exercises

46.2.6.1 Ex: Comparison between the quantum and the classical vortex

Consider a vortex around a straight line along the z-axis at $r = 0$. Compare the radial velocity variation of a quantum vortex with that of a classical one.

Solution: *Because of symmetry, the flux lines around the axis are concentric. Therefore,* $\mathbf{v}_s(\mathbf{r}) = v_s(\mathbf{r})\hat{\theta}$. *Choosing the loop* C *as a centered circle of radius* r*, we get*

$$\Gamma = \int_0^{2\pi} v_s(\mathbf{r},t)\hat{\theta}\cdot(\hat{\theta}rd\theta) = 2\pi r v_s(\mathbf{r},t) = \frac{\hbar}{m}\ell \ .$$

Therefore, the velocity field of the superfluid is a quantized vortex,

$$\mathbf{v}_s(\mathbf{r},t) = \ell\frac{\hbar}{mr}\hat{\theta} \ .$$

[3] The dynamics of atoms trapped in a harmonic potential is similar to the Jaynes-Cummings dynamics of an optical mode. However, the non-linear condensate self-interaction changes the situation and makes the collisions being collective.

This is in contrast to classical fluids, where vortices generally satisfy the rotational field $\mathbf{v} = \mathbf{\Omega} \times \mathbf{r}$*, where* Ω *is the angular velocity. In this case, instead of decreasing, the amplitude of the velocity field increases with the radius.*

46.2.6.2 Ex: Singularity in vortices

Show for the above simple example,

$$\nabla \times \mathbf{v}_s(\mathbf{r}, t) = \hat{\mathbf{z}} \frac{\ell h}{m} \delta(x)\delta(y) \ .$$

Solution: *The rotation reads in cylindrical coordinates* (r, θ, z)*:*

$$\nabla \times \mathbf{v}_s = \left(\frac{1}{r} \frac{\partial}{\partial \theta} v_z - \frac{\partial}{\partial z} v_\theta \right) \hat{\mathbf{r}} + \left(\frac{\partial}{\partial z} v_r - \frac{\partial}{\partial r} v_z \right) \hat{\theta} + \left(\frac{1}{r} \frac{\partial}{\partial r} (r v_\theta) - \frac{1}{r} \frac{\partial}{\partial \theta} v_r \right) \hat{\mathbf{z}} \ .$$

For our case,

$$\nabla \times \mathbf{v} = \left(\frac{1}{r} \frac{\partial}{\partial r} (r v_\theta) \right) \hat{\mathbf{z}} = \ell \frac{\hbar}{mr} \ .$$

46.2.6.3 Ex: Phase-engineering of a vortex state

The first vortex in a dilute gas was created at the JILA [857]. Study the paper and explain in detail, how the vortex was created.

Solution: *Beginning with a standard BEC of* ^{87}Rb *in the fundamental state* $|1, -1\rangle$ *confined to a harmonic potential, the hyperfine state* $|2, 1\rangle$ *was coupled by microwave-radiofrequency two-photon radiation. The sum of the frequencies has been tuned* $\Delta_{rf}/2\pi = 94$ *Hz out of resonance. The radiation intensity was adjusted to a Rabi frequency of* $\Omega_{rf} = (2\pi)35$ *Hz, causing the Bloch vector of the effective two-level system to precede with a generalized Rabi frequency* $G_{rf} = (\Omega_{rf}^2 + \Delta_{rf}^2)^{1/2} = (2\pi)100$ *Hz. Spatial and temporal control over the conversion rate between the hyperfine states was obtained by an additional laser beam focused into the BEC (*$P = 10$ *nW,* $w_0 = 180$ *μm) and rotating with frequency* ω_{rot} *about the symmetry axis of the trap. The laser was tuned* $\Delta_l = (2\pi)800$ *MHz to the blue of the D2 line, thus causing an inhomogeneous and time-varying dynamic Stark shift* $\Omega_l(\mathbf{r}, t)^2/4\Delta_l$*, where* Ω_l *is the Rabi frequency at the D2 transition. While ground state atoms located at the trap center did not feel the Stark shift modulation, atoms located at a distance* r_{rot} *of the center were subjected to the total contrast of the modulation and, therefore, to the microwave radiation through the two modulation sidebands located in* $\Delta_{rf} \pm \omega_{rot}$*. To satisfy the resonance condition for one of the sidebands and excite transitions from the ground state to the state* $|2, 1\rangle$*, the rotation frequency was synchronized with the precession frequency,* $|\omega_{rot}| = G_{rf}$*. This is equivalent to accommodating the precession phase of the Bloch vector,* $G_{rf}t$*, with the azimuthal Broglie phase of the atoms created in the state* $|2, 1\rangle$*,* $\omega_{rot}t$*, ensuring a unique de Broglie phase along the rotation path. The*

phase gradient of the matter wave then generated a circular flow and formed a vortex.

46.3 Atom optics

Unlike the photons [770], there is no doubt about the fact that atoms are particles. On the other hand, the deep analogy between light and matter, resulting from the particle-wave duality, prompted de Broglie in 1924 to ascribe a *wave* to each massive particle, whose wavelength would be a function of the particle's momentum. Whether an atom behaves more like a particle or a wave depends on the specific experimental situation. For example, interferometers emphasize its wave nature: Atoms are able to interfere with *themselves*, when their Broglie wavelength is coherently split and then recombined. (Bosonic) atoms are able to interfere with other atoms, if their de Broglie wavelengths are greater than their distances. For this to happen, it requires high densities and very low temperatures, that is, high phase space densities. When the phase space densities are so high that the Broglie waves come into contact, effects of quantum statistics begin to influence the dynamics of the atoms, and fermions will behave differently from bosons.

Analogously to the distinction between classical and laser optics, we can separate the area of conventional atomic optics working with individual, mutually incoherent atoms, from the area of coherent atomic optics working with Bose-Einstein condensates. Unlike for the study of phenomena related to superfluidity, gases with weak interatomic interactions are generally more useful for the study of the coherent properties of condensates and for application in atomic optics. Nevertheless, interatomic collisions increase the complexity of the dynamics of matter waves interacting with atom optical devices, by introducing non-linarities analogous to those known from nonlinear optics and thus raising the field of *nonlinear atom optics*.

46.3.1 Atomic optical tools

The basic equipment of an atomic optics laboratory [904, 6, 1032, 463, 1060] comprises atomic beams, atom traps, lenses and waveguides, various types of mirrors and resonators, Stern-Gerlach type matter wave polarizers, de Broglie wave phase shifters based on Bragg diffraction, and a multitude of atomic beam gratings. Obviously, gratings allow the construction of atom interferometers, which are used in experiments and high precision devices, for example, atomic gyroscopes and gravimeters. Other applications for atomic beams controlled by atom optical elements are in atomic holography for the projection of complex pattern into integrated semiconductor circuits [923], in lithography [1309], and in microscopy [376].

An important feature of atoms (as compared to light) is the existence of a rich internal structure providing a wealth of additional degrees of freedom, whose dynamics (of the Bloch vector) is frequently entangled with the motional dynamics (of the de Broglie wave). This allows to monitor (e.g. in matter wave interferometers) the evolution of the motional state of the matter wave via an observation of the internal excitation. Moreover, in some interferometers, the de Broglie wave is not even split, and one does interferometry with completely immobile atoms or ions [642].

The epitome of a coherent light source is the laser, and we may ask whether there is a material analogue, which would be a source of coherent matter [1386, 179, 1231, 625, 933, 730] serving for *coherent atom optics*. In fact, we may already consider a trapped condensate as a stationary *atom laser* pulse with the trapping potential playing the role of the laser resonator. While most atom optical devices (including conventional atomic interferometers) do not require mutual coherence of atoms, certain applications take advantage of an intense, highly directional, monochromatic, and coherent atom source. In this respect, atom lasers are much superior to thermal atomic beams. While a thermal beam contains about 10^{-12} atoms per mode and a magneto-optical trap about 10^{-6}, a condensed mode may contain more than 10^6 atoms. Condensates offer the advantage of large de Broglie wave amplitudes and de Broglie wavelengths as long as their actual size (which can be much longer than optical wavelengths). And for an atom laser, the coherence length can even be longer than that of the condensate from which it emerged. This obviously has a major impact on the sensitivity and resolution of atom optical elements, in particular those, where atomic coherence is important, for example, atom interferometers. Without doubt atom lasers will replace conventional atomic beams in precision measurement of fundamental constants and tests of fundamental symmetries ([Phys. World (mar,97) p.43]). Finally, atom lasers are crucial for nonlinear optics.

Also of interest are the references [1229, 923, 1072, 774, 1121, 80, 608, 390, 1059, 355, 620, 1092, 656, 1156, 133, 376, 1366].

46.3.2 The atom laser

A large number of techniques for making an *atom laser* has already been developed [881, 36, 890, 30, 154, 570, 849] and theories on atom lasers have been formulated [565, 931, 1384, 1353, 644]. The following sections are devoted to explaining, why the term atom laser is justified. For the reasoning we will let as guide by the optical laser.

We already mentioned the *trapping potential* (replacing the resonator in lasers) as a major ingredients of an atom laser [4]. Another necessary feature would be the availability of an *output coupling* mechanism, which we still need to discuss in the following. Apart from these more practical aspects, we need to prove, that atom lasers are indeed *phase-coherent*, and we have to clarify the role of *bosonic stimulation* and of *irreversibility* in the production process of a BEC.

46.3.2.1 Bosonic stimulation and irreversibility

The gain mechanism for optical lasers is photonic stimulation of atoms inciting them to emit other photons into the stimulating mode. The atomic laser operates in a similar way. Atoms trapped in a potential constitute a thermal reservoir. Binary collisions redistribute the atoms among the vibrational energy levels of the potential. If a vibrational level already contains an atomic population, Bose-Einstein quantum statistics will encourage atoms involved in a collision process to join this level. Ultimately, this comes down to an irreversible pumping of a single level, where the atoms accumulate to build a single degenerate quantum state. Bose condensation is always

[4] Coherent reflection of atom laser beams has been demonstrated [167, 45, **?**], and an atom laser cavity with efficient transverse focusing has been built [156]

the result of *bosonic stimulation*. However, the dynamics and time scale for the formation of a condensate have been controversially discussed, until some experiments [890] could directly visualize *in vivo* the process of nucleation and the exponential amplification at the center of a thermal cloud (see Fig. 46.7).

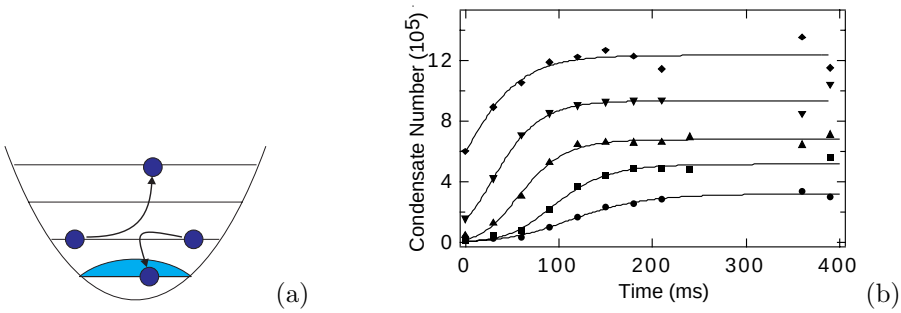

Figure 46.7: (a) Illustration of the idea of bosonic stimulation. (b) The curves show the growth of a condensate toward thermal equilibrium for different initial numbers of condensed atoms.

The very high concentration of population in a single phase space cell during the creation of a condensate represents a dramatic reduction of entropy. Since the total entropy can not decrease, the condensate must be coupled to a thermal reservoir receiving the excess entropy. This coupling is necessarily irreversible. In practice, the reservoir is the cloud of thermal atoms, whose energy is spread over many vibrational states. Irreversibility is introduced by collisions and the subsequent removal of the hottest atoms.

46.3.2.2 Phase of a condensate and first and higher-order coherences

First-order coherence and long-range order are necessary conditions for assigning a single global phase to the condensate. The existence of a single phase, and the possibility of measuring it, were questioned in the past. Certainly, the phase of a BEC is not observable *by itself*, but only *the relative phase* of two condensates.

The intrinsic phase-coherence of condensates has demonstrated in many experiments. An early example [575] employed internal state interferometry by splitting and remixing ^{87}Rb condensates trapped in the different Zeeman states $|F, m_F\rangle = |1, -1\rangle$ and $|2, 1\rangle$. They found that the phase was remembered for times longer than 150 ms. In another experiment [33, 712, 1353], illustrated in Fig. 46.8, a condensate was spatially split in two halves and then recombined. The interpenetration of the two halves at a well-defined relative velocity gave rise to a clear matter wave interference pattern. This ability of ballistically expanding condensates to interfere demonstrated the absence of a random phase lag during the expansion process and that the preservation of the condensates' long range order. However, under the repulsive influence of the mean-field energy, the phase profile of a released condensate evolves in a non-uniform but well-defined manner [1209].

The homogeneity of the phase of a *confined* condensate was also confirmed experimentally [1259, 569, 155] through interferometric techniques based on Bragg diffrac-

tion (see Sec. 47.2.2). The spatial coherence of an output coupled atom laser has been verified with a double-slit experiment [155]. And the temporal coherence of an atom laser beam was shown to be Fourier-limited by the finite output coupling time [**?**].

Similar to Young's double slit experiment in optics, the observation of matter wave interference only indicates first-order coherence, i.e. amplitude fluctuations in the matter field. Signatures for the presence of higher-order coherences in condensates were discovered in other experiments: The second-order correlation function, which represents a measure for intensity fluctuations (number of particles) in the matter field, was derived from measurements of the condensate's release energy [714]. And the third-order coherence can be deduced from a comparison of the three-body recombination rates for condensed and thermal clouds [217].

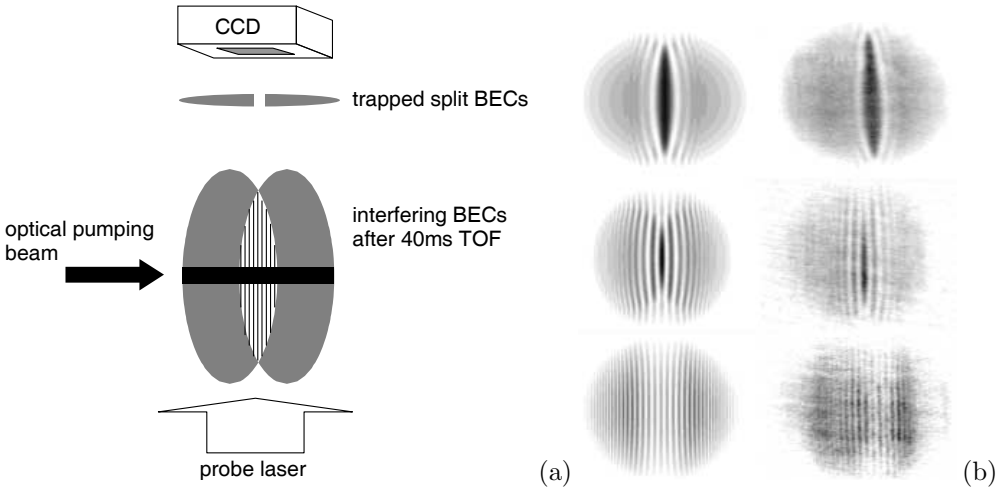

Figure 46.8: (a) Scheme for observation of matter wave interference. (b) Interference fringes.

A reliable characterization of atom number fluctuations and matter wave phase fluctuations in condensates is important for the simple reason, that these fluctuations will limit ultimately the resolution of atom interferometers, analogous to the *Schawlow-Townes limit* in lasers.

46.3.2.3 Output coupling

The *output coupler* for a trapped condensate plays a role similar to that of the partially reflecting mirror of a laser resonator. It transfers a fraction of condensed atoms out of the trapping potential through a coherent coupling to untrapped states. The coupling can be conveniently implemented via adiabatic potentials (see 38.1.3 and 43.4.3) generated by radiation (e.g. radiofrequency pulses [881] or continuous radiofrequency [154]). Also, pairs of laser beams in Raman configuration can create a coherent quasi-continuous and well-collimated atomic beam [570] and tunneling can give rise to a pulsed mode-locked atom laser (*mode-locked laser*) [30].

A trapped condensate represents a *finite reservoir* from which an atom laser can

be fed. For a really cw atom laser, an incoherent pumping mechanism, continuously feeding the BEC, while it delivers atoms to the atom laser, is still lacking [838].

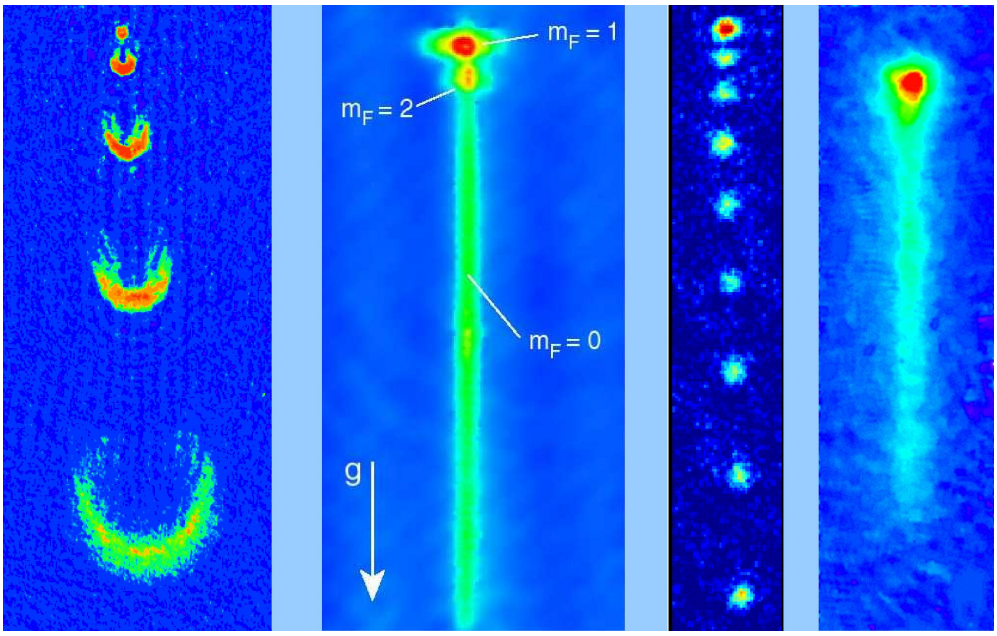

Figure 46.9: Several types of atomic lasers realized, from left to right at the MIT in 1997, in Munich in 1999, at Yale in 1998, and at NIST in 1999. The vertical sizes of the images are, from left to right: 5, 2, 0.5, and 1 mm.

46.3.3 Atomic interferometry with Bose-Einstein condensates

The most obvious use of an atom laser is within an atomic interferometer [1260, 1237, 168, 569, 155, 1209, 714, 217, 992, 353, 900, 926]. Many types of interferometers have been developed over the years. First of all, we note that the interferometric idea can be realized in the spatial domain (e.g. an atomic beam passing through a light wave) or in the time domain (e.g. a trapped atomic cloud or an immobile trapped ion irradiated by a pulsed light) [178, 642, 1073, 511].

Furthermore, depending on the involved degree of freedom (kinetic or internal excitation), we may distinguish two types of interferometers. Matter wave interferometers operating with the kinetic degree of freedom often use beam splitters based on Bragg diffraction [746, 992, 569, 1209]. Matter wave interferometers involving internal degrees of freedom generally couple two species of condensates, that is, two condensates in different states of internal excitation, for example, in different Zeeman [1261], hyperfine [939, 575, 900], or dressed states [780]. The phases of two BECs in different internal states, which we will call $|\pm\rangle$, evolve according to their respective chemical potentials, $\varphi_{|\pm\rangle}(t) = \mu_{|\pm\rangle}t$. The accumulated phases are not directly observable, but their difference, $\Delta\varphi(t)$, can be measured by *Ramsey interferometry*.

46.3.4 Non-linear atomic optics

In classical nonlinear optics, the interaction between matter (e.g. dilute gases) and light is described by Maxwell's equations. The electromagnetic field $\mathbf{E}$ creates a macroscopic polarization,

$$\mathbf{P}(\mathbf{r},t) = \chi(\mathbf{E})\mathbf{E}(\mathbf{r},t) = \chi^{(1)}\cdot\mathbf{E} + \chi^{(3)} : \mathbf{EEE} + \dots \,. \tag{46.28}$$

which in turn acts back onto the field. Higher-order processes, such as *self-focusing*, *second-harmonic generation*, *four-wave mixing*, etc. are described by the non-linear susceptibility $\chi^{(3)}$. These processes require the presence of a non-linear medium (the vacuum polarization itself being too small [696, 553]).

The role of binary collisions in coherent matter wave optics, as described by the nonlinear term in the Gross-Pitaevskii equation (45.21), is very similar to the role of the third-order nonlinear susceptibility in quantum optics [787, 746, 354, 518, 1318, 697, 586, 700, 792, 318, 591]. For example, if the atomic interaction is repulsive, the nonlinear term tries to increase the size of the condensate as much as possible within the limits imposed by the trapping potential. This behavior is analogous to the phenomenon of *self-defocusing* known in non-linear optics.

Small-amplitude elementary oscillations are well described by the *Bogolubov-de Gennes equations*, which are a linearized version of the Gross-Pitaevskii equation [297]. On the other hand, large-amplitude oscillations, which are sensitive to the nonlinear mean-field interaction [1222], showed a splitting of the frequency for quasi-particle excitation, in analogy with the generation of the second-harmonic (*SHG*) in quantum optics [591].

Other phenomena, such as matter wave *phase conjugation* and four waves mixing (*4WM*) [518] have been observed in experiments [354]. The three matter wave modes for the nonlinear mixing were produced out of a single condensate by applying two short consecutive sequences of Bragg diffraction pulses. The condensates are created in the same spatial region, but at different times. The nonlinear mixing during the process of spatial separation was observed by time-of-flight images.

The geometry of the laser beams is shown in Fig. 46.10(a) in the laboratory system. A first standing wave light pulse is generated by lasers $\mathbf{k}_1$ and $\mathbf{k}_2$ detuned from each other by an amount, such that the Bragg condition is satisfied and the momentum $\mathbf{p}_2 = \hbar\mathbf{k}_1 - \hbar\mathbf{k}_2$ is transmitted to the diffracted atoms. Then, a second standing wave light pulse formed by lasers $\mathbf{k}_1$ and $\mathbf{k}_3 = -\mathbf{k}_1$ transmits to the diffracted atoms the momentum $\mathbf{p}_3 = 2\hbar\mathbf{k}_1$. The duration and intensity of the standing waves are adjusted such as to create an approximately equal distribution of N_j^0 atoms in all three condensate momentum modes, each mode having a different momentum, $\mathbf{p}_1 = 0$, $\mathbf{p}_2$, and p_3. Initially, the three wavepackets $\hat{\psi}_j \equiv \hat{\psi}_0(\mathbf{r})\mathrm{e}^{i\mathbf{p}_j\mathbf{r}/\hbar}$ overlap. The nonlinear term in the Gross-Pitaevskii equation mixes the wavepackets while they separate to form other wavepackets, $\hat{\psi}_4 \sim g\hat{\psi}_j^+\hat{\psi}_m\hat{\psi}_n\mathrm{e}^{i\mathbf{p}_4\cdot\mathbf{r}/\hbar}$, where,

$$\begin{aligned} N_4 &= -N_j + N_j^0 = N_m - N_m^0 = N_n - N_n^0 = \sum\nolimits_{\kappa=1}^{3}(N_\kappa^0 - N_\kappa) \\ \mathbf{p}_4 &= -\mathbf{p}_j + \mathbf{p}_m + \mathbf{p}_n \\ p_4^2 &= -p_j^2 + p_m^2 + p_n^2 \,. \end{aligned} \tag{46.29}$$

To produce the new momenta, $\mathbf{p}_4 \neq \mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3$, the corresponding wavepackets must gather atoms from all three initial packets $\mathbf{p}_1 \neq \mathbf{p}_2 \neq \mathbf{p}_3$.

The experimental observation of a newly emerging wavepacket $\hat{\psi}_4$ has two complementary interpretations: In the inertial system defined by $\mathbf{p}_1 = -\mathbf{p}_3$ [see Fig. 46.10(b)], the wavepackets $\hat{\psi}_1$ and $\hat{\psi}_3$ suffer elastic collisions. The direction in which the condensates are scattered is, a priori, isotropic. The injection of a third condensate $\hat{\psi}_2$ bosonically stimulates the formation of a forth one, $\hat{\psi}_4$, in a predefined direction $\mathbf{p}_4 = -\mathbf{p}_2$. The laws of conservation for the particle numbers, momenta, and energies (46.29) only allow processes, which can be interpreted as degenerate 4WM in this inertial system. Each of the wavepackets $\hat{\psi}_1$ and $\hat{\psi}_3$ sacrifice N_4 atoms to create a new wavepacket $\hat{\psi}_4$ and to amplify the wavepacket $\hat{\psi}_2$. The redistribution of atoms is a coherent process.

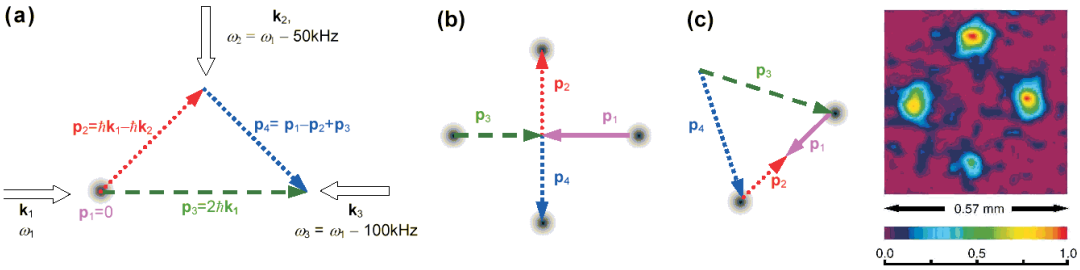

Figure 46.10: Matter wave 4WM can be illustrated (a) in the laboratory system, or (b) in the inertial system defined by $p_1 = -p_3$, or (c) in the system defined by $p_1 = -p_2$. In each system the process has a different physical interpretation (see text). The right image shows the experimental result.

The second interpretation becomes clear in the inertial system, in which $\mathbf{p}_1 = -\mathbf{p}_2$ [see Fig. 46.10(c)]. The conservation of energy only allows scattering products satisfying $p_4 = p_3$, that is, $\hat{\psi}_1^+ \hat{\psi}_2 \hat{\psi}_3$ and $\hat{\psi}_2^+ \hat{\psi}_1 \hat{\psi}_3$. In this system, the process can be interpreted as Bragg diffraction of the wavepacket $\hat{\psi}_3$ by the matter wave lattice formed by $\hat{\psi}_1$ and $\hat{\psi}_2$. The wavepacket $\hat{\psi}_4$ is nothing more than the first diffraction order. Unlike the Bragg diffraction in an optical lattice (see Sec. 47.2), the Bragg diffraction by a matter wave lattice requires nonlinear mixing through binary atomic collisions. Thus, the number of redistributed atoms depends on parameters such as the interatomic interaction strength, the size of the condensate, and the collision time between the wavepackets, i.e. the time that the wavepackets spend together before separating.

Despite the similarity with the optical counterpart, matter wave 4WM is fundamentally different: The number of particles must be conserved and the energy-momentum dispersion relation is not linear. Furthermore, while photons require the presence of a nonlinear medium in order to participate in higher-order processes, atomic matter waves mix through binary collisions.

46.4 Quantum atom optics

When describing a condensate by the Gross-Pitaevskii equation, we specify a phase and an atom number. However, both are conjugate quantities, which can not be specified without uncertainty. So, what does the BEC really look like: a Glauber state or rather a Fock state? We need to be careful. Certainly, it makes no sense talking about the absolute phase of a single BEC. Only the *relative phase* between *two* BECs matters. The condition for interference is, that we do not know, from which condensate the interfering atom came $\Delta N \Delta\varphi \geq 1$. So, the relative atom number must be uncertain.

46.4.1 Quantum transport

Now, let us imagine two BECs in a double-well potential. Atoms may be move between the wells via *Josephson tunneling*, even if the height of the barrier is higher than the atomic energy. Hence, the motion is a type of *quantum transport*. Be $\psi(\mathbf{r},t) = \psi_1(\mathbf{r})e^{i\mu_1 t/\hbar} + \psi_2(\mathbf{r})e^{i\mu_2 t/\hbar}$. In elongated traps the Josephson current is obtained as the expectation value of the *flux operator*,

$$I(z,t) = \frac{i\hbar}{2m}\int\left(\psi(\mathbf{r},t)\frac{d}{dz}\psi^*(\mathbf{r},t) - c.c.\right)dxdy\ . \tag{46.30}$$

One obtains,

$$I(z,t) = \frac{i\hbar}{2m}\int\left(\psi_1\frac{d\psi_1^*}{dz} + \psi_1\frac{d\psi_1^*}{dz} + \psi_1\frac{d\psi_1^*}{dz}e^{i(\mu_1-\mu_2)t/\hbar} + \psi_1\frac{d\psi_1^*}{dz}e^{i(\mu_1-\mu_2)t/\hbar} - c.c.\right)dxdy\ . \tag{46.31}$$

Choosing the original phase of the two condensates equal to zero, the time-independent terms are real and cancel each other, leaving,

$$\begin{aligned} I(z,t) &= \frac{i\hbar}{2m}\int\left(\psi_1\frac{d\psi_2}{dz} - \psi_2\frac{d\psi_1}{dz}\right)2i\sin\frac{(\mu_1-\mu_2)t}{\hbar}dxdy \\ &\equiv I_0\sin\frac{(\mu_1-\mu_2)t}{\hbar}\ . \end{aligned} \tag{46.32}$$

This shows that the current oscillates in time. This feature is well-known for *Josephson junction* in superconductors.

The question is now, what will be the steady-state of the two BECs [982]. Experiments have shown, that the BECs will gradually evolve into a superposition of number states, until they are coherent. The time scale is set by Josephson tunneling. The same interference pattern would result from BECs initially having well-defined phases [5,6]

[5] Also, a *spin-squeezed state* i.e. a state with sub-Poissonian number statistics approaching pure number states have been compared to coherent states. Superposition of the first ones exhibited no interference while superposition of the second ones lead to observable interference.

[6] If two Josephson-coupled BECs are initially in Fock-states, the current must initially be a quantum superposition of all currents corresponding to all possible atom number differences. This quantum superposition decoheres rapidly, leaving behind a semi-classical oscillation.

46.4.2 Optical lattices and the Mott insulator

We have already pointed out in Sec. 43.3.2, that laser beams tuned far away from resonances serve to construct trapping potentials for atoms. Laser beams incident on the atomic cloud under various angles allow the engineering of a large diversity of geometries for attractive potentials (with red tuned lasers) or repulsive potentials (with blue tuned lasers). Various cooling methods can be combined with dipolar traps, for example, Doppler cooling [647], Raman cooling [579], evaporative cooling [5], or gravitational Sisyphus cooling [948]. A particularly interesting geometry is that of are optical lattice, which we will discuss in the following sections.

46.4.2.1 Bragg scattering from optical lattices

In solid state physics the structure of crystal is studied by Bragg or von Laue scattering with X-ray radiation. Similar techniques can be used in optical lattices [146, 1157, 1360, 1361, 1217]. Under certain conditions, we can even expect to open a *photonic band gap* [37, 361, 1158], which draws an analogy between optical lattices and *photonic crystal*.

A great advantage of optical lattices is the possibility of directly visualizing the momentum distribution of the confined atoms, that is, the distribution of atoms over the *Brillouin zone*.

46.4.2.2 Bloch bands with mean field interaction

The Gross-Pitaevski equation is,

$$H\psi = \frac{-\hbar^2}{2m}\frac{d^2}{dx^2} + v\cos Kx + c|\psi|^2 = \mu\psi \ . \tag{46.33}$$

We have a periodic potential, $U(x) = U(x+X)$. In the following, we restrict ourselves to $1D$. Assume e.g. a sine wave potential,

$$U(x) = U_0\cos(2Kx) \ . \tag{46.34}$$

The Gross-Pitaevskii equation is rescaled via $k/K \to k$, $2Kx \to x$, $4\varepsilon t \to t$, $\psi/\sqrt{n} \to \psi$ and $C = \pi n a_s/K^2$. All frequencies are scaled like $U/4\varepsilon \to U$. Then,

$$-\tfrac{1}{2}\frac{\partial^2\psi}{\partial x^2} + (U\cos x - U)\ \psi + C|\psi|^2\psi = \mu\psi \ . \tag{46.35}$$

The Bloch-theorem says that the Schrödinger equation be solved by any Bloch state. Those are superpositions of plane-wave momentum states [**?**],

$$\psi(x) = e^{\imath kx}u_k(x) \ , \tag{46.36}$$

with $u_k(x) = u_k(x+X)$. We obtain,

$$-\tfrac{1}{2}\left(\frac{\partial}{\partial x} + \imath k\right)^2 u_k + U\cos x\ u_k + C|u_k|^2u_k = [\mu(k) + U]u_k \ . \tag{46.37}$$

Inserting the plane-wave expansions $u_k(x) = \sum_{q=-N}^{N} a_q(k) e^{iqx}$ into the Schrödinger equation, we get,

$$\sum_{q=-N}^{N} \Big[\tfrac{1}{2}(q+k)^2 a_q e^{\imath qx} + \tfrac{1}{2} U a_q (e^{\imath(q+1)x} + e^{\imath(q-1)x}) + C \sum_{m,n=-N}^{N} a_m a_n^* a_q e^{\imath(m-n+q)x} - [\mu(k)+U] a_q e^{\imath qx} \Big] = 0 \tag{46.38}$$

$$\tfrac{1}{2}(q+k)^2 a_q + \tfrac{1}{2} U(a_{q-1} + a_{q+1}) + C a_q \sum_{n=-N}^{N} |a_n|^2 - [\mu(k)+U] a_q = 0 \ .$$

We choose a cut-off q_0 so that $a_{q>q_0} = 0$. For a given k the coefficients a_q and the chemical potential μ, and thus the Bloch wave $u_k(x)$ can easily be calculated by minimizing the left hand side of the above equation. Note that for $C = 0$ we have we linear set of differential equation that can be solved as an eigenvalue problem (see Sec. 26.2.2).

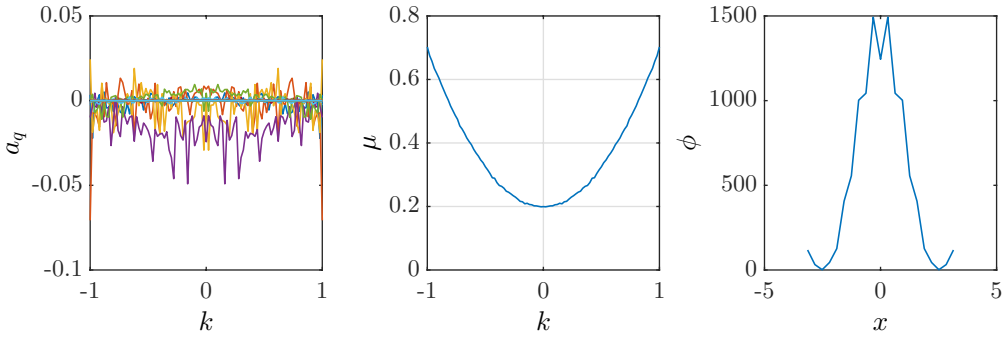

Figure 46.11: (code) Nonlinear interaction matrix finds just one minimum, dependence on k, [1389, 1391].

If we only consider the two lowest Bloch bands

$$u_k(x) = e^{\imath kx} a(x) + e^{\imath(k-K)x} b(x) \tag{46.39}$$

with $|a|^2 + |b|^2 = 1$, so that

$$|u_k|^2 = \left(e^{\imath kx} a + e^{\imath(k-K)x} b \right) \left(a e^{\imath kx} + b e^{\imath(k-K)x} \right) = 1 + 2ab \cos Kx \ , \tag{46.40}$$

and insert this into the Gross-Pitaevski equation Eq. (46.37), we find that the system of differential equations Eq. (46.38) simplifies to,

$$\begin{pmatrix} \frac{\hbar^2 k^2}{2m} + c & \frac{v}{2} + abc \\ \frac{v}{2} + abc & \frac{\hbar^2 (k-K)^2}{2m} + c \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} = \mu \begin{pmatrix} a \\ b \end{pmatrix} \ . \tag{46.41}$$

For $-2ab = \frac{v}{c}$ the off-diagonal elements vanish, and because the interacting BEC shields the potential. Since $|2ab| \leq 1$, this is only possible for $c \geq v$.

If we substitute $\mu = \tilde{\mu} + \frac{1}{2}\frac{\hbar^2 k^2}{2m} + \frac{1}{2}\frac{\hbar^2 (k-K)^2}{2m} + \frac{3}{2}c$, multiply the first row with b, the second with a and add both rows, we obtain,

$$2\tilde{\mu} = \frac{v}{2ab} \ . \tag{46.42}$$

Example 283 (*Estimations*): Estimated radial BEC size $r_t \simeq 10\ \mu m$, estimated number of atoms per antinode $n_{1D} \simeq 1000\ \mu\mathrm{m}^{-1}$,

$$\omega_r = \frac{\hbar k^2}{2m} = 2\pi \cdot 3.8\,\mathrm{kHz} \tag{46.43}$$

$$g_{1D} = \frac{4\pi\hbar^2 a_s}{m r_t^2} \tag{46.44}$$

$$g_{1D} n_{1D} = h \cdot 77\,\mathrm{Hz} \tag{46.45}$$

Since we need at least two Bloch bands to see interesting effects, we must arrange for much stronger mean fields.

46.4.2.3 The Mott insulator

In the Mott insulating state, the atoms are *localized* at individual sites of an optical lattice. On one hand, the localization impedes any phase relation between atoms at different sites, that is, at a given site the phase uncertainty $\Delta\phi$ is complete. But at the same time, there is a perfect correlation of the atom number at each site known as *spin squeezing* [7], because (in a homogeneous lattice) every site contains exactly the same number of atoms, that is, the atom number uncertainty ΔN tends to zero. At a given lattice site, the number of atoms and the phase of the wavefunction can not be simultaneously fixed: $\Delta N \Delta\phi > 1$.

The absence of relative coherence between different sites and of the ability to interfere prohibits the description of the system by a single global wavefunction and the use of the Gross-Pitaevskii equation. Nevertheless, the Mott insulating state is not equivalent to a completely randomized sample. On the contrary, the coherence only changes its character [8].

The *Mott transition* of a condensate from a superfluid state and to state of a *Mott insulator* occurs as a *quantum phase transition*, because it is driven by quantum fluctuations rather than of thermal noise. Therefore, it is a direct result of Heisenberg's uncertainty relation.

46.4.2.4 The Bose-Hubbard model

The *Bose-Hubbard model* gives an approximate description of the physics of interacting *bosons* in a lattice. The model is closely related to the fermionic Hubbard model, used in solid state physics for the description of superconducting systems and the hopping of electrons between the atoms of a solid crystalline lattice.

[7] The spin squeezing feature makes the Mott insulator interesting for spectroscopy at the *Heisenberg limit* and for quantum computation.

[8] Remember, that the Fock state is a complicated superposition of Glauber states. The disappearance and reappearance of coherence is reminiscent to the phenomenon of collapse and revival in the Jaynes-Cummings model.

The Bose-Hubbard model starts from the following Hamiltonian [982, 537],

$$\hat{H} = -J \sum_{(i,j)} \hat{a}_i^\dagger \hat{a}_j + \sum_i \varepsilon_i \hat{n}_i + \tfrac{1}{2} U \sum_i \hat{n}_i(\hat{n}_i - 1) \ , \tag{46.46}$$

where

$$J \equiv \int d^3\mathbf{x} \ w^*(\mathbf{x} - \mathbf{x}_i) \left[-\tfrac{\hbar}{2m} \nabla^2 + V_0(\mathbf{x}) \right] w^*(\mathbf{x} - \mathbf{x}_i) \ , \tag{46.47}$$

and

$$U \equiv \frac{4\pi a_s \hbar^2}{m} \int d^3\mathbf{x} \ |w^*(\mathbf{x})|^4 \ , \tag{46.48}$$

with $\varepsilon_i \equiv \frac{4\pi a_s \hbar^2}{m} \int d^3\mathbf{x} \ V_{trap}(\mathbf{x}) |w(\mathbf{x} - \mathbf{x}_i)|^2 \approx V_{trap}(\mathbf{x})$ and $w(\mathbf{x}) = w(x)w(y)w(z)$ are the *Wannier functions* for an individual particle. We assume for the moment a homogeneous condensate.

The Hilbert space dimension of the Bose-Hubbard model grows exponentially with the number of atoms N and the number of sites L,

$$D_b = \frac{(N_b + L + 1)!}{N_b!(L-1)!} \ . \tag{46.49}$$

For the Fermi-Hubbard model, the Pauli exclusion principle leads to the Hilbert space dimension,

$$D_f = \binom{L}{N_f} \ . \tag{46.50}$$

In three dimensional lattices the Hilbert space grows even faster. Therefore, it is a difficult computational task to model or simulate such systems, and generally not possible fro more than 20 atoms and 20 lattice sites.

At zero temperature, the Bose-Hubbard model (in the absence of disorder) predicts the atomic ensemble to be an a Mott insulating state (MI) when $J \ll U$, a superfluid state (SF) when $J \gg U$, or a *supersolid phase* (SS), where both solid and superfluid phases (diagonal and off-diagonal) coexist. Mott insulation phases are characterized by integer site occupation numbers, by the existence of an energy gap for particle-hole excitations, and zero compressibility. In the presence of disorder, a third phase, the *Bose glass* exists. This phase is insulation because of the Anderson localization effects. Bose glass is characterized by a finite compressibility, the absence of a gap, and an infinite superfluid susceptibility [449]. See also (watch talk).

In the limit of strong tunneling and weak interactions, $J \gg U$, the matter wave function looks like a *Bloch state*,

$$|\psi_{SF}\rangle \sim \left(\sum_{i=1}^{M} \hat{a}_i^\dagger \right)^N |0\rangle \ . \tag{46.51}$$

The variance of the number of particles per site is Poissonian, $\sigma_{SF} \sim \sqrt{N_i}$, that is, the wavefunction per lattice site is (quasi)-coherent. However, the total wavefunction is delocalized over all lattice sites, the local wavefunctions have a rigid phase relationship

and no long-range coherence. Otherwise, the matter wave function is an independent product of *Fock states*,

$$|\psi_{MI}\rangle \sim \prod_{i=1}^{M} (\hat{a}_i^\dagger)^n |0\rangle \ . \tag{46.52}$$

The momentum distribution in terms of Wannier functions is [558, 1390],

$$n(\mathbf{k}) = |w(\mathbf{k})|^2 \sum_{i,j} e^{i\mathbf{k}(\mathbf{r}_i - \mathbf{r}_j)} \langle \hat{a}_i^\dagger \hat{a}_j \rangle \ . \tag{46.53}$$

46.4.3 Schrödinger cats

Ruostekoski *et al.* [1120] proposed a double BEC system consisting of two momentum sidemodes and a far-off resonance laser beam that constantly spontaneously redistributes the atoms between the sidemodes. Homodyne detection of the scattered photons established *relative phase* information in such a way, that the relative number information is blurred in such a way that both sidemodes evolve into a simultaneous superposition of phase and number states. They disregard thermal excitations and two-body collisions. The cats are very sensitive to decoherence.

Cirac *et al.* [266] and Gordon *et al.* [524] consider Josephson double species condensates. The relative atom numbers Rabi flop. Mediated by the mean-field the systems may evolve into cats. The proposals have been reexamined by Dalvit *et al.* [324]. Other contributions come from [517, 617, 1127, 1074, 661]. First experiments on spin-squeezed states have been made by [982].

46.4.4 Exercises

46.4.4.1 Ex: Superfluid to Mott insulator transition

Consider a condensate trapped in a 3D *simple cubic* optical lattice with lattice spacing l. The Hamiltonian can be written as,

$$\hat{H} = -J \sum_{i,j} \delta_{ij}^{(1)} \hat{a}_i^\dagger \hat{a}_j + \tfrac{U}{2} \sum_i \hat{a}_i^\dagger \hat{a}_i^\dagger \hat{a}_i \hat{a}_i \ ,$$

where $\hat{a}_i$ ($\hat{a}_i^\dagger$) is the operator annihilating (creating) one boson in the lattice site i; $\delta_{ij}^{(1)} = 1$ only when i and j are nearest neighbors, otherwise it is zero. Assume a total of $M \gg 1$ sites, periodic boundary conditions in the x, y, and z directions, and $U > 0$. On this lattice we consider the construction operator $\hat{b}_s^\dagger$ defined in the following way:

$$\hat{b}_s^\dagger = \tfrac{1}{\sqrt{M}} \sum_i \hat{a}_i^\dagger \ .$$

a. Describe the action of this construction operator.
b. Derive the commutation relation,

$$[\hat{a}_\alpha, \hat{b}_s^\dagger] = \tfrac{1}{\sqrt{M}} \ .$$

c. Derive the commutation relation,

$$[\hat{a}_\alpha, (\hat{b}_s^\dagger)^N] = \tfrac{N}{\sqrt{M}} (\hat{b}_s^\dagger)^{N-1} \ .$$

d. Suppose that the following N-atom state exists:

$$|N, SF\rangle \equiv \tfrac{1}{\sqrt{N!}}(\hat{b}_s^\dagger)^N|0\rangle \ ,$$

where SF stands for a name label (and not for quantum numbers). Show that for $N = M$ we have $\hat{a}_\alpha|N, SF\rangle = |N-1, SF\rangle$.
e. Define the density operator for the site i as $\hat{n}_i = \hat{a}_i^\dagger \hat{a}_i$. Calculate the density fluctuation,

$$\Delta n_i = \sqrt{\langle \hat{n}_i^2\rangle - \langle \hat{n}_i\rangle^2}$$

of the state $|N, SF\rangle$ with $N = M$.
f. Calculate the total energy $\langle H\rangle$ with the state $|N, SF\rangle$.
g. Next consider the state,

$$|N, MI\rangle \equiv \prod_j \hat{a}_j^\dagger|0\rangle \ .$$

Calculate $\langle \hat{a}_i^\dagger \hat{a}_j\rangle$ and the density fluctuations Δn_i for this state.
h. Calculate the total energy $\langle H\rangle$ with the state $|N, MI\rangle$.
i. Discuss the energy for the states $|N, SF\rangle$ and $|N, MI\rangle$. Which one is the ground state? How to make a ground state change from $|N, SF\rangle$ to $|N, MI\rangle$?

Chapter 47

Interaction of Bose-Einstein condensates with light

Light can essentially be used in two ways for the manipulation of matter waves: 1. Tuned *far from resonance*, light serves to create conservative optical dipole potentials (see Secs. 43.3.2 and 46.4.2). In such circumstances the states of internal atomic excitation can be adiabatically eliminated from the description of the center-of-mass dynamics. 2. *Close to resonance* the situation is quite different, but even then, the coherent excitation of internal states may allow for a controlled manipulation of the atomic motion. Among the examples discussed in the following sections are the adiabatic sweeps, the Raman output coupler, Bragg pulses, photoassociation, and matter wave superradiance (see Fig. 47.1).

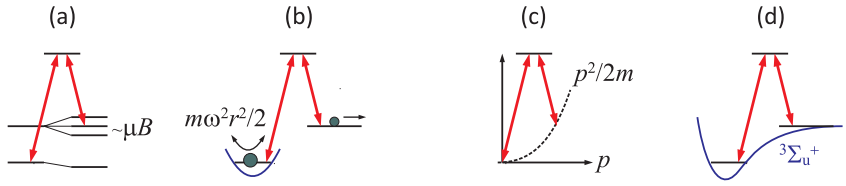

Figure 47.1: Different types of coherent coupling: (a) coherent coupling of hyperfine levels, (b) coupling from a confined state to the continuum of free states, (c) mutual coupling of different velocity states of an atom, and (d) coupling between a (collisional) state of two free atoms with a bound molecular state.

47.1 Scattering of light by degenerate gases

47.1.1 The structure factor for degenerate quantum gases

We introduced in Sec. 39.1.1 the notion of the structure factor, where it was used to characterize the scattering of light by thermal distributions of atoms. To characterize the scattering of matter waves, we must generalize the notion of the structure factor. We wrote in (39.3) the Fourier transform of the density distribution, which now becomes, after inserting $\hat{n}(\mathbf{r}) = \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r})$ and the plane wave expansion (45.70),

$$\hat{\rho}^\dagger(\mathbf{q}) = \int \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r})e^{\imath\mathbf{q}\cdot\mathbf{r}}d^3r = \tfrac{V}{(2\pi)^3}\iiint \hat{a}^\dagger_{\mathbf{k}'}\hat{a}_{\mathbf{k}}e^{\imath(\mathbf{k}-\mathbf{k}'+\mathbf{q})\cdot\mathbf{r}}d^3k'd^3kd^3r\ . \qquad (47.1)$$

With (45.76) and assuming sharp momenta (45.71),

$$\hat{\rho}^\dagger(\mathbf{q}) = V^2 \iint \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}} \delta_{\mathbf{k}',\mathbf{k}+\mathbf{q}} d^3k' d^3k = \sum_{\mathbf{k}',\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}'} \hat{a}_{\mathbf{k}} \delta_{\mathbf{k}',\mathbf{k}+\mathbf{q}} \ . \tag{47.2}$$

Finally,

$$\boxed{\hat{\rho}^\dagger(\mathbf{q}) = \sum_{\mathbf{k}} \hat{a}^\dagger_{\mathbf{k}+\mathbf{q}} \hat{a}_{\mathbf{k}} = \sum_{\mathbf{k}} |\mathbf{k}+\mathbf{q}\rangle\langle\mathbf{k}|} \ . \tag{47.3}$$

Hence, $\hat{\rho}^\dagger(\mathbf{q})$ describes the scattering of an atom with the momentum $\mathbf{k}$ to $\mathbf{k}+\mathbf{q}$. We also find,

$$\hat{\rho}^\dagger(\mathbf{q}) = \hat{\rho}(-\mathbf{q}) \ . \tag{47.4}$$

Understanding the fundamental state $|g\rangle$ as the state without excitations, we define the *static structure factor* (39.5) now normalized to the number of particles [1237],

$$\boxed{S(\mathbf{q}) \equiv \tfrac{1}{N}\langle g|\hat{\rho}(\mathbf{q})\hat{\rho}^\dagger(\mathbf{q})|g\rangle} \ , \tag{47.5}$$

as a generalization of the classical structure factor. The static structure factor describes the probability to excite a condensate by creating a quasi-particle with momentum $\mathbf{k}$. We will need these notions in the Sec. 47.2.3.

The *dynamic structure factor* is obtained from $S(\mathbf{q}) = \int S(\mathbf{q},\omega)d\omega$ and measures the density of correlations in the ground state with 0 momentum. The formula describes, how an atom probes its environment by scattering quasi-particles back and forth,

$$S(\mathbf{q},\omega) = \tfrac{1}{N}\sum_f \langle g|\hat{\rho}(\mathbf{q})|f\rangle\langle f|\hat{\rho}(\mathbf{q})|g\rangle \hbar\delta(\hbar\omega - E_f + E_g) \ . \tag{47.6}$$

Solve the Excs. 47.1.6.1 to 47.1.6.5.

Example 284 (*Spatial coherence and the correlation function*): The *spatial coherence* can be defined by [CCT & Aspect],

$$\boxed{F(\mathbf{x}) \equiv \int \langle \mathbf{r}|\hat{\rho}|\mathbf{r}+\mathbf{x}\rangle d^3r = \int e^{\imath\mathbf{k}\cdot\mathbf{x}}\langle\mathbf{k}|\hat{\rho}|\mathbf{k}\rangle d^3k} \ . \tag{47.7}$$

We will demonstrate this relationship in Exc. 47.1.6.6. The *coherence length* ξ is given by $F(\xi) = \frac{1}{e}F(0) = \frac{1}{e}$. A *second order correlation function* is defined by,

$$\boxed{\begin{aligned} g^{(2)}(\mathbf{r}_1,\mathbf{r}_2) &= \frac{\langle\hat{\psi}^\dagger(\mathbf{r}_1)\hat{\psi}^\dagger(\mathbf{r}_2)\hat{\psi}(\mathbf{r}_2)\hat{\psi}(\mathbf{r}_1)\rangle}{\langle\hat{n}(\mathbf{r}_1)\rangle\langle\hat{n}_2(\mathbf{r})\rangle} \\ g^{(2)}(\mathbf{r}) &\equiv g^{(2)}(\mathbf{r}_1,\mathbf{r}_1+\mathbf{r}) \end{aligned}} \ .$$

47.1.2 The structure factor in Bragg spectroscopy

47.1.2.1 The Hamiltonian of the Rayleigh scattering process

In Sec. 23.5.3 we saw the Galilei-boost (??),

$$|\mathbf{k}+\mathbf{q}\rangle = e^{\imath\mathbf{q}\cdot\hat{\mathbf{r}}}|\mathbf{k}\rangle \ . \tag{47.8}$$

In the second quantization we generalize to,

$$|\mathbf{k}+\mathbf{q}\rangle = \int \hat{\psi}^\dagger(\mathbf{r}) e^{\imath \mathbf{q}\cdot\mathbf{r}} \hat{\psi}(\mathbf{r}) d^3r |\mathbf{k}\rangle = \hat{\rho}^\dagger(\mathbf{q})|\mathbf{k}\rangle \ . \tag{47.9}$$

Thus, we can implement the second quantization by simply replacing $e^{\imath \mathbf{q}\cdot\mathbf{r}}$ by $\hat{\rho}^\dagger(\mathbf{q})$. Now, the Hamiltonian for the process of a photon absorption from the mode $\hat{c}_{\mathbf{k}_i}$, taking into account the photonic recoil, was introduced in (38.6),

$$\hat{H}_{int} = \hbar\Omega(\hat{\mathbf{r}}) e^{-\imath \mathbf{k}_i\cdot\hat{\mathbf{r}}} \hat{c}_{\mathbf{k}_i} \hat{\sigma}^+ + c.c. \ . \tag{47.10}$$

If the process is followed by the reemission of a photon to the mode $\hat{c}_{\mathbf{k}_f}$,

$$\boxed{\hat{H}_{int} = \hbar\Omega(\hat{\mathbf{r}}) e^{\imath(\mathbf{k}_f-\mathbf{k}_i)\cdot\mathbf{r}} \hat{c}^\dagger_{\mathbf{k}_f} \hat{c}_{\mathbf{k}_i}} \ . \tag{47.11}$$

Going to second quantization, as done in (47.9), and doing the Fourier transform [1],

$$\tilde{H}_{int} = C \sum_{\mathbf{p}_f,\mathbf{p}_i} \hat{c}^\dagger_{\mathbf{k}_f} \hat{c}_{\mathbf{k}_i} \hat{a}^\dagger_{\mathbf{p}_f} \hat{a}_{\mathbf{p}_i} \delta_{\mathbf{k}_f-\mathbf{k}_i+\mathbf{p}_f-\mathbf{p}_i} \ . \tag{47.12}$$

We assume here, that the light modes $\mathbf{k}_i$ and $\mathbf{k}_f$ are predefined, but the velocities $\mathbf{p}_i$ are distributed. Otherwise, in the expression (47.12), we must also sum over light modes [2],

$$\boxed{\tilde{H}_{int} = C \sum_{\mathbf{k}_i,\mathbf{k}_f,\mathbf{p}_i,\mathbf{p}_f} \hat{c}^\dagger_{\mathbf{k}_f} \hat{c}_{\mathbf{k}_i} \hat{a}^\dagger_{\mathbf{p}_f} \hat{a}_{\mathbf{p}_i} \delta_{\mathbf{k}_f-\mathbf{k}_i+\mathbf{p}_f-\mathbf{p}_i}} \ , \tag{47.13}$$

where C is a normalization constant. This Hamiltonian describes the elementary scattering process as a process of four wave mixing (4WM) [712, 1238]. The light and the atoms are treated on equal footings as modes which can receive (quasi-)particle populations, and the scattering corresponds to a redistribution of populations between the modes [3].

The Hamiltonian (47.13) can be applied to various situations, such as spontaneous or stimulated Rayleigh scattering or Bragg scattering, depending on which ones of the modes $\mathbf{k}_f$, $\mathbf{k}_i$, $\mathbf{p}_f$, and $\mathbf{p}_i$ are populated or filtered by imposed boundary conditions.

Using momentum conservation $\mathbf{q} \equiv \mathbf{k}_f - \mathbf{p}_i = -\mathbf{p}_f + \mathbf{p}_i$, we obtain the cross section,

$$\left(\frac{d\sigma}{d\Omega}\right)_{\mathbf{k}_i\to\mathbf{k}_f} = C^2 \sum_f |\langle f|\hat{H}_{int}|i\rangle|^2 = C^2 \sum_f |\langle f| \sum_{\mathbf{p}_i} \hat{c}^\dagger_{\mathbf{k}_i+\mathbf{q}} \hat{c}_{\mathbf{k}_i} \hat{a}^\dagger_{\mathbf{p}_i-\mathbf{q}} \hat{a}_{\mathbf{p}_i} |i\rangle|^2 \ , \tag{47.14}$$

Example 285 (*Description of Bragg scattering via the structure factor*): In this example we irradiate two plane waves in directions $\mathbf{k}_1$ and $\mathbf{k}_2$ into a Bose-Einstein condensate. The total intensity will be,

$$I_{mod}(\mathbf{r},t) = I\cos(\mathbf{q}\cdot\mathbf{r} - \omega t) \qquad \text{with} \qquad \mathbf{q} = \mathbf{k}_1 - \mathbf{k}_2 \ . \tag{47.15}$$

[1] $\hat{a}_{\mathbf{p}}$ and $\hat{a}^\dagger_{\mathbf{p}}$ are the operators of the quantized atomic field, while $\hat{c}_{\mathbf{k}}$ and $\hat{c}^\dagger_{\mathbf{k}}$ are the operators of the light fields.

[2] Note the different form of this Hamiltonian as compared to (39.10).

[3] This is analogous to the way, in which a 'collision' redistributes atomic populations between momentum modes. We will discuss this general concept of 4WM in Secs. 47.3.4 and 46.3.4.

and the optical potential,

$$V_{mod} = \frac{\hbar\Gamma^2}{8\Delta} I \cos(\mathbf{q}\cdot\mathbf{r} - \omega t) = \frac{\hbar\Gamma^2}{8\Delta}\frac{I}{2I_{sat}}(e^{\imath\mathbf{q}\cdot\mathbf{r}-\imath\omega t} + e^{-\imath\mathbf{q}\cdot\mathbf{r}+\imath\omega t}) \qquad (47.16)$$
$$\rightarrow \hat{V}_{mod} = \frac{V}{2}[\hat{\rho}^\dagger(\mathbf{q})e^{-\imath\omega t} + \hat{\rho}^\dagger(-\mathbf{q})e^{\imath\omega t}] \ .$$

Now, the transition rate is [1238],

$$\frac{W}{N} = 2\pi\Omega_R^2 S(\mathbf{q},\omega) = \frac{2\pi}{N\hbar}\left(\frac{V}{2}\right)^2 \sum_f |\langle f|\hat{\rho}^\dagger(\mathbf{q})|g\rangle|^2 \delta(\hbar\omega - (E_f - E_g)) \ , \quad (47.17)$$

with $\frac{V}{2} = \hbar\Omega_R$.

Resolve Exc. 47.1.6.7.

47.1.3 Bosonic stimulation

We assume in the following weak light intensities (and hence a negligible contribution of the Mollow fluorescence spectrum). That is, without cooperative effects the light would be elastically scattered by Rayleigh scattering. Now, we adopt a notation labeling the multimodal state by the numbers of photons and atoms distributed over the available light and momentum modes. That is, the initial state consists of $n_{\mathbf{p}}$ atoms distributed over momentum atomic states $\mathbf{p}$ and $N_{\mathbf{k}}$ photons distributed over wave vector modes $\mathbf{k}$ denoted by $|...N_{\mathbf{k}}...\rangle_{rad} \otimes |...n_{\mathbf{p}}...\rangle_{at}$:

$$|i\rangle \equiv |...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}...\rangle_{at} \ \otimes |...N_{\mathbf{k}_i}...N_{\mathbf{k}_f}...\rangle_{rad} \equiv \left|\begin{matrix}...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}... \\ ...N_{\mathbf{k}_i}...N_{\mathbf{k}_f}...\end{matrix}\right\rangle \ , \qquad (47.18)$$

where we introduced the vector-like notation for notational compactness.

A particular scattering process can be treated like a 'collision' by redistributing the initial populations to final populations:

$$|f\rangle = \left|\begin{matrix}...n_{\mathbf{p}_i} - 1...n_{\mathbf{p}_f} + 1... \\ ...N_{\mathbf{k}_i} - 1...N_{\mathbf{k}_f} + 1...\end{matrix}\right\rangle \ . \qquad (47.19)$$

We write the matrix element,

$$\langle f|\hat{H}_{int}|i\rangle \propto \left\langle\begin{matrix}...n_{\mathbf{p}_i''}...n_{\mathbf{p}_f''}... \\ ...N_{\mathbf{k}_i''}...N_{\mathbf{k}_f''}...\end{matrix}\right| C \sum_{\mathbf{k}_i',\mathbf{k}_f',\mathbf{p}_i',\mathbf{p}_f'} \hat{c}^\dagger_{\mathbf{k}_f'}\hat{c}_{\mathbf{k}_i'}\hat{a}^\dagger_{\mathbf{p}_f'}\hat{a}_{\mathbf{p}_i'}\delta_{\mathbf{k}_f'-\mathbf{k}_i'+\mathbf{p}_f'-\mathbf{p}_i'} \left|\begin{matrix}...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}... \\ ...N_{\mathbf{k}_i}...N_{\mathbf{k}_f}...\end{matrix}\right\rangle \ . \qquad (47.20)$$

Assuming that all modes are not degenerate, such that $[\hat{a}_{\mathbf{p}_f}, \hat{a}^\dagger_{\mathbf{p}_i}] = \delta_{\mathbf{p}_f,\mathbf{p}_i}$, that is, $\hat{a}^\dagger_{\mathbf{p}_f}$ and $\hat{a}_{\mathbf{p}_f}$ only act on the mode $|n_{\mathbf{p}_f}\rangle_{at}$, etc.,

$$\sum_{\mathbf{p}_i'} \hat{a}_{\mathbf{p}_i'}|...n_{\mathbf{p}_i}...\rangle_{at} = \sum_{\mathbf{p}_i} \sqrt{n_{\mathbf{p}_i}}|...n_{\mathbf{p}_i} - 1...\rangle_{at} \qquad (47.21)$$
$$\text{and} \quad \sum_{\mathbf{p}_f'} \hat{a}^\dagger_{\mathbf{p}_f'}|...n_{\mathbf{p}_f}...\rangle_{at} = \sum_{\mathbf{p}_f} \sqrt{n_{\mathbf{p}_f}+1}|...n_{\mathbf{p}_f}+1...\rangle_{at} \ ,$$

as well as,

$$\sum_{\mathbf{k}'_i} \hat{c}_{\mathbf{k}'_i} |...N_{\mathbf{k}_i}...\rangle_{rad} = \sum_{\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} |...N_{\mathbf{k}_i} - 1...\rangle_{rad} \tag{47.22}$$

$$\text{and} \quad \sum_{\mathbf{k}'_f} \hat{c}^\dagger_{\mathbf{k}'_f} |...N_{\mathbf{k}_f}...\rangle_{rad} = \sum_{\mathbf{k}_f} \sqrt{N_{\mathbf{k}_f}+1} |...N_{\mathbf{k}_f}+1...\rangle_{rad} \ .$$

Let us now assume for a moment, that the photon is scattered to the vacuum, that is, the final mode of light is initially empty, $N_{\mathbf{k}_f} = 0$ [4],

$$\begin{aligned} &\langle f|\hat{H}_{int}|i\rangle_{inel} \qquad (47.23)\\ &\propto \left\langle \begin{matrix} ...n_{\mathbf{p}''_i}...n_{\mathbf{p}''_f}... \\ ...N_{\mathbf{k}''_i}...N_{\mathbf{k}''_f}... \end{matrix} \middle| \sum_{\mathbf{p}_f,\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}}\sqrt{n_{\mathbf{p}_f}+1}\sqrt{n_{\mathbf{p}_i}} \middle| \begin{matrix} ...n_{\mathbf{p}_i}-1...n_{\mathbf{p}_f}+1... \\ ...N_{\mathbf{k}_i}-1...1_{\mathbf{k}_f}... \end{matrix} \right\rangle \\ &= \sum_{\mathbf{p}_f,\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}}\sqrt{n_{\mathbf{p}_f}+1}\sqrt{n_{\mathbf{p}_i}} \delta_{N_{\mathbf{k}''_i},N_{\mathbf{k}_i}-1}\delta_{N_{\mathbf{k}''_f},N_{\mathbf{k}_f}+1}\delta_{n_{\mathbf{p}''_i},n_{\mathbf{p}_i}-1}\delta_{n_{\mathbf{p}''_f},n_{\mathbf{p}_f}+1} \\ &= \sqrt{N_{\mathbf{k}_i}}\sqrt{n_{\mathbf{p}_f}+1}\sqrt{n_{\mathbf{p}_i}} \ . \end{aligned}$$

Obviously, the differential scattering cross-section,

$$\boxed{\left(\frac{d\sigma}{d\Omega}\right)_{inel} \propto N_{\mathbf{k}_i}(n_{\mathbf{p}_f}+1)n_{\mathbf{p}_i}} \ . \tag{47.24}$$

depends, in addition to the numbers of provided photons $N_{\mathbf{k}_i}$ and atoms $n_{\mathbf{p}_i}$ in the initial mode, also on the *number of atoms in the final mode* $n_{\mathbf{p}_f}$. This amplification of the probability of the scattering process is called *bosonic stimulation*.

Now, we consider the degenerate case, where the initial atomic momentum mode coincides with the final mode, $n_{\mathbf{p}_f} = n_{\mathbf{p}_i}$. In this case,

$$\sum_{\mathbf{p}'_f=\mathbf{p}'_i} \hat{a}^\dagger_{\mathbf{p}'_f}\hat{a}_{\mathbf{p}'_i}|...n_{\mathbf{p}_i}...n_{\mathbf{p}_f}...\rangle_{at} = \sum_{\mathbf{p}'_i} \hat{a}^\dagger_{\mathbf{p}'_i}\hat{a}_{\mathbf{p}'_i}|...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}...\rangle_{at} = \sum_{\mathbf{p}_i} n_{\mathbf{p}_i}|...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}...\rangle_{at} \ , \tag{47.25}$$

and a calculus analogous to (47.23) yields,

$$\langle f|\hat{H}_{int}|i\rangle_{el} \propto \left\langle \begin{matrix} ...n_{\mathbf{p}''_i}...n_{\mathbf{p}''_f}... \\ ...N_{\mathbf{k}''_i}...N_{\mathbf{k}''_f}... \end{matrix} \middle| \sum_{\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \middle| \begin{matrix} ...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}... \\ ...N_{\mathbf{k}_i}-1...1_{\mathbf{k}_f}... \end{matrix} \right\rangle \tag{47.26}$$

$$= \sum_{\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \ {}_{rad}\langle ...N_{\mathbf{k}''_i}...N_{\mathbf{k}''_f}...|...N_{\mathbf{k}_i}-1...1_{\mathbf{k}_f}...\rangle_{rad} \ {}_{at}\langle ...n_{\mathbf{p}''_i}...n_{\mathbf{p}''_f}...|...n_{\mathbf{p}_i}...n_{\mathbf{p}_i}...\rangle_{at}$$

$$= \sum_{\mathbf{p}_i,\mathbf{k}_f,\mathbf{k}_i} \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \delta_{N_{\mathbf{k}''_i},N_{\mathbf{k}_i}-1}\delta_{N_{\mathbf{k}''_f},N_{\mathbf{k}_f}+1}\delta_{n_{\mathbf{p}''_i},n_{\mathbf{p}_i}}\delta_{n_{\mathbf{p}''_f},n_{\mathbf{p}_i}} = \sqrt{N_{\mathbf{k}_i}} n_{\mathbf{p}_i} \ .$$

Now, the differential scattering cross-section,

$$\boxed{\left(\frac{d\sigma}{d\Omega}\right)_{el} \propto N_{\mathbf{k}_i} n^2_{\mathbf{p}_i}} \ , \tag{47.27}$$

[4] We will discuss later the case, where the scattering is (bosonically) stimulated by the number of photons already present in the final mode prior to the scattering process.

only depends on the number of provided photons $N_{\mathbf{k}_i}$ and the number of atoms $n_{\mathbf{p}_i}$ in the initial mode.

47.1.3.1 Elastic and inelastic scattering

The interpretation of the result is the following: Light can be scattered in two ways: (i) with or (ii) without change of atomic moment distribution. The event of a photon scattering (47.19) then it consists of two terms (47.24) and (47.27) [1044],

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{el} + \left(\frac{d\sigma}{d\Omega}\right)_{inel} . \tag{47.28}$$

The first term of (47.28) occurs when the momentum of the scattering atom does not change, $\mathbf{p} = \mathbf{q}$, that is, when the populations of the momentum states $n_{\mathbf{p}}$ and $n_{\mathbf{q}}$ do not change. The corresponding term (47.27) describes elastic Rayleigh scattering. This process is coherent, that is, the phase relationship between the incident wave and the outgoing wave is fixed, because the photon emission is self-stimulated. I.e. it decays to the original mode via *forward scattering* within the angle defined by the *phase matching condition* $\vartheta < \lambda/d$, where d is the size of the atomic sample [712]. This contribution is dispersive, reversible, and conservative, and it is at the origin of the dipole force.

The second term of (47.28) is the inelastic part of Rayleigh scattering, where an atom with the initial momentum $n_{\mathbf{p}}$ is scattered to the momentum state $n_{\mathbf{q}}$. This term is absorptive, dissipative, and spontaneous. The frequency of the photons is shifted, a momentum is imparted to the atom, such that the process is incoherent. Hence, a suggestive way of expressing the differential scattering cross-section (47.19) is,

$$\frac{d\sigma}{d\Omega} \propto \left| \sum_i n_i \langle i|\hat{H}_{int}|i\rangle \right|^2 + \sum_{i\neq f} n_i(1+n_f)|\langle i|\hat{H}_{int}|f\rangle|^2 , \tag{47.29}$$

where $|i\rangle$ and $|f\rangle$ denote momentum states of the atomic sample.

The bosonic stimulation of inelastic Rayleigh scattering represents a way to overcome, on one hand the restrictive phase matching condition, and on the other the incoherence of the scattering into large angles. For non-interacting systems of localized bosons $S(\mathbf{q},\omega)$ can be expressed using single particle states $|i\rangle$ with energy E_i and population N_i [see (39.3) and (39.6)],

$$S(\mathbf{q},\omega) = N \left| \sum_i n_i \langle i|\hat{H}_{int}|i\rangle \right|^2 \delta(\omega) + N \sum_{i\neq f} |\langle f|\hat{H}_{int}|i\rangle|^2 n_i(n_f+1)\delta[\omega-(E_f-E_i)/\hbar] , \tag{47.30}$$

with $S_0(\mathbf{q}) = |\langle\hat{\rho}^\dagger(\mathbf{q})\rangle|^2 = \left|\sum_i n_i\langle i|\hat{H}_{int}|i\rangle\right|^2$.

47.1.4 Playing with bosonic and fermionic states

Here, we want to address the question, whether scattering processes are influenced by bosonic stimulation or cooperative enhancement. Let us consider the case of N atoms (bosons or fermions) generated from vacuum by operators $\hat{a}_m^\dagger(\mathbf{q})|0\rangle$, where m

indicates some additional quantum number (for example, the vibrational state of a loose trapping potential) helping us to enumerate fermionic states, and $\mathbf{q}$ indicates the momentum (considered independent from the trapping potential for short enough times). The operators respect the rules,

$$\begin{aligned} &[\hat{a}_m(\mathbf{0}), \hat{a}_n(\mathbf{q})]_\mp = 0 = [\hat{a}_m^\dagger(\mathbf{0}), \hat{a}_n^\dagger(\mathbf{q})]_\mp \\ \text{and} \quad &[\hat{a}_m(\mathbf{0}), \hat{a}_n^\dagger(\mathbf{q})]_\mp = \delta_{m,n}\delta_{\mathbf{0},\mathbf{q}} \quad \text{and} \quad \hat{a}_m(\mathbf{q})|0\rangle = 0 \ , \end{aligned} \tag{47.31}$$

where upper signs hold for bosons and lower signs for fermions. Initially the N atoms are in the bosonic, respectively, fermionic many-body state [919],

$$\boxed{|\Psi_b^{(N)}(\mathbf{0})\rangle = \tfrac{1}{\sqrt{N!}}\hat{a}_0^\dagger(\mathbf{0})^N|0\rangle \quad \text{resp.} \quad |\Psi_f^{(N)}(\mathbf{0})\rangle = \prod_{n=0}^{N-1}\hat{a}_n^\dagger(\mathbf{0})|0\rangle} \ . \tag{47.32}$$

Note that $|\Psi_b^{(N)}(\mathbf{0})\rangle = |N\rangle$ is a Fock state satisfying $\langle\Psi_b^{(N)}(\mathbf{0})|\Psi_b^{(N)}(\mathbf{0})\rangle = 1$, while $|\Psi_f^{(N)}(\mathbf{0})\rangle$ is a product state being normalized as well, $\langle\Psi_f^{(N)}(\mathbf{0})|\Psi_f^{(N)}(\mathbf{0})\rangle = 1$.

Probing the number of atoms in a many-body state is done by,

$$N = \langle\Psi|\hat{N}|\Psi\rangle \quad \text{where} \quad \hat{N} = \int \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r})d^3r = \sum_{m,\mathbf{k}}\hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{k}) \ , \tag{47.33}$$

or if we are only interested in a particular momentum state $\mathbf{k}$ and vibrational state m,

$$\langle\Psi|\hat{N}_m(\mathbf{k})|\Psi\rangle = \langle\Psi|\hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{k})|\Psi\rangle = \|\hat{a}_m(\mathbf{k})|\Psi\rangle\|^2 \ . \tag{47.34}$$

Other possible many-body states are bosonic or fermionic product states,

$$\boxed{|\Psi^{(N_1)}(\mathbf{0})\rangle|\Psi^{(N_2)}(\mathbf{q})\rangle} \ . \tag{47.35}$$

We will see in 47.1.6.9 that product states are normalized if the partial states are normalized. Explicitly,

$$\begin{aligned} |\Psi_b^{(N_1)}(\mathbf{0})\rangle|\Psi_b^{(N_2)}(\mathbf{q})\rangle &= \frac{1}{\sqrt{N_1!N_2!}}\hat{a}_0^\dagger(\mathbf{0})^{N_1}\hat{a}_0^\dagger(\mathbf{q})^{N_2}|0\rangle \\ |\Psi_f^{(N_1)}(\mathbf{0})\rangle|\Psi_f^{(N_2)}(\mathbf{q})\rangle &= \prod_{n=0}^{N_1-1}\hat{a}_n^\dagger(\mathbf{0})\prod_{n=0}^{N_2-1}\hat{a}_n^\dagger(\mathbf{q})|0\rangle \ . \end{aligned} \tag{47.36}$$

Note, that product states in the same mode need renormalization when merged,

$$|\Psi_b^{(N_1)}(\mathbf{0})\Psi_b^{(N_2)}(\mathbf{0})\rangle = \frac{1}{\sqrt{N_1!N_2!}}\hat{a}_0^\dagger(\mathbf{0})^{N_1+N_2}|0\rangle = \sqrt{\binom{N_1+N_2}{N_1}}|\Psi_b^{(N_1+N_2)}(\mathbf{0})\rangle \ , \tag{47.37}$$

for example, $|\Psi_b^{(N)}(\mathbf{0})\Psi_b^{(1)}(\mathbf{0})\rangle = \sqrt{N+1}|\Psi_b^{(N+1)}(\mathbf{0})\rangle$.

A $\pi/2$-Bragg pulse has the faculty to transfer 50% of the atoms into a momentum mode $\mathbf{q}$, thus creating a new state where every single atom lives in a coherent

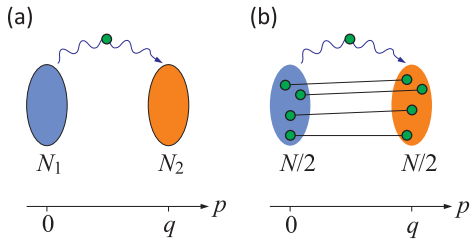

Figure 47.2: Cartoon of (a,b) bosonic stimulation and (c,d) cooperative enhancement.

superposition of two momenta,

$$\boxed{\begin{aligned} |\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \frac{[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^N}{\sqrt{2^N N!}}|0\rangle = \sum_{n=0}^{N}\binom{N}{n}\frac{\hat{a}_0^\dagger(\mathbf{0})^N\hat{a}_0^\dagger(\mathbf{q})^{N-n}}{\sqrt{2^N N!}}|0\rangle \\ |\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \prod_{n=0}^{N-1}\frac{[\hat{a}_n^\dagger(\mathbf{0})+\hat{a}_n^\dagger(\mathbf{q})]}{\sqrt{2^N}}|0\rangle \end{aligned}} \quad . \tag{47.38}$$

In the following, we will study scattering processes, that is, fluctuations, in the presence of the states (47.35) or (47.38).

47.1.4.1 Bosonic stimulation versus cooperative enhancement by a Bragg grating

Now, we scatter a photon, whose fate is not of interest here, but which triggers possible transitions of an atom sitting together with N_1 atoms in the momentum state $\mathbf{0}|0\rangle$ towards another momentum state $\mathbf{q}|0\rangle$ initially populated with N_2 atoms via the operator,

$$\hat{H} = \sum_m \hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{0}) \ , \tag{47.39}$$

which in fact is nothing else than the static structure factor. Applying this process to bosonic or fermionic clouds, as defined in (47.32), we find *bosonic stimulation* only in the case of bosons,

$$\boxed{\langle\Psi^{(N_1-1)}(\mathbf{0})\Psi^{(N_2)}(\mathbf{q})|\hat{H}|\Psi^{(N_1)}(\mathbf{0})\Psi^{(N_2-1)}(\mathbf{q})\rangle = \delta_{\mathbf{k},\mathbf{q}}\begin{cases}\sqrt{N_1 N_2} & \text{for bosons}\\ 1 & \text{for fermions}\end{cases}} \ , \tag{47.40}$$

as will be shown in Exc. 47.1.6.10(a). The transition probabilities are then,

$$\frac{d\sigma}{d\Omega} = |\langle f|\hat{H}|i\rangle|^2 = \delta_{\mathbf{k},\mathbf{q}}\begin{cases}N_1 N_2 & \text{for bosons}\\ 1 & \text{for fermions}\end{cases} \ . \tag{47.41}$$

Note, that these results does not change in the presence of a Bragg grating not participating in the dynamics:

$$\langle\Psi_b^{(M-1)}(\mathbf{0})\Psi_b^{(brgg,N+1)}(\mathbf{0},\mathbf{q})|\hat{H}|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle = 1 \ . \tag{47.42}$$

However, applying the same scattering process between a BEC with M atoms and the Bragg state defined in (47.38) consisting of N atoms, we identify two interesting possibilities for which we find,

$$\boxed{\begin{array}{lcl}\langle\Psi_b^{(M-1)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})|\hat{H}|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\rangle & = & (\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\sqrt{MN}\\ \langle\Psi_b^{(M)}(\mathbf{q})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})|\hat{H}|\Psi_b^{(M-1)}(\mathbf{q})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle & = & \delta_{\mathbf{k},\mathbf{q}}\sqrt{MN}\end{array}} \,. \tag{47.43}$$

Interestingly, we find the same expression for bosons and for fermions,

$$\boxed{\langle\Psi_{b,f}^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\Psi_{b,f}^{(1)}(\mathbf{q})|\hat{H}|\Psi_{b,f}^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle = \sqrt{\tfrac{N}{2}}\left[\delta_{\mathbf{k},\mathbf{0}} \pm \tfrac{N-1}{2}(\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\right]} \,. \tag{47.44}$$

as will be shown in Exc. 47.1.6.10(b). The transition probabilities are then for boson and for fermions,

$$\frac{d\sigma}{d\Omega} = |\langle f|\hat{H}|i\rangle|^2 = \delta_{\mathbf{k},\mathbf{q}}\frac{N}{2}\frac{(N-1)^2}{4} \,. \tag{47.45}$$

This means that, if $\mathbf{k}=\mathbf{0}$ or $\mathbf{k}=\mathbf{q}$, the scattering is subject to *cooperative enhancement* by a factor of $N/2$ (which is the number of atoms in each of the momentum state $\mathbf{0}$ and $\mathbf{q}$) independently on the quantum nature of the atom (boson or fermion). That is, the probability that the scattered atoms joins one of the two momentum goes, for large N, like N^2, but for $N=1$ there is no enhancement possible. Do Exc. 47.1.6.11.

47.1.4.2 Interpretation of bosonic stimulation as cooperative enhancement

The distinction between spontaneous and stimulated processes is not always obvious, as there is a whole world of cooperative processes in between those two concepts, for instance, superradiance, Bragg scattering, and enhanced spontaneous emission into a resonant cavity. All those processes have in common that they are amplified by fluctuations.

Example 286 (*Stimulated emission versus spontaneous emission: Cooperativity in a cavity*): Let us first discuss the case of a cavity. Vacuum fluctuations (VF) are structured by a cavity (finesse F) leading to a modified DOS becoming anisotropic and developing spectral resonances. In resonance the VFs are enhanced (we get a standing wave of VFs), while off resonance they are suppressed. Therefore, an excited atom placed inside a cavity will suffer 'spontaneous stimulation' to decay into the cavity mode. Alternatively, we may say that the atom not only reacts to the local VFs but to all VFs reflected F times by the cavity mirrors provided these VFs are in phase (which is the case when the cavity is resonant). That is, *cavity-enhanced VFs amplify scattering into cavity modes* and, as we argued in Sec. 40.1.4 the VFs are measured by the structure factor (40.44).
Note, that the presence of photons in the cavity does not stimulate 'additionally', because stimulated emission and absorption are reversible processes.

Example 287 (*Bragg scattering: Cooperativity in a lattice*):

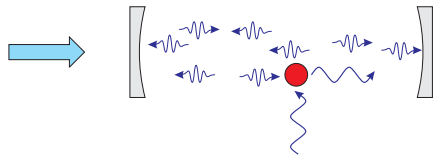

Figure 47.3: Cartoon of cooperative enhancement in a cavity.

Example 288 (*Matter wave superradiance and CARL: Cooperativity in a BEC*): We have seen that the stimulated processes mentioned above do not rely on quantum statistics, but rather on symmetry and coherence. Let us start with a naive picture of bosonic stimulation, a concept which can be applied to matter waves [713]. The physical process behind bosonically stimulated scattering is, that the presence of a macroscopically occupied state increases the density fluctuations of the system, and bosonically enhanced scattering is simply the diffraction of particles from these density fluctuations measured by $S(\mathbf{q},\omega)$.

47.1.5 Collective scattering for condensates with interactions

Until now we totally disregarded interactions between particles. Correlations are introduced in a BEC by interactions between the atoms. Therefore, collective scattering effects are influenced by interactions, while on the other hand an ideal gas ($gn \to 0$) scatters like an ultra-cool non-degenerate thermal cloud. In this sense, particle-like excitations ($\mathbf{p}^2/2m \gg gn$) in an interacting BEC behave like thermal atoms. The mean-field energy can be seen as resulting from excitations of phonon pairs. These pairwise excitations populate the momentum modes, which modify the scattering of light via bosonic stimulation. That is, an interacting condensate ($gn > 0$) gives a collective response to an incident light beam. Note that $\mu > 0$ is possible when $V(\mathbf{r}) \neq 0$ and $gn \neq 0$ even if $T \to 0$, which is the case here considered.

What is the nature of the collective behavior? 1. The Bogolubov spectrum is modified. In the phononic regime, the absence of dispersion allows the definition of a speed of sound. 2. The scattering of light can be suppressed by excitation of phonon pairs. This effect is anisotropic and more pronounced in forward direction. That is, the resonance at which the light is scattered is shifted and broadened. The latter effect is understood via destructive interference of two processes: Scattering from a BEC to the momentum mode $\mathbf{k}$ and from the momentum mode $-\mathbf{k}$ to a BEC.

It is important to be aware that the notion of *bosonic stimulation* $\sim n_i(1+n_f)$ and *fermionic inhibition* $\sim n_i(1-n_f)$ also has its limitations, when interatomic interactions are not negligible, that is, when the quantum depletion is remarkable [527, 862]. The effect of interatomic collisions can be taken into account as contributions of pair correlations to the ground state of the BEC,

$$|\psi_0, n_0\rangle = |n_0, 0, 0\rangle - \sum_{\mathbf{k}} (v_{\mathbf{k}}^2/u_{\mathbf{k}}^2)|n_0-2, 1, 1\rangle + \sum_{\mathbf{k}} (v_{\mathbf{k}}^2/u_{\mathbf{k}}^2)^2 |n_0-4, 2, 2\rangle - \dots , \quad (47.46)$$

where $|n_0, n_{\mathbf{k}}, n_{-\mathbf{k}}\rangle$ denotes the state with n_0 atoms in the trap's ground state and $n_{\pm\mathbf{k}}$ atoms in the momentum mode $\mathbf{k}$, where $v_{\mathbf{k}}^2$ is the average population of momentum

mode $\mathbf{k}$. The populated recoil modes result in a increase of spontaneous emission by a factor of $v_{\mathbf{k}}^2 = 1 + u_{\mathbf{k}}^2$. We can also understand the modification of the scattering rate as resulting from small scale inhomogeneities generated by pair correlations. The effect is strongest at small scattering angles, that is in forward direction.

47.1.6 Exercises

47.1.6.1 Ex: Sum rules for the dynamic structure factor

Derive the following sum rules for the norm, the kinetic energy, and the compressibility,

$$\begin{aligned} S(\mathbf{q}) &= \int S(\mathbf{q},\omega)d\omega \\ \frac{\hbar^2 q^2}{2m} &= \int \hbar\omega S(\mathbf{q},\omega)d\omega \\ \frac{\kappa^2}{2} &= \int \frac{S(\mathbf{q},\omega)}{\hbar\omega}d\omega\Big|_{\mathbf{q}\to 0} \end{aligned} .$$

Solution: *According to [877] ...*

47.1.6.2 Ex: Interaction energy of a condensate via spatial coherence

Show that the total energy of a condensate is given by $\langle U\rangle = \frac{1}{2}\int n(\mathbf{r}_1)U(\mathbf{r}_1 - \mathbf{r}_2)g^{(2)}(\mathbf{r}_1,\mathbf{r}_2)n(\mathbf{r}_2)d^3r_1 d^3r_2$.

Solution: *The interaction energy expressed by the correlation function is,*

$$\langle U\rangle = \tfrac{1}{2}\int n(\mathbf{r}_1)U(\mathbf{r}_1-\mathbf{r}_2)g^{(2)}(\mathbf{r}_1,\mathbf{r}_2)n(\mathbf{r}_2)d^3r_1 d^3r_2 \simeq \frac{2\pi\hbar^2}{m}a g^{(2)}(0)\tfrac{1}{2}\int n(\mathbf{r})^2 d^3r \ .$$

47.1.6.3 Ex: Structure factor of a condensate in the local density approximation

Calculate the structure factor of a condensate in the local density approximation (LDA) [204, 1237].

Solution: *With* $E_r = \frac{\hbar^2 q^2}{2m}$ *and* $\mu = \frac{\hbar^2}{2m\xi^2}$, *where* $\xi = (8\pi na)^{-1/2}$, *using the Bogolubov expression,*

$$S(\mathbf{q},\omega) = \frac{\hbar^2 q^2}{2m\epsilon(\mathbf{q})}\delta(\omega - \epsilon(\mathbf{q})/\hbar)$$

inserting the Bogolubov dispersion relation $\epsilon(\mathbf{q}) = \sqrt{\frac{\hbar^2 q^2}{2m}\left(\frac{\hbar^2 q^2}{2m} + gn(\mathbf{r})\right)}$ *and calculating the average over the Thomas-Fermi profile,* $n(\mathbf{r}) = g^{-1}[\mu - V_{ext}(\mathbf{r})]$*, we obtain,*

$$S_{LDA}(\mathbf{q},\omega) = \frac{15\pi}{8}\frac{\hbar^2\omega^2 - E_r^2}{E_r\mu^2}\left(1 - \frac{\hbar^2\omega^2 - E_r^2}{2E_r\mu}\right)^{1/2} .$$

This holds for $q\xi < 1$*, where for contrapropagating waves* $q = 2\cdot 2\pi/\lambda$*. Alternatively*

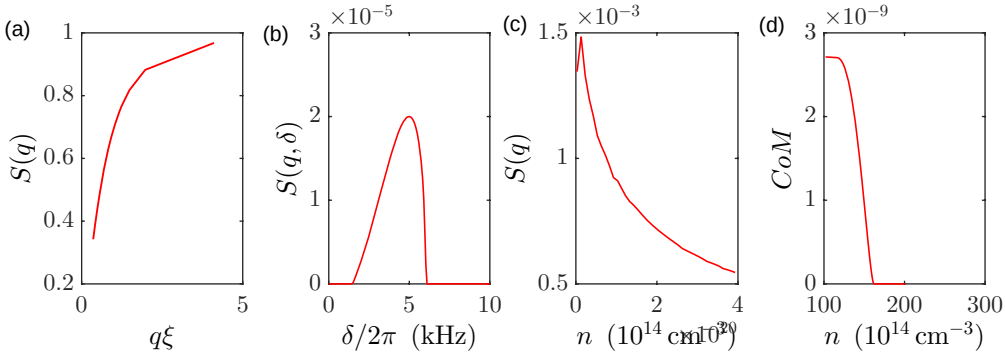

Figure 47.4: (code) (a) Static structure factor. (b) Dynamic structure factor. (c) Integrated dynamic structure factor. (d) Center-of-mass momentum.

[527, 861, 862],

$$S(q) = (u_q - v_q)^2 = (\cosh\phi_q - \sinh\phi_q)^2$$
$$\tanh 2\phi_q = \frac{\mu}{E_r(q) + \mu}$$
$$E_r(q) = \frac{\hbar^2 q^2}{2m} .$$

47.1.6.4 Ex: Structure structure of a Fermi gas

Calculate the structure factor for Bragg scattering on a Fermi gas.

Solution: *We calculate the Bragg scattering profile using the two-level model in addition to the Schrödinger equation and construct the sum of the density distributions at* $0\hbar q$ *and* $2\hbar q$*. Then, we calculate the axial center-of-mass momentum as a function of* ω*,*

$$p_{cm}(q,\omega) = \int n_{q,\omega}(z)dz .$$

On the other hand, the center-of-mass momentum is related to the dynamic structure factor via [1331],

$$p_{cm}(q,\omega) = \frac{\hbar\Omega_{br}^2}{2}\, S(q,\omega) \star \frac{1 - \cos(\omega t_{br})}{\omega^2} .$$

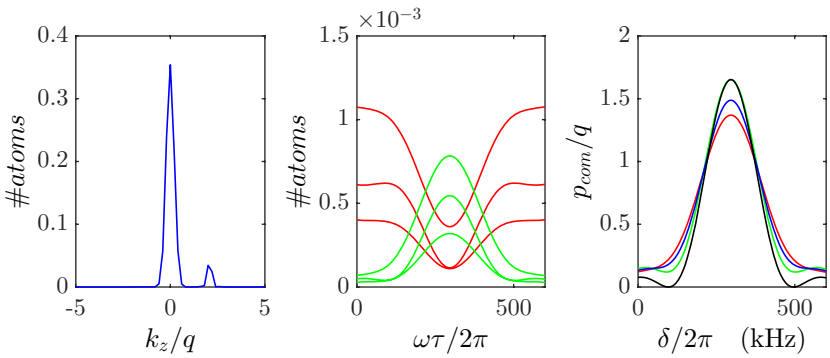

Figure 47.5: (code) (a) Density distribution after Bragg diffraction. (b) Diffraction efficiency as a function of Bragg detuning. (c) Center-of-mass momentum after Bragg diffraction.

In a Fermi gas the atoms are not correlated, so that the structure factor is $S(q,\omega) = \delta(\omega - \omega_R)$. *The center-of-mass momentum is thus approximately,*

$$p_{cm}(q,\omega) = \frac{\hbar\Omega_{br}^2}{2} \frac{1-\cos[(\omega-\omega_R)]t_{br})}{(\omega-\omega_R)^2} .$$

However, the inhomogeneity of the gas causes.
Alternatively, with $N(\mathbf{k}) = \theta(k_F - k)$,

$$\begin{aligned} S_{fermi}(\mathbf{q}) &= \int d\mathbf{k} N(\mathbf{k})[1 - N(\mathbf{k}+\mathbf{q})] \\ &= \int d\phi d\vartheta dk \; k^2 \sin\vartheta \; \theta(k_F - k) \left[1 - N(k_F - |\mathbf{k}+\mathbf{q}|)\right] \\ &= ??? \\ &= \left\{ \begin{pmatrix} \frac{3q}{4k_F} - \frac{q^3}{16k_F^3} & for & 0 < q < 2k_F \\ 1 & for & 2k_F < q \end{pmatrix} \right. \end{aligned}$$

47.1.6.5 Ex: Structure factor of a heteronuclear mixture

In this exercise we discuss the structure factor of a heteronuclear mixture (specifically contemplating ^{6}Li mixed with ^{87}Rb) generalizing the available theory for Li spin mixtures to heteronuclear mixtures [288, 472, 473, 1331]. The total dynamic structure factor is,

$$S(q,\omega) = S_{87,87}(q,\omega) + S_{6,6}(q,\omega) + S_{6,87}(q,\omega) + S_{87,6}(q,\omega) .$$

Exciting the Bragg resonance for Li, the Rb cloud would stay unaffected,the such that around $\omega/2\pi = 295$ kHz, $S_{87,87}(q,\omega) = 0$, as well as, $S_{6,87}(q,\omega) = S_{87,6}(q,\omega) = 0$. For Fermi gas $S_{6,6}(q,\delta) \to 1$, except if Bose gas induces Li-Li correlations, as in the case of BCS-pairing of phonon-mediated Efimov states.

How does Rb influence the Bragg scattering of Li? Via a variation of the apparent mass as a displacement of the Bragg resonance or as a second peak appearing at a specific detuning of the Bragg beams at $\omega_{6,6} * 6/(6+87)$?

Solution: *We have,*

$$p_{cm}(q,\omega) = \frac{\hbar\Omega_{br}^2}{2}\ S(q,\delta) \star \frac{1-\cos(\omega t_{br})}{\omega^2}\ .$$

and

47.1.6.6 Ex: Spatial coherence of a condensate

Derive the relationship (47.7).

Solution: *Using the expression (23.101), that is,*

$$\langle\mathbf{r}|\mathbf{k}\rangle = \tfrac{1}{(2\pi)^{3/2}}e^{\imath\mathbf{k}\cdot\mathbf{r}}\ ,$$

we calculate,

$$\begin{aligned}\int\langle\mathbf{r}|\hat{\rho}|\mathbf{r}+\mathbf{x}\rangle d^3r &= \iiint\langle\mathbf{r}|\mathbf{k}\rangle\langle\mathbf{k}|\hat{\rho}|\mathbf{k}'\rangle\langle\mathbf{k}'|\mathbf{r}+\mathbf{x}\rangle d^3kd^3k'd^3r\\ &= \tfrac{1}{(2\pi)}\iiint e^{\imath\mathbf{k}\cdot\mathbf{r}}\langle\mathbf{k}|\hat{\rho}|\mathbf{k}'\rangle e^{\imath\mathbf{k}'\cdot(\mathbf{r}+\mathbf{x})}d^3kd^3k'd^3r\\ &= \iint\langle\mathbf{k}|\hat{\rho}|\mathbf{k}'\rangle e^{\imath\mathbf{k}'\cdot\mathbf{x}}\delta^{(3)}(\mathbf{k}-\mathbf{k}')d^3kd^3k' = \int\langle\mathbf{k}|\hat{\rho}|\mathbf{k}\rangle e^{\imath\mathbf{k}\cdot\mathbf{x}}d^3k\ .\end{aligned}$$

47.1.6.7 Ex: Structure factor for Bragg scattering

Demonstrate the following relationships,

$$\frac{dp_{cm}(\mathbf{q},\omega)}{dt} = -m\omega_z^2 z_{cm} + \hbar q\frac{\Omega_{br}^2}{2}\int d\delta'[S(\mathbf{q},\omega')-S(-\mathbf{q},-\omega')]\frac{\sin(\omega-\omega')t_{br}}{\omega-\omega'}$$

$$\ddot{p}_{cm}(q,\omega)+\omega_z^2 p_{cm} = \hbar q\frac{\Omega_{br}^2}{2}\int d\omega'[S(\mathbf{q},\omega')-S(-\mathbf{q},-\omega')]\cos(\omega-\omega')t_{br}\longrightarrow 0\ .$$

Solution:

47.1.6.8 Ex: Commutation expressions for bosons and fermions

Verify the following useful commutation relations:
a. For bosons,

$$\hat{a}_m(\mathbf{k})\hat{a}_n^\dagger(\mathbf{q})^N = N\delta_{m,n}\delta_{\mathbf{k},\mathbf{q}}\hat{a}_n^\dagger(\mathbf{q})^{N-1} + \hat{a}_n^\dagger(\mathbf{q})^N\hat{a}_m(\mathbf{k}) \ , \tag{47.47}$$

which can be generalized to,

$$\begin{aligned}&\hat{a}_m(\mathbf{k})[\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)]^N \\ &\quad = N\delta_{m,n}\left(\delta_{\mathbf{k},\mathbf{q}_1} + \delta_{\mathbf{k},\mathbf{q}_2}\right)[\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)]^{N-1} + [\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)]^N\hat{a}_m(\mathbf{k}) \ .\end{aligned} \tag{47.48}$$

b. For fermions do not support macroscopic populations of the type $\hat{a}_n^\dagger(\mathbf{q})^N$. Performing a number P of permutations of the operators and assuming that one fermion of the product state is in the internal state n, we calculate,

$$\hat{a}_n(\mathbf{k})\prod_{m=0}^{N-1}\hat{a}_m^\dagger(\mathbf{q}) = (-1)^P\left[\delta_{\mathbf{k},\mathbf{q}}\prod_{m\neq n}^{N-1}\hat{a}_m^\dagger(\mathbf{q}) - \prod_{m=0}^{N-1}\hat{a}_m^\dagger(\mathbf{q})\hat{a}_n(\mathbf{k})\right] \ . \tag{47.49}$$

If none of the fermions of the product state is in state n the first part of the sum simply vanishes. This expression can also be generalized to,

$$\begin{aligned}&\hat{a}_n(\mathbf{k})\prod_{m=0}^{N-1}[\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)] = (-1)^P\prod_{m\neq n}^{N-1}[\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)]\hat{a}_n(\mathbf{k})[\hat{a}_n^\dagger(\mathbf{q}_1) + \hat{a}_n^\dagger(\mathbf{q}_2)] \\ &= (-1)^P\left[(\delta_{\mathbf{k},\mathbf{q}_1} + \delta_{\mathbf{k},\mathbf{q}_2})\prod_{m\neq n}^{N-1}[\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)] - \prod_{m=0}^{N-1}[\hat{a}_m^\dagger(\mathbf{q}_1) + \hat{a}_m^\dagger(\mathbf{q}_2)]\hat{a}_n(\mathbf{k})\right] \ .\end{aligned} \tag{47.50}$$

Solution: *a. For bosons the subsequent arguments the following side calculation will be useful,*

$$\begin{aligned}\hat{a}_m(\mathbf{k})\hat{a}_n^\dagger(\mathbf{q})^N &= \delta_{m,n}\delta_{\mathbf{k},\mathbf{q}}\hat{a}_n^\dagger(\mathbf{q})^{N-1} + \hat{a}_n^\dagger(\mathbf{q})\hat{a}_m(\mathbf{k})\hat{a}_n^\dagger(\mathbf{q})^{N-1} \\ &= ... = N\delta_{m,n}\delta_{\mathbf{k},\mathbf{q}}\hat{a}_n^\dagger(\mathbf{q})^{N-1} + \hat{a}_n^\dagger(\mathbf{q})^N\hat{a}_m(\mathbf{k}) \ .\end{aligned}$$

b. For fermions do not support macroscopic populations of the type $\hat{a}_n^\dagger(\mathbf{q})^N$. Performing a number P of permutations of the operators and assuming that one fermion of the product state is in the internal state n, we calculate,

$$\begin{aligned}\hat{a}_n(\mathbf{k})\prod_{m=0}^{N-1}\hat{a}_m^\dagger(\mathbf{q}) &= (-1)^P\prod_{m\neq n}^{N-1}\hat{a}_m^\dagger(\mathbf{q})\hat{a}_n(\mathbf{k})\hat{a}_n^\dagger(\mathbf{q}) = (-1)^P\prod_{m\neq n}^{N-1}\hat{a}_m^\dagger(\mathbf{q})[\delta_{\mathbf{k},\mathbf{q}} - \hat{a}_n^\dagger(\mathbf{q})\hat{a}_n(\mathbf{k}) \\ &= (-1)^P\left[\delta_{\mathbf{k},\mathbf{q}}\prod_{m\neq n}^{N-1}\hat{a}_m^\dagger(\mathbf{q}) - \prod_{m=0}^{N-1}\hat{a}_m^\dagger(\mathbf{q})\hat{a}_n(\mathbf{k})\right] \ .\end{aligned}$$

If none of the fermions of the product state is in state n the first part of the sum simply vanishes.

47.1.6.9 Ex: Extracting the atom number from many-body states

Verify the normalization of (a) the bosonic Fock state (47.32), (b) the fermionic product state (47.32), (c) the bosonic product state (47.35), (d) the bosonic Bragg grating state (47.37), and (e) the fermionic Bragg grating state (47.37). **Help:** Speed up the calculations by using the results of 47.1.6.8.

Solution: *a. For the BEC Fock state we have,*

$$\begin{aligned}\langle\Psi_b^{(N)}(\mathbf{0})|\hat{N}_m(\mathbf{k})|\Psi_b^{(N)}(\mathbf{0})\rangle &= \tfrac{1}{N!}\langle 0|\hat{a}_0(\mathbf{0})^N\hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{k})\hat{a}_0^\dagger(\mathbf{0})^N|0\rangle\\ &= \tfrac{1}{N!}\left\|N\delta_{m,0}\delta_{\mathbf{k},\mathbf{q}}\hat{a}_n^\dagger(\mathbf{0})^{N-1}|0\rangle\right\|^2\\ &= N\delta_{m,0}\delta_{\mathbf{k},\mathbf{q}}\||\Psi_b^{(N-1)}\rangle\|^2 = N\delta_{m,0}\delta_{\mathbf{k},\mathbf{q}}\ ,\end{aligned}$$

yielding $\langle\Psi_b^{(N)}(\mathbf{0})|\hat{N}|\Psi_b^{(N)}(\mathbf{0})\rangle = \sum_{m,\mathbf{k}}\langle\Psi_b^{(N)}(\mathbf{0})|\hat{N}_m(\mathbf{k})|\Psi_b^{(N)}(\mathbf{0})\rangle = N$.
b. For the Fermi sea state we have,

$$\begin{aligned}\langle\Psi_f^{(N)}(\mathbf{0})|\hat{N}_m(\mathbf{k})|\Psi_f^{(N)}(\mathbf{0})\rangle &= \langle 0\left|\prod_{n'=0}^{N-1}\hat{a}_{n'}(\mathbf{0})\hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{k})\prod_{n=0}^{N-1}\hat{a}_n^\dagger(\mathbf{0})\right|0\rangle\\ &= \|\hat{a}_m(\mathbf{k})\hat{a}_m^\dagger(\mathbf{0})\prod_{n\neq m}^{N-1}\hat{a}_n^\dagger(\mathbf{0})|0\rangle\|^2 = \delta_{\mathbf{0},\mathbf{k}}\|\Psi_f^{(N-1)}(\mathbf{0})\|^2 = \delta_{\mathbf{0},\mathbf{k}}\ ,\end{aligned}$$

yielding $\langle\Psi_f^{(N)}(\mathbf{0})|\hat{N}|\Psi_f^{(N)}(\mathbf{0})\rangle = N$.
c. For the bosonic product state we have,

$$\begin{aligned}&\langle\Psi_b^{(N_1)}(\mathbf{0})\Psi_b^{(N_2)}(\mathbf{q})|\hat{N}_0(\mathbf{k})|\Psi_b^{(N_1)}(\mathbf{0})\Psi_b^{(N_2)}(\mathbf{q})\rangle\\ &\quad= \frac{1}{N_1!N_2!}\langle 0|\hat{a}_0(\mathbf{q})^{N_2}\hat{a}_0(\mathbf{0})^{N_1}\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{k})\hat{a}_0^\dagger(\mathbf{0})^{N_1}\hat{a}_0^\dagger(\mathbf{q})^{N_2}|0\rangle\\ &\quad= \frac{1}{N_1!N_2!}\|N_1\delta_{\mathbf{k},\mathbf{0}}\hat{a}_0^\dagger(\mathbf{0})^{N_1-1}\hat{a}_0^\dagger(\mathbf{q})^{N_2}|0\rangle + \hat{a}_0^\dagger(\mathbf{0})^{N_1}\hat{a}_0(\mathbf{k})\hat{a}_0^\dagger(\mathbf{q})^{N_2}|0\rangle\|^2\\ &\quad= \frac{1}{N_1!N_2!}\left(N_1^2\delta_{\mathbf{k},\mathbf{0}}\|\hat{a}_0^\dagger(\mathbf{0})^{N_1-1}\hat{a}_0^\dagger(\mathbf{q})^{N_2}|0\rangle\|^2 + N_2^2\delta_{\mathbf{k},\mathbf{q}}\|\hat{a}_0^\dagger(\mathbf{0})^{N_1}\hat{a}_0^\dagger(\mathbf{q})^{N_2-1}|0\rangle\|^2\right)\\ &\quad= N_1\delta_{\mathbf{k},\mathbf{0}} + N_2\delta_{\mathbf{k},\mathbf{q}}\ ,\end{aligned}$$

yielding $\langle\Psi_b^{(N_1)}(\mathbf{0})\Psi_b^{(N_2)}(\mathbf{q})|\hat{N}|\Psi_b^{(N_1)}(\mathbf{0})\Psi_b^{(N_2)}(\mathbf{q})\rangle = \sum_{\mathbf{k}}(N_1\delta_{\mathbf{k},\mathbf{0}} + N_2\delta_{\mathbf{k},\mathbf{q}}) = N_1 + N_2$.
d. To probe the number of bosons of the Bragg-state being in momentum state $\mathbf{k}$*, we do,*

$$\begin{aligned}&\langle\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})|\hat{N}(\mathbf{k})|\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle\\ &\qquad= \tfrac{1}{2^N N!}\langle 0|[\hat{a}_0(\mathbf{0}) + \hat{a}_0(\mathbf{q})]^N\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{k})[\hat{a}_0^\dagger(\mathbf{0}) + \hat{a}_0^\dagger(\mathbf{q})]^N|0\rangle\\ &\qquad= \tfrac{1}{2^N N!}\|N(\delta_{\mathbf{k},\mathbf{0}} + \delta_{\mathbf{k},\mathbf{q}})[\hat{a}_0^\dagger(\mathbf{0}) + \hat{a}_0^\dagger(\mathbf{q})]^{N-1}|0\rangle\|^2\\ &\qquad= \tfrac{N^2}{2N}(\delta_{\mathbf{k},\mathbf{0}} + \delta_{\mathbf{k},\mathbf{q}})\||\Psi_{b,N-1}^{(sctt)}\rangle\|^2 = \tfrac{N}{2}(\delta_{\mathbf{k},\mathbf{0}} + \delta_{\mathbf{k},\mathbf{q}})\ ,\end{aligned}$$

yielding $\langle\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})|\hat{N}|\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle = N$.
e. For fermions we get analogously,

$$\begin{aligned}\langle\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})|\hat{N}_m(\mathbf{k})|\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \|\tfrac{1}{\sqrt{2^N}}\hat{a}_m(\mathbf{k})\prod_{n=0}^{N-1}[\hat{a}_n^\dagger(\mathbf{0})+\hat{a}_n^\dagger(\mathbf{q})]|0\rangle\|^2\\ &= \tfrac{1}{2^N}[\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}}]\|\prod_{n\neq m}^{N-1}[\hat{a}_n^\dagger(\mathbf{0})+\hat{a}_n^\dagger(\mathbf{q})]|0\rangle\|^2\\ &= \tfrac{1}{2}(\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\||\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\rangle\|^2 = \tfrac{1}{2}(\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\ ,\end{aligned}$$

also yielding $\langle\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})|\hat{N}|\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle = \frac{N}{2}$.

47.1.6.10 Ex: Bosonic stimulation and cooperative enhancement by lattices of bosons and fermions

Compare bosons and fermions with respect to (a) bosonic stimulation and (b) cooperative enhancement.

Solution: *a. To discuss bosonic stimulation we study the Rayleigh scattering of a single atom out of a matter wave populated with* N_1 *atoms into another one populated with* N_2 *atoms,*

$$|\Psi_b^{(N_1)}(\mathbf{0})\rangle|\Psi_b^{(N_2-1)}(\mathbf{q})\rangle \overset{\hat{H}}{\curvearrowright} |\Psi_b^{(N_1-1)}(\mathbf{0})\rangle|\Psi_b^{(N_2)}(\mathbf{q})\rangle\ ,$$

mediated by the scattering Hamiltonian $\hat{H} \equiv \sum_m \hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{0})$, *with* $\mathbf{k}\neq\mathbf{0}$. *For bosonic clouds we get,*

$$\begin{aligned}&\langle\Psi_b^{(N_1-1)}(\mathbf{0})\Psi_b^{(N_2)}(\mathbf{q})|\hat{H}|\Psi_b^{(N_1)}(\mathbf{0})\Psi_b^{(N_2-1)}(\mathbf{q})\rangle\\ &\quad= (\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\frac{\langle 0|\hat{a}_0(\mathbf{0})^{N_1-1}\hat{a}_0(\mathbf{q})^{N_2}|\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{0})|\hat{a}_0^\dagger(\mathbf{0})^{N_1}\hat{a}_0^\dagger(\mathbf{q})^{N_2-1}|0\rangle}{\sqrt{N_1!N_2!(N_1-1)!(N_2-1)!}}\\ &\quad= 0+\delta_{\mathbf{k},\mathbf{q}}\sqrt{N_1N_2}\ ,\end{aligned}$$

using

$$\hat{a}_0(\mathbf{q})^{N_2}\hat{a}_0^\dagger(\hat{a}(\mathbf{q})^{N_2-1}|0\rangle = (N_2-1)\hat{a}_0(\mathbf{q})^{N_2-1}\hat{a}_0^\dagger(\mathbf{q})^{N_2-2}|0\rangle = ... = (N_2-1)!\hat{a}_0(\mathbf{q})|0\rangle = 0\ .$$

For fermionic clouds we get,

$$\begin{aligned}&\langle\Psi_f^{(N_1-1)}(\mathbf{0})\Psi_f^{(N_2)}(\mathbf{q})|\hat{H}|\Psi_f^{(N_1)}(\mathbf{0})\Psi_f^{(N_2-1)}(\mathbf{q})\rangle\\ &\quad= \langle 0|\prod_{m_1'=0}^{N_1-2}\hat{a}_{m_1'}(\mathbf{0})\prod_{m_2'=0}^{N_2-1}\hat{a}_{m_2'}(\mathbf{q})|\hat{a}_n^\dagger(\mathbf{q})\hat{a}_n(\mathbf{0})|\prod_{m_1=0}^{N_1-1}\hat{a}_{m_1}^\dagger(\mathbf{0})\prod_{m_2=0}^{N_2-2}\hat{a}_{m_2}^\dagger(\mathbf{q})|0\rangle\\ &\quad= \langle 0|\prod_{m_2'\neq n}^{N_2-2}\hat{a}_{m_2'}(\mathbf{q})\hat{a}_n(\mathbf{q})\hat{a}_n^\dagger(\mathbf{q})\prod_{m_2=0}^{N_2-2}\hat{a}_{m_2}^\dagger(\mathbf{q})\prod_{m_1'=0}^{N_1-2}\hat{a}_{m_1'}(\mathbf{0})\hat{a}_n(\mathbf{0})\hat{a}_n^\dagger(\mathbf{0})\prod_{m_1\neq n}^{N_1-2}\hat{a}_{m_1}^\dagger(\mathbf{0})|0\rangle\\ &\quad= \langle 0|\hat{a}_n(\mathbf{0})\hat{a}_n^\dagger(\mathbf{0})|0\rangle = 1\ .\end{aligned}$$

This shows that, in contrast to bosons, the scattering of fermions is not bosonically enhanced.

b. We study the two processes,

$$|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle \overset{\hat{H}}{\curvearrowright} |\Psi_b^{(M-1)}(\mathbf{0})\Psi_b^{(brgg,N+1)}(\mathbf{0},\mathbf{q})\rangle$$
$$|\Psi_b^{(M)}(\mathbf{q})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle \overset{\hat{H}}{\curvearrowright} |\Psi_b^{(M+1)}(\mathbf{q})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\rangle \ ,$$

For the first one we find,

$$\begin{aligned}
&\langle\Psi_b^{(M-1)}(\mathbf{0})\Psi_b^{(brgg,N+1)}(\mathbf{0},\mathbf{q})|\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{0})|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle \\
&= \frac{\langle 0|\hat{a}_0(\mathbf{0})^{M-1}[\hat{a}_0(\mathbf{0})+\hat{a}_0(\mathbf{q})]^{N+1}\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{0})\hat{a}_0^\dagger(\mathbf{0})^M[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^N|0\rangle}{\sqrt{2^{N+1}(N+1)!2^{M-1}(M-1)!2^N N!2^M M!}} \\
&= \frac{\langle 0|\hat{a}_0(\mathbf{0})^{M}[\hat{a}_0(\mathbf{0})+\hat{a}_0(\mathbf{q})]^{N+1}\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0^\dagger(\mathbf{0})^M[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^N|0\rangle}{(M-1)!N!2^{M+N}\sqrt{M(N+1)}} + 0 \\
&= \frac{\left\langle 0 \left| \begin{array}{c} \hat{a}_0(\mathbf{0})^M(N+1)(\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})[\hat{a}_0(\mathbf{0})+\hat{a}_0(\mathbf{q})]^N\hat{a}_0^\dagger(\mathbf{0})^M[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^N \\ +\hat{a}_0(\mathbf{0})^M\hat{a}_0^\dagger(\mathbf{k})[\hat{a}_0(\mathbf{0})+\hat{a}_0(\mathbf{q})]^{N+1}\hat{a}_0^\dagger(\mathbf{0})^M[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^N \end{array} \right| 0 \right\rangle}{(M-1)!N!2^{M+N}\sqrt{M(N+1)}} \\
&= \frac{(N+1)(\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})M!N!2^{M+N}\left\langle \Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})|\Psi_b^{(M)}(\mathbf{0})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})0\right\rangle}{(M-1)!N!2^{M+N}\sqrt{M(N+1)}} \\
&= (\delta_{\mathbf{k},\mathbf{0}}+\delta_{\mathbf{k},\mathbf{q}})\sqrt{M(N+1)} \ ,
\end{aligned}$$

and for the second one,

$$\begin{aligned}
&\langle\Psi_b^{(M+1)}(\mathbf{q})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})|\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{0})|\Psi_b^{(M)}(\mathbf{q})\Psi_b^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle \\
&= \frac{\langle 0|\hat{a}_0(\mathbf{q})^{M+1}[\hat{a}_0(\mathbf{0})+\hat{a}_0(\mathbf{q})]^{N-1}\hat{a}_0^\dagger(\mathbf{k})\hat{a}_0(\mathbf{0})\left[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})\right]^N\hat{a}_0^\dagger(\mathbf{q})^M|0\rangle}{\sqrt{2^{N-1}(N-1)!2^{M+1}(M+1)!2^N N!2^M M!}} \\
&= \frac{\delta_{\mathbf{k},\mathbf{q}}\langle 0|\hat{a}_0(\mathbf{q})^{M+1}[\hat{a}_0(\mathbf{0})+\hat{a}_0(\mathbf{q})]^{N-1}\hat{a}_0^\dagger(\mathbf{q})^{M+1}N[\hat{a}_0^\dagger(\mathbf{0})+\hat{a}_0^\dagger(\mathbf{q})]^{N-1}|0\rangle}{M!(N-1)!2^{M+N}\sqrt{N(M+1)}} \\
&= \frac{\delta_{\mathbf{k},\mathbf{q}}N(N-1)!(M+1)!2^{M+N}\left\langle \Psi_b^{(M+1)}(\mathbf{0})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})|\Psi_b^{(M+1)}(\mathbf{0})\Psi_b^{(brgg,N-1)}(\mathbf{0},\mathbf{q})0\right\rangle}{M!(N-1)!2^{M+N}\sqrt{N(M+1)}} \\
&= \delta_{\mathbf{k},\mathbf{q}}\sqrt{N(M+1)} \ .
\end{aligned}$$

For fermions we get analogously,

$$\begin{aligned}
\langle\Psi_f^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\Psi_f^{(1)}(\mathbf{k})|\Psi_f^{(brgg,N)}(\mathbf{0},\mathbf{q})\rangle &= \sum_m \|\tfrac{1}{\sqrt{2^N}}\hat{a}_m^\dagger(\mathbf{k})\hat{a}_m(\mathbf{0})\prod_{n=0}^{N-1}[\hat{a}_n^\dagger(\mathbf{0})+\hat{a}_n^\dagger(\mathbf{q})]|0\rangle\|^2 \\
&= \tfrac{1}{2^N}\sum_m \|\hat{a}_m^\dagger(\mathbf{k})\prod_{n\neq m}^{N-1}[\hat{a}_n^\dagger(\mathbf{0})+\hat{a}_n^\dagger(\mathbf{q})]|0\rangle\|^2 \\
&\simeq N\left\|\hat{a}_0^\dagger(\mathbf{k})|\tfrac{1}{\sqrt{2}}\Psi_f^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\rangle\right\|^2 \\
&= \tfrac{N}{2}\langle\Psi_f^{(brgg,N-1)}(\mathbf{0},\mathbf{q})|1-\hat{N}(\mathbf{k})|\Psi_f^{(brgg,N-1)}(\mathbf{0},\mathbf{q})\rangle \\
&= \tfrac{N}{2}\left[1-\tfrac{N-1}{2}(\delta_{\mathbf{0},\mathbf{k}}+\delta_{\mathbf{0},\mathbf{q}})\right] \ .
\end{aligned}$$

47.1.6.11 Ex: Cooperative enhancement versus bosonic stimulation

CARL amplification comes from cooperativity not from bosonic stimulation [919, 713, 1166], that is, it should work for fermions and boltzons. To demonstrate this proceed as follows:
a. Set up the single-atom Hamiltonian for a 3D harmonic potential in which the atoms (bosons or fermions) are initially placed allowing for the possibility of momentum recoil by photon scattering. This disregards the trap's inhomogeneity, but is a good assumption for short times. What are the eigenfunction of this Hamiltonian? Calculate the expectation value for the density distribution. Express the field operators in momentum space. Express the lowest energy states for a bosonic/fermionic cloud in momentum representation.
b. Now apply a $\pi/2$-Bragg-pulse imparting the recoil $\mathbf{K}$ to the cloud. What is the resulting state? Recalculate the expectation value for the density distribution.
c. Now, assume the presence of another free (test) atom (or photon). Write down the Hamiltonian and the wavefunction for this atom. It is supposed to interact with the atomic cloud via the (perturbatively treated) interaction potential,

$$\hat{V} = \lambda \int d^3r \hat{\psi}_1^\dagger(\mathbf{r})\hat{\psi}_2^\dagger(\mathbf{r})\hat{\psi}_2(\mathbf{r})\hat{\psi}_1(\mathbf{r}) \ .$$

Calculate the probability that the atom is scattered at a particular wavevector, i.e. determine the cooperative enhancement factor.
d. Is cooperative enhancement possible with just one atom?
e. How about cooperative enhancement in a cavity, when cooperativity is ensured by a single atom plus all its mirror images?

Solution: *a. Following [919] we consider a field $\hat{\psi}_1(\mathbf{r})$ containing N identical bosons or fermions in a harmonic trap,*

$$\hat{H}_{ho} = \hbar\omega_m(\hat{n} + \tfrac{1}{2}) \ ,$$

with the single particle orbitals $\varphi_m(\mathbf{r}) = X_{m_x}(x)Y_{m_y}(y)Z_{m_z}(z)$. The Hamiltonian of the harmonic oscillator plus recoil and the corresponding eigenfunctions are,

$$\hat{H}_1\varphi_m(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} = \left(\frac{\mathbf{p}_1^2}{2M} + \hbar\omega_m\right)\varphi_m(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} = \left(\hbar\omega_{rec}(\mathbf{k}) + \hbar\omega_m\varphi_m(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}}\right) = E_1\varphi_m(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}} \ ,$$

with the recoil shift $\omega_{rec}(\mathbf{k}) = \hbar\mathbf{k}^2/2M$. For example, the density distribution for bosons is,

$$n_b(\mathbf{r}) = \langle\hat{n}_b(\mathbf{r})\rangle = \langle\hat{\psi}_1^\dagger(\mathbf{r})\hat{\psi}_1(\mathbf{r})\rangle = N|\varphi_0(\mathbf{r})|^2 \qquad with \qquad \int |\varphi_0(\mathbf{r})|^2 d^3r = 1 \ . \quad (47.51)$$

Let us now define the field operators in momentum space,

$$\hat{a}_m^\dagger(\mathbf{k}) \equiv \int d^3r\varphi_m(\mathbf{r})e^{\imath\mathbf{k}\cdot\mathbf{r}}\hat{\psi}_1^\dagger(\mathbf{r}) \qquad , \qquad \varphi_m(\mathbf{r})\hat{\psi}_1^\dagger(\mathbf{r}) \equiv \int d^3k\hat{a}_m^\dagger(\mathbf{k})e^{-\imath\mathbf{k}\cdot\mathbf{r}} \ . \quad (47.52)$$

In momentum space the initial states for bosonic or fermionic clouds are,

$$|\phi_b(0)\rangle = \frac{1}{\sqrt{N!}}\hat{a}_0^\dagger(0)^N|0\rangle \quad , \quad |\phi_f(0)\rangle = \prod_{m=0}^{N-1}\hat{a}_m^\dagger(0)|0\rangle \ .$$

b. After the Bragg pulse the many-body state will be,

$$|\psi_b(\tau_{brgg})\rangle = \frac{1}{\sqrt{2^N N!}}[\hat{a}_0^\dagger(0)+\hat{a}_0^\dagger(\mathbf{K})]^N|0\rangle \quad , \quad |\psi_f(\tau_{brgg})\rangle = \frac{1}{\sqrt{2^N}}\prod_{m=0}^{N-1}[\hat{a}_0^\dagger(0)+\hat{a}_0^\dagger(\mathbf{K})]|0\rangle \ .$$

We see that the 50/50-Bragg pulse transforms every atom independently from the other into a superposition of momentum states. To calculate the new density distribution it is thus sufficient to substitute in Eq. (47.52),

$$\tfrac{1}{\sqrt{2}}\hat{a}_0^\dagger(0) \curvearrowright \tfrac{1}{\sqrt{2}}[\hat{a}_0^\dagger(0)+\hat{a}_0^\dagger(\mathbf{K})] = \tfrac{1}{\sqrt{2}}\int d^3r\varphi_0(\mathbf{r})\left(1+e^{\imath\mathbf{K}\cdot\mathbf{r}}\right)\hat{\psi}_1^\dagger(\mathbf{r}) \ ,$$

and repeat the calculation of (47.51),

$$n_b(\mathbf{r}) = \left|\varphi_0(\mathbf{r})\tfrac{1}{\sqrt{2}}\left(1+e^{\imath\mathbf{K}\cdot\mathbf{r}}\right)\hat{\psi}_1^\dagger(\mathbf{r})\right|^2 = N\varphi_0(\mathbf{r})|^2(1+1\cos\mathbf{K}\cdot\mathbf{r}) \ .$$

c. The wavefunction of the additional atom be $\hat{\psi}_2(\mathbf{r})$. The free-atom Hamiltonian and the corresponding eigenfunctions are,

$$\hat{H}_2\tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} = \frac{\mathbf{p}_2^2}{2M}\tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} = \hbar\omega_2(\mathbf{k})\tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} = E_2\tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} \ .$$

d.

47.2 Bragg diffraction

An important technique for manipulating the atomic motion is by *Bragg diffraction* [5]. It allows the coherent transfer of atoms to other states of motion or to superpositions of motional states, and is extremely useful for applications, such as the realization of matter wave beamsplitters [746] and atomic lasers, or for the targeted excitation of quasi-particles [746, 1259, 1237].

To implement Bragg diffraction, we consider two laser pulses with different frequencies and propagation directions $\omega, \mathbf{k}_\omega$ and $\omega-\Delta\omega, \mathbf{k}_{\omega-\Delta\omega}$, detuned from an atomic resonance and intersecting at the position of atoms under an angle ϑ, as shown in Fig. 47.6(a). The superposition of the electric fields of the light beams,

$$\begin{aligned} E &= E_0e^{\imath(\mathbf{k}_\omega\cdot\mathbf{r}-\omega t)} + E_0e^{\imath[\mathbf{k}_{\omega-\Delta\omega}\cdot\mathbf{r}-(\omega-\Delta\omega)t]} = E_0e^{\imath(\mathbf{k}_\omega\cdot\mathbf{r}-\omega t)}\left(1+e^{-\imath(\mathbf{q}\cdot\mathbf{r}-\Delta\omega t)}\right) \\ &= 2E_0e^{\imath(\mathbf{k}_\omega\cdot\mathbf{r}-\omega t)}e^{-\frac{\imath}{2}(\mathbf{q}\cdot\mathbf{r}-\Delta\omega t)}\cos\tfrac{\mathbf{q}\cdot\mathbf{r}-\Delta\omega t}{2} \ , \end{aligned} \tag{47.53}$$

[5] The idea is analogous to the manipulation of the **k**-vector of light waves by acousto-optic modulators.

where $\mathbf{q} \equiv \mathbf{k}_\omega - \mathbf{k}_{\omega-\Delta\omega}$, produces a standing light wave with an intensity proportional to,

$$|E|^2 = 4E_0^2 \cos^2 \tfrac{\mathbf{q}\cdot\mathbf{r}-\Delta\omega t}{2} = 2E_0^2[1 + \cos(\mathbf{q}\cdot\mathbf{r} - \Delta\omega t) \ , \tag{47.54}$$

with which the atoms interact.

The Bragg diffraction technique has proven extremely efficient: up to 100% of the atoms can be transferred to well-defined momentum sidemodes. In general, the components of a cloud with different momentum modes overlap during the time scale of the Bragg pulses. They only separate spatially after a ballistic flight time, which then allows their identification via absorption imaging.

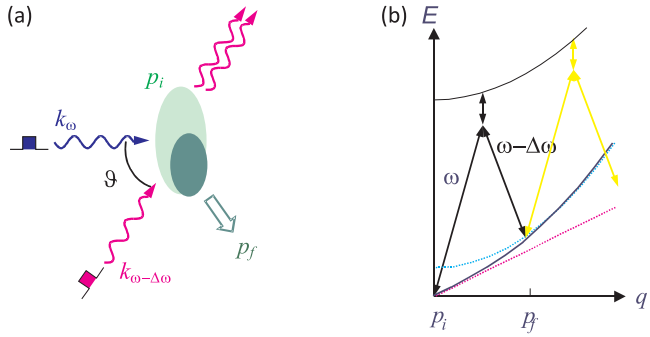

Figure 47.6: Bragg scattering of atoms at a standing light wave. (a) Geometric layout: Short pulses of two laser beams in Raman configuration enclosing an angle of ϑ and detuned from each other by $\Delta\omega$ are simultaneously irradiated into the cloud. (b) Bogolubov dispersion relation for interacting condensates (blue line). The quadratic dispersion relation (cyan) holds for free particles, and the linear dispersion relation (magenta) for phonon excitations.

47.2.1 Interpretations of the Bragg diffraction process

Bragg's diffraction can be treated within the formalism developed in Sec. 47.1.2, as will be shown later, in Sec. 47.2.3. But before that, let us present a simplified approach and several simple pictures illustrating the dynamics of Bragg diffraction.

47.2.1.1 Bragg diffraction picture

The *first interpretation* of this phenomenon is as *matter wave Bragg diffraction* at a standing light wave (i.e. an one-dimensional optical lattice) formed by two crossing pulsed laser beams [6]. We consider atoms initially at rest exposed to the standing wave (47.53) with $\Delta\omega = 0$ and $\mathbf{q} \equiv q\hat{\mathbf{e}}_z$, such that the dipolar potential $U \propto |E|^2$ is, with (47.54),

$$U(z) = U_0 \cos^2 \tfrac{qz}{2} \ . \tag{47.55}$$

[6]Note, that the initial population of the recoil mode should be small. Otherwise, since Bragg diffraction is a coherent and thus reversible process, atoms initially in the recoil mode are transferred back to the original matter wave mode.

Assuming a given finite interaction time τ, the modulation of the local phase of the atoms becomes [7],

$$\boxed{\psi_\tau(z) = \psi_0(z) e^{\imath U(z)\tau/\hbar} = \psi_0(z) e^{\frac{\imath}{2\hbar} U_0 \tau(\cos qz + 1)} = \psi_0(z) e^{\imath U_0 \tau/2\hbar} \sum_n \imath^n J_n(\tfrac{U_0\tau}{2\hbar}) e^{inqz}} \ , \tag{47.56}$$

where J_n are the Bessel functions of the first kind [8].

Example 289 (*Bragg diffraction after a time-of-flight*): To calculate the density distribution after a certain flight time t_{ToF}, we construct the Fourier transform of $\psi_\tau(z)$,

$$\tilde{\psi}_\tau(q) = \tilde{\psi}_0(q) \star \sum_n J_n^2(U_0\tau/2\hbar)\delta(q - nk) \ , \tag{47.57}$$

and we evaluate it via $\tilde{z} \equiv t_{ToF}\hbar q/m$,

$$\tilde{\psi}_\tau(\tilde{z}) = \tilde{\psi}_0(\tilde{z}) \star \sum_n J_n^2(U_0\tau/2\hbar)\delta(\tilde{z} - nt_{ToF}\hbar k/m) \ . \tag{47.58}$$

The density distribution of the expanded condensate $\rho_0(\tilde{z}) = |\tilde{\psi}_0(\tilde{z})|^2 = e^{-(\tilde{z}/2r_{ToF})^2}$, where $r_{ToF} = t_{ToF}\sqrt{k_B T/m}$, is,

$$\rho(\tilde{z}) = \sum_n \rho_0(\tilde{z} - nt_{ToF}\hbar k/m)|J_n(U_0\tau/2\hbar)|^2 \ . \tag{47.59}$$

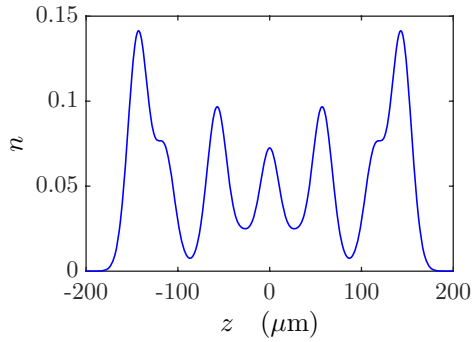

Figure 47.7: (code) Density distribution after time-of-flight.

The condensed wavefunction evolves into a superposition of motional modes, which correspond to the diffraction orders of Bragg scattering and their amplitudes through the Bessel functions J_n. The diffraction efficiency increases with laser intensity and with time.

Now, we need to generalize this result to the propagating standing wave of the expression (47.54). The intensity generates a dipole potential,

$$U(z,t) \approx U_0 \cos^2 \tfrac{q_z z - \Delta\omega t}{2} \ , \tag{47.60}$$

[7] Using the Jacobi-Anger expansion, $e^{\imath\beta\cos x} = \sum_n \imath^n J_n(\beta) e^{\imath nx}$.
[8] Andreas got $\psi_0(z)\sum_n J_n^2(U_0\tau/2\hbar)e^{inqz/2}$.

so that the condensate now evolves according to,

$$\psi(z,t) = \psi_0(z) e^{\imath/\hbar \int_{t_0}^{t_0+\tau} U(z,t)dt} = \psi_0(z) e^{\imath/\hbar \int_{t_0}^{t_0+\tau} U_0 \cos^2 \frac{q_z z - \Delta\omega t}{2} dt} \ . \tag{47.61}$$

For short interaction times, $\tau \ll 2\pi/\Delta\omega$, ...

47.2.1.2 Compton scattering picture

The *second interpretation* is that of *Compton scattering*: Spontaneous Rayleigh scattering of a photon from a mode $\mathbf{k}_\omega$ into a solid angle around $\mathbf{k}_{\omega-\Delta\omega}$ leaves an atom with the recoil momentum $\hbar\mathbf{q} \equiv \mathbf{p}_f \cdot \mathbf{p}_i$. Of course, one can *stimulate* the Rayleigh scattering process by providing the laser mode $\mathbf{k}_\omega - \Delta\omega$ at the entrance. By replacing the spontaneous output mode with a stimulated input mode, we increase the probability for an atomic recoil in the momentum mode $\hbar\mathbf{q}$, which is thus pre-selected by the choice of $\mathbf{k}_{\omega-\Delta\omega}$. Since the elementary scattering process must conserve energy and total momentum,

$$\begin{aligned} \hbar\omega + \frac{p_i^2}{2m} &= \hbar(\omega - \Delta\omega) + \frac{p_f^2}{2m} \\ \hbar\mathbf{k}_i + \mathbf{p}_i &= \hbar\mathbf{k}_f + \mathbf{p}_f \ , \end{aligned} \tag{47.62}$$

we obtain the *Bragg condition*,

$$\boxed{E = \Delta\omega = \frac{p_f^2}{2m} - \frac{p_i^2}{2m} = \frac{(\mathbf{p}_f - \mathbf{p}_i)^2}{2m} + \frac{(\mathbf{p}_f - \mathbf{p}_i)\cdot\mathbf{p}_i}{m} = \frac{q^2}{2m} + \frac{\mathbf{q}\cdot\mathbf{p}_i}{m}} \ . \tag{47.63}$$

Expressed by the Bragg angle, the condition reads,

$$q = \sqrt{(\mathbf{p}_f - \mathbf{p}_i)^2} = \sqrt{\hbar^2\mathbf{k}_i^2 + \hbar^2\mathbf{k}_f^2 - 2\hbar^2\mathbf{k}_i\mathbf{k}_f} \simeq \hbar\mathbf{k}_i\sqrt{2 - 2\cos\theta} = 2\hbar k_i \sin\vartheta/2 \ . \tag{47.64}$$

The efficiency for transferring atoms to the recoil mode depends on the fulfillment of this condition. The Bragg condition can be employed to select higher diffraction orders.

47.2.1.3 Stimulated Raman scattering picture

A *third interpretation* is as *stimulated Raman scattering* between two different kinetic states of the atom [see 47.6(b)]. In fact, the momentum modes $\mathbf{p}_i$ and $\mathbf{p}_f$ have different energies, which, for a condensate, are determined by the Bogolubov spectrum [512]. By varying the angle ϑ in the Bragg condition (47.63), we can choose the amount of energy to be transferred and thus probe the spectrum, i.e. measure the excitation energy $E(\mathbf{q},\mu)$ as a function of the momentum $\mathbf{q}$ and the chemical potential μ in the particle regime $\mathbf{q}^2/2m \gg \mu$, as well as in the phonon regime $\mathbf{q}^2/2m \ll \mu$. On the other hand, varying the detuning $\Delta\omega$ in the Bragg condition (47.63), we selectively address different velocity classes of a gas or condensate, which allows us to probe its velocity distribution. This procedure is called spectroscopy of *recoil-induced resonances* (RIR) [305, 1259]. RIR spectroscopy also provides detailed information on the mean-field energy and the (inhomogeneous) density distribution of a condensate. Note, finally, that Bragg scattering is closely related to *Kapitza-Dirac* scattering of atomic beams, well-known in conventional atom optics [693, 531].

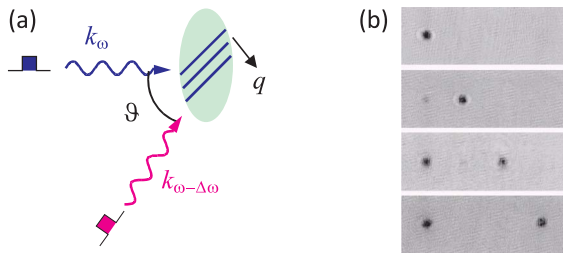

Figure 47.8: Bragg scattering of atomic clouds. (a) Geometric layout as in 47.6. Here, we assume $p_i = 0$. (b) Experiment showing coherent splitting by a Bragg pulse.

47.2.1.4 Coherent splitting

There is a general interest in the possibility of dividing phase space by coherent coupling of otherwise independent modes. We are talking, of course, about double slits or beamsplitters, which represent an essential tool of quantum mechanics. Bragg diffraction realizes a beamsplitter for atomic clouds analogous to the optical beamsplitter. In fact, Bragg diffraction has been used for the realization of output couplers for atom lasers and for atom interferometers. A suggestion that is sometimes made is the following: 'A condensate is a macroscopically populated momentum mode. The Bragg beamsplitter divides the phase space into two entangled output modes. Shouldn't it be possible to generate a macroscopic superposition of two condensates, i.e. a really macroscopic Schrödinger cat?' of the type

$$(|\Psi_+\rangle + |\Psi_-\rangle) \ . \tag{47.65}$$

Their is an obvious fundamental interest to study such states and the mechanisms leading to their decoherence (see Sec. 36.1.1).

To clarify the situation, we first have to say, what we mean by *Schrödinger cat*. A Schrödinger cat is a quantum superposition of many-body states. A perfect cat made of N two-level atoms can be expressed as $|++...\rangle \pm |--...\rangle$. The Einstein-Podolsky-Rosen (EPR) and the Greenberger-Horne-Zeilinger states (GHz) belong to this category. The degree of entanglement of the cat is measured by the information entropy defined as $S = -\langle \log_2 \hat{\rho} \rangle$, where $\hat{\rho}$ is the density operator. The information entropy measures the amount of classical information that can be encoded in the quantum state. For example, the entropy of a perfect cat state is $S = 1$ bit, because if we find one of the atoms in the state $|+\rangle$, we know that all others are in the same state.

Second, we have to explain, what we mean by a *beamsplitter*. Subject to a beam splitting process, every individual atom has the choice between one of two output ports. However, if the process is coherent, every atom will evolve into a coherent superposition, but it does so independently from the other atoms. That is, we can write the state of the atomic cloud as a product state of *Schrödinger kittens* $(|+\rangle \pm |-\rangle)^N$, but no real cat. The information entropy is $S = N$ bit, as for independent atoms. *Clearly, the state (47.65) is NOT the state generated by a beamsplitter!* Nevertheless, the beamsplitter creates a certain correlation between the two modes (see Sec.35.8).

It may come as a surprise, that a condensate composed of totally delocalized atoms coherently interacting with a homogeneous light field (the photons of the Bragg

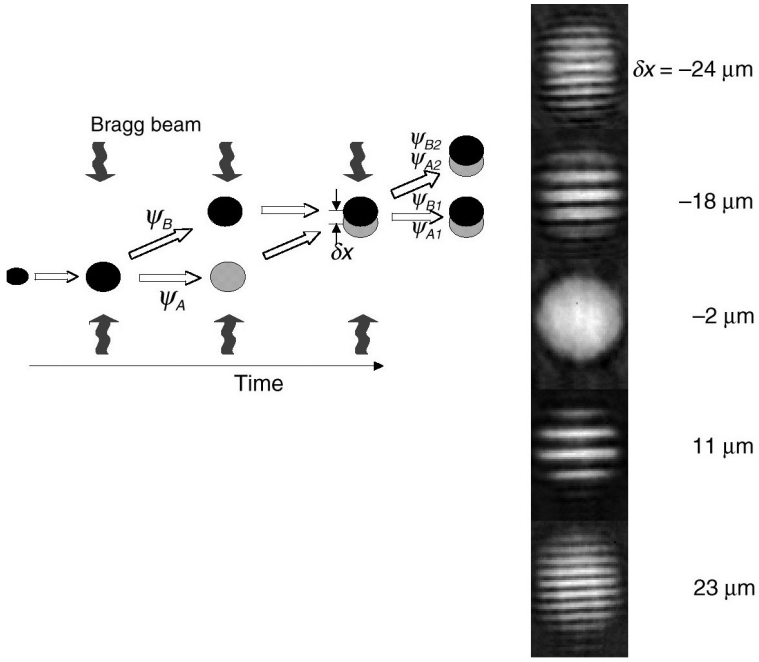

Figure 47.9: Bragg interferometer.

beams are totally delocalized over the field mode including the condensate volume) increases its entropy from 1 to N bits. This argument, however, would be the same for a non-condensed *thermal* cloud being sufficiently cold that the thermal de Broglie wavelengths exceeds the size of the cloud. That is, even in condensates the photons are scattered by individual atoms. The interaction with the light *localizes* one atom in the condensate before removing it from there by recoil. Nevertheless, cooperative interaction of several atoms with a light mode is possible, e.g. in superradiance or when the photons are recycled by means of an optical cavity, as in the Jaynes-Cummings model.

47.2.2 Bragg interferometry of a thermal gas

Even above the critical temperature the momentum distribution of a dilute thermal gas is (slightly) modified by quantum statistics, i.e. by the classical, bosonic or fermionic nature of the gas. The momentum distributions have been calculated in Chp. 44. We have already emphasized that Bragg interferometry can be used to measure the momentum distribution of a gas via RIR spectroscopy, whether the gas is condensed or thermal. Now, let us discuss Bragg interferometry on a thermal gas, based on the articles [853] and [344].

47.2.2.1 Free evolution of a thermal cloud

To describe the Bragg scattering process quantitatively, we interpret it as a *Raman transition between discrete atomic momentum states governed by a Schrödinger equa-*

tion. On the other hand, as long as no radiation is incident the atomic center-of-mass wavefunctions evolve freely or under the constraint of an external potential. That is, both processes concern the same motional degree of freedom. In order to derive a complete quantum model, let us first develop the formalism for the description of the free evolution of a thermal cloud, then we explain how a resonant radiation can be included.

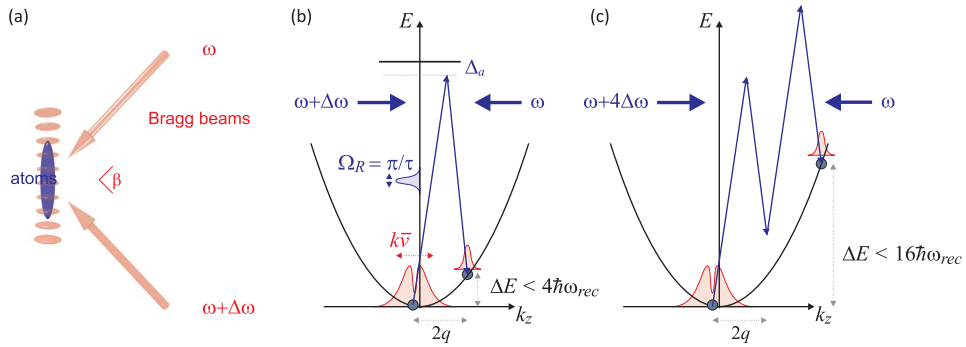

Figure 47.10: (a) Geometry for Bragg diffraction. (b) Illustration of a Raman transition between two points of the free-particle dispersion curve, when the atoms are initially thermally distributed. (c) Same as (a), but now the detuning $\Delta\omega$ is adjusted for second-order Bragg diffraction.

We consider a thermal atomic cloud initially distributed over many momentum classes according to the Maxwell-Boltzmann velocity distribution,

$$D(k_z) = \frac{\hbar}{(2\pi m k_B T)^{1/2}} e^{-\hbar^2 k_z^2/2mk_BT} = \frac{e^{-\pi k_z^2/k_{therm}^2}}{k_{therm}} , \tag{47.66}$$

using $k_{therm} \equiv 2\pi/\lambda_{therm}$ and (43.9). Because of the inhomogeneity of the distribution, any evolution of atoms belonging to specific momentum classes caused by velocity-selective radiation pulses, must be calculated with individual atoms. The final momentum distribution (e.g. after a pulse sequence) can then be obtained by weighing with the individual evolution with the initial momentum distribution [9].

We describe the quantum state of a thermal atom $|\psi\rangle$ as a plane wave, $\langle z|\psi\rangle \propto e^{\imath k_z z}$, which in momentum space corresponds to a Dirac distribution, $\langle k_z|\psi\rangle \propto \delta(z - z_0)$. Without radiative coupling, we describe the evolution in momentum space by the solution of the Schrödinger equation (or propagator),

$$\langle k_z|\psi(t)\rangle = e^{\imath \hat{H} t/\hbar} \langle k_z|\psi(0)\rangle . \tag{47.67}$$

In free space, with the Hamiltonian $\hat{H}_{free} = \hbar^2 k_z^2/2m$, the wavefunction is obviously constant.

In order to couple two intervals of momentum distribution by resonant radiation, we first need to duplicate the Hilbert space,

$$a_{i,k_z}(t) \equiv \langle i|\psi_{k_z}(t)\rangle = \langle i|\langle k_z|\psi(t)\rangle \tag{47.68}$$

[9] The procedure neglects interatomic interactions, which is always a good presumption, for example, for an ultracold Fermi gas [347] or for ^{88}Sr atoms, which have a very small scattering length.

with $i = 1, 2$. Note that, in this case, the Hilbert spaces are not disjunct.

To obtain the atomic momentum distribution after the application of a pulse sequence, we calculate the evolution of the amplitudes a_{j,k_z} for a variety of initial momenta and weigh the final populations of the momentum states with the distribution function $D(k_z)$. The number of atoms expected in the zeroth and first Bragg diffraction order is, therefore,

$$N_j(t) = \int D(k_z)|a_{j,k_z}(t)|^2 dk_z \ . \tag{47.69}$$

47.2.2.2 Bragg scattering and RIR

For large momentum distributions, $T \gg T_{rec}$, the atomic cloud occupies many momentum states, such that the Bragg scattering produces a RIR-like signal. That is, the scattering probability is proportional to the *population difference* of the initial and final momentum states, as discussed in Sec. 42.3.2. The number of scattered atoms/photons is, therefore,

$$\dot{N}_{brg} \propto \Omega_R \left.\frac{\partial D(k_z)}{\partial k_z}\right|_{k_z=\hbar m\Delta\nu/q} \ . \tag{47.70}$$

where,

$$\Omega_R = \frac{\Omega_1\Omega_2}{2\Delta_a} = \frac{1}{\Delta_a}\frac{3\lambda^2}{4\pi}\frac{\Gamma}{\hbar\omega}\sqrt{I_1 I_2} = \frac{3\pi c^2 I}{\hbar\omega^3}\frac{\Gamma}{\Delta_a} \tag{47.71}$$

is the two-photon Rabi frequency. For very narrow momentum distributions, $T \ll T_{rec}$, we may assume the atomic cloud to occupy only a single momentum state,

$$\dot{N}_{brg} \propto \Omega_R D(k_z) \ . \tag{47.72}$$

The transition rate per atom is then given by [1238],

$$\frac{W}{N} = \frac{2\pi\hbar}{N}\Omega_R^2 \sum_f |\langle f|\hat{\rho}^\dagger(\mathbf{k})|g\rangle|^2 \delta(\hbar\nu - E_f + E_g) \equiv 2\pi\Omega_R^2 S(\mathbf{k}, \nu) \ . \tag{47.73}$$

As illustrated in Fig. 47.10, to scatter an atom with the initial wavevector k_z to the next higher momentum state $k_z + 2q$, the Bragg condition requires,

$$\Delta\nu_R = \nu_{R2} - \nu_{R1} = \frac{\hbar(k_z + 2q)^2}{2m} - \frac{\hbar k_z^2}{2m} = \frac{2\hbar q}{m}(k_z + q) \ . \tag{47.74}$$

If we tune $\Delta\nu(\pm\Delta k_z)$ until the Bragg signal $\dot{N}_{brg}$ drops to $e^{-1/2}$,

$$\Delta\nu_R(\Delta k_z) - \Delta\nu_R(-\Delta k_z) = \frac{4\hbar\Delta k_z q}{m} = \frac{4\hbar q}{m}\frac{\sqrt{m k_B T}}{\hbar} = 4q\sqrt{\frac{k_B T}{m}} \ . \tag{47.75}$$

47.2.2.3 Bragg scattering by free atoms

Let us first assume that during the Bragg pulse only two discrete atomic momentum states $j = 0, 1$ are coupled [699, 148, 853, 344], and that trapping potentials are absent or can be neglected. This is justified for Bragg pulse sequences much shorter

than an oscillation period of the trap. We denote the probability amplitudes for the two momentum states by momentum space wavefunctions a_{j,k_z}. They correspond to atoms with initial momenta $\hbar k_z$ that are coupled to states with momentum $\hbar k_z' = \hbar(k_z + 2q)$. The temporal evolution of the amplitudes under the action of the Bragg light is given by the solutions of the Schrödinger equation [853, 344],

$$\begin{pmatrix} a_{0,k_z}(t) \\ a_{1,k_z}(t) \end{pmatrix} = e^{-\imath \hat{H}_R t/\hbar} \begin{pmatrix} a_{0,k_z}(0) \\ a_{1,k_z}(0) \end{pmatrix} , \tag{47.76}$$

with the Hamiltonian,

$$\boxed{\hat{H}_R = \begin{pmatrix} \frac{\hbar^2}{2m}k_z^2 & \frac{1}{2}\hbar\Omega_R \\ \frac{1}{2}\hbar\Omega_R & \frac{\hbar^2}{2m}k_z'^2 - \hbar\delta \end{pmatrix}} , \tag{47.77}$$

where $\Delta = 2\hbar q^2/m - \delta$ is the detuning of the Bragg lasers from the recoil shift. When the Bragg light is switched off, the Hamiltonian simplifies to,

$$\hat{H}_{free} = \begin{pmatrix} \frac{\hbar^2}{2m}k_z^2 & 0 \\ 0 & \frac{\hbar^2}{2m}k_z'^2 - \delta \end{pmatrix} . \tag{47.78}$$

Concatenating temporal evolutions described by $e^{-\imath \hat{H}_R t/\hbar}$ and $e^{-\imath \hat{H}_{free} t/\hbar}$, the phase evolution of individual atoms in momentum state superpositions can be calculated for arbitrary sequences of pulses separated by intervals of free evolution, for example, Ramsey-type sequences.

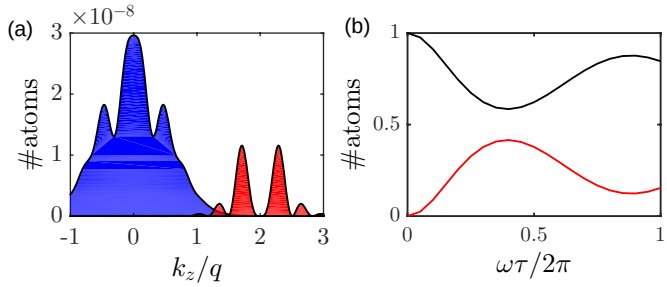

Figure 47.11: (code) (a) Distribution of momentum classes in the direction of k_z after irradiation of a 2π Bragg pulse. The width of the structure is determined by the power broadening of the Raman transition. (b) Temporal evolution of the populations of the momentum states 0 and $2q$.

47.2.2.4 Bragg scattering by trapped particles

When trapped atoms are considered, the problem arises that the Hilbert space of momentum states is simultaneously coupled by two interactions: a moving optical lattice (generated by the Bragg lasers) and the (harmonic) trap. However, the situation gets simpler if a separation of the scales is possible. In general, the duration of a pulse

is very short, $\tau \ll 2\pi/\omega_z$. In contrast, the duration of a free evolution period Δt (e.g. in a Ramsey cycle) may be such, that it is no more negligible compared to a trap oscillation period, so that we need to account for the action of the trapping potential explicitly.

As the trap couples the atomic momenta with the atomic positions ($E_{kin} + E_{pot} = const$), the initial spatial distribution of the atoms must now be considered. For simplicity, we describe it as a thermal Gaussian, similarly to what has been done in Eq. (47.66) for the momentum distribution,

$$G(z) = \sqrt{\frac{m\omega_z^2}{2\pi k_B T}} e^{-m\omega_z^2 z^2/2k_B T} = \frac{e^{-\pi z^2/a_z^4 k_{therm}^2}}{a_z^2 k_{therm}} \ . \tag{47.79}$$

Beginning with the positions z and initial momenta k_z, after a diffraction pulse transferring the recoil $2q$ to part of the atoms and being short enough not to change their positions, the atoms follow classical trajectories. The atomic momenta (now depending on time) are simply the solution of the equation of motion $\hbar \dot{k}_z = -m\omega_z^2 z$ with the initial conditions $z(0) = z$ and $k_z(0) = k_z$, respectively, $k'_z(0) = k_z + 2q$,

$$\begin{aligned} \tilde{k}_z(t) &= k_z \cos\omega_z t - \frac{m\omega_z}{\hbar} z \sin\omega_z t \\ \tilde{k}'_z(t) &= (k_z + 2q)\cos\omega_z t - \frac{m\omega_z}{\hbar} z \sin\omega_z t \ , \end{aligned} \tag{47.80}$$

where the first expression holds for non-diffracted atoms and the second for diffracted atoms. These momenta are substituted for k_z and k'_z, respectively, in the Hamiltonians (47.77) and (47.78). As the Bragg pulses are short compared to the oscillation period, $\tau \ll 2\pi/\omega_z$, the effect of the trapping potential may be neglected during Bragg scattering. This means that the Hamiltonian $\hat{H}_R$ depends on $\tilde{k}_z(t)$, but can be treated as time-independent for the short intervals τ. In contrast, the Hamiltonian for free propagation $\hat{H}_{free}$ depends on the time, if Δt is long. In this case, the phase evolution of the atoms in both coupled states can be described by the time evolution operator as,

$$\boxed{e^{-\imath \hat{H}_{free} t/\hbar} = \begin{pmatrix} \exp\left(-\imath \int_0^t dt \frac{\hbar}{2m} \tilde{k}_z^2(t)\right) & 0 \\ 0 & \exp\left(-\imath \int_0^t dt \left[\frac{\hbar}{2m} \tilde{k}_z'^2(t) - \delta\right]\right) \end{pmatrix}} \ . \tag{47.81}$$

Since the amplitudes a_{j,z,k_z} now also depend on the initial atomic positions, the final populations of the momentum states must be additionally weighted with the initial spatial distribution. Therefore, the Eq. (47.69) for the expected the numbers of diffracted and non-diffracted atoms must be replaced by,

$$N_j(t) = \iint D(k_z) G(z) \left|a_{j,z,k_z}(t)\right|^2 dk_z dz \ . \tag{47.82}$$

In practice, however, it might be a good approximation to assume small displacements around a δ-shaped position distribution. Note, that the transformation (47.80) must be repeated for every free evolution pulse of a sequence.

Example 290 (*Approximation for small displacements*): In practice, we may neglect the displacements, $z \simeq 0$. Then the equations (47.80) simplify to,

$$\tilde{k}_z(t) = k_z \cos\omega_z t \qquad \text{and} \qquad \tilde{k}'_z(t) = (k_z + 2q)\cos\omega_z t \ .$$

Inserting them in (47.81) we obtain for the propagator,

$$e^{-\imath \hat{H}_{free} t/\hbar}$$
$$= \exp\left(-\frac{\imath\hbar k_z^2}{4m\omega_z}(\cos\omega_z t \sin\omega_z t + \omega_z t)\right)\begin{pmatrix} 1 & 0 \\ 0 & \exp\left(-\frac{\imath\hbar q k_z}{2m\omega_z}(\cos\omega_z t \sin\omega_z t + \omega_z t)\right)\end{pmatrix} .$$

In Exc. 47.2.4.1 we will study the behavior of an ultracold atomic cloud subject to a gravitational potential during a Ramsey-Bordé sequence.

47.2.2.5 Bloch equations approach

Experimentally, we observe decoherence of the dynamics described above on a very slow time scale. This phenomenon can be included in a description based on Bloch equations,

$$\frac{d}{dt}\vec{\rho}_{k_z}(\tau) = M_j \vec{\rho}_{k_z}(\tau) \ , \tag{47.83}$$

with

$$\vec{\rho}_{k_z}(\tau) = \begin{pmatrix} \rho_{00,k_z}(\tau) \\ \rho_{01,k_z}(\tau) \\ \rho_{10,k_z}(\tau) \\ \rho_{11,k_z}(\tau) \end{pmatrix} \qquad \text{and} \qquad M_j = \begin{pmatrix} 0 & \Gamma & \frac{\imath}{2}\Omega_R & -\frac{\imath}{2}\Omega_R \\ 0 & -\Gamma & -\frac{\imath}{2}\Omega_R & \frac{\imath}{2}\Omega_R \\ \frac{\imath}{2}\Omega_R & -\frac{\imath}{2}\Omega_R & -\gamma - \imath\Delta_j & 0 \\ -\frac{\imath}{2}\Omega_R & \frac{\imath}{2}\Omega_R & 0 & -\gamma + \imath\Delta_j \end{pmatrix} \tag{47.84}$$

with the solution,

$$\vec{\rho}_{k_z}(\tau) = e^{M_3 t} e^{M_2 t} e^{M_1 t} \vec{\rho}_{k_z}(0) \tag{47.85}$$

with,

$$\Delta_1 = \frac{\hbar}{2m}(k_z + 2q)^2 - \Delta\nu - \frac{\hbar}{2m}k_z^2 \tag{47.86}$$
$$\Delta_3 = \frac{\hbar}{2m}\left[(k_z + 2q)\cos\omega_{tr}\tau\right]^2 - \frac{\hbar}{2m}\left[(k_z + 2q)\cos\omega_{tr}\tau - 2q\right]^2 - \Delta\nu \ .$$

We weigh populations with the initial momentum distribution,

$$N_j(\tau) \equiv \int D(k_z)\rho_{jj,k_z}(\tau)dk_z \ . \tag{47.87}$$

47.2.2.6 Kapitza-Dirac scattering

An atomic beam with longitudinal de Broglie wavelength $\lambda_{dB} = h/p$ diffracted by a solid periodic grating with a slit distance of d receives a transverse amplitude modulation. In the far field, this generates focuses at angles defined by $n\lambda_{dB}/d = \sin\vartheta$.

Alternatively, the grating may consist of a standing light wave detuned from resonances. The standing wave will create a periodic optical potential, which imprints a transverse phase modulation on the atomic beam. In the far field, the result will be the same as for the solid grating. Each atom will evolve into a superposition of momentum sidemodes $\pm n2\hbar k$, without any momentum having been transferred to the atoms. The diffraction angle is again $\sin\vartheta = \pm n2\hbar k/p = \pm n\lambda_{dB}/(\lambda/2)$, where $\lambda/2 = d$ is the periodicity of the standing light wave. However, this is only true if the phase shift is much smaller than π. This scheme is called the *Raman-Nath regime* or the regime of *Kapitza-Dirac scattering*. An equivalent condition for this regime is, that the interaction time is less than a period of oscillation in the optical potential, $\tau \ll \sqrt{\hbar/\omega_{rec}/U}$, or $v_{trans}\tau \ll \lambda$.

The Raman-Nath regime is realized by a very focused optical standing wave. A wave that is not plane can be considered a superposition of many spatial modes. Since (off-resonant) scattering (absorption followed by induced emission) corresponds to a photon redistribution between spatial modes, in a tight waist the phase matching condition is somewhat relaxed and minor corrections to the energy balance are possible. In a certain sense, Kapitza-Dirac scattering is the inverse process of 'forward scattering' of a laser beam passing through an atomic cloud: the roles of light and atoms are exchanged. The requirement that the interaction time be short implies, that the light grating is 'optically dilute' for the atomic beam [10].

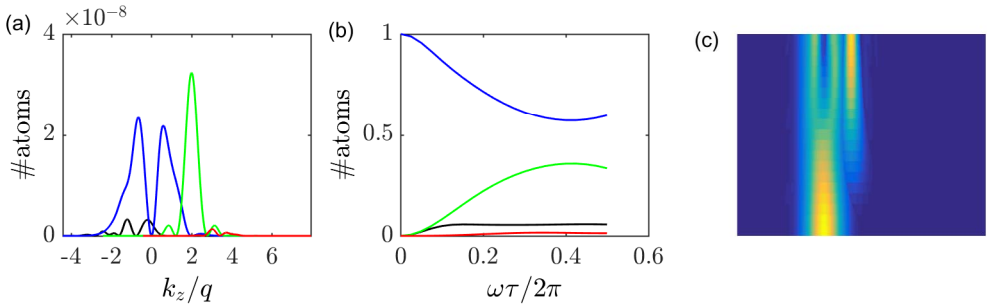

Figure 47.12: (code) (a) Distribution of momentum classes in the direction of k_z after irradiation of a π Bragg pulse. (b,c) Temporal evolution of the populations of the momentum states nq.

For larger Rabi frequencies,

$$\Omega_R \gg \frac{2\hbar q\sigma_{k_z}}{m} , \tag{47.88}$$

with $\sigma_{k_z} = \sqrt{mk_BT/\hbar^2}$ being the width of the momentum distribution, the Doppler broadening is dominated by power broadening, meaning that Bragg diffraction occurs all over the atomic cloud. At some point, however, the Rabi frequency becomes comparable to the energy difference between adjacent momentum states, and Kapitza-Dirac scattering sets in. According to [148] the scattering will stay two-state like as

[10] Note, that we usually employ the term of *optical diluteness* the other way round, i.e. an atomic cloud can be optically dilute (or dense) for a laser beam.

long as the Rabi frequency fulfills the condition,

$$\Omega_R \ll \frac{\hbar}{m}(4q^2 - 2q\sigma_{k_z}) \; . \tag{47.89}$$

In the Kapitza-Dirac regime, the large energy uncertainty, connected with the fast coupling rate, allows several momentum states to be coupled simultaneously. In particular the Bragg Hamiltonian is replaced by,

$$\hat{H}_\tau = \begin{pmatrix} \ddots & \ddots & & & \\ \ddots & \frac{\hbar(k_z-2q)^2}{2m} + \delta & \frac{\Omega_R}{2} & & \\ & \frac{\Omega_R}{2} & \frac{\hbar k_z^2}{2m} & \frac{\Omega_R}{2} & \\ & & \frac{\Omega_R}{2} & \frac{\hbar(k_z+2q)^2}{2m} - \delta & \ddots \\ & & & \ddots & \ddots \end{pmatrix} \; . \tag{47.90}$$

The crossover from the Bragg-diffraction regime to Kapitza-Dirac scattering is a smooth transition. As we will see below, for intermediate Rabi frequencies (here $1\,\mathrm{MHz} > \Omega_R/2\pi > 100\,\mathrm{kHz}$) the neighboring diffraction states, corresponding to momentum shifts of $4\hbar q$ and $-2\hbar q$ (second and minus first order), are scarcely populated. For higher and higher Rabi frequencies, $\Omega_R/2\pi > 1\,\mathrm{MHz}$, the scattering populates more and more diffraction orders.

47.2.2.7 Higher-order Bragg scattering

Higher-order Bragg scattering is possible as well. Then the $2n$-photon Rabi frequency must be calculated and inserted in the second diagonal of (47.90).

47.2.3 Bragg spectroscopy of a condensate

To measure the Bogolubov spectrum, we need to excite perturbations in a condensate and study its reaction [1238].

Let us now imagine that the potential has the form of a standing wave. Technically this can be done by two laser beams having the same frequency crossing at the position of the atoms,

$$V_{trap}(\mathbf{r}, t) \equiv \tfrac{V}{2} e^{\imath \mathbf{q}_1 \cdot \mathbf{r} - \imath\omega t} + \tfrac{V}{2} e^{\imath \mathbf{q}_2 \cdot \mathbf{r} - \imath\omega t} \; . \tag{47.91}$$

Choosing the coordinate system such that, $\mathbf{q}_1 \equiv (k_x, 0, k_z)$ and $\mathbf{q}_1 \equiv (k_x, 0, -k_z)$,

$$V_{trap}(\mathbf{r}, t) = \tfrac{V_x}{2} e^{\imath k_z z - \imath\omega t} + \tfrac{V_x}{2} e^{-\imath k_z z + \imath\omega t} \; , \tag{47.92}$$

with $V_x \equiv V e^{ik_x x}$. With this weak perturbation applied to the atoms, we make the ansatz,

$$\psi(\mathbf{r}, t) = e^{-\imath\mu t/\hbar} \left(\psi_0(\mathbf{r}, t) + u(t) e^{\imath k_z z - \imath\omega t} - v(t) e^{-\imath k_z z + \imath\omega t} \right) \; , \tag{47.93}$$

where the amplitudes of the perturbation, $u(t)$ and $v(t)$, only vary slowly in time. Assuming that ψ_0 is fairly homogeneous, i.e. $\langle \psi_0 | \nabla_z | \psi_0 \rangle \simeq 0$, the momentum transferred to the BEC is,

$$\langle \psi(\mathbf{r}, t) | - \imath\hbar\nabla_z | \psi(\mathbf{r}, t) \rangle = \hbar k_z (|u|^2 - |v|^2) \; . \tag{47.94}$$

We can now solve the Gross-Pitaevskii equation (45.20) in the same way as in Sec. 45.4.1 inserting the ansatz (47.93). The terms proportional to $e^{\imath k_z z - \imath\omega t}$ are,

$$\frac{\hbar^2\mathbf{k}_z^2}{2m}u+\frac{V}{2}\psi_0+g\left(|\psi_0|^2+|u|^2+|v|^2\right)u+g\psi_0^2 v+g|v|^2u+g|\psi_0|^2u=\left(\imath\hbar\frac{\partial}{\partial t}+\hbar\omega+\mu\right)u\,, \tag{47.95}$$

and the analogously for $e^{-\imath k_z z+\imath\omega t}$. Using $\mu = gn = g|\psi_0|^2$ and assuming that the perturbation is weak, $|u|, |v| \ll |\psi_0|$, we obtain,

$$\begin{aligned}\left(\frac{\hbar^2k^2}{2m}+gn\right)u+\frac{V}{2}\psi_0-gnv&=\left(\imath\hbar\frac{\partial}{\partial t}+\hbar\omega\right)u\\ -\left(\frac{\hbar^2k^2}{2m}+gn\right)v-\frac{V}{2}\psi_0+gnu&=\left(-\imath\hbar\frac{\partial}{\partial t}+\hbar\omega\right)v\,.\end{aligned} \tag{47.96}$$

This effect is called *Bragg diffraction* of atoms by a standing light wave.

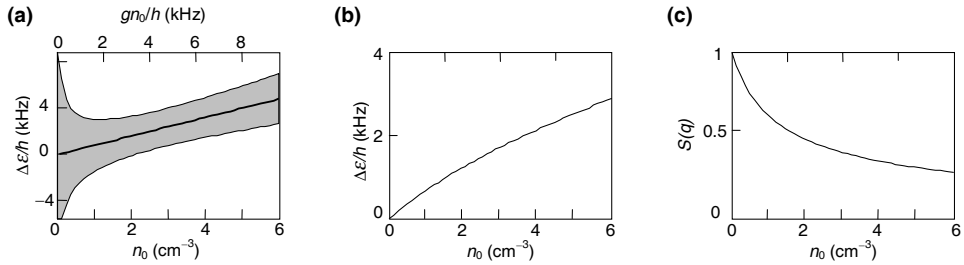

Figure 47.13: Spectrum of elementary excitations.

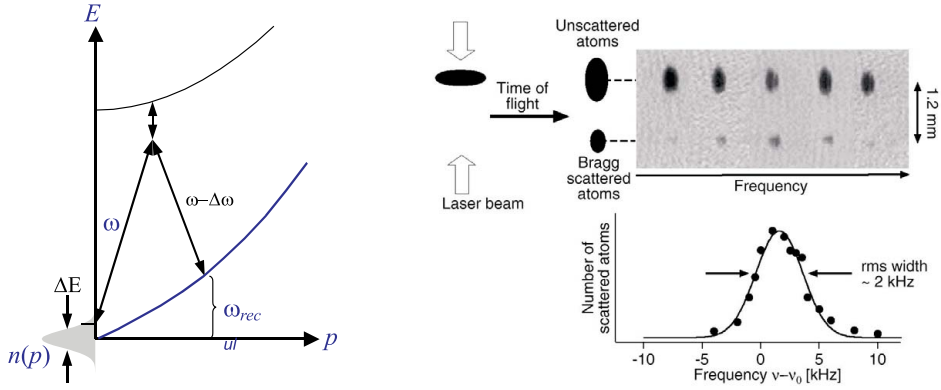

Figure 47.14: Spectrum of elementary excitations.

Using $\mathcal{L} \equiv \frac{\hbar^2\mathbf{k}^2}{2m} + V_{trap} + 2gn - \mu - \imath\hbar\frac{\partial}{\partial t}$, we can write,

$$\begin{pmatrix}\mathcal{L}-\hbar\omega_{\mathbf{k}} & -gn\\ -gn & \mathcal{L}+\hbar\omega_{\mathbf{k}}\end{pmatrix}\begin{pmatrix}u\\ v^*\end{pmatrix}=0\,. \tag{47.97}$$

These equations can be decoupled using the Bogolubov transform.

We calculate the momentum transferred to the BEC, assuming ψ_0 to be fairly homogeneous,

$$\langle\psi(\mathbf{r},t)|-\imath\hbar\nabla|\psi(\mathbf{r},t)\rangle=\hbar\mathbf{q}(|u|^2-|v|^2)\ . \tag{47.98}$$

47.2.4 Exercises

47.2.4.1 Ex: Bragg diffraction in a Ramsey-Bordé interferometer

Simulate the behavior of a cold atomic cloud subject to a gravitational potential during a Ramsey-Bordé sequence using the formalism developed in Sec. 47.2.2.

Solution: *We just need to modify the equations (47.80). The atomic momenta depending on time are now simply the solution of the equation of motion $\hbar\dot{k}_z=mg$ with the initial conditions $z(0)=z$ and $k_z(0)=k_z$, respectively, $k_z(0)=k_z+2q$,*

$$\tilde{k}_z(t)=k_z+\frac{mg}{\hbar}t\qquad\text{and}\qquad\tilde{k}'_z(t)=k_z+2q+\frac{mg}{\hbar}t\ ,$$

and the free space propagator (47.81) becomes,

$$e^{-\imath\hat{H}_{free}t/\hbar}=\begin{pmatrix}\exp\left(-\frac{\imath\hbar}{2m}\int_0^t\left[k_z+\frac{mg}{\hbar}t\right]^2dt\right)&0\\0&\exp\left(-\frac{\imath\hbar}{2m}\int_0^t\left[k_z+2q+\frac{mg}{\hbar}t\right]^2dt+\imath\delta t\right)\end{pmatrix}$$
$$=\exp\left(-\imath\left[\frac{\hbar k_z^2}{2m}t+\frac{g}{2}k_zt^2+\frac{mg^2}{6\hbar}t^3\right]\right)\begin{pmatrix}1&0\\0&\exp\left(-\imath\left[\frac{\hbar qk_z}{m}t+\frac{2mgq}{\hbar}t^2\right]-\imath\Delta t\right)\end{pmatrix}\ .$$

See also Excs. 23.5.6.2 and 23.5.6.3. We can now use this propagator to simulate a Ramsey-Bordé interferometer type sequence in a gravitational field, assuming resonant Bragg pulses, $\delta=2\hbar q^2/m$. It consists of the following sequence:
(i) First $\frac{\pi}{2}$-Bragg pulse,

$$\psi^{(1)}_{k_z}(t=\tfrac{\pi}{2\Omega_R})=e^{-\imath\pi\hat{H}_R/2\hbar\Omega_R}\psi_{k_z}(0)\ ,$$

(ii) free evolution,

$$\psi^{(2)}_{k_z}(t=\tau)=e^{-\imath\hat{H}_{free}(\tilde{k}_z,\tilde{k}'_z)\tau/\hbar}\psi^{(1)}_{k_z}(0)\qquad\text{with}\qquad\left\{\begin{array}{l}\tilde{k}_z(t)=k_z+\frac{mg}{\hbar}t\\\tilde{k}'_z(t)=k_z+2q+\frac{mg}{\hbar}t\end{array}\right.\ ,$$

(iii) π-pulse,

$$\psi^{(3)}_{k_z}(t=\tfrac{\pi}{\Omega_R})=e^{-\imath\pi\hat{H}_R/\hbar\Omega_R}\psi^{(2)}_{k_z}(0)\ ,$$

(iv) free evolution,

$$\psi^{(2)}_{k_z}(t=\tau)=e^{-\imath\hat{H}_{free}(\tilde{\tilde{k}}_z,\tilde{\tilde{k}}'_z)\tau/\hbar}\psi^{(1)}_{k_z}(0)\qquad\text{with}\qquad\left\{\begin{array}{l}\tilde{\tilde{k}}_z(t)=\tilde{k}'_z-2q+\frac{mg}{\hbar}t=k_z+\frac{2mg}{\hbar}t\\\tilde{\tilde{k}}'_z(t)=\tilde{k}_z+2q+\frac{mg}{\hbar}t=k_z+2q+\frac{2mg}{\hbar}t\end{array}\right.\ ,$$

(v) and second $\frac{\pi}{2}$-pulse,

$$\psi^{(3)}_{k_z}(t=\tfrac{\pi}{2\Omega_R})=e^{-\imath\pi\hat{H}_R/2\hbar\Omega_R}\psi^{(2)}_{k_z}(0)\ .$$

Note, that the model is only good for short sequences, $mg\Delta t\ll\hbar q$.

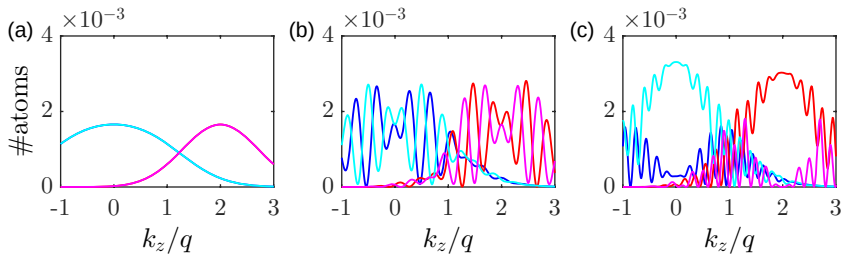

Figure 47.15: (code) Momentum distributions during a Ramsey-Bordé pulse sequence with $N = 10^5$ strontium atoms of temperature $T = 800\,\mathrm{nK}$ subject to Bragg pulses at $\lambda_{brg} = 461\,\mathrm{nm}$ under 60° angle (a) after the first $\frac{\pi}{2}$-pulse, (b) after the π-pulse, and (c) after the second $\frac{\pi}{2}$-pulse. Blue and red line are calculated with $g = 9.81\,\mathrm{m/s^2}$, cyan and magenta lines with $(1 + 7 \cdot 10^{-10})g$. The Rabi frequency is $\Omega_R = (2\pi)\ 30\,\mathrm{kHz}$ and the free evolution time $\tau = 100\,\mu\mathrm{s}$.

47.3 Matter wave superradiance

47.3.1 Classical superradiance

The Bragg beam splitter introduced in the last section does not give rise to collective scattering, even when the atoms are as strongly correlated as in a condensate. On the other hand, collective scattering is known to occur in a classical gas: When two atoms excited to an internal energy level, $\sim hc/\lambda$, are separated by a distance R too large to form a molecule, but smaller than the wavelength of the excited transition, $a_B \ll R \ll \lambda$, the atoms are coupled to the electromagnetic continuum by the same radiation that they emit (see Fig. 47.16). The dipole moments of the atoms stimulate each other to emit, and we observe a synchronized and accelerated relaxation, resulting in a coherent and directional burst of radiation [366, 1085]. The directionality of the radiation is due to a destructive interference of the dipolar radiation patterns emitted by the atoms in all directions except the direction chosen by the first emitted photon. This direction is random (except when bosonically stimulated). The atomic sample evolves, during this time, to a state of coherent superposition, until all the atoms are deexcited. This phenomenon is called *Dicke superradiance*. A similar effect exists for matter waves, and will be discussed in the following sections [649].

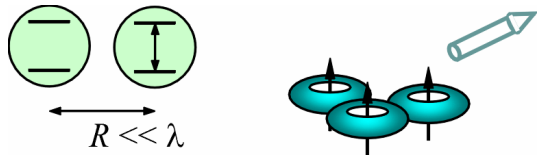

Figure 47.16: Superradiance assumes small interatomic distances compared to the wavelength of the excited dipole. Toroidal interference patterns interfering constructively in only one direction.

47.3.2 Matter wave superradiance & CARL

We consider the process of Rayleigh scattering from a condensate. The scattering rate obviously depends on the number of atoms and the laser intensity. The crucial point now is, that this rate can be stimulated by populations in the output modes, that is, the modes of scattered light and the atomic recoil modes. Matter and light participate in the scattering process as equal partners. In Sec. 47.2.1 we showed that Bragg scattering can be interpreted as *optical stimulation of matter wave scattering*. By analogy, it is possible to imagine a process of *wave matter stimulation of light scattering*. We will now discuss such a process, called *superradiant Rayleigh scattering* or *matter wave superradiance* (MWSR) [649], with the help of the small cartoon shown in Fig. 47.17. See also (watch talk).

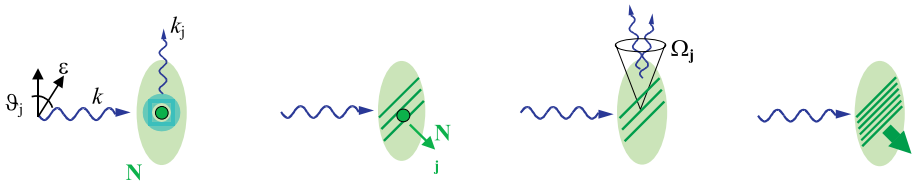

Figure 47.17: Cartoon for MWSR (see text).

Let us imagine an elongated condensate, subject to a magnetic field directed along its long axis and illuminated perpendicularly to the long axis by a linearly polarized laser beam. The scattered light is emitted into a (toroidal) dipolar radiation pattern. The fraction of the light scattered into the solid angle Ω_j, which is inclined by angle ϑ_j with respect to the polarization of the incident laser is $\Omega_j \sin^2\vartheta_j/(8\pi/3)$. Of course, the number of scattered photons also depends on the optical cross section σ and the number of scattering atoms N_0. When an atom, recoiling due to the transfer of one unit of photonic momentum, moves with a speed of a few centimeters per second through the condensate, it interferes with other atoms of the condensate, thus forming a wave matter grating. The grating, the lifetime of which is long in comparison to the scattering rate, now stimulates subsequent photons to follow the same path Ω_j and receives, in turn, the scattering atoms. In other words, the bosonic stimulation of the scattering process by the N_j atoms already populating the recoil mode amplifies the photon scattering rate by a factor of $N_j + 1$. The differential optical cross section (power P_j scattered into the direction Ω_j divided by the laser intensity I) is [649],

$$\frac{d\sigma}{d\Omega_j} = \frac{P_j}{I} = \frac{\Omega_j \sin^2\vartheta_j}{8\pi/3}\sigma N_0(N_j+1)\ . \tag{47.99}$$

Each scattering event of a photon into the mode Ω_j transfers an atom to the recoil mode N_j:

$$\dot{N}_j = P_j/\hbar\omega \equiv G_j N_j \qquad \text{where} \qquad G_j = \frac{I}{\hbar\omega}\sigma\frac{\Omega_j \sin^2\vartheta_j}{8\pi/3}N_0\ . \tag{47.100}$$

The phase matching condition is satisfied for a solid angle of approximately $\Omega_j = \lambda^2/A_j$, where A_j is the cross-sectional area of the condensate. If l_j is the length of

condensate, we can write,

$$G_j = \frac{I}{\hbar\omega}\sigma\frac{\sin^2\vartheta_j}{8\pi/3}n_0\lambda^2 l_j \ . \tag{47.101}$$

With the atomic density $n_0 = N_0/(A_j l_j)$, the factor $n_0\lambda^2 l_j$ describes the optical density of the BEC in the direction of the scattering. Therefore, we obtain *exponential gain* for the atom number N_j, that is, the process is self-amplifying.

Using the terms of the *dressed atom* picture, we would say that the excited state of our system is formed by the BEC and the laser mode. This state relaxes to a state formed by the recoiled atoms and the scattered photons. The exponential gain occurs, when this system exhibits inversion. The inversion is maintained, until the BEC is completely transferred to the momentum recoil modes [11].

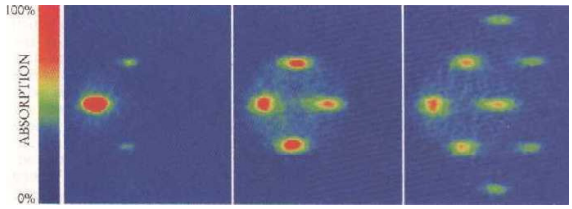

Figure 47.18: Observation of matter wave superradiance.

It is instructive to compare Dicke superradiance and matter wave superradiance. Dicke superradiance is induced by an electronic coherence between adjacent atoms. It requires a sufficiently long coherence time for the atomic dipoles. On the other hand, MWSR is a coherence effect between two states of the atomic center-of-mass motion, i.e. the condensed state and a momentum sidemode. A long lifetime of this coherence is necessary to allow for correlations between successive scattering events. The coherence lifetime corresponds to a coherence length, which for a condensate is equal to its physical size, whereas for a thermal cloud, it only corresponds to its thermal Broglie wavelength. This explains why it is difficult to observe MWSR with non-condensed atomic clouds.

Since the scattered photons quickly leave the BEC, there is no feedback or bosonic stimulation by the optical output mode. This can be interpreted as a fast decaying cavity mode, and the regime is called the *bad cavity limit*. Let us now imagine, that the photons were recycled, for example, via an optical cavity constructed around the BEC and reflecting back the photons emitted in the solid angle Ω_j [12]. The mirrors of the cavity create reflection images of the radiating atoms, which increase the *density of states*, the scattering rate, and the gain G_j increase by a factor of $8F/\pi$. An

[11] Superradiant scattering is due to a nonlinear coupling between two matter waves and two optical waves in a *four-wave mixing* process (4WM) interpreted as scattering of light *from* a wave matter *stimulated* by a wave matter mode. The process does not require nonlinearity due to collisions, but it works with an ideal gas, $g \to 0$. This distinguishes it from the 4WM of four matter waves, studied in Sec. 46.3.4 and interpreted as a scattering of atoms by a matter wave stimulated by matter wave mode, and 4WM in quantum optics involving four photons. But in all cases bosonic stimulation is crucial.

[12] Alternatively, we may imagine a scheme decelerating of the group velocity of the light pulse.

interesting question now is, what happens in the limit $F \to \infty$. If the decay of the cavity mode, and therefore the removal of photons from the coherent interaction zone (which is precisely the volume occupied by the BEC) is slow, the MWSR process seems to be doubly stimulated, optically and atomically. However, in this case we also expect the inverse process, where photons are scattered back to the original mode, to occur and to be stimulated by the number of atoms N_0 in the condensate. We see that the simple picture of bosonic stimulation does not work in this case, and a more complete model including the possibility of Rabi oscillations amplified by stimulated emission is necessary [13].

47.3.3 Amplification of matter and light waves

The feedback-induced exponential gain giving rise to the phenomenon of MWSR can be used to construct a phase-coherent amplifier of matter and light waves. After all, the momentum side modes observed in the MWSR process [649] already represent amplified vacuum fluctuations. To experimentally realize a *coherent matter wave amplifier* [749, 651], it is sufficient to replace the vacuum fluctuations of the original MWSR experiment with a small *seed condensate*: $\sim 0.1\%$ of the 'mother condensate' proved sufficient to stimulate the matter wave amplifier. The seed condensate was created by Bragg diffraction transferring atoms from the mother BEC to another momentum state (see Sec. 47.2). The matter wave grating formed by interference of the seed condensate and the mother BEC was subsequently amplified by a MWSR pulse. The gain for the atom number in the seed condensate was 10 to 100 depending on the intensity and duration of the MWSR pulse. Finally, the coherence of the amplification process was demonstrated by *active atom interferometry* using the Ramsey scheme: One of the interferometer arms consisted of the amplified seed condensate and the other of a reference condensate (local oscillator) especially created by Bragg diffraction from the mother condensate. The observation of interference between these two matter waves proved the coherence of the amplification process and the existence of a well-defined phase relationship between the input and the output of the matter wave amplifier.

In analogy to electronics, we may consider the coherent matter wave amplifier as an *active device* complementing the atom optical toolbox of *passive device*s (see Sec. 46.3.1).

47.3.4 Four-wave mixing of optical and matter waves

We will now make an attempt to categorize the various scattering processes involving condensates. Let us first return to the radiation pressure [Fig. 47.20(a)], where an incident photon is spontaneously scattered into a random direction. The isotropy of

[13] The phenomenon of the matter wave superradiance can be understood without quantization of the atomic motion [**?**] and, in particular, without quantum degeneracy. A cold and dense thermal cloud can show the phenomenon of MWSR [1413]. The scattered light forms together with the pump light, a propagating standing light wave, from which the atoms are scattered by Bragg diffraction. Atoms are accelerated by the CARL effect [305, 173, 775, 918, 917, 749, 651, 650] through a coherent redistribution of photons between the pump and scattered modes. However, as was shown later-on, the different recoil modes of the condensate exhibit phase-coherence, which is not explained by a theories treating the atomic motion semi-classically.

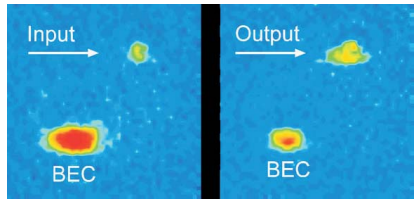

Figure 47.19: Matter wave amplification of a 'seed condensate' at the expense of a 'mother condensate'. Time-of-flight imaging visualizes the condensate's momentum distribution.

the scattering process can, however, be broken when certain directions (i.e. spatial modes) are favored by bosonic stimulation. The symmetry of the roles of matter wave modes and light modes allows us to treat both on the same footing, for example, we can stimulate scattered modes either by matter of light waves.

Let us first have a look at stimulation by optical modes [Fig. 47.20(b) and (c)]. Fig. (b) describes optical four-wave mixing (4WM) in nonlinear optical media, i.e. *optically stimulated scattering of photons* from a standing light wave, which is a 4WM process of 4 photons. Fig. (c) describes Bragg scattering, i.e. an *optically stimulated scattering of atoms* by a standing light wave, which is a 4WM process of 2 photons and 2 atoms.

Similarly, a scattering process can also be stimulated by a macroscopic number of atoms in a recoil mode [Fig. 47.20(d) and (f)]. Fig. (d) describes superradiant Rayleigh scattering and matter wave amplification, i.e. scattering of photons *stimulated by a de Broglie wave*, which again corresponds to 4WM of 2 photons and two atoms. Fig. (e) describes amplification of a laser pulse by superradiant Rayleigh scattering, i.e. scattering of photons in a matter wave with *double stimulation by light waves and de Broglie waves*, which once again is a 4WM process of 2 photons and 2 atoms. Finally, Fig. (f) describes the basic process of nonlinear atom optics, i.e. the scattering of atoms by a matter wave *stimulated by de Broglie waves*, which is a 4WM process of 4 atoms.

47.4 Condensates in electronically excited states

The interaction between condensates and light has, so far, been treated in the limit where the *population of excited states can be neglected or adiabatically eliminated.* An example was the coherent coupling of different kinetic states of an atom by a method called *Bragg diffraction* discussed in Sec. 47.2.

On the other hand, atoms can have metastable excited states, which can introduce new degrees of freedom, and a whole world of new problems emerges that need to be addressed: How do condensed atoms move, when they are in different states of internal excitation (or superposition of states), and how do atoms in different states interact with each other? We will now turn our attention to coherent coupling of internal states [14].

[14] We will disregard, for the moment, possible effects due to inhomogeneous broadening caused by the finite volume of the cloud inside the potential (Zeeman shift in magnetic traps or dynamic Stark shift optical traps) or effects due to interatomic interactions. But we have to keep in mind, that

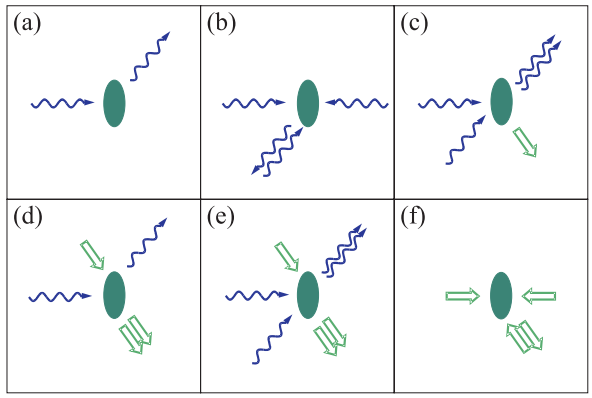

Figure 47.20: Schematic comparison of 4WM processes between light and matter wave modes. (a) Spontaneous emission, (b) classical 4WM of light modes, (c) Bragg scattering, (d) superradiant Rayleigh scattering, respectively, matter wave amplification, (e) optical amplification, and (f) 4WM of matter waves.

In Sec. 47.4.1 we will show how to generalize the second-quantized formalism introduced in 45.2.1 in order to deal with coupled condensates in different states of internal excitation.

In Sec. 47.4.2 we will discuss examples of how coherent coupling of two states can be accomplished either by radiofrequency/microwave radiation or by two laser beams in Raman configuration. In order to avoid spontaneous relaxation, we often choose state with low excitation energy, for example, within the hyperfine structure ($\hat{H} \sim \mathbf{I}\cdot\mathbf{J}$) or the Zeeman structure ($\hat{H} \sim \mu \cdot B$) of the electronic ground state. But one can also consider the coupling between different *kinetic states* of free atoms $\hat{H} \sim \mathbf{p}^2/2m$, or the *output coupling* of atoms confined to a trapping potential ($\hat{H} \sim \frac{m}{2}\omega^2\mathbf{r}^2$), or even a chemical coupling between a vibrational state of two atoms bound together to form a molecular and a state, where the same two atoms are free and involved in an elastic collision.

Finally, in Sec. 47.4.3 we will show how to harness the forces induced by atom-light coupling in order to design new geometries of trapping potentials.

47.4.1 Theory of the interaction of condensates with light

Let us consider two Bose-Einstein condensates in the mean-field approximation consistent of atoms in two different internal excitation states, ψ_1 and ψ_2, separated by the energy $\hbar\omega_0$. We illuminate the BEC by a plane wave of monochromatic light with the frequency ω. The formal procedure consists of constructing the Hamiltonian of

interatomic interaction can have a big impact on the dynamics, because the chemical potential of each condensate depends on its number of atoms. Thus, in view of the inhomogeneity of the trapping potential, the transfer of atoms can excite oscillations and sound waves in the condensates.

individual atoms, as done in Eq. (38.2), and then quantizing the field of matter [1036],

$$\hat{H}_{atom} = |1\rangle \hat{H}^{(1)}_{cm} \langle 1| + |2\rangle (\hat{H}^{(2)}_{cm} + \hbar\omega_0)\langle 2| \qquad \text{where} \qquad \hat{H}^{(j)}_{cm} = \frac{\hat{\mathbf{p}}^2}{2m} + V^{(j)}_{trap}(\hat{\mathbf{r}}) \ , \tag{47.102}$$

where we allow for the fact that the trapping potentials can be different for the two excitation states. We assume that atoms in different states of excitation are distinguishable, such that their respective wavefunctions commute:

$$\hat{\psi}_j(\mathbf{r}) \equiv |j\rangle\langle j|\hat{\psi}(\mathbf{r}) \quad , \quad [\hat{\psi}_j(\mathbf{r}), \hat{\psi}_{j'}(\mathbf{r})] = \delta_{jj'}\delta^3(\mathbf{r}-\mathbf{r}') \ . \tag{47.103}$$

However, we need to consider interatomic collisions which, in the mean-field approximation (45.19) are described by,

$$\hat{H}^{(j)}_{mf} = \int \hat{\psi}^\dagger_j(\mathbf{r}) \frac{2\pi\hbar^2 a_s}{m} \hat{\psi}_j(\mathbf{r}) d^3r \ . \tag{47.104}$$

The total atomic Hamiltonian is then a generalization of the many-body Hamiltonian (45.6),

$$\boxed{\mathcal{H}_{atom} = \int \hat{\psi}^\dagger_1(\mathbf{r}) \left(\hat{H}^{(1)}_{cm} + \hat{H}^{(1)}_{mf}\right) \hat{\psi}_1(\mathbf{r}) d^3r + \int \hat{\psi}^\dagger_2(\mathbf{r}) \left(\hat{H}^{(2)}_{cm} + \hat{H}^{(2)}_{mf} + \hbar\omega_0\right) \hat{\psi}_2(\mathbf{r}) d^3r} \ . \tag{47.105}$$

47.4.1.1 Interaction with a single light mode

The normalized annihilation operator for a photon in mode $\mathbf{k}$ is,

$$\vec{\mathcal{E}}^+(\mathbf{r}) = \sqrt{\tfrac{\hbar\omega}{2\varepsilon_0 V}} \vec{\epsilon} \hat{a} e^{\imath \mathbf{k}\cdot\mathbf{r}} \ . \tag{47.106}$$

The semi-classical Hamiltonian (the light not being quantized) of individual particles is, in the rotating wave approximation,

$$\hat{H}_{field} = \hbar\omega \hat{a}^\dagger \hat{a} \qquad \text{and} \qquad \hat{H}_{int} = -\hat{\mathbf{d}} \cdot \hat{\vec{\mathcal{E}}} = -|2\rangle \hat{\mathbf{d}}^+ \cdot \hat{\vec{\mathcal{E}}}^+ \langle 1| - |1\rangle \hat{\mathbf{d}}^- \cdot \hat{\vec{\mathcal{E}}}^- \langle 2| \ . \tag{47.107}$$

For a condensate we still need to second-quantize the interaction part of the Hamiltonian which, disregarding collisions gives [15],

$$\boxed{\mathcal{H} = \hat{H}_{field} + \mathcal{H}_{atom} - \int \left(\hat{\mathbf{d}}^+ \cdot \hat{\vec{\mathcal{E}}}^+ \hat{\psi}^\dagger_2(\mathbf{r}) \hat{\psi}_1(\mathbf{r}) + \hat{\mathbf{d}}^- \cdot \hat{\vec{\mathcal{E}}}^- \hat{\psi}^\dagger_1(\mathbf{r}) \hat{\psi}_2(\mathbf{r})\right) d^3r} \ . \tag{47.108}$$

With the Hamiltonian (47.108) we derive the Heisenberg equations for the condensate respecting the commutation rules (47.103) [16],

$$\begin{aligned} \dot{\hat{\psi}}_2 &= -\tfrac{\imath}{\hbar}(\hat{H}_{cm} + \hbar\omega_0)\hat{\psi}_2 + \tfrac{\imath}{\hbar}\hat{\mathbf{d}}^+ \cdot \hat{\vec{\mathcal{E}}}^+ \hat{\psi}_1 \\ \dot{\hat{\psi}}_1 &= -\tfrac{\imath}{\hbar}\hat{H}_{cm}\hat{\psi}_1 + \tfrac{\imath}{\hbar}\hat{\mathbf{d}}^- \cdot \hat{\vec{\mathcal{E}}}^- \hat{\psi}_2 \ . \end{aligned} \tag{47.109}$$

[15] Or, by defining the Rabi frequency g_1 generated by a single photon, $\mathcal{H}_{int} = -\imath\hbar g_1 \hat{a} \int d^3\mathbf{r} \hat{\psi}^\dagger_2(\mathbf{r}) e^{\imath\mathbf{k}\cdot\mathbf{r}} \hat{\psi}_1(\mathbf{r}) + h.c.$.

[16] In the first quantization, these equations would simply be the equations of motion for the amplitudes of the fundamental and excited states.

We transform to the non-rotating coordinate system by $\tilde{\psi}_2 \equiv \psi_2 e^{\imath\omega t}$ and $\tilde{\vec{\mathcal{E}}}^+ \equiv \hat{\vec{\mathcal{E}}}^+ e^{\imath\omega t}$ introducing the detuning $\Delta \equiv \omega - \omega_0$:

$$\partial_t \tilde{\psi}_2 = \imath(\Delta - \tfrac{1}{\hbar}\hat{H}_{cm})\tilde{\psi}_2 + \tfrac{\imath}{\hbar}\hat{\mathbf{d}}^+ \cdot \tilde{\vec{\mathcal{E}}}^+ \tilde{\psi}_1 \ . \tag{47.110}$$

Making the adiabatic approximation $\partial_t \tilde{\psi}_2 = 0$ and disregarding the external degree of freedom, $\hat{H}_{cm} = 0$, we obtain,

$$\tilde{\psi}_2 = \frac{\imath \hat{\mathbf{d}}^+ \cdot \tilde{\vec{\mathcal{E}}}^+}{\hbar\Delta} \tilde{\psi}_1 \ . \tag{47.111}$$

47.4.1.2 Heisenberg equation for the light field

Similarly, we can write the Heisenberg equation for the light mode,

$$\frac{d\hat{a}}{dt} = \frac{\imath}{\hbar}[\mathcal{H}, \hat{a}] = -\imath\omega\hat{a} + \imath\sqrt{\tfrac{\omega}{2\varepsilon_0 V}} \int \hat{\mathbf{e}}_{\mathbf{k}} e^{-\imath\mathbf{k}\cdot\mathbf{r}} \cdot \left(\hat{\mathbf{d}}^+ \hat{\psi}_2^\dagger \hat{\psi}_1 + \hat{\mathbf{d}}^+ \hat{\psi}_1^\dagger \hat{\psi}_2\right) d^3r \ . \tag{47.112}$$

The integration of this gives the distribution of the fields (incident and scattered), such that,

$$\tilde{\vec{\mathcal{E}}}^+(\mathbf{r}) = \tilde{\vec{\mathcal{E}}}^+_{in}(\mathbf{r}) + \int K(\mathbf{d}, \mathbf{r} - \mathbf{r}') \hat{\psi}_1^+(\mathbf{r}') \hat{\psi}_1(\mathbf{r}') d^3\mathbf{r}' \ , \tag{47.113}$$

with the kernel:

$$K(\mathbf{d}, \mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \left[k^2 (\mathbf{R} \times \mathbf{d}) \times R \frac{e^{\imath kR}}{R} + [3\mathbf{R}(\mathbf{R}\cdot\mathbf{d} - \mathbf{d})] \left(\frac{1}{R^3} - \frac{\imath k}{R^2} \right) e^{\imath kR} \right] \ . \tag{47.114}$$

We focus on the first term dominating in the far-field, and neglect the second term by letting $R \approx r - \hat{\mathbf{e}}_R \cdot \mathbf{r}'$ and $\hat{R} \approx r$. We also define $\mathbf{k}_s \equiv k\hat{\mathbf{e}}_R$, and we only retain the term of order $1/R$. In this Born approximation for optically thin media, we obtain,

$$K(\mathbf{d}, \mathbf{r}) \simeq \frac{1}{4\pi\varepsilon_0} \frac{e^{ikR}}{r} k^2 (\mathbf{r} \times \mathbf{r}) \times \mathbf{d} e^{-\imath\mathbf{k}_s \mathbf{r}'} \ . \tag{47.115}$$

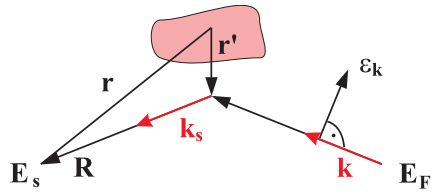

Figure 47.21: Scheme for the light scattering off a condensate.

47.4.1.3 Incident plane waves

When we now excite the condensate by a plane wave,

$$\hat{\vec{\mathcal{E}}}^+_{in}(\mathbf{r}) = \tfrac{1}{2}\vec{\epsilon} e^{\imath\mathbf{k}\cdot\mathbf{r}} \ , \tag{47.116}$$

we derive in the Born approximation of the equation (47.113):

$$\tilde{\vec{\mathcal{E}}}_s^+(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0}\frac{e^{\imath kR}}{r}k^2\mathbf{r}\times(\mathbf{r}\times\hat{\mathbf{d}}^-)\int e^{-\imath\mathbf{k}_s\mathbf{r}'}\hat{\psi}_1^\dagger(\mathbf{r}')\hat{\psi}_2(\mathbf{r}')d^3r' \ , \tag{47.117}$$

and from this the fluorescence spectrum.

47.4.2 STIRAP & adiabatic sweep

A frequent problem for experimenters is the need to transfer a magnetically trapped atomic cloud from one Zeeman or hyperfine state to another. We will present here two techniques called STImulated Raman Adiabatic Passage and *adiabatic sweep*.

47.4.2.1 Adiabatic sweep

To discuss the adiabatic sweep, we consider the example of a ^{87}Rb cloud trapped in the state $|F, m_F\rangle = |2, -2\rangle$. The application of resonant radiofrequency radiation to the transition $|2, -2\rangle$-$|2, -1\rangle$ also couples all other m_F states and causes a diffusion of the atomic populations toward an uncontrollable mixture of states. An alternative is the application of a ramp sweeping the radiofrequency from red to blue (or vice versa). Such a ramp is able to transfer the entire population toward the opposite Zeeman state $|2, +2\rangle$. To see this, we solve the Schrödinger equation, $|\psi(t + dt)\rangle = e^{\imath H\ dt}|\psi(t)\rangle$, iteratively,

$$H = \begin{pmatrix} 0 & \frac{1}{2}\Omega & 0 & 0 & 0 \\ \frac{1}{2}\Omega & -\Delta & \frac{1}{2}\Omega & 0 & 0 \\ 0 & \frac{1}{2}\Omega & -2\Delta & \frac{1}{2}\Omega & 0 \\ 0 & 0 & \frac{1}{2}\Omega & -3\Delta & \frac{1}{2}\Omega \\ 0 & 0 & 0 & \frac{1}{2}\Omega & -4\Delta \end{pmatrix} . \tag{47.118}$$

The initial population distribution is $|\psi(t)\rangle = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \end{pmatrix}^t$. Ω is the Rabi frequency generated by the radiofrequency, $\Delta(t)$ is the instantaneous detuning. The curves of Fig. 47.22 show the temporal evolution of populations $|\langle k|\psi(t)\rangle|^2$.

The disadvantage of this method is that only the external (fully stretched) states $|m_F| = F$ can be interconverted.

47.4.2.2 Sweep through a dark resonance

To discuss STIRAP, let us think of how to transfer atoms from the state $|1\rangle \equiv |2, 2\rangle$ to $|2\rangle \equiv |2, 1\rangle$. The general idea consists in applying two radiation fields with Rabi frequencies Ω_{13} and Ω_{23}, tuned a bit out of resonance with an intermediate state $|3\rangle$, $\Delta_{13} = \Delta_{23} \neq 0$, in a counterintuitive pulse sequence. That is, the field Ω_{23} is applied first and then adiabatically turned down, while the field Ω_{13} is ramped up. This method is capable of transferring all atoms.

Considering the example of the preceding section, we will discuss here another option (see Fig. 47.23). We consider continuous microwave fields with fixed tunings Δ_{13} to the red of the state $|3\rangle \equiv |1, 1\rangle$ state. Now, we apply a ramp to the second

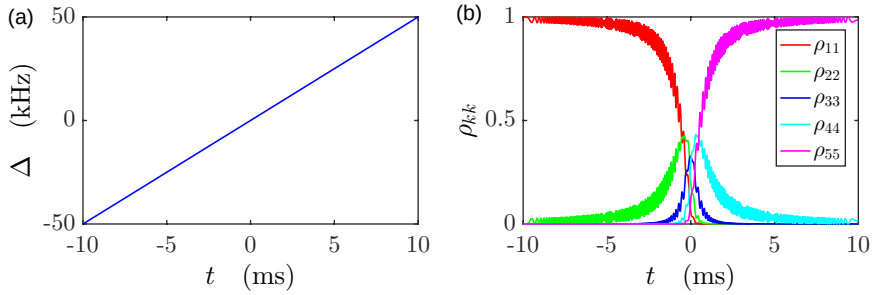

Figure 47.22: (code) Adiabatic sweep through the ground state ^{87}Rb $F = 2$. The Rabi frequency is $\Omega = (2\pi)8$ kHz. The frequency ramp is $\Delta(t) = \frac{t}{t_m}\,(2\pi)50$ kHz with $t_m = 10$ ms. The red line shows the evolution of the population in the state $|2,-2\rangle$, the green line of state $|2,+2\rangle$, and the blue line is the sum of the populations of all other states.

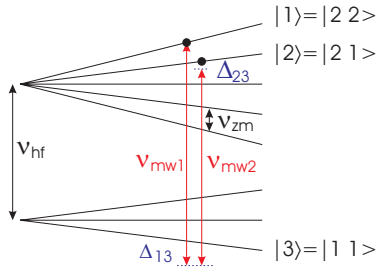

Figure 47.23: STIRAP.

microwave field Δ_{23}, such that the two radiation fields, at some point, cross the Raman resonance, for example,

$$\nu_{mw1} = \nu_{hf} + 3\nu_{zm} + \Delta_{13} \qquad \text{and} \qquad \nu_{mw2}(t) = \nu_{hf} + 2\nu_{zm} + \Delta_{23}(t)\ . \tag{47.119}$$

The evolution of the populations can be simulated by iterative solution of the Schrödinger equation, $|\psi(t+dt)\rangle = e^{iH\ dt}|\psi(t)\rangle$ with,

$$\hat{H} = \begin{pmatrix} 0 & 0 & \frac{1}{2}\Omega_{13} \\ 0 & \Delta_{23} - \Delta_{12}(t) & \frac{1}{2}\Omega_{23} \\ \frac{1}{2}\Omega_{13} & \frac{1}{2}\Omega_{23} & \Delta_{23} \end{pmatrix}\ . \tag{47.120}$$

The initial population distribution is $|\psi(t)\rangle = \begin{pmatrix} 1 & 0 & 0 \end{pmatrix}^t$. The curves of Fig. 47.24 show the temporal evolution of the populations $|\langle k|\psi(t)\rangle|^2$.

47.4.3 Condensate in adiabatic potentials

Adiabatic potentials have already been introduced in Secs. 38.1.3 and 43.4.3. Here, we will focus on the dynamics of condensed atoms in different states of electronic excitation, when these states are subject to different potentials and radiation fields

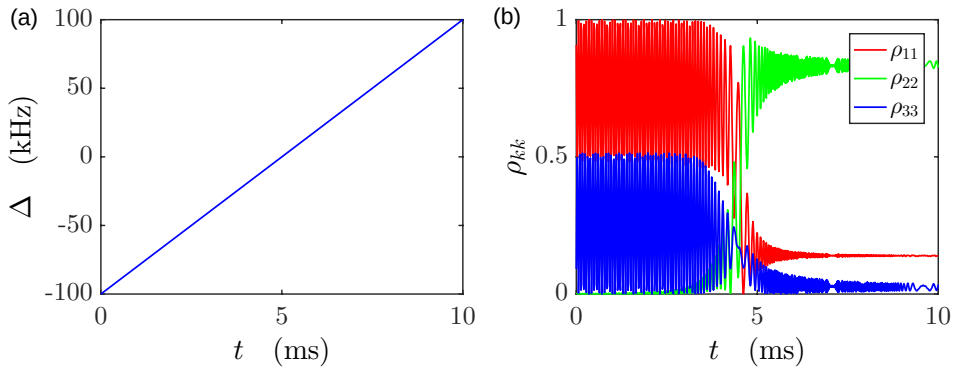

Figure 47.24: (code) STIRAP ramp through a dark resonance. Here, the Rabi frequencies are $\Omega_{13} = \Omega_{23} = 2\pi 10$ kHz. The frequency of the first microwave is $\Delta_{13} = (2\pi)10$ kHz and the frequency ramp of the second microwave is given by $\Delta_{23}(t) = \frac{2t-t_m}{t_m}\ (2\pi)100$ kHz, where $t_m = 10$ ms.

that can induce transitions between the states. In particular, we consider paramagnetic atoms in different Zeeman states placed in inhomogeneous static magnetic fields and subject to single-mode or multi-mode radiofrequency radiation fields [299]. To simplify the problem, let us concentrate on two-level systems, e.g. a system with the total spin $F = \frac{1}{2}$ [1437], and only consider the one-dimensional case.

47.4.3.1 Coupled Gross-Pitaevskii equations

For a single atom the Hamiltonian is the one given in (38.13),

$$\hat{H}(\mathbf{r}) = |1\rangle \left(\tfrac{1}{2}\mu_B g_F B(\mathbf{r}) - \tfrac{1}{2}\hbar\omega\right) \langle 1| + |2\rangle \left(-\tfrac{1}{2}\mu_B g_F B(\mathbf{r}) + \tfrac{1}{2}\hbar\omega\right) \langle 2| + |1\rangle \tfrac{1}{2}\hbar\Omega \langle 2| + |2\rangle \tfrac{1}{2}\hbar\Omega \langle 1| \,. \tag{47.121}$$

With the definition,

$$\hat{\psi}_k(\mathbf{r}) \equiv \langle k|\hat{\psi}(\mathbf{r})\rangle \ , \tag{47.122}$$

and the abbreviation $\hbar\Delta(\mathbf{r}) \equiv \mu_B g_F B(\mathbf{r}) - \hbar\omega(\mathbf{r})$ we proceed to the second quantization via,

$$\boxed{\begin{aligned} \mathcal{H} &= \sum_{k\neq m} \int d^3r\ \hat{\psi}_k^\dagger \left[\frac{-\hbar^2\nabla^2}{2m} + \tfrac{1}{2}u_{kk}\hat{\psi}_k^\dagger\hat{\psi}_k + \tfrac{1}{2}u_{k,m}\psi_m^\dagger\hat{\psi}_m\right]\hat{\psi}_k \\ &+ \left[(-1)^k\tfrac{\hbar}{2}\Delta(\mathbf{r})\hat{\psi}_k^\dagger\hat{\psi}_k + \tfrac{\hbar}{2}\Omega(\mathbf{r})(\hat{\psi}_k^\dagger\hat{\psi}_m + \psi_m^\dagger\hat{\psi}_k)\right] \end{aligned}} \ . \tag{47.123}$$

The total energy of the system is the sum of the energies of the individual condensates (kinetic, potential, and collisional interaction) *plus* the interspecies collisional interaction energy. The coefficients $u_{kl} = 4\pi\hbar^2 a_{kl}/m$ with the scattering lengths a_{kl} govern the impact of the collisions.

The interaction with the radiofrequency field leads to Rabi oscillations with fre-

quency Ω [17] The tuning of the radiofrequency depends on the position, due to the non-homogeneous Zeeman shift Δ. Also, to simplify the model, we assume $u_{kl} = 0$ for $k \neq l$,

$$\hat{H} = \sum_{k \neq m} \int d^3r \, \hat{\psi}_k^\dagger \left[\frac{-\hbar^2 \nabla^2}{2m} + \tfrac{1}{2} u_{kk} \hat{\psi}_k^\dagger \psi_k \right] \psi_k + \left[(-1)^k \tfrac{\hbar}{2} \Delta(\mathbf{r}) \hat{\psi}_k^\dagger \hat{\psi}_k + \tfrac{\hbar}{2} \Omega \left(\hat{\psi}_k^\dagger \psi_m + \hat{\psi}_m^\dagger \hat{\psi}_k \right) \right] . \tag{47.124}$$

From the Heisenberg equations of motion for the field operators of the matter wave and the light, we obtain [1437],

$$\imath \dot{\hat{\psi}}_1 = -\tfrac{1}{\hbar}[\hat{H}, \hat{\psi}_1] = \frac{\delta \hat{H}}{\hbar \delta \hat{\psi}_1^\dagger} = \left(\frac{-\hbar^2 \nabla^2}{2m} + u_{11} \hat{\psi}_1^\dagger \hat{\psi}_1 - \tfrac{\hbar}{2} \Delta(\mathbf{r}) \right) \hat{\psi}_1 + \tfrac{\hbar}{2} \Omega \hat{\psi}_2 \tag{47.125}$$

$$\imath \dot{\hat{\psi}}_2 = -\tfrac{1}{\hbar}[\hat{H}, \hat{\psi}_2] = \frac{\delta \hat{H}}{\hbar \delta \hat{\psi}_2^\dagger} = \left(\frac{-\hbar^2 \nabla^2}{2m} + u_{22} \hat{\psi}_2^\dagger \hat{\psi}_2 + \tfrac{\hbar}{2} \Delta(\mathbf{r}) \right) \hat{\psi}_2 + \tfrac{\hbar}{2} \Omega \hat{\psi}_1 .$$

The adiabatic potentials follow from a point-wise diagonalization of the Hamiltonian, assuming that the atomic movement evolves in sufficiently small steps.

47.4.3.2 One-dimensional case

The reduction of the dimensionality of the Gross-Pitaevskii equation is shown in Sec. 48.1. Applying this to our case, we consider a one-dimensional potential $V(\mathbf{r}) = V(z)$ and assume condensates being radially homogeneous within the radial diameter r_h. In this case, we can neglect the radial kinetic energy. As normalization then requires,

$$\int_{-r_h}^{r_h} \int_{-r_h}^{r_h} \int_{-\infty}^{\infty} |\hat{\psi}(\mathbf{r})|^2 d^3r = (2r_h)^2 \int_{-\infty}^{\infty} |\hat{\psi}(z)|^2 dz = 1 , \tag{47.126}$$

replacing $\hat{\psi}(\mathbf{r}) = \frac{\hat{\phi}(z)}{2r_h}$ and $g_{kk} = \frac{u_{kk}}{(2r_h)^2}$, the Gross-Pitaevskii equation and the normalization condition adopt a particularly simple form,

$$\imath\hbar \frac{\partial}{\partial t} \hat{\phi}(z) = \left(-\frac{\hbar^2}{2m} \frac{\partial^2}{\partial z^2} + V_{trap}(z) + N g_{1D} |\hat{\phi}(z)|^2 \right) \hat{\phi}(z) . \tag{47.127}$$

The coupled equations are now,

$$\imath \dot{\hat{\phi}}_1 = \left(\frac{-\partial_z^2}{2m} + g_{11} \hat{\phi}_1^\dagger \hat{\phi}_1 - \frac{m}{4} \omega_z^2 z^2 - \tfrac{1}{2} \Delta_0 \right) \hat{\phi}_1 + \tfrac{1}{2} \Omega \phi_2 \tag{47.128}$$

$$\imath \dot{\hat{\phi}}_2 = \left(\frac{-\partial_z^2}{2m} + g_{22} \hat{\phi}_2^\dagger \hat{\phi}_2 + \frac{m}{4} \omega_z^2 z^2 + \tfrac{1}{2} \Delta_0 \right) \hat{\phi}_2 + \tfrac{1}{2} \Omega \hat{\phi}_1 .$$

with,

$$\int_{-\infty}^{\infty} |\hat{\phi}_1(z)|^2 + |\hat{\phi}_2(z)|^2 dz = 1 . \tag{47.129}$$

This set of equations can be solved numerically by first identifying the ground state using the 'steepest descent' method and then propagating it in real time while slowly varying $\Delta(\mathbf{r}, t)$ or $\Omega(t)$.

[17] We are neglecting the possibility, that the coupling force may, in principle, be inhomogeneous, if the orientation of the magnetic field is not uniform.

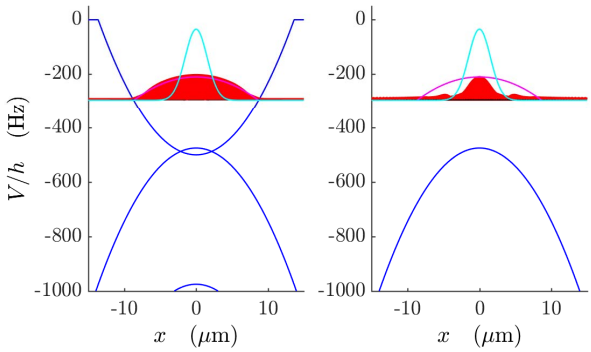

Figure 47.25: (code) Two coupled condensates.

47.4.3.3 Damping

A heuristic way of introducing damping could be as follows: We write down the condensate velocity field as,

$$m\mathbf{v}(\mathbf{r},t) = \hbar \frac{\hat{\phi}^*(\mathbf{r},t)\nabla\hat{\phi}(\mathbf{r},t) - \nabla\hat{\phi}^*(\mathbf{r},t)\hat{\phi}(\mathbf{r},t)}{2\imath n(\mathbf{r},t)} \ , \tag{47.130}$$

and subject it to a friction force,

$$E_{fr} = -\gamma r v \ . \tag{47.131}$$

The problem with the coupled GPE approach is that in the absence of damping any even small modification of the coupling triggers collective oscillations, so that the ground state is not found. A numerical method to minimize the total energy cannot be used, because the minimum is the untrapped state, so that all atoms are lost. It seems that a master equation approach is necessary to introduce damping. An alternative (but cheap) way is the following. The coupled GPEs were written in the dressed states basis. Thus, if the Rabi frequency is strong enough to completely decouple the dressed states, the dressed states represent good quantum numbers, and the GPEs are appropriately written in a diagonal basis, i.e. the GPEs decouple on adiabatic potentials [18],

$$V_{ad,k}(z) = -(-1)^k \frac{1}{2}\sqrt{\hbar^2\Omega^2 + [\mu_B g_F B(z) - \hbar\omega]^2} \ , \tag{47.132}$$

and we obtain,

$$\imath\dot{\hat{\phi}}_k = \left(\frac{-\partial_z^2}{2m} + V_{ad,k}(z) + g_{kk}\hat{\phi}_k^\dagger\hat{\phi}_k\right)\hat{\phi}_k \ . \tag{47.133}$$

47.4.3.4 Observations

An interesting question is, whether BECs trapped at different antinodes will synchronize their phases. Traditionally, BECs mutually influence their de Broglie waves

[18] Gravitation can be included by $V_{ad,k}(z) \to V_{ad,k}(z) + mgz$.

either by colliding or by some kind of coherent coupling, e.g. Josephson tunneling or radiative coupling of internal or motional states. Sound propagation through a standing wave requires tunneling. It cannot propagate if the potential is too deep. Then excitations stay local. Is it possible to translate the ring cavity coupling mechanism to the quantum regime of Bose-condensates confined to different antinodes? By analogy to the classical situation, one expects the de Broglie wave to correlate. In the matter wave language we would say, that the BEC wavefunctions transfer their excitations via the standing wave, i.e. they share a common excitation energy via the exchange of phonons. In the presence of a dissipation mechanism (e.g. via cavity cooling, by friction with a thermal cloud, etc.), which carries away the excess entropy, the excitations will damp [632]. This means the condensates mutually adjust and synchronize their phases. It is worth noticing, that the BEC will merge although they might be trapped at very distant locations, were coupling by tunneling is prohibited. Cavity-mediated cooling in ring cavities is known to damp essentially the center-of-mass motion. The relative motion of the trapped particles is damped on a much longer time-scale. In the case of BECs, however, the situation is different from the single-particle case: The strong motional correlations within a BEC, we have to treat them like a single particle. Since BECs trapped at different antinodes are likely to have different sizes, they also have different collective secular frequencies. Therefore the center-of-mass motion and the relative motion of different BECs periodically exchange kinetic energy, which leads to an indirect cooling also of the relative motion. TOF interference experiments can reveal phase differences [663].

47.4.3.5 Microwave and radio frequency spectra

For an irradiated magnetic field $B_{rf}(t) = B_{rf}\hat{\mathbf{e}}_{rf}\cos\omega t$ the coupling matrix element is,

$$\hbar\Omega = \frac{1}{4}\mu_B g_F(\mathbf{B}_{rf}\times\hat{\mathbf{e}}_z)\sqrt{F(F+1)-m_F(m_F\pm 1)}\ . \tag{47.134}$$

With $P_{in} = 35$ dBm coupled into the microwave, typically $P_{out} = 200$ W are radiated [385]. At the atomic location, at a distance of $r = 30$ cm, we get $B_{rf} = \sqrt{\mu_0 P/4\pi c r^2} = 8.6$ mG, and thus expect $\Omega \lesssim (2\pi)$ 1 kHz. Typical measured Rabi frequencies are 7.6 kHz. Let us count with the 5 kHz in the following. For an irradiated power of +27 dBm we may get some $\Omega = 2\pi \times xxx$ kHz.

To estimate the *chemical potential*, we use the Thomas-Fermi approximation,

$$2\mu = \hbar\omega_{ho}\left(\frac{15Na}{a_{ho}}\right)^{2/5}\ , \tag{47.135}$$

where $\omega_{ho} \equiv (\omega_r^2\omega_z)^{1/3}$ and $a_{ho} = \sqrt{\hbar/m\omega_{ho}}$ is the size of the ground state of the Ioffe trap. For $N = 1\times 10^5$ condensed atoms, we expect $2\mu \approx 20\hbar\omega_{ho} \approx h\times 8$ kHz. The Thomas-Fermi radius is $R_{tf} = \sqrt{2\mu/m\omega_{trap}^2} \approx 4.5$ μm. Note that this is not too far from a $1D$ situation defined by $\omega_r \ll \mu \ll \hbar\omega_z$ (or equivalently $a_z \gg \xi \gg a_r$). The radio frequency ω_{rf} is resonant over the range from $\mu_B B_0/\hbar$ to $\mu_B B_0/\hbar + \mu$. The radio frequency is resonant in the range $\hbar\omega = U(\frac{g}{\omega_x^2} \pm R_{tf}, 0)$, i.e. over an interval $\hbar\Delta\omega = 2mgR_{tf} \approx h\times 20$ kHz [154].

47.4.4 Exercises

47.4.4.1 Ex: Output coupler for trap extraction applications

Write down, in second quantization, the Hamiltonian of a condensate trapped in a harmonic potential and couple it to a free condensate. Simulate the coupled GPEs.

Solution:

47.4.4.2 Ex: Gravitational acceleration in radio frequency combs

The first scenario is to observe Bloch oscillations in a radio frequency lattice due to gravitational acceleration. In order to obtain an equidistant lattice, we chose small magnetic offset fields leading to steep constant gradients. For example for $\omega_{n+1}-\omega_n = 2\pi\times 4\,\mathrm{kHz}$, $B_0 = 0.16\,\mathrm{G}$, $\nabla_x B = 140\,\mathrm{G/cm}$ and $\Omega = 2\pi\times 1\,\mathrm{kHz}$, we get $d \approx 0.6\,\mu\mathrm{m}$ and $V_{ad} = h\times 1\,\mathrm{kHz} \approx 0.7E_r$ [299]. The velocity acquired by gravitational acceleration

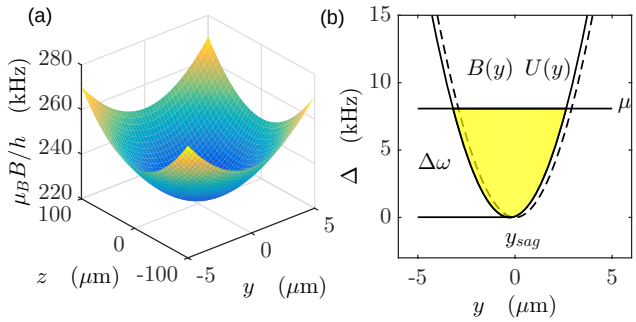

Figure 47.26: (code) (a) Two-dimensional cut through a Ioffe trapping potential with $B_0 = 0.16\,\mathrm{G}$, $\omega_r/2/\pi = 950\,\mathrm{Hz}$, and $\omega_z/2/\pi = 50\,\mathrm{Hz}$. (b) Vertical cut through the Ioffe trap without (dashed line) and with gravity (solid line). The range over which the BEC can be excited is the shaded area, the upper limit of which corresponds to the chemical potential $\mu/h = 4\,\mathrm{kHz}$ with $N = 10^6$ condensed atoms.

in a field-free case along one lattice period is $v_{gr} = dt = \sqrt{2ad} \approx 3.5\,\mathrm{mm/s}$. The atoms are Bragg-reflected when the acquired velocity matches the Bragg condition $v_{brg} \approx 7.5\,\mathrm{mm/s}$, which occurs after a time $t = v_{brg}/a \approx 0.8\,\mathrm{ms}$. The secular frequency of the potential sites is,

$$\omega_{ho} = \frac{2\mu_B g_F b_y}{\sqrt{2m\hbar\Omega}} \ . \tag{47.136}$$

For $b_y = 140\,\mathrm{G/cm}$ and $\Omega = 2\pi\times 1\,\mathrm{kHz}$ we expect $\omega_{ho} \approx 2\pi\times 6.3\,\mathrm{kHz}$.

Solution: *The gravitational potential difference over a single lattice period, $\Delta E_{grav} = mgd \approx h\times 2.1\,\mathrm{kHz}$, is on the same order of magnitude as the first Bloch band [30]. The solid state approach introduces Bloch bands [cf. Fig. 47.28(a)], If the Bloch states are characterized by $|n, q(t)\rangle$. The mean velocity is,*

$$\langle v\rangle_n(q(t)) = \frac{1}{\hbar}\frac{dE_n(q(t))}{dq} \tag{47.137}$$

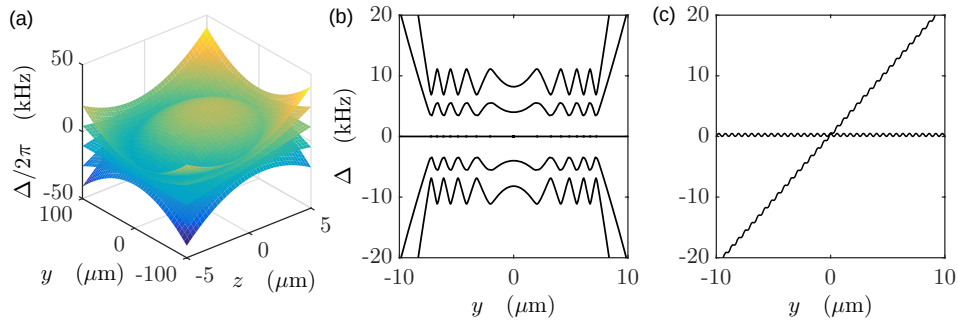

Figure 47.27: (code) (a) Adiabatic potentials for the $F = 2$ hyperfine state without gravity. Two frequencies are irradiated at $\omega_n/2\pi = 30, 90\,\mathrm{kHz}$ with $\Omega/2\pi = 1\,\mathrm{kHz}$. (b) Upper adiabatic potential without and with gravity and $\omega_n/2\pi = (6+3n)\,\mathrm{kHz}$ with $\Omega/2\pi = 1\,\mathrm{kHz}$. (c) Periodic potential with the lattice constant d and the modulation depth V_{ad}. The different shape of the lattice comes from the fact that in (a,b) we are still in the flat harmonic part of the potential.

with

$$q(t) = q(0) + mat/\hbar\ , n \tag{47.138}$$

where $a = g$. The velocity thus exhibits an oscillatory time dependence shown in Fig. 47.28(b). Our goal is to observe these oscillations in a radio frequency lattice in order to use them as a tool for probing and characterizing this lattice. For this purpose we produce a ^{87}Rb BEC, keep the rf-shield on. Irradiate additional rf- or mw-radiation and wait for a time t. Then we switch off the magnetic field and do time-of-flight imaging. We expect periodic change of the velocity acquired during the irradiation time. This velocity $v_n(t)$ influences the falling distance at time-of-flight,

$$s(t, t_{tof}) = \frac{a}{2} t_{tof}^2 + v_n(t) t_{tof}\ . \tag{47.139}$$

For small velocities $v_n(t) \approx 1$ mm/s, the displacement $v_n(t)t_{tof}$ may be barely visible. There are however problems: 1. High loss rates due to collisions and Majorana spin-flips limit the lifetime. 2. The fast down-ramping makes that the BEC is not in equilibrium. We observe interference fringes, which do not result from rf. 3. Switch-off problems giving rise to Majorana losses, when a magnetic zero is swept across the BEC. This makes nice Stern-Gerlach pictures. Nevertheless, we see BEC pulses outcoupled by rf, falling the gravitational field. The critical point of the experiment is probably the adiabatic transfer of the atoms into the lattice. It is possible to ramp the rf power, but not the frequency. In exchange, we can ramp the magnetic field offset which allows us to tune the resonant locations. The grating should be switched on or ramped in slowly to guarantee that the BEC completely goes to the lowest band.

47.4.4.3 Ex: Egg-shell trap and frustrated outcoupling

It is at first sight counterintuitive that non-resonant frequency components, i.e. frequency components which would not couple the atoms to other Zeeman states, never-

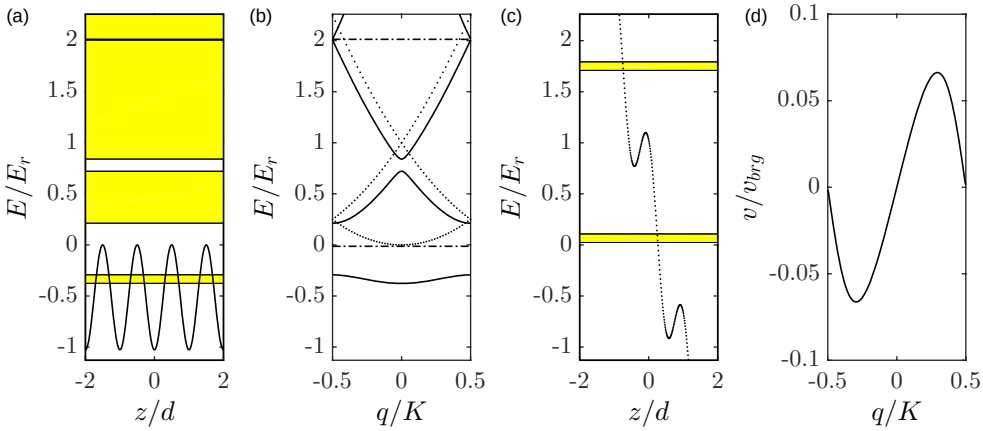

Figure 47.28: (code) (a) Lattice potential without gravity. The shaded areas denote the Bloch bands in position space. The parameters are taken from Fig. 47.27. The corresponding lattice constant is $d = 0.6$ μm and the potential depth is $V_{ad} = 1.2E_r$. (b) Bloch bands in momentum space (solid lines). The dotted lines represent expected energy levels in the harmonic approximation. The dashed line show the free particle case. (c) Mean velocity. (d) Bloch bands in momentum space (solid lines). The dotted lines represent expected energy levels in the harmonic approximation. The dashed line show the free particle case.

theless contribute to generate an adiabatic potential. In order to test this, we image the following second scenario. This scenario is to make an rf-knife as for evaporation or atom lasing. Then irradiate rf component slightly higher then the first one. In the adiabatic picture the outcoupling should be stopped. On the other hand, if the frequencies are too close (like degenerate) this picture cannot be true. Where is the limit? This is an additional limitation for the smallness of the lattice constant: $V_{Stark,1} \ll |\mu_B g_F B - \hbar\omega_2|$. States should couple unperturbed potentials to avoid interferences, i.e. ???

Solution: *The radiofrequency is ramped from -40 kHz (red) to $+40$ kHz (blue), then a Stern-Gerlach experiment is performed, and finally time-of-flight images are taken. To understand the observed images, we have to proceed in several steps. 1. The Rabi frequency is estimated by comparing the speed with which other Zeeman states are populated with Schrödinger equation simulations of an adiabatic transfer due to the frequency ramp. It is $\Omega \approx 2\pi \times 1$ kHz. 2. The time-of-flight duration is easily calibrated by comparison with in-situ images. 3. The Stern-Gerlach force is easily calibrated by comparing the behavior of $m_F = 0$ and $m_F \geq 1$ atoms. The impact of gravity during the trapping period is seen by comparing the behavior of $m_F = 0$ and $m_F \geq 1$ atoms. As soon as $m_F \leq -1$ atoms are produced, these anti-trapped atoms are accelerated away from the Ioffe trap, which we describe as $B = \sqrt{B_0^2 + b_y^2 y^2}$, with the force $-\partial_y \mu_B g_F m_F B(y) = -\mu_B g_F m_F b_y^2 y / \sqrt{B_0^2 + b_y^2 y^2}$, where $b_y = 140\,\mathrm{G/cm}$ plus*

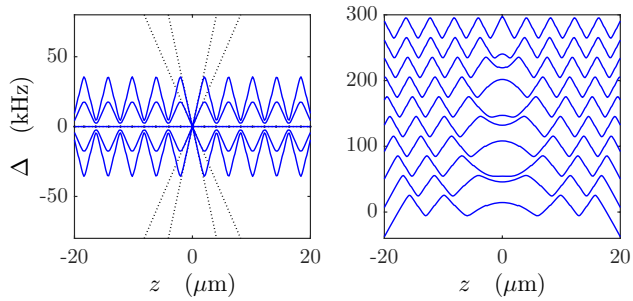

Figure 47.29: (code) (a) Adiabatic potentials. (b) Downramping B_0.

gravity. We thus have to solve the differential equation,

$$\dot{y} = v \tag{47.140}$$
$$\dot{v} = \frac{-\mu_B g_F m_F b_y^2 y}{m\sqrt{B_0^2 + b_y^2 y^2}} + g \ .$$

for different atoms labelled k produced at time t_k with the initial conditions $y(t_k) \approx 0$

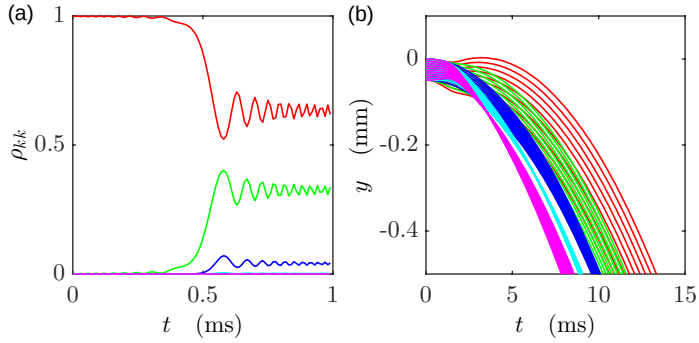

Figure 47.30: (code) (a) Evolution of the populations of the five Zeeman states. The adiabatic ramp is performed in 1 ms.

and $\dot{y}(t_k) = 0$. 2. The Stern-Gerlach acceleration is due to residual magnetic field gradients during the trap switch off. Therefore, the direction of the Stern-Gerlach force, $-\nabla\mu_B g_F m_F B_{SG}(y,z) = -\mu_B g_F m_F \mathbf{b}_{SG}$, is not controlled (but nevertheless reproducible). The final values of the Ioffe trap acceleration period are used as starting conditions for the equation,

$$\dot{y} = v \tag{47.141}$$
$$\dot{v} = \frac{-\mu_B g_F m_F b_{SG,y}}{m} \ .$$

4. And finally, time-of-flight,

$$s = \frac{g}{2} t_{ToF}^2 + v t_{ToF} \ . \tag{47.142}$$

The easiest way to handle these equations is numerical iteration.

47.4.4.4 Ex: Optical dipole trap with $1D$ gradients from Ioffe wires

The third scenario consists in the generation of steep $1D$ magnetic field gradients is most convenient with microtraps [1348]. On the other hand, we wish to expose an elongated atomic cloud to a $1D$ periodic potential. To separate the trapping potential from periodic potential to be probed by the atoms, let us consider 1 μK cold ^{87}Rb atoms stored in an optical dipole trap with radial secular frequencies of $\omega_r = (2\pi)\ 1\,\text{kHz}$ and an axial frequency of $\omega_r = (2\pi)\ 10\,\text{Hz}$. The thermal cloud is then $\bar{z} = \sqrt{k_B T/m\omega_z} \approx 160\,\mu\text{m}$ long and has a radial size of $\bar{z} \approx 1.6\,\mu\text{m}$. Let us also assume that the magnetic field gradient is provided by two parallel current-carrying wires running perpendicularly to the dipole trap axis (see scheme of Fig. 47.31).

Solution: *We simulate,*

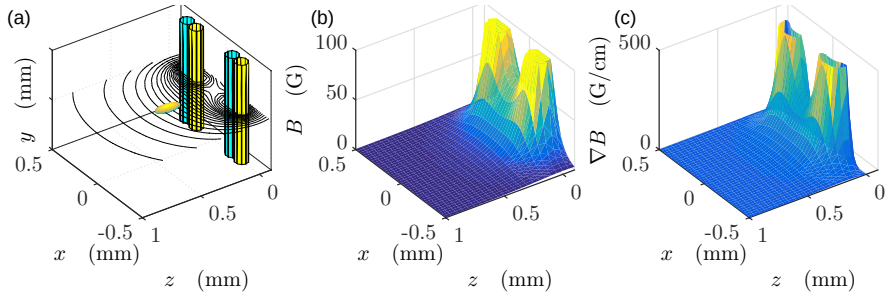

Figure 47.31: (code) (a) Scheme of dipole trap and magnetic fields. (b) Magnetic field. (c) Gradient.

47.4.4.5 Ex: Multiple BECs coupled by radiation via GPEs

Programs on multiple BECs coupled by radiation via GPEs.

Solution: *Before doing GPE simulations, do adiabatic ramp to check appropriate parameters. Some literature [316, 1007, 30, 155, 154, 295, 625, 988, 850, 284, 1437, 1438]. Look up Numerical Recipes Chapter 16.1.*

Comments: Runge-Kutta does not improve a lot. Seems like the way Ψ converges for $r \to \infty$ makes the change; take larger intervals or suppress Ψ at ∞.

47.5 Interaction between condensates and optical cavities

In 47.4.1 we have set up the many-body Hamiltonian (47.108) describing the interaction of a matter wave (treated in mean-field approximation) with an incident light field. We emphasized the role of photonic recoil in (47.231). In the following sections we aim at applying this theory to the particular case of atoms interacting with two counterpropagating modes of an optical ring cavity. The system has already been studied in Chp. 42 in the context of CARL, where the atomic motion, as well as the light fields, have mostly been treated classically.

CARL is based on a coherent redistribution of photons between the two counterpropagating modes of a moving standing light wave mediated by atoms which are located in the mode volume. Cooperative Compton scattering induces a collective atomic recoil and a self-bunching of the atoms, which results in an exponential gain for the optical mode receiving the scattered photons. The recent observation of the MWSR [649] in a BEC raises the question about an ultra-cold version of CARL [918, 617]. In MWSR the long coherence time of a BEC establishes a strong correlation between subsequent elastic Rayleigh scattering events mediated by very stable quasi-particle excitations. The feedback of these excitations on the laser creates an *exponential* gain for the optical mode receiving the scattered photons [650, 305, 173, 775, 918, 917, 749, 651, 650].

We have discussed the classical CARL earlier in the superradiant as well as the good-cavity regime. We have also generalized the problem to the case of quantized atomic motion (see Sec. ??) and to quantized radiation fields (see Sec. ??). The internal states were always adiabatically eliminated. In the following, we will fully quantize the bosonic atomic particle field.

The advantages of this second quantization is that interatomic interactions, quantum fluctuations, and decoherence of the matter wave can be taken into account. Various proposals have been made focusing on either one of the above three aspects. Fundamental aspects of the BEC-in-a-cavity-system lead into two directions: 1. quantum synchronization and 2. quantum correlations.

The system under consideration is a BEC of two-level atoms with transition resonance frequency ω_0 trapped in an external magnetic trap, located inside the mode volume of a ring cavity and interacting with its light modes. The atomic field operators obey the commutation relations,

$$\begin{aligned} [\hat{\psi}_k(\mathbf{r}), \hat{\psi}_m^\dagger(\mathbf{r}')] &= \delta_{km}\delta^{(3)}(\mathbf{r}, \mathbf{r}') \\ [\hat{\psi}_k(\mathbf{r}), \hat{\psi}_m(\mathbf{r}')] &= 0 = [\hat{\psi}_k^\dagger(\mathbf{r}), \hat{\psi}_m^\dagger(\mathbf{r}')] \ , \end{aligned} \tag{47.143}$$

where $k, m = 1, 2$ label the internal state of the atoms. In general, the light field consists of only *two* counterpropagating monochromatic modes with Rabi frequencies $2g\hat{a}_\pm^\dagger \hat{a}_\pm$. Choosing the coordinate system properly, we can set the wavevectors of the modes as $\mathbf{k}_+ \cdot \hat{\mathbf{e}}_r = k\hat{z} = -\mathbf{k}_- \cdot \hat{\mathbf{e}}_r$. The second-quantized Hamiltonian is a generalization of (42.4),

$$\mathcal{H} = \mathcal{H}_{atom} + \mathcal{H}_{atom-atom} + \mathcal{H}_{atom-cav} + \hat{H}_{cav} + \hat{H}_{laser-cav} \ , \tag{47.144}$$

where,

$$\boxed{\begin{aligned}
\mathcal{H}_{atom} &= \int d^3r \hat{\psi}_1^\dagger(\mathbf{r}) \left(\frac{\hat{p}^2}{2m} + V_1(\mathbf{r}) \right) \hat{\psi}_1(\mathbf{r}) \\
&\quad + \int d^3r \hat{\psi}_2^\dagger(\mathbf{r}) \left(\frac{\hat{p}^2}{2m} + V_2(\mathbf{r}) - \Delta_a \right) \hat{\psi}_2(\mathbf{r}) \\
\mathcal{H}_{atom-atom} &= \textstyle\sum_{i=1,2} \int d^3r \hat{\psi}_i^\dagger(\mathbf{r}) \hat{\psi}_i^\dagger(\mathbf{r}) \frac{u_{ii}}{2} \hat{\psi}_i(\mathbf{r}) \hat{\psi}_i(\mathbf{r}) \\
&\quad + \int d^3r \hat{\psi}_1^\dagger(\mathbf{r}) \hat{\psi}_2^\dagger(\mathbf{r}) \frac{u_{12}}{2} \hat{\psi}_2(\mathbf{r}) \hat{\psi}_1(\mathbf{r}) \\
\mathcal{H}_{atom-cav} &= \textstyle\sum_\pm g\hat{a}_\pm \int d^3r \hat{\psi}_2^\dagger(\mathbf{r}) e^{\pm \imath kz} \hat{\psi}_1(\mathbf{r}) + h.c. \\
\hat{H}_{cav} &= -\textstyle\sum_\pm \Delta_c \hat{a}_\pm^\dagger \hat{a}_\pm \\
\hat{H}_{laser-cav} &= -\textstyle\sum_\pm \imath\eta_\pm (\hat{a}_\pm - \hat{a}_\pm^\dagger)
\end{aligned}} \ , \tag{47.145}$$

with $u_{ij} \equiv 4\pi\hbar^2 a_{s,ij}/m$.

Various approximations can be made depending on the subject of interest. For example, if only one cavity mode, $\hat{a}_\pm$, is strongly pumped, such that the field becomes intense, we may remove the term $\hat{H}_{laser-cav}$ and describe the field mode classically by a Rabi frequency Ω. The interaction between the pump mode and the cavity is then, $\hat{H}_{atom-pump} = \frac{\hbar\Omega}{2} e^{-\imath\omega_2 t} \int d^3r \hat{\psi}_2^\dagger(\mathbf{r}) e^{\imath k\hat{z}} \hat{\psi}_1(\mathbf{r}) + h.c.$.

A talk on this subject is available at (watch talk).

47.5.1 Ideal gas Hamiltonian after adiabatic elimination

Assuming the light fields to be tuned far from resonance we disregard spontaneous emission, as explained in Sec. 42.1.2, and adiabatically eliminate the internal states, as shown in Sec. 42.1.3 [1051, 278]. On the other hand, we treat the light field and the atomic motion in second quantization. The canonical way to describe a BEC interacting with *two* optical modes $\hat{a}_\pm$ is to second-quantize the single-particle Hamiltonian (42.26),

$$\boxed{\begin{aligned}
\mathcal{H} &\simeq \int d^3r \hat{\psi}^\dagger(\mathbf{r}) \left(\frac{\hat{\mathbf{p}}^2}{2m} + V_{trap}(\mathbf{r}) + \frac{u}{2}\hat{N}(\mathbf{r}) \right) \hat{\psi}(\mathbf{r}) + (\hat{N}U_0 - \Delta_c) \sum_\pm \hat{a}_\pm^\dagger \hat{a}_\pm \\
&+ U_0 \hat{a}_+^\dagger \hat{a}_- \int d^3r \hat{\psi}^\dagger(\mathbf{r}) e^{-2\imath kz} \hat{\psi}(\mathbf{r}) + h.c. - \imath \sum_\pm \eta_\pm (\hat{a}_\pm - \hat{a}_\pm^\dagger)
\end{aligned}} \ , \tag{47.146}$$

where $\hat{\psi}(\mathbf{r})$ is now the ground-state wave function of the matter wave, $u = 4\pi\hbar^2 a_s/m$ in the *mean-field approximation* and,

$$U_0 = \frac{g^2}{\Delta_a} \ , \tag{47.147}$$

when the mode to mode coupling strength. This adiabatically approximated Hamiltonian looks very similar to (42.26).

47.5.2 Expansion into momentum states

It is useful to convert the Hamiltonian to momentum space via a plane wave expansion of the BEC according to (45.70),

$$\hat{\psi}(\mathbf{r}) = \sqrt{\tfrac{V}{(2\pi)^3}} \int \hat{c}_{\mathbf{q}} e^{\imath \mathbf{q}\cdot\mathbf{r}} d^3q \qquad \text{with} \qquad [\hat{a}_{\mathbf{q}}, \hat{a}_{\mathbf{q}'}] = \delta_{\mathbf{q},\mathbf{q}'} \ . \tag{47.148}$$

The conversion of that Hamiltonian part $\mathcal{H}_{bec}$ to momentum space has been demonstrated in (45.78),

$$\mathcal{H}_{bec} = \sum_{\mathbf{q}} \frac{\mathbf{q}}{2m} \hat{c}^\dagger_{\mathbf{q}} \hat{c}_{\mathbf{q}} + \sum_{\mathbf{q},\mathbf{q}'} \hat{c}'^\dagger_{\mathbf{q}} V_{\mathbf{q}',\mathbf{q}} \hat{c}_{\mathbf{q}} + \frac{u}{2} \sum_{\mathbf{q},\mathbf{q}',\mathbf{q}''} \hat{c}^\dagger_{\mathbf{q}} \hat{c}'^\dagger_{\mathbf{q}} \hat{c}''_{\mathbf{q}} \hat{c}_{\mathbf{q}} + \mathbf{q}' - \mathbf{q}'' \ . \tag{47.149}$$

The light field part $\hat{H}_{cav}$ remains unchanged and the atom-light interaction becomes using (47.3),

$$\begin{aligned} \mathcal{H}_{bec-cav} &= U_0 \int \hat{\psi}^\dagger(\mathbf{r}) \hat{a}^\dagger_+ \hat{a}_- e^{-\imath(\mathbf{k}_+ - \mathbf{k}_-)\cdot\mathbf{r}} \hat{\psi}(\mathbf{r}) d^3r + h.c. \qquad (47.150) \\ &= \imath\hbar U_0 \hat{a}^\dagger_+ \hat{a}_- V \int\int \hat{c}^\dagger(\mathbf{q}') \hat{c}(\mathbf{q}) \delta^3(\mathbf{q} - \mathbf{q}' - 2k\hat{\mathbf{e}}_z) d^3q d^3q' = U_0 \hat{a}^\dagger_+ \hat{a}_- \sum_{\mathbf{q}} \hat{c}^\dagger_{\mathbf{q}-2\mathbf{k}} \hat{c}_{\mathbf{q}} \ . \end{aligned}$$

All in all,

$$\boxed{\begin{aligned} \mathcal{H} &= \sum_{\mathbf{q}} \frac{\mathbf{q}^2}{2m} \hat{c}^\dagger_{\mathbf{q}} \hat{c}_{\mathbf{q}} + \sum_{\mathbf{q},\mathbf{q}'} \hat{c}^\dagger_{\mathbf{q}'} V_{\mathbf{q}',\mathbf{q}} \hat{c}_{\mathbf{q}} + \frac{u}{2} \sum_{\mathbf{q},\mathbf{q}',\mathbf{q}''} \hat{c}^\dagger_{\mathbf{q}} \hat{c}^\dagger_{\mathbf{q}'} \hat{c}_{\mathbf{q}''} \hat{c}_{\mathbf{q}+\mathbf{q}'-\mathbf{q}''} \\ &+ (\hat{N}U_0 - \Delta_c) \sum_{\pm} \hat{a}^\dagger_\pm \hat{a}_\pm + U_0 \hat{a}^\dagger_+ \hat{a}_- \sum_{\mathbf{q}} \hat{c}^\dagger_{\mathbf{q}-2\mathbf{k}} \hat{c}_{\mathbf{q}} - \imath \sum_{\pm} \eta_\pm (\hat{a}_\pm - \hat{a}^\dagger_\pm) \end{aligned}} \ . \tag{47.151}$$

The BEC-CARL equations of motion are readily obtained from the Heisenberg equations,

$$\begin{aligned} \imath \frac{d\hat{c}_{\mathbf{p}}}{dt} &= [\hat{c}_{\mathbf{p}}, \mathcal{H}] = \frac{q^2}{2m} \hat{c}_{\mathbf{p}} + \sum_{\mathbf{q}} V_{\mathbf{p},\mathbf{q}} \hat{c}_{\mathbf{q}} + u \sum_{\mathbf{q},\mathbf{q}'} \hat{c}^\dagger_{\mathbf{q}} \hat{c}_{\mathbf{q}'} \hat{c}_{\mathbf{q}-\mathbf{q}'+\mathbf{p}} + U_0 \hat{a}^\dagger_+ \hat{a}_- \hat{c}_{\mathbf{p}+2\mathbf{k}} + h.c. \\ \imath \frac{d\hat{a}_\pm}{dt} &= [\hat{a}_\pm, \mathcal{H}] = (\hat{N}U_0 - \Delta_c) \hat{a}_\pm + U_0 \hat{a}_\mp \sum_{\mathbf{q}} \hat{c}^\dagger_{\mathbf{q}\mp 2\mathbf{k}} \hat{c}_{\mathbf{q}} + \imath\eta_\pm \ . \end{aligned} \tag{47.152}$$

47.5.2.1 Discretization of the momentum space

Assuming the BEC to be initially at rest with 0 temperature, its momentum state can be written as $\hat{c}_{\mathbf{0}}$. And if the dynamics only involves the z-axis, then all momentum states are separated by multiples of $2\hbar k$, such that we may replace the labeling by integer numbers: $\hat{c}_{\mathbf{q}} \to \hat{c}_n$. We get,

$$\begin{aligned}\mathcal{H} = &\sum_n \frac{n^2 q^2}{2m}\hat{c}_n^\dagger \hat{c}_n + \sum_{n,n'} \hat{c}_{n'}^\dagger V_{n',n}\hat{c}_n + \frac{u}{2}\sum_{n,n',n''} \hat{c}_n^\dagger \hat{c}_{n'}^\dagger \hat{c}_{n''}\hat{c}_{n+n'-n''} \\ &+ \sum_\pm \left(\hat{N}U_0 - \Delta_c\right)\hat{a}_\pm^\dagger \hat{a}_\pm + U_0 \hat{a}_+^\dagger \hat{a}_- \sum_n \hat{c}_{n-1}^\dagger \hat{c}_n + h.c. - \imath\eta_\pm(\hat{a}_\pm - \hat{a}_\pm^\dagger) \ .\end{aligned} \tag{47.153}$$

Neglecting the external trapping potential and collisions the Heisenberg equations for the field and the atomic motion now read,

$$\begin{aligned}\frac{d\hat{c}_n}{dt} &= -\imath[\hat{c}_n, \mathcal{H}] = -\imath\frac{n^2k^2}{2m}\hat{c}_n + U_0\hat{a}_+^\dagger \hat{a}_- \hat{c}_{n+1} + h.c. \\ \frac{d\hat{a}_\pm}{dt} &= -\imath[\hat{a}_\pm, \mathcal{H}] = (\hat{N}U_0 - \Delta_c)\hat{a}_\pm + U_0\hat{a}_\mp \sum_n \hat{c}_{n\mp 1}^\dagger \hat{c}_n + \imath\eta_\pm \ .\end{aligned} \tag{47.154}$$

These equations look identical to those found in (42.160).

47.5.3 Damping of BECs in cavities

Horak et al. [634] treat the BEC as an entity, as if is was located at a single antinode. They find that excitations can be damped. Local phase shifts in a BEC give rise to excitations. How about if the phase shift occurs only at a spatially well-defined location, i.e. at a specified antinode? Following [632, 633] in the Lamb-Dicke limit only low-lying modes are damped. Higher-order modes are damped via self-interaction and trap anharmonicity.

47.5.3.1 Self-consistent ground state

There is no entanglement if the field is too strong $|\alpha|^2 \gg 1$. If the internal states can be adiabatically eliminated, the basic equations now read (use $U_N \equiv NU_0$) with $u = 4\pi\hbar^2 a_s/m$,

$$\begin{aligned}\frac{d}{dt}\alpha_\pm(t) &= -[\kappa - \imath\Delta_c + \imath U_N]\alpha_\pm(t) - \imath U_N\langle e^{\mp 2\imath k\hat{z}}\rangle\alpha_\mp(t) + \eta_\pm \\ \imath\hbar\frac{d}{dt}\psi(z,t) &= \left[\frac{\hat{p}^2}{2m} + \hbar U_0\left|\alpha_+(t)e^{\imath kz} + \alpha_-(t)e^{-\imath kz}\right|^2 + u|\psi(z,t)|^2\right]\psi(z,t) \ ,\end{aligned} \tag{47.155}$$

where $\langle e^{\mp\imath k\hat{z}}\rangle = \int \psi^*(z,t)e^{\mp\imath k\hat{z}}\psi(z,t)dz$. The wavefunction is scaled such that $\int |\psi|^2 d^3z = N$.

If we assume that the cavity field adiabatically follows the BEC, $\dot{\alpha}_\pm = 0$,

$$\alpha_\pm(t) = \eta_\pm \frac{\kappa - \imath\Delta_c + \imath U_N - \imath U_N\langle e^{-2\imath k\hat{z}}\rangle}{(\kappa - \imath\Delta_c + \imath U_N)^2 + N^2U_0^2\langle e^{2\imath k\hat{z}}\rangle\langle e^{\mp\imath k\hat{z}}\rangle} \ . \tag{47.156}$$

The equations are solved self-consistently, i.e. we start from trial field and wavefunction,

$$\alpha_\pm(0) \equiv \eta_\pm \quad , \quad \psi(0) \equiv \frac{e^{-x^2}}{|e^{-x^2}|} \ . \tag{47.157}$$

Then the potential is calculated, for example,

$$V = \begin{cases} U_0 |\alpha e^{\imath kx} + \beta e^{-\imath kz}|^2 & \text{for} \quad |z| < z_{max} \\ 2\eta^2 & \text{for} \quad |z| > z_{max} \end{cases} \tag{47.158}$$

Then the groundstate wavefunction ψ is found by iterating Eq. (47.155)(b) with the method of steepest descent,

$$H = -\frac{\hbar^2}{2m}\nabla^2 + V + Nu|\psi|^2 \tag{47.159}$$
$$\psi(t+dt) = \frac{\psi(t)(1-\hbar^{-1}H\ dt)}{|\psi(t)(1-\hbar^{-1}H\ dt)|} \ .$$

The solution is used to calculate $\langle e^{\mp \imath k\hat{z}} \rangle$ and $\alpha_\pm$. If the laser is locked to resonance, we can use $\Delta_c = U_N$. And now $\alpha_\pm$ is used to calculate the potential in the GPE again. This procedure is repeated until convergence.

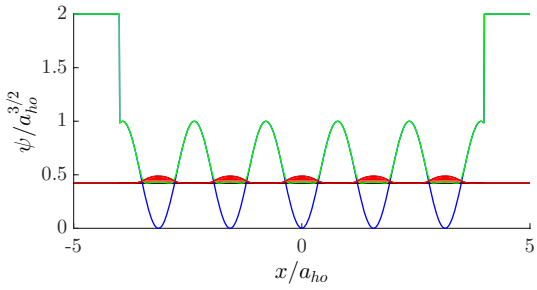

Figure 47.32: (code) BEC in a periodic potential. Shown is the potential $V(x)$ and the wavefunction $\psi(x)$ with an offset corresponding to $min(H)$. The normalization is $z = z/a_{ho}$, $(\psi/a_{ho})^{3/2}$.

Horak et al. [632] seem to believe that a BEC falling through a cavity field is adiabatically transferred to the ground state. If the trap is deep, this must result in trapping along the axial cavity direction.

Example 291 (*Optimum cavity-finesse*): Size in the Thomas-Fermi limit $V = 3 \times 3 \times 20\,\mu\text{m}^3$. The chemical potential is $\mu = h \times 3\,\text{kHz}$. The atom number $N = 10^5$. Near the D_2 line about 50 antinodes are filled with BEC.
In a simulation for cavity-damping Horak et al. [634] assumed $N = 10^5$, $\kappa = 100\omega_r = 50\varepsilon$, $NU_0 = 10\kappa$, $\eta^2 = 20\kappa N\omega_r$. With these parameters we expect for

our system,

$$\kappa/2\pi = 700\,\mathrm{kHz} \qquad \text{or} \qquad F = 2400 \tag{47.160}$$
$$\Delta_a = \frac{Ng^2}{10\kappa} = 2\pi \times 1.4\,\mathrm{GHz}$$
$$\alpha_+ = \frac{\eta}{\kappa} = \sqrt{20000} \qquad \text{or} \qquad P = 17\,\mu\mathrm{W}$$
$$\gamma_{scat} = \frac{g^2\Gamma}{\Delta_a^2}\alpha_+^2 = 600\,\mathrm{s}^{-1}$$
$$U = \hbar U_0 4\alpha_+^2 = \hbar\frac{10\kappa}{10^5}80000 = 800\hbar\omega_r\ .$$

This is about two orders of magnitude too short.

As soon as the ground state is found, one may propagate the equations (47.155) in *real time* with the Hamiltonian,

$$H = \frac{\hat{p}^2}{2m} + U_0|\alpha_\pm(t)e^{\imath kx} + \alpha_\mp(t)e^{-\imath kx}|^2 + Nu|\psi(x,t)|^2 \tag{47.161}$$

in the usual way. However, the subsystems may evolve on very different time-scales, so that a scale separation, as done for (47.156) may be appropriate.

47.5.4 BECs in two internal states coupled by a cavity

A lossy cavity can act as an effective *zero temperature reservoir*. One possible implementation [663] realizes a three-level cycling scheme, with two BECs in two ground states $|g_1\rangle$ and $|g_2\rangle$ coherently coupled by a two-photon transition (Raman-lasers or microwave-radiofrequency combination). The ground states are additionally coupled by an irreversible Raman transition via an intermediate spontaneously decaying level $|e\rangle$. One transition is not driven but stimulated by a ring cavity mode $\hat{a}$.

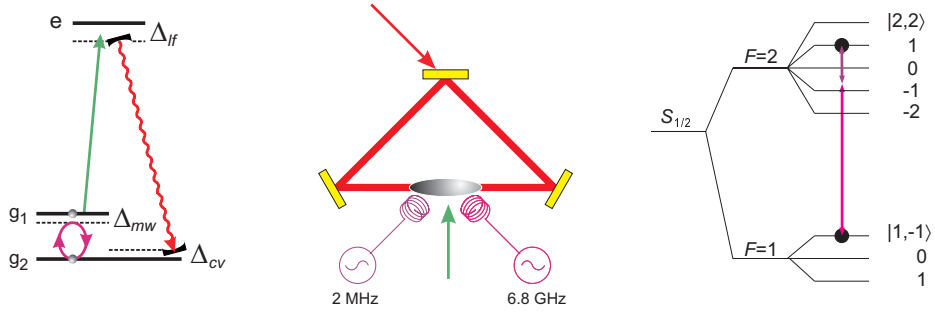

Figure 47.33: (code) (a) Level scheme with a microwave-driven hyperfine structure, a laser-driven optical transition, and a cavity-enhanced Raman deexcitation. (b) Ring cavity used for the experiment. (c) Scheme for coupling the Zeeman states $|2,1\rangle$ and $|1,-1\rangle$ with a two-photon transition in a magnetic trap.

The Hamiltonian consists of three parts, the BEC energy $\mathcal{H}_{bec}$, the interaction energy with the coherent coupling assumed to be classical $\mathcal{H}_{cpl}$ and the interaction

with the mode of a ring cavity $\mathcal{H}_{cav}$ treated quantum mechanically ($\hbar = 1$),

$$\begin{aligned}\mathcal{H} &= \mathcal{H}_{bec} + \mathcal{H}_{cpl} + \mathcal{H}_{cav} \qquad (47.162)\\ &= \int d^3r\ \hat{\psi}_1^\dagger \left(\tfrac{-\nabla^2}{2m} + V + \tfrac{u_{11}}{2}\hat{\psi}_1^\dagger\hat{\psi}_1 + \tfrac{u_{12}}{2}\hat{\psi}_2^\dagger\hat{\psi}_2 \right)\hat{\psi}_1 +\\ &+ \int d^3r\ \hat{\psi}_2^\dagger \left(\tfrac{-\nabla^2}{2m} + V + \tfrac{u_{12}}{2}\hat{\psi}_1^\dagger\hat{\psi}_1 + \tfrac{u_{22}}{2}\hat{\psi}_2^\dagger\hat{\psi}_2 \right)\hat{\psi}_2 +\\ &+ \int d^3r\ \left(-\Delta_{mw}\hat{\psi}_1^\dagger\hat{\psi}_1 + \tfrac{\Omega_{mw}}{2}\hat{\psi}_1^\dagger\hat{\psi}_2 + h.c. \right) + \int d^3r\ \left(g_{cv}\hat{a}\hat{\psi}_1^\dagger\hat{\psi}_2 + h.c. \right) - \Delta_{cv}\hat{a}^\dagger\hat{a}\ .\end{aligned}$$

The BEC energy consists of the two energies (kinetic, potential, self) of the individual BECs and the cross-species interaction proportional to $u_{kl} = 4\pi\hbar^2 a_{kl}/m$. The interaction energy with the classical microwave frequency (mostly we will assume $\Delta_{mw} = 0$) leads to Rabi flopping with frequency Ω_{mw}. Finally, the incident light field is treated classically with a Rabi frequency Ω_{lf} and a detuning Δ_{lf}, while the cavity field is treated quantum mechanically with a coupling constant Ω_{cv} and a detuning Δ_{cv}. The irreversible coupling leads to an energy contribution where $g_{cv} \equiv \Omega_{lf}\Omega_{cv}/2\Delta_{lf}$ is the two-photon Rabi-frequency if the auxiliary state is adiabatically eliminated. From the Heisenberg equations of motion for the matter wave and the optical field operators we obtain,

$$\begin{aligned}\dot{\hat{\psi}}_1 &= \imath[H, \hat{\psi}_1] = -\imath\frac{\delta H}{\delta\hat{\psi}_1^\dagger} \qquad (47.163)\\ &= -\imath\left(\frac{-\nabla^2}{2m} + V + u_{11}|\hat{\psi}_1|^2 + u_{12}|\hat{\psi}_2|^2 \right)\hat{\psi}_1 - \imath\left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a} \right)\hat{\psi}_2 - \imath\Delta_{mw}\hat{\psi}_1\ ,\\ \dot{\hat{\psi}}_2 &= \imath[\hat{H}, \hat{\psi}_2] = -\imath\frac{\delta H}{\delta\hat{\psi}_2^\dagger}\\ &= -\imath\left(\frac{-\nabla^2}{2m} + V + u_{12}|\hat{\psi}_1|^2 + u_{22}|\hat{\psi}_2|^2 \right)\hat{\psi}_2 - \imath\left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a}^\dagger \right)\hat{\psi}_1\ ,\\ \dot{\hat{a}} &= \imath[\hat{H}, \hat{a}] - \tfrac{\kappa}{2}\hat{a} = -\imath\frac{\delta H}{\delta\hat{a}^\dagger} - \tfrac{\kappa}{2}\hat{a}\\ &= -\imath\int d^3r\ g_{cv}\hat{\psi}_1\hat{\psi}_2^\dagger - \left(\imath\Delta_{cv} + \tfrac{\kappa}{2} \right)\hat{a}\ .\end{aligned}$$

Example 292 (*Single atoms in two states interacting with a cavity*): As a first example, we start from the matter wave Hamiltonian (47.162) for two coupled BECs and neglect the center-of-mass motion (and consequence the condensate part, i.e. self-interaction, kinetic energy and the external potential). Furthermore, we assume $\hat{\psi}_i(\mathbf{r}) = \hat{c}_i\delta^3(\mathbf{r})$,

$$\begin{aligned}\mathcal{H} &= \mathcal{H}_{bec} + \mathcal{H}_{clp} + \mathcal{H}_{cav} \qquad (47.164)\\ &= -\Delta_{mw}\hat{c}_1^\dagger\hat{c}_1 + \tfrac{\Omega_{mw}}{2}\hat{c}_1^\dagger\hat{c}_2 + g_{cv}\hat{a}\hat{c}_1^\dagger\hat{c}_2 + h.c. - \Delta_{cv}\hat{a}^\dagger\hat{a}\ .\end{aligned}$$

Consequently, the Heisenberg equations of motion are simply,

$$\begin{aligned}\dot{\hat{c}}_1 &= -\imath\left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a} \right)\hat{c}_2 - \imath\Delta_{mw}\hat{c}_1 \qquad (47.165)\\ \dot{\hat{c}}_2 &= -\imath\left(\tfrac{\Omega_{mw}}{2} + g_{cv}\hat{a}^\dagger \right)\hat{c}_1\\ \dot{\hat{a}} &= -\imath g_{cv}\hat{c}_1\hat{c}_2^\dagger - \left(\imath\Delta_{cv} + \tfrac{\kappa}{2} \right)\hat{a}\ .\end{aligned}$$

Obviously, since the matter wave degree of freedom is ignored, the dynamics only concerns the Bloch vector. Simulations of these equations are exhibited in Fig. 47.34 and in movies that can be watched under (watch movie) and (watch movie).

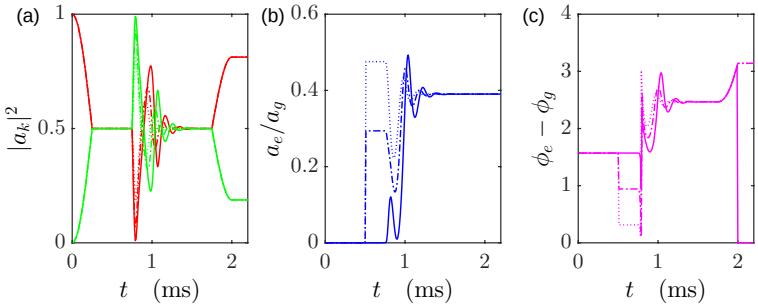

Figure 47.34: (code) Bloch vector phase stabilization in the cavity. (a) Populations and (b) coherences.

47.5.4.1 Phase description

If we replace all field operator $\hat{\psi}_k$ and $\hat{c}$ in the Eqs. (47.163) by c-numbers, we obtain a set of three equations that can be simulated by numerical procedures. Obviously, the equations then do not allow for quantum fluctuations and correlations. Furthermore, by setting,

$$\psi_k(\mathbf{r},t) \equiv \sqrt{N_k(t)}\varphi(\mathbf{r})e^{\imath\Phi_k} \ , \tag{47.166}$$

where $k = 1, 2$ and φ is invariable and normalized to $1 = \int d^3r \ |\varphi|^2$, we assume the condensates can only vary global phases and atom numbers and not their shape or local phases. Then, defining the chemical potentials as,

$$\mu_k \equiv \int d^3r \ \varphi \left(\frac{-\nabla^2}{2m} + V + u_{kk}N_k|\varphi|^2 + u_{kl}N_L|\varphi|^2 \right) \varphi \ , \tag{47.167}$$

and introducing new variables via $\Phi \equiv \Phi_1 - \Phi_2$ and $P_\Phi \equiv \frac{1}{2}(N_2 - N_1)$ we arrive at,

$$\boxed{\begin{array}{rcl} \dot{\Phi} & = & \mu_2 - \mu_1 - \Delta_{mw} - \dfrac{2P_\Phi}{\sqrt{N_1N_2}} \ \mathfrak{Re} \ \left(\frac{1}{2}\Omega_{mw} + g_{cv}c\right) e^{-\imath\Phi} \\ \dot{P}_\Phi & = & -2\sqrt{N_1N_2} \ \mathfrak{Im} \ \left(\frac{1}{2}\Omega_{mw} + g_{cv}c\right) e^{-\imath\Phi} \\ \dot{c} & = & -\imath g_{cv}\sqrt{N_1N_2}e^{\imath\Phi} - \left(\imath\Delta_{cv} + \frac{1}{2}\kappa\right) c \end{array}} \ , \tag{47.168}$$

as shown in 47.5.5.6.

47.5.4.2 Thomas-Fermi approximation

With $N = N_1 + N_2$ and $u_{12} - u_{11} \approx u_{22} - u_{12}$ difference of the self-energies is,

$$\begin{aligned}(\mu_2 - \mu_1) &= [(u_{12} - u_{11})N_1 + (u_{22} - u_{12})N_2] \int d^3r \ |\varphi|^4 \\ &\simeq (u_{12} - u_{11})N \int d^3r \ |\varphi|^4 \ .\end{aligned} \tag{47.169}$$

The integral is on the order of 1, but to be more accurate, we integrate the square of the Thomas-Fermi profile. This is an approximation, because the shape of the Thomas-Fermi profile depends on the number of condensed atoms. On the other hand, the approximation should be good when the mean-field energy is dominant. The density distribution of a BEC with N atoms in the Thomas-Fermi approximation is,

$$n = \frac{1}{u}\left(\mu - \frac{m}{2}\omega_\rho^2\rho^2 - \frac{m}{2}\omega_z^2 z^2\right) \ , \tag{47.170}$$

where $u = 4\pi\hbar^2 a_s/m$ and $2\mu = \left(\frac{15u}{4\pi}Nm^{3/2}\omega_\rho^2\omega_z\right)^{2/5}$. The BEC shape function is normalized. Hence,

$$\int d^3r \ |\varphi|^4 = \frac{1}{N^2}\int d\mathbf{r} \ n^2 = \frac{15}{4Nu_s(\hbar\mu)^{5/2}}\int(\hbar\mu\tilde{\rho}^2 - \tilde{z}^2)^2\tilde{\rho}d\tilde{\rho}d\tilde{z} = \frac{4\mu}{7Nu} \ . \tag{47.171}$$

Now, the equations to be simulated read,

$$\begin{aligned}\dot{\Phi} &= \frac{u_{12} - u_{11}}{7u\hbar}4\mu - \Delta_{mw} - \frac{4P_\Phi}{\sqrt{N^2 - 4P_\Phi^2}}\mathfrak{Re}\ \left(\tfrac{1}{2}\Omega_{mw} + g_{cv}c\right)e^{-\imath\Phi} \\ \dot{P}_\Phi &= -\sqrt{N^2 - 4P_\Phi^2}\,\mathfrak{Im}\ \left(\tfrac{1}{2}\Omega_{mw} + g_{cv}c\right)e^{-\imath\Phi} \\ \dot{c} &= -\tfrac{\imath}{2}g_{cv}\sqrt{N^2 - 4P_\Phi^2}e^{\imath\Phi} - (\imath\Delta_{cv} + \tfrac{1}{2}\kappa)c \ .\end{aligned} \tag{47.172}$$

Example 293 (*Interpretation of the ultracold fusion via analogy with two-level system*): The chemical potential of the BECs in both states shifts the energy levels up depending on the inversion, $\mu_2 - \mu_1 \propto N_2 - N_1$. If the inversion oscillates the spontaneous Raman cycle periodically meets resonance, and takes place. Note that, since atomic motion is not considered, the energy gap due to the finite cavity detuning can only be bridged in resonance, $\mu_2 - \mu_1 = \kappa$. Oscillation simulates Doppler shift of thermal motion in Doppler cooling. Raman scattering takes the role of spontaneous emission in the cooling process. The only role of the cavity is to introduce irreversibility. Raman scattering is only supported in one direction: However, it is not relevant to have a ring cavity.

47.5.4.3 Basic Josephson junction (case i)

To gain an understanding of the Eqs. (47.168), let us treat some special cases. Let us first assume the absence of a driven auxiliary level, $\Omega_{lf}, \Omega_{cv}, g_{cv} = 0$. If $\sqrt{N_1 N_2} \simeq \frac{1}{2}N$,

the last equations read,

$$\begin{aligned}\dot\Phi &= \mu_2 - \mu_1 - \Delta_{mw} - \frac{2\Omega_{mw}}{N} P_\Phi \cos\Phi \\ \dot P_\Phi &= \frac{N\Omega_{mw}}{2}\sin\Phi\ .\end{aligned} \tag{47.173}$$

To be able to draw an analogy between our system and the equations describing Josephson Junctions we set $u_{11} = u_{22}$. This assumption is questionable as in reality $u_{11} < u_{12} < u_{22}$ and thus $\mu_2 - \mu_1 \propto N$ rather than $\mu_2 - \mu_1 \propto N_2 - N_1$. All conclusions based on this approximation should be taken with great caution.

Setting $\sqrt{N_1 N_2} \approx \frac{1}{2}N$ so that $\mu_2 - \mu_1 = (u_{11} - u_{12})(N_2 - N_1)\int d\mathbf{r}\,|\varphi^4(\mathbf{r})| = 2\hbar U P_\Phi$ and furthermore assuming $\Delta_{cv} = 0$ and $P_\Phi \ll N$,

$$\dot\Phi = 2UP_\Phi \quad , \quad \dot P_\Phi = \frac{N\Omega}{2}\sin\Phi\ . \tag{47.174}$$

These equations are formally identical to those describing a *Josephson junction* in a superconductor, if we interpret Φ as the voltage across the junction and P_Φ as the Josephson current.

47.5.4.4 Resistively shunted Josephson junction (case ii)

With the same approximations as above, but now including a driven auxiliary level, $\Omega_{lf}, \Omega_{cv}, g_{cv} \neq 0$,

$$\begin{aligned}\dot\Phi &= 2UP_\Phi - \frac{4P_\Phi}{N}\mathfrak{Re}\ \left(\tfrac{1}{2}\Omega_{mw} + g_{cv}c\right)e^{-\imath\Phi} \approx 2UP_\Phi \\ \dot P_\Phi &= -N\mathfrak{Im}\ \left(\tfrac{1}{2}\Omega_{mw} + g_{cv}c\right)e^{-\imath\Phi}\ , \\ \dot c &= -\tfrac{\imath}{2}g_{cv}Ne^{\imath\Phi} - \left(\imath\Delta_{cv} + \tfrac{1}{2}\kappa\right)c\ .\end{aligned} \tag{47.175}$$

We adiabatically eliminate c to second order, i.e. $\ddot c = 0$,

$$\begin{aligned}\ddot c &= \tfrac{1}{2}g_{cv}N\dot\Phi e^{\imath\Phi} - \left(\imath\Delta_{cv} + \tfrac{1}{2}\kappa\right)\left[-\tfrac{\imath}{2}g_{cv}Ne^{\imath\Phi} - \left(\imath\Delta_{cv} + \tfrac{1}{2}\kappa\right)c\right] = 0 \\ c &= \frac{-\imath g_{cv}Ne^{\imath\Phi}}{2\imath\Delta_{cv} + \kappa} - \frac{2g_{cv}N\dot\Phi e^{\imath\Phi}}{\left(2\imath\Delta_{cv} + \kappa\right)^2}\ .\end{aligned} \tag{47.176}$$

Finally,

$$\frac{1}{2U}\ddot\Phi = \dot P_\Phi = \frac{N\Omega_{mw}}{2}\sin\Phi + \frac{g_{cv}^2N^2\kappa}{4\Delta_{cv}^2 + \kappa^2} - \frac{8g_{cv}^2N^2\Delta_{cv}\kappa}{(4\Delta_{cv}^2 + \kappa^2)^2}\dot\Phi \tag{47.177}$$

defining a fictive mass M, a friction coefficient a_r and a force F_d by,

$$M = \frac{1}{2U} \quad , \quad a_r = \frac{8\Delta_{cv}g_{cv}^2N^2\kappa}{(\kappa^2 + 4\Delta_{cv}^2)^2} \quad , \quad F_d = \frac{g_{cv}^2N^2\kappa}{\kappa^2 + 4\Delta_{cv}^2}\ , \tag{47.178}$$

we obtain

$$M\ddot\Phi + a_r\dot\Phi - \tfrac{1}{2}\Omega_{mw}N\sin\Phi = F_d\ . \tag{47.179}$$

This equation describes the motion of a fictitious phase particle. Another application of this equation is a pendulum driven by a tangential force, subject to friction and to gravitation. It is also used to describe a phase-locked loop or a resistively shunted Josephson junction. In the absence of the inertial term, i.e. in the overdamped case we obtain the so-called Adler equation. The force can be derived from a potential. One can also write down the kinetic and potential energies,

$$E_{kin} = \frac{P_\Phi^2}{2M} = U\dot{\Phi}^2 \quad , \quad V = F_d\Phi + \frac{\Omega_{mw}N}{2}\cos\Phi \ . \tag{47.180}$$

The washboard type potential is shown in Fig. 47.35(d). Hence, from the Hamiltonian $H = E_{kin} + E_{pot}$, we recover the equation of motion (without dissipation) using the Ehrenfest correspondences,

$$\dot{\Phi} = \frac{\partial H}{\partial P_\Phi} = P_\Phi/M \quad , \quad \dot{P}_\Phi = -\frac{\partial H}{\partial \Phi} = F_d - \tfrac{1}{2}\Omega_{mw}N\sin\Phi \ . \tag{47.181}$$

With $P_\Phi = -\imath\partial/\partial\Phi$ we find the commutator,

$$[\Phi, P_\Phi] = \imath \ . \tag{47.182}$$

Stationary solutions, $\dot{\Phi} = 0$, occur at the phases,

$$\Omega_{mw}\sin\Phi = -\frac{2F_d}{N} \ . \tag{47.183}$$

Fig. 47.35(b) shows the range of possible Ω for which stable phases exist. In order to check if the solutions are stable, we expand $\Phi \equiv \Phi_0 + \Phi_1$ with $\dot{\Phi} = 0$ and $\sin(\Phi_0 + \Phi_1) \approx \sin\Phi_0 + \Phi_1\cos\Phi_0$, and get in first order

$$a_r\dot{\Phi}_1 - \frac{\Omega_{mw}N}{2}\Phi_1\cos\Phi_0 = 0 \ . \tag{47.184}$$

The solution $\Phi_1 \sim e^{\varepsilon t}$ with $\varepsilon = \Omega N/2a_r\ \cos\Phi_0$ is stable only if $\varepsilon < 0$, which requires $\Phi_0 < 3\pi/2$ and excludes the upper half of the branch. For simulations,

$$\begin{aligned} \dot{\Phi} &= \Psi \\ \dot{\Psi} &= \Omega_{mw}NU\sin\Phi - 2Ua_r\Psi + 2UF_d \\ c &= \frac{-igNe^{\imath\Phi}}{2i\nu + \kappa} - \frac{2gN\dot{\Phi}e^{\imath\Phi}}{(2i\nu+\kappa)^2} \ . \end{aligned} \tag{47.185}$$

47.5.4.5 Stationary solutions of full model (case iii)

We now come back to the Eqs. (47.168). They read at steady-state using $c = |c|e^{\imath\Phi_C}$,

$$\begin{aligned} \frac{\mu_1 - \mu_2}{\hbar} + \Delta_{mw} &= \frac{-2P_\Phi}{\sqrt{N_1N_2}}\mathfrak{Re}\ \left(\tfrac{1}{2}\Omega_{mw} + g_{cv}|c|e^{\imath\Phi_C}\right)e^{-\imath\Phi} \\ 0 &= \mathfrak{Im}\ \left(\tfrac{1}{2}\Omega_{mw} + g_{cv}|c|e^{\imath\Phi_C}\right)e^{-\imath\Phi} \\ \left(\imath\Delta_{cv} + \tfrac{1}{2}\kappa\right)|c| &= -ig_{cv}\sqrt{N_1N_2}e^{\imath(\Phi-\Phi_C)} \ . \end{aligned} \tag{47.186}$$

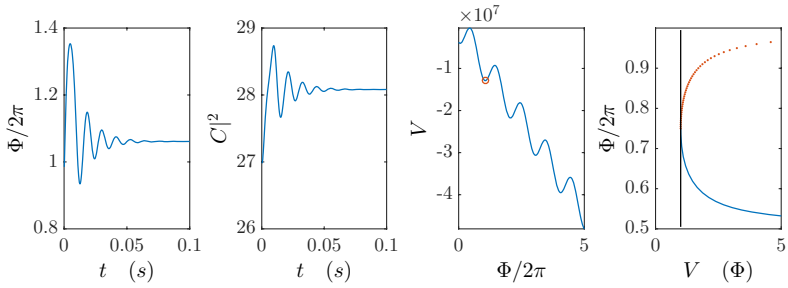

Figure 47.35: (code) Simulation of the shunted JJ model Eq. (47.179). (a) Damping of the phase difference. (b) Stable branch from a linear stability analysis. (c) Photon number in the cavity from Eq. (47.172)(c). (d) Washboard potential for the fictitious phase particle.

Setting $\Delta_{mw} = 0$ and evaluating real parts and imaginary parts separately, we arrive at,

$$\begin{aligned}
\frac{\mu_1 - \mu_2}{\hbar} &= \frac{-2P_\Phi}{\sqrt{N_1 N_2}} \left(\tfrac{1}{2}\Omega_{mw} \cos\Phi + g_{cv}|c| \cos(\Phi_C - \Phi) \right) \\
0 &= -\tfrac{1}{2}\Omega_{mw} \sin\Phi + g_{cv}|c| \sin(\Phi_C - \Phi) \\
\tfrac{1}{2}\kappa|c| &= g_{cv}\sqrt{N_1 N_2} \sin(\Phi - \Phi_C) \\
\Delta_{cv}|c| &= -g_{cv}\sqrt{N_1 N_2} \cos(\Phi - \Phi_C)
\end{aligned} \tag{47.187}$$

and

$$\begin{aligned}
\frac{\mu_1 - \mu_2}{\hbar} &= \frac{-2P_\Phi}{\sqrt{N_1 N_2}} \left(\tfrac{1}{2}\Omega_{mw} \cos\Phi - \frac{\Delta_{cv}|c|^2}{\sqrt{N_1 N_2}} \right) \\
\kappa|c|^2 &= -\Omega_{mw}\sqrt{N_1 N_2} \sin\Phi \\
\left(\Delta_{cv}^2 + \tfrac{1}{4}\kappa^2\right)|c|^2 &= g_{cv}^2 N_1 N_2
\end{aligned} \tag{47.188}$$

yielding

$$\Omega_{mw} \sin\Phi = -\frac{4F_d\sqrt{N_1 N_2}}{N^2} \quad , \quad |c|^2 = \frac{4F_d N_1 N_2}{\kappa N^2} \tag{47.189}$$

and

$$\begin{aligned}
\Omega_{mw} \cos\Phi &= -\frac{\sqrt{N_1 N_2}}{P_\Phi} \frac{(\mu_1 - \mu_2)}{\hbar} + \frac{2\Delta_{cv}|c|^2}{\sqrt{N_1 N_2}} \\
\Omega^2 &= \left(\frac{4F_d\sqrt{N_1 N_2}}{N^2} \right)^2 + \left(2\sqrt{N_1 N_2}U + \frac{8\Delta_{cv}\sqrt{N_1 N_2}F_d}{\kappa N^2} \right)^2
\end{aligned} \tag{47.190}$$

identify a bistable region

This yields if initially $N_1 = N_2 = \frac{1}{2}N$ and $\Delta = 0$,

$$\begin{aligned}
\Omega \sin\Phi &= -\frac{2F_d}{N} \quad , \quad |c|^2 = \frac{F_d}{\kappa} \\
\Omega^2 &= \left(\frac{2F_d}{N} \right)^2 + \left(NU + \frac{4\Delta_{cv}F_d}{\kappa N} \right)^2 ,
\end{aligned} \tag{47.191}$$

which confirms Eq. (47.184).

47.5.4.6 Paradox with fixed atom numbers

According to Pitaevskii a phase synchronization requires the exchange of atoms. If we knew the exact atom number in each well, the relative phases had to be uncertain. This is how the Mott-Insulator works. If no atoms are exchanged by Josephson tunneling, we could measure N_j, and due to cavity coupling still know that the phases are fixed. *Probably* Pitaevskii is right: It makes no sense talking of the de Broglie phases of BECs at different antinodes, if the BECs are not coherently coupled. The cavity mode do not couple the de Broglie phases. If this is true, then a cavity standing wave can support two ground state BECs without a fixed relationship between them. Any phase difference between them turn into excitations *only as soon as the BECs are directly coupled*.

How about there is some coherence in the atom numbers (spin squeezing) like in the Mott insulator. Then coherence would reappear as the BECs are melted.

On the other hand, if the BEC would decouple, sound could not propagate. Is N_j the right quantum number, shouldn't we rather consider atom-photon correlations, polaritons, or what? Also the notion of well-known or fixed atom numbers has to be clarified, because their location may change due to the displacement of the standing wave. For example, we could say: *fixed atom number at a given location*, having in mind a device that constantly and non-destructively measures the number of atoms within a well-defined area of space. Or we could say: *fixed atom number in a given antinode* and imagine a system, which tracks the antinodes' location and constantly and non-destructively measures the number of atoms within this antinode. Also we can imagine a Gedankenexperiment were exactly two BECs produced in different vacuum chambers are trapped in different antinodes of the same ring cavity standing wave.

47.5.4.7 Simulation of the 1D coupled GPE equations

Our goal is to directly simulate the complete set of coupled GPEs (47.166). We will however assume that the intermediate state of the two-photon coupling can be adiabatically eliminated and we will restrict ourselves to one dimension.

In order to go to 1D, we first calculate the chemical potential of a cylindrically symmetric BEC. In the Thomas-Fermi limit,

$$n(\mathbf{r}) = \frac{\mu - U(\mathbf{r})}{u} \ , \tag{47.192}$$

The chemical potential follows from the normalization condition,

$$N = \int_{n(\mathbf{r})>0} n(\mathbf{r}) d^3r = \frac{4\pi}{u} \frac{4}{15} \frac{\sqrt{2}\mu^{5/2}}{m^{3/2}\omega_r^2\omega_z} \ . \tag{47.193}$$

We obtain,

$$\mu = \left(\frac{15Nu}{\sqrt{2}16\pi} m^{3/2}\omega_r^2\omega_z \right)^{2/5} \ , \tag{47.194}$$

with $u \equiv 4\pi\hbar^2 a_s/m$. The radial size of the BEC follows from $n(r_{hw}, 0) = \frac{n(0,0)}{2}$ and reads,

$$r_{hw} = \sqrt{\frac{\mu}{m\omega_r^2}} \ . \tag{47.195}$$

Often it is a good approximation to assume condensates which are *radially homogeneous* two-dimensional condensates over a width r_{hw}. This may be the case for pancake shape traps. In this case we may neglect the radial kinetic energy. Since the normalization then requires,

$$\int_{-r_h}^{r_h}\int_{-r_h}^{r_h}\int_{-\infty}^{\infty}|\psi(\mathbf{r})|^2 d^3r = (2r_{hw})^2\int_{-\infty}^{\infty}|\psi(z)|^2 dz = 1 \ , \tag{47.196}$$

by substituting $\psi(\mathbf{r}) = \frac{\phi(z)}{2r_{hw}}$ and $u_{1D} = \frac{u}{(2r_{hw})^2}$, the GPE and the normalization condition adopts a particularly simple form,

$$\imath\hbar\frac{\partial}{\partial t}\phi(z) = \left(-\frac{\hbar^2}{2m}\frac{\partial^2}{\partial z^2} + V_{trap}(z) + N\ u_{1D}|\phi(z)|^2\right)\phi(z) \ . \tag{47.197}$$

Now applying the Thomas-Fermi approximation for a harmonic potential, we get,

$$|\phi(z)|^2 = \frac{\mu - \frac{m}{2}\omega_z^2 z^2}{N\ u_{1D}} \ . \tag{47.198}$$

with,

$$\mu = \left(\tfrac{9}{32}u_{1D}^2 N^2 m\omega_z^2\right)^{1/3} \ . \tag{47.199}$$

47.5.4.8 Finding the ground state with steepest descent

Characteristic length scale $z \in [-7\,\mu\text{m}, 7\,\mu\text{m}]$, radial trap frequency $\omega_z = 2\pi\cdot 40\,\text{Hz}$, potential,

$$V_1 = V_2 = \frac{m}{2}\omega_z^2 z^2 \ . \tag{47.200}$$

We start with Gaussian density distribution assuming that all atoms are inthe ground state,

$$\psi = \frac{e^{-z^2/2z_{ho}^2}}{\sqrt{\int e^{-z^2/z_{ho}^2}dz}} \ , \tag{47.201}$$

with $z_{ho} = \sqrt{\hbar/m\omega_z}$.

In reality the BEC is rather in the Thomas-Fermi limit. To calculate this, we propagate the one-dimensional GPE,

$$\left[\frac{-\hbar^2}{2m}\nabla^2 + V(z) + Nu_{1D}|\psi|^2\right]\psi = \imath\hbar\frac{d}{dt}\psi \tag{47.202}$$

in imaginary time in order to find the ground state. Here $u_{1D} = \frac{\pi\hbar^2 a_s}{m r_{hw}^2}$. The resulting wavefunction is our starting point for all subsequent simulations.

47.5.4.9 Coupled condensates with cavity, Runge-Kutta method

The interaction strengths for the states $|2,1\rangle$ and $|1,-1\rangle$ are $(u_{11}, u_{12}, u_{22}) = (0.97, 1, 1.03)u_{1D}$. We take the equations of [663]. Defining the following spinor,

$$\Psi \equiv \begin{pmatrix}\psi_1\\ \psi_2\\ c\end{pmatrix} \ , \tag{47.203}$$

and writing the coupled GPE equations like,

$$K[\Psi] \equiv -\frac{\imath}{\hbar} dt \begin{pmatrix} \left(\frac{-\hbar^2}{2m}\nabla^2 + V_1 + Nu_{11}|\psi_1|^2 + Nu_{12}|\psi_2|^2\right)\psi_1 + \hbar\left(\frac{\Omega_{mw}}{2} + g_{cv}c\right)\psi_2 + \hbar\Delta_{mw}\psi_1 \\ \left(\frac{-\hbar^2}{2m}\nabla^2 + V_1 + Nu_{22}|\psi_2|^2 + Nu_{12}|\psi_1|^2\right)\psi_2 + \hbar\left(\frac{\Omega_{mw}}{2} + g_{cv}c^*\right)\psi_1 \\ \hbar\int g_{cv}\psi_1\psi_2^* dz + \hbar\left(\Delta_{cv} - \imath\frac{\kappa}{2}\right)c \end{pmatrix} , \tag{47.204}$$

we can employ the forth-order Runge-Kutta method via,

$$\begin{aligned} \delta\psi_a &= K[\Psi] \quad , \quad \delta\psi_1 = K\left[\Psi + \tfrac{1}{2}\delta\psi_a\right] \quad , \\ \delta\psi_C &= K\left[\Psi + \tfrac{1}{2}\delta\psi_1\right] \quad , \quad \delta\psi_d = K\left[\Psi + \delta\psi_C\right] \\ \Psi &= \psi_1 + \frac{\delta\psi_{1a}}{6} + \frac{\delta\psi_{1b}}{3} + \frac{\delta\psi_{1c}}{3} + \frac{\delta\psi_{1d}}{6} \ . \end{aligned} \tag{47.205}$$

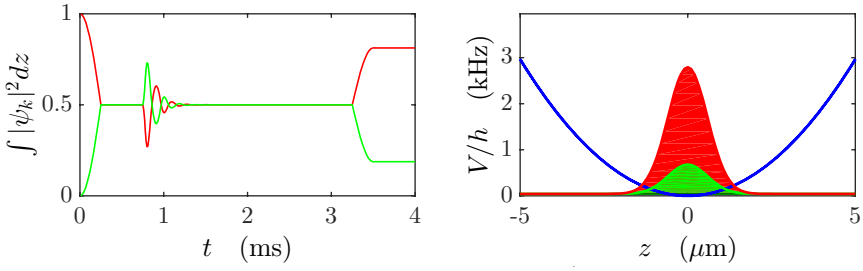

Figure 47.36: (code) Ramsey cycle with intermediate cavity damping.

Even though better than the Euler method, the Runge-Kutta method diverges too fast, and especially the calculation of the gradient is too slow.

47.5.4.10 Coupled condensates without cavity, time-splitting spectral algorithm

An alternative method is the *time-splitting spectral algorithm*, which is more robust for trap oscillation, because it accepts periodic boundary conditions. Write the one-dimensional GPE in the form,

$$\imath\hbar\frac{\partial\psi(x,t)}{\partial t} = -\frac{\hbar^2}{2m}\Delta\psi(x,t) + V(x)\psi(x,t) + N\frac{4\pi\hbar^2 a_s}{m(2r_{hw})^2}|\psi(x,t)|^2\psi(x,t) \tag{47.206}$$

for $a < x < b$. Choose periodic boundary conditions, $\psi(a,t) = \psi(b,t)$ and $\psi_x(a,t) = \psi_x(b,t)$. Various methods are known to solve the GPE numerically, such as the *Crank-Nicholson algorithm*. The time-splitting spectral algorithm consists in solving the first and the second of the following equations in two distinct steps [85, 84, 83, 486],

$$\begin{aligned} \frac{\partial\psi(x,t)}{\partial t} &= -\imath\frac{V(x)}{\hbar}\psi(x,t) - \imath N\frac{u_{1D}}{\hbar}|\psi(x,t)|^2\psi(x,t) \\ \frac{\partial\psi(x,t)}{\partial t} &= \imath\frac{\hbar^2}{2m}\psi_{xx}(x,t) \ , \end{aligned} \tag{47.207}$$

i.e. we discretize in space using $x = a + j(b-a)/M$ and $k = 2\pi l/(b-a)$ such that $k(x-a) = 2\pi lj/M$. We propagate half the way, $\Delta t/2$, in time,

$$\varphi_x \equiv e^{-\frac{\imath}{\hbar}(V(x)+u_{1D}|\psi(x,t)|^2)\frac{\Delta t}{2}}\psi(x,t) \tag{47.208}$$

for $j = 0, .., M-1$. Now we propagate the spectral components, $(\mathcal{F}\varphi)_k \equiv \sum_{j=0}^{M-1}\varphi_x e^{-2\pi\imath lj/M}$, in momentum space and transform back, $\left(\mathcal{F}^{-1}\varphi\right)_x \equiv M^{-1}\sum_{l=-M/2}^{M/2-1}\varphi_k e^{2\pi\imath lj/M}$,

$$\phi_x \equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}(\mathcal{F}\varphi)_k\right] \ . \tag{47.209}$$

for $l = -M/2, .., M/2-1$. Finally, we propagate the remaining time, $\Delta t/2$,

$$\psi(x, t+dt) = e^{-\frac{\imath}{\hbar}(V(x)+u_{1D}|\phi_x|^2)\frac{\Delta t}{2}}\phi_x \ . \tag{47.210}$$

Now we just have to generalize this method to coupled GPEs. We simplify the notation by writing the wavefunction as a spinor, $\vec{\psi} \equiv \begin{pmatrix}\psi_1\\ \psi_2\end{pmatrix}$. Now the non-kinetic part of the coupled GPE can be written,

$$\frac{\partial\vec{\psi}(x,t)}{\partial t} = M\vec{\psi}(x,t) \tag{47.211}$$

with the matrix,

$$M = \begin{pmatrix} -\frac{\imath}{\hbar}V(x) - \frac{\imath}{\hbar}u_{1D}|\psi_1(x,t)|^2 - \imath\Delta_{mw} & -\frac{\imath}{2}\Omega_{mw} \\ -\frac{\imath}{2}\Omega_{mw} & -\frac{\imath}{\hbar}V(x) - \frac{\imath}{\hbar}u_{1D}|\psi_2(x,t)|^2 \end{pmatrix} \tag{47.212}$$

and the solution

$$\vec{\psi}(x,t) = e^{Mt}\vec{\psi}(x,0) \ . \tag{47.213}$$

Let us now abbreviate the matrix by,

$$M = \begin{pmatrix} A & B \\ B & D \end{pmatrix} \ . \tag{47.214}$$

The matrix is diagonalized with the unitary transforms,

$$U = \frac{1}{\sqrt{2\Delta}}\begin{pmatrix} \frac{A-D}{2B} + \Delta & \frac{A-D}{2B} - \Delta \\ 1 & 1 \end{pmatrix} \quad \text{and} \quad U^{-1} = \frac{1}{\sqrt{2\Delta}}\begin{pmatrix} 1 & -\frac{A-D}{2B} + \Delta \\ -1 & \frac{A-D}{2B} + \Delta \end{pmatrix} \ . \tag{47.215}$$

The eigenvalue matrix is,

$$U^{-1}MU = \begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix} \tag{47.216}$$

with $E_{1,2} = \frac{1}{2}A + \frac{1}{2}D \pm B\Delta$. Here we used the abbreviation $\Delta = \sqrt{\left(\frac{D-A}{2B}\right)^2 + 1}$. The formal solution now reads,

$$\vec{\psi}(x,t) = \exp\left[U\begin{pmatrix} E_1 & 0 \\ 0 & E_2 \end{pmatrix}U^{-1}t\right]\vec{\psi} = U\begin{pmatrix} e^{E_1 t} & 0 \\ 0 & e^{E_2 t} \end{pmatrix}U^{-1}\vec{\psi}(x,0) \ . \tag{47.217}$$

This formula can easily be computed, because the block matrices of transform U are diagonal in x.

The next step is to propagate the spectral components in momentum space independently for both states and transform back,

$$\phi_{x1} \equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}\left(\mathcal{F}\varphi_{x1}\right)_k\right] \tag{47.218}$$
$$\phi_{x2} \equiv \mathcal{F}^{-1}\left[e^{\imath\frac{\hbar}{2m}k^2\Delta t}\left(\mathcal{F}\varphi_{x2}\right)_k\right] \ .$$

Finally, we propagate the remaining time, $\Delta t/2$, using the same procedure as above.

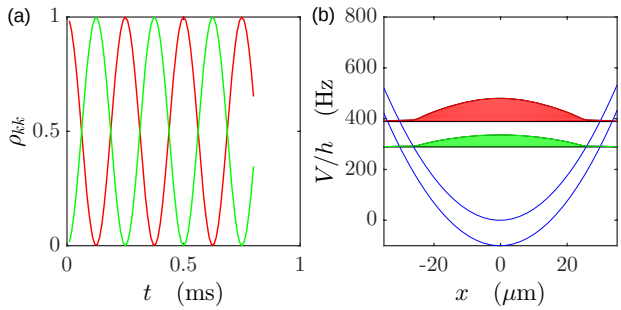

Figure 47.37: (code) Rabi flopping with oscillating BEC.

47.5.4.11 Experimental realization

To implement the proposed scheme, we need two stable ground states, e.g. hyperfine states coupled by a microwave radiation. The low field seeking states of ^{87}Rb, $|2,2\rangle$ and $|1,-1\rangle$, cannot be coupled by a microwave single-photon transition, nor by an optical two-photon transition. Furthermore, those states have different magnetic trapping strength, which would reduce the spatial overlap of the clouds. There are two options to circumvent the problem. Either, we transfer the atoms into an optical trap and apply a magnetic offset field. In this case we could use for example the $|2,-1\rangle$ and $|1,-1\rangle$ states and couple them by a microwave single photon transition. Or we transfer the atoms to a superposition of the low field seeking states $|2,1\rangle$ and $|1,-1\rangle$. These states must then be resonantly coupled with a two-photon transition, i.e. combination of a microwave and a radiofrequency. This is the option pursued in our approach.

47.5.4.12 Preparation of the system

We start from an experimental setup used for the first studies of condensates interacting with resonators [1217]. Atoms are trapped and precooled in magneto-optical traps and then transferred via several intermediate traps to a Ioffe type magnetic trap. Here a cloud of typically $N = 2 \cdot 10^5$ ^{87}Rb atoms is Bose-condensed by forced evaporation in the $|2,2\rangle$ hyperfine state.

Trap frequencies for atoms in the $|m_F| = 2$ states are measured to be in radial direction $\omega_r = 2\pi \cdot 281$ Hz and in axial direction $\omega_z = 2\pi \cdot 41.3$ Hz. In $|m_F| = 1$ states they are smaller by a factor of $\sqrt{2}$.

47.5.4.13 Transfer of the atoms to the cavity mode

Due to a misalignment of the Ioffe wires with respect to the cavity mode a large transverse homogeneous magnetic field must be applied ... compensation coils ... current stabilization of Agilent supply. A TEM_{00} mode of the cavity is permanently driven by a light field. In order to minimize heating and losses due to Rayleigh scattering [224], the BEC is moved around, between and into the center of the lobes of the TEM_{00} intensity distribution.

47.5.4.14 Transfer from $|2,2\rangle$ to $|2,1\rangle$

The atoms are transferred via the intermediate $|1,1\rangle$ state by means of two successive adiabatic microwave sweeps. The duration of both sweeps is $\Delta t = 600$ μs. Their frequency span is $\Delta\nu = 800$ kHz. The efficiency for the transfer is about 80% and heats the atomic cloud considerably. The populations of the various Zeeman states are probed using the Stern-Gerlach technique.

The Rabi frequency of the microwave is determined by varying the sweep time, measuring the transfer efficiency and fitting a Landau-Zener formula. The resulting microwave Rabi frequency is $\Omega_{mi} = 2\pi \cdot 72$ kHz. The adiabatic transfer achieved with the frequency sweeps can be described and simulated with three-level Bloch and Schrödinger equations.

47.5.4.15 Two-photon coupling $|2,1\rangle$ to $|1,-1\rangle$

We label the interesting states $|2\rangle \equiv |2,1\rangle$ and $|1\rangle \equiv |1,-1\rangle$. The hyperfine structure splitting is $\nu_{hf} = 6\ 834\ 682\ 610.904\ 30$ Hz, Zeeman-shift of the resonance frequency according to the Breit-Rabi formula $\nu_{zm} = -4$ kHz. The resonance frequency is at $\nu_{eg} = \nu_{hf} + \nu_{zm}$.

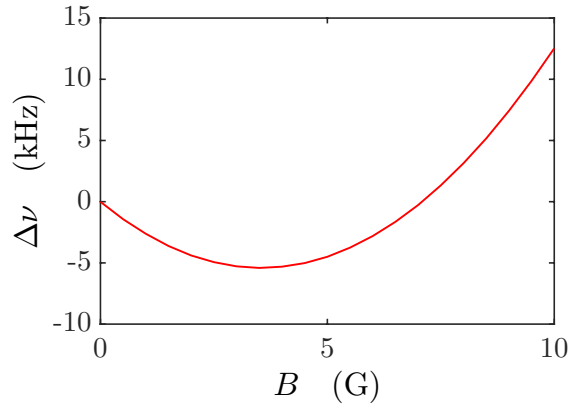

Figure 47.38: (code) (a) Frequency difference between $|2,1\rangle$ and $|1,-1\rangle$ as a function of magnetic field.

The two-photon transition uses $|i\rangle \equiv |2,0\rangle$ as an intermediate state. The detuning from this intermediate state is typically $\Delta_{is} = \pm 2\pi \cdot 200$ kHz. The measured total

Rabi frequency is then $\Omega_{mw} = \frac{\Omega_{mi}\Omega_{rf}}{2\Delta_{is}} = 2\pi \cdot 720$ Hz. From this we derive the radiofrequency Rabi frequency, $\Omega_{rf} = 2\pi \cdot 4$ kHz.

47.5.4.16 Imaging

The populations of both states are measured independently by time-of-flight absorption imaging. First, a vertical probe beam resonant to the transition between the $S_{1/2}, F = 2$ levels and the $P_{1/2}, F' = 3$ levels records the population in state $|e\rangle$. Then, a laser beam resonant to the repumping transition from $S_{1/2}, F = 1$ to $P_{1/2}, F' = 2$ pumps the $|1\rangle$ atoms into the $S_{1/2}, F = 2$ levels, where they are imaged by a horizontal probe beam. This allows us to measure the populations $N_k/(N_e + N_g)$ with low noise. Purging pulse???

47.5.4.17 Rabi flopping and excitation spectra

With three-level Bloch or Schrödinger equations we can simulate the Rabi flopping of the populations and the excitation spectra. However, we experimentally observe damping of the coherence that is not understood within the three-level model. They do not arise from the presence of the intermediate state $|i\rangle$, which is not populated during the interaction. To understand the damping we have to take into account spatial inhomogeneities and interatomic interaction in the condensate.

47.5.4.18 Collapse and revival

We observe collapse and revivals.

47.5.4.19 Mean-field effects

The triplet scattering length of ^{87}Rb is $a_s = 99a_B$. The scattering lengths for the useful low field seeking hyperfine states are $a_{|1,-1\rangle} = 1.03a_s$, $a_{|1,-1\rangle|2,1\rangle} = a_s$, and $a_{|2,1\rangle} = 0.97a_s$. Because $a_{|1,-1\rangle|2,1\rangle}/\sqrt{a_{|1,-1\rangle}a_{|2,1\rangle}} \approx 1.0005 > 1$ the BECs in the two hyperfine states tend to demix [575].[19]

Raised questions:

1. Why is it important that the chemical potential and any magnetic field fluctuations are small compared to the cavity linewidth, $\mu, \Delta B(t) \ll \kappa$?

2. The large impact of the ring cavity seems surprising in view of the poor cavity to free space ratio?

3. Why does it have to be a "ring" cavity? Only to prevent the spatial structuring of the BEC at the antinodes?

4. There are two phases, the de Broglie phase of the atomic motion (external degree) of freedom and the Bloch vector phase of the electronic motion (internal degree of freedom). Which one synchronizes? Both? Cool the atomic motion via dissipation of internal energy.

[19] Note that Jaksch et al. assume $a_{11} = a_{22} = 103a_B$.

47.5.4.20 Laser locking scheme

The cloud can be overlapped with the modes of a ring cavity with finesse $F = 150000$, which corresponds to the cavity linewidth $\kappa = 2\pi \times 10$ kHz. The cavity has the coupling strength $g_{cv} = 2\pi \times 80$ kHz.

An antenna couples a microwave frequency ω_{mw} into the cloud. The frequency is adjusted to resonance with the Zeeman-shifted hyperfine splitting, such that $\omega_{mw} = \omega_{hf} + \omega_{zm} = \omega_{|2\ 1\rangle} - \omega_{|1\ -1\rangle} + \frac{1}{2}\mu_B B_{offset}$. A titanium-sapphire laser at $\lambda = 797$ nm with frequency ω_{11} is tightly phase-locked to a TEM_{11} mode using the Pound-Drever-Hall method. This laser continuously probes the cavity during a whole experimental cycle. An AOM driven with a radiofrequency ω_{ao} shifts the laser frequency to $\omega_{pp} = \omega_{11} + \omega_{ao}$. This frequency pumps the atoms transversally to the ring cavity's optical axis. The AOM frequency is chosen such, that the Raman condition is fulfilled with the next but one cavity mode, i.e. $\omega_{pr} + \delta_\kappa = \omega_{11} + 2\delta_{fsr} = \omega_{mw} + \omega_{pp}$. Additionally, the pump frequency is modulated creating sidebands at the frequency $\omega_{eo} = \omega_{pr} + \delta_\kappa$, which are resonant with the next but one cavity mode in order to probe right detuning.

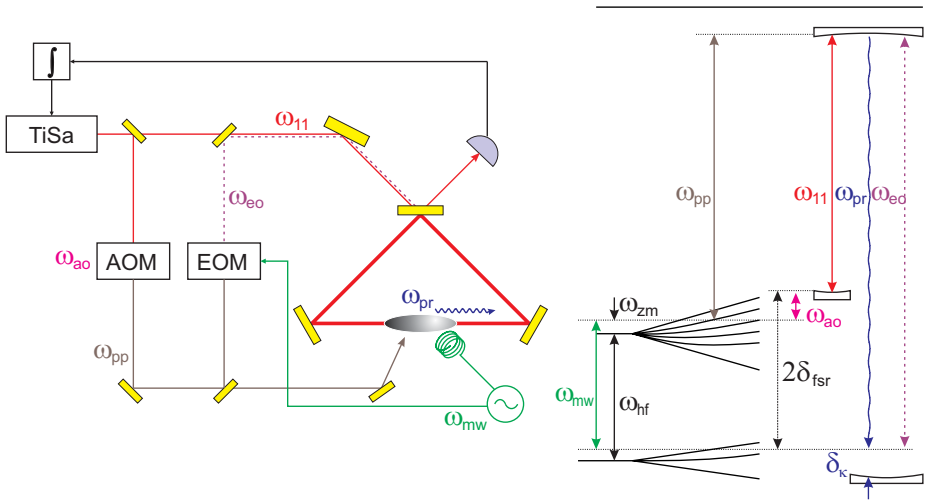

Figure 47.39: (code) (a) Laser locking scheme for ring cavity-assisted cycling. (b) Level scheme.

The Rabi frequency of the Raman laser ω_{pp} can be tuned over wide ranges, as well as its detuning from the auxiliary level. For example with $\Omega_{lf} = \Gamma = 2\pi \times 6$ MHz and $\Delta_{lf} = 10\Gamma = 2\pi \times 30$ GHz the light-shift is $g = \Omega_{lf}\Omega_{cv}/2\Delta_{1f} = 2\pi \times 10$ Hz. Consequently, the Raman coupling strength is $\sqrt{N}g$.

47.5.4.21 Time sequence

Let us now design the sequence and timing of a possible experiment. 1. Preparation of a BEC inside the Ioffe wire trap. 2. Transfer to $|21\rangle$ via $|11\rangle$. 3. Irradiation of a two-photon microwave $\pi/2$ pulse coupling the $|21\rangle$ and $|1-1\rangle$ states. 4. Attenuated

irradiation of the two-photon microwave frequency and transversal irradiation of an external light field. 5. Phase-interferometry.

47.5.4.22 Phase measurement

To prove the fusion of the two BECs, it is necessary to measure the evolution of their relative phase under the influence of the ring cavity-assisted cycling scheme. Internal state Ramsey interferometer with BECs have been demonstrated [574]. We use the definition of the two-species one-body density matrix,

$$\rho_{kl}(\mathbf{x},\mathbf{x}') \equiv \langle \hat{\psi}_l^\dagger(\mathbf{x}')\hat{\psi}_k(\mathbf{x})\rangle \simeq \sqrt{N_l N_k}\varphi^*(\mathbf{x}')\varphi(\mathbf{x})e^{\imath\Phi_k-\imath\Phi_l} \tag{47.219}$$

and at $\mathbf{x}=0$,

$$\begin{aligned}\rho_{12}(0,0) &= \sqrt{N_1N_2}|\varphi(0)|^2 e^{\imath\Phi} \\ \rho_{kk}(0,0) &= N_k|\varphi(0)|^2 \ .\end{aligned} \tag{47.220}$$

The fringe visibility is,

$$v(\mathbf{x}) = \frac{2|\rho_{12}(\mathbf{x},\mathbf{x})|}{\rho_{11}(\mathbf{x},\mathbf{x})+\rho_{22}(\mathbf{x},\mathbf{x})} \tag{47.221}$$

and at $\mathbf{x}=0$,

$$v(0) = \frac{2\sqrt{N_lN_2}}{N_l+N_2} = \sqrt{1-\frac{4P_\Phi^2}{N^2}} \ . \tag{47.222}$$

Probably one has to average over several initial phase randomly distributed over $[0,2\pi]$ [663].

47.5.4.23 Undamped Josephson coupling

The basic equations for a Josephson type coupling of a BEC in two states are [1377],

$$\imath\begin{pmatrix}\dot\Psi_1\\ \dot\Psi_2\end{pmatrix} = \begin{pmatrix}H_2^0+H_2^{MF}-\frac{\delta}{2} & \Omega\\ \Omega & H_1^0+H_1^{MF}+\frac{\delta}{2}\end{pmatrix}\begin{pmatrix}\Psi_2\\ \Psi_1\end{pmatrix} \ . \tag{47.223}$$

From this follows with $N_{ij}=\int dz\Psi_i^*(z)\Psi_j(z)$,

$$\begin{aligned}\dot N_2 &= -\imath\Omega(N_{21}-N_{12}) \\ \dot N_1 &= +\imath\Omega(N_{21}-N_{12}) \\ \dot N_{21} &= -\imath\delta N_{21}+\imath\Lambda(t)-\imath\Omega(N_2-N_1) \ .\end{aligned} \tag{47.224}$$

Here,

$$\Lambda(t) = \underbrace{-2z_0\int dz\ z\Psi_2^*(z)\Psi_1(z)}+\underbrace{\int dz(H_2^{MF}-H_1^{MF})\Psi_2^*(z)\Psi_1(z)} \ . \tag{47.225}$$

The first term in $\Lambda(t)$ comes from the different positions of the two condensates and is neglected here. The second term results from the mean-field energy difference. It would vanish, when the scattering lengths would be the same for both states, because

$$H_2^{MF}-H_1^{MF} = (\lambda_{22}-\lambda_{21})|\Psi_2|^2-(\lambda_{11}-\lambda_{21})|\Psi_1|^2 \ . \tag{47.226}$$

We now make the ansatz,

$$\Psi_j(z,t) = \sqrt{N_i(t)}e^{\imath\phi_i(t)}\Phi_i(z) \ . \tag{47.227}$$

Here, we allow the phase and the atom number to evolve in time, while the spatial evolution is separated. In Ref. [**?**] this spatial modulation is neglected!

By plugging into (1) we obtain the following equation of motion,

$$\begin{aligned}\dot{\eta} &= -k(1-\eta^2)^{1/2}\sin\phi \\ \dot{\phi} &= -[(\mu_2-\mu_1)-\delta] + k\eta(1-\eta^2)^{-1/2}\cos\phi \ .\end{aligned} \tag{47.228}$$

with

$$\begin{aligned}\eta &= \frac{N_2-N_1}{N} = \frac{2}{N}P_\Phi \\ \phi &= \phi_2-\phi_1 \\ k &= 2\Omega\underbrace{\int dz\Phi_2(z)\Phi_1(z)}_{1} = 2\Omega \ .\end{aligned} \tag{47.229}$$

Comparison with Ref. [**?**] yields (setting the cavity coupling to zero, $g=0$):

$$\begin{aligned}\frac{2}{N}\dot{P}_\Phi &= -2\Omega(1-\frac{4}{N^2}P_\Phi^2)^{1/2}\sin\phi \\ \dot{P}_\Phi &= -(N^2-4P_\Phi^2)^{1/2}\mathfrak{Im}\ (\frac{1}{2}\Omega e^{-\imath\phi}) \ .\end{aligned} \tag{47.230}$$

This coincides except for a factor of $-\frac{1}{2}$,

$$\begin{aligned}\dot{\phi} &= -[(\mu_2-\mu_1)-\delta] + k\eta(1-\eta^2)^{-1/2}\cos\phi \\ \dot{\phi} &= -[\mu_2-\mu_1-\delta] + 4\Omega\frac{P_\Phi}{\sqrt{N^2-4P_\Phi^2}}\cos\phi \\ \dot{\phi} &= \mu_2-\mu_1-\delta - \frac{4P_\Phi}{\sqrt{N^2-4P_\Phi^2}}\mathfrak{Re}\ (\frac{1}{2}\Omega e^{-\imath\phi}) \ .\end{aligned} \tag{47.231}$$

This coincides except for a factor of $-\frac{1}{2}$ in the last term.

47.5.4.24 Analytic estimations

Using Eq. (47.179) we calculate the friction coefficient $a_r = 56$, the force $F_d = 1125\omega$ and the critical Rabi frequency $2F_d/N = 0.38\omega$. Let us pick a point out of the stable branch in Fig. 47.35(b), for $\Phi = 1.25\omega$ we obtain from Eq. (47.184) $\Omega = -2F_d\sin\Phi/N = 0.27\omega$. The stationary photon number in the cavity is then obtained from the first Eq. (47.188), $|c|^2 = F_d/\kappa = 28$.

For an atom number $N = 6000$ and a mean density of $n = 1.8\times10^{14}$ cm^3 the selfenergy is $NU = 0.2\omega \approx h\times 44$ Hz and the mass of the phason is $M = (2U)^{-1} = 15000\omega^{-1}$. The real atom number will probably be 50 times higher.

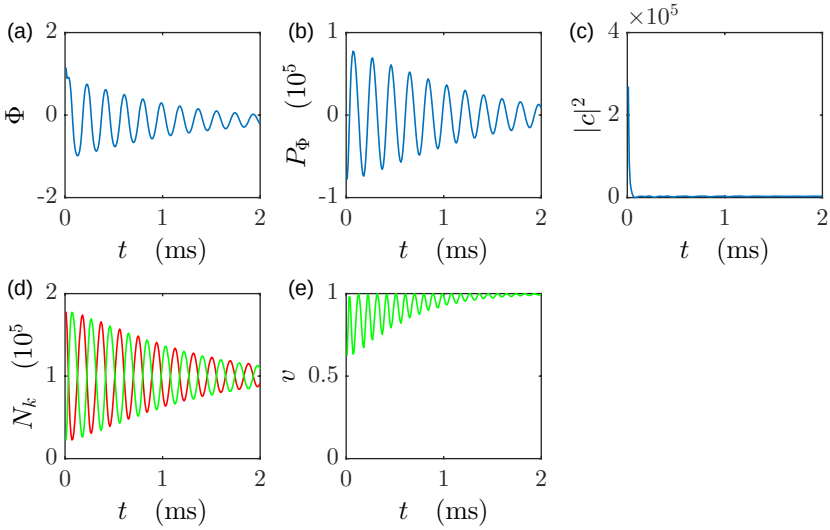

Figure 47.40: (code) Numerical simulation of the semiclassical two-mode model (47.172). Time-dependence of (a) the relative phase, (b) the particle number difference, (c) the light in the resonant cavity mode, and (d) the particle numbers in both modes. The parameters are $\Delta_{mw} = 0$, $\Omega_{mw} = 2\pi\times 5$ kHz, $\Delta_{lf} = -2\pi\times 20$ GHz, $\Omega_{lf} = 2\pi\times 6$ MHz, and $\Delta_{cv} = \Delta_{mw} - \kappa/2$. (e) Fringe visibility.

47.5.4.25 Arrays of coupled Josephson junctions

One-dimensional arrays of coupled Josephson junctions have been realized with standing wave dipole beams [240]. By combining this idea and the internal states JJs it may be possible to realize two-dimensional arrays of couples JJs. Is this useful for quantum computing?

Imagine a standing wave, where one or more antinodes are filled each one with two BEC species, i.e. BECs in different hyperfine levels. We couple the two levels with Raman beams. The question is now, whether the ring cavity damping mechanism allows to unite the BECs *within every well*. The idea of [663] of coupling via an auxiliary level is replaced by the ring cavity cooling mechanism?

47.5.5 Exercises

47.5.5.1 Ex: BEC damping in cavities

Programs on BEC damping in cavities.

Solution: *BecStandingWave1: periodic potential, steepest descent, then free expansion.*
BecStandingWave2: periodic potential, shifted after some time, shows Blochbands.
BecCavity0: Horak et al. PRA 61, 033609.
BecCavity1: steepest descent self-consistent with two stationary ring-cavity field modes.
BecCavity2: steepest descent self-consistent with two stationary ring-cavity field modes,

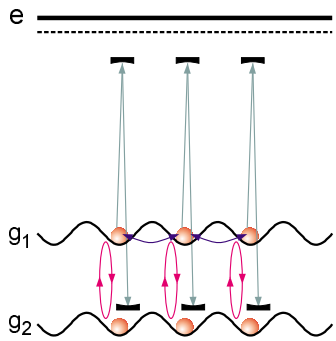

Figure 47.41: (a) Idea for a possible implementation of a $2D$ network of Josephson junctions.

correct norm, correct scaling.
BecCavity3: steepest descent followed by real-time propagation self-consistent with two stationary ring-cavity field modes.
BecCavity4: steepest descent propagation self-consistent with two time-dependent ring-cavity field modes.
BecCavity5: steepest descent self-consistent with two stationary ring-cavity field modes, correct norm, correct scaling to wavelength.
BecCavity5b: real-time self-consistent with two stationary ring-cavity field modes, correct norm, correct scaling to wavelength.

47.5.5.2 Ex: Second-quantized CARL equations

Calculate the commutators $[\hat{\psi}_j(\mathbf{r}), \mathcal{H}]$ and $[\hat{a}_\pm, \mathcal{H}]$, where $\mathcal{H}$ is the Hamiltonian (47.145) and $\hat{\psi}_1$ and $\hat{\psi}_2$ the ground and excited state wave functions, respectively.

Solution: *Using the commutation rules (47.143) we immediately find, ignoring collisions,*

$$
\begin{aligned}
[\hat{\psi}_1(\mathbf{r}), \mathcal{H}_{bec}] &= \left(\frac{-\nabla^2}{2m} + V_1(\mathbf{r}) \right) \hat{\psi}_1(\mathbf{r}) \\
[\hat{\psi}_2(\mathbf{r}), \mathcal{H}_{bec}] &= \left(\frac{-\nabla^2}{2m} + V_2(\mathbf{r}) - \Delta_a \right) \hat{\psi}_2(\mathbf{r}) \\
[\hat{\psi}_1(\mathbf{r}), \mathcal{H}_{atom-cav}] &= \sum_\pm g \hat{a}_\pm^\dagger \hat{\psi}_2(\mathbf{r}) e^{\mp \imath kz} \\
[\hat{\psi}_2(\mathbf{r}), \mathcal{H}_{atom-cav}] &= \sum_\pm g \hat{a}_\pm \hat{\psi}_1(\mathbf{r}) e^{\pm \imath kz} \\
[\hat{a}_\pm, \mathcal{H}_{atom-cav}] &= g \int d^3 r \hat{\psi}_2(\mathbf{r}) e^{\mp \imath kz} \hat{\psi}_1^\dagger(\mathbf{r}) \\
[\hat{a}_\pm, \mathcal{H}_{cav}] &= -\Delta_c \hat{a}_\pm \\
[\hat{a}_\pm, \mathcal{H}_{laser-cav}] &= \imath \eta_\pm \ .
\end{aligned}
$$

47.5.5.3 Ex: Second-quantized adiabatically approximated CARL Hamiltonian

a. Derive the adiabatically approximated CARL Hamiltonian in second quantization.
b. Derive the CARL equations of motion from the adiabatically approximated Hamiltonian in second quantization.
c. Show that the derived Hamiltonian simplifies to (42.26) in the single atom limit.

Solution: *a. With the results derived in Exc. 47.5.5.2 the Heisenberg equation of motion for the excited state field operator reads,*

$$\begin{aligned} 0 \stackrel{!}{=} \imath\frac{d\hat{\psi}_2(\mathbf{r})}{dt} &= [\hat{\psi}_2(\mathbf{r}), \mathcal{H}] \\ &= \left(\frac{-\nabla^2}{2m} + V_2(\mathbf{r}) - \Delta_a\right)\hat{\psi}_2(\mathbf{r}) + \sum_{\pm} g\hat{a}_{\pm}\hat{\psi}_1(\mathbf{r})e^{\pm\imath\mathbf{k}_{\pm}\cdot\mathbf{r}} \ . \end{aligned}$$

We neglect the kinetic and potential energy of the center-of-mass motion, which are small compared to Δ_a, and resolve for $\hat{\psi}_2$,

$$\hat{\psi}_2(\mathbf{r},\infty) = \frac{g}{\Delta_a}\left(\hat{a}_+\hat{\psi}e^{\imath kr} + \hat{a}_-\hat{\psi}e^{-\imath kr}\right) \ ,$$

where we simplified the notation by setting $\hat{\psi} \equiv \hat{\psi}_1$. We insert this result into the contributions to the Hamiltonian (47.145) containing $\hat{\psi}_2$,

$$\begin{aligned} \mathcal{H}_{atom} &= \int d^3r\hat{\psi}^\dagger(\mathbf{r}')\left(\frac{p^2}{2m} + V(\mathbf{r})\right)\hat{\psi}(\mathbf{r}') + \int d^3r\hat{\psi}_2^\dagger(\mathbf{r}')\left(\frac{p^2}{2m} + V(\mathbf{r}) - \Delta_a\right)\hat{\psi}_2(\mathbf{r}') \\ &\simeq H_{bec} + \frac{g^2}{\Delta_a^2}\int d^3r\left(\hat{a}_+^\dagger\hat{\psi}^\dagger e^{-\imath kr} + \hat{a}_-^\dagger\hat{\psi}^\dagger e^{\imath kr}\right)(-\Delta_a)\left(\hat{a}_+\hat{\psi}e^{\imath kr} + \hat{a}_-\hat{\psi}e^{-\imath kr}\right) \\ &= \mathcal{H}_{bec} - NU_0\left(\hat{a}_+^\dagger\hat{a}_+ + \hat{a}_-^\dagger\hat{a}_-\right) - U_0^\dagger\hat{a}_+\hat{a}_-\int d^3r\hat{\psi}^\dagger e^{-2\imath kr}\hat{\psi} - U_0\hat{a}_+\hat{a}_-^\dagger\int d^3r\hat{\psi}^\dagger e^{2\imath kr}\hat{\psi} \ , \end{aligned}$$

and

$$\begin{aligned} \mathcal{H}_{atom-cav} &= g\int d^3r\hat{\psi}_2^\dagger(\mathbf{r}')e^{\imath kr}\hat{\psi}(\mathbf{r}')a_+ + g\int d^3r\hat{\psi}_2^\dagger(\mathbf{r}')e^{-\imath kr}\hat{\psi}(\mathbf{r}')\hat{a}_- + h.c. \\ &= U_0\int d^3r\left(\hat{a}_+^{\dagger\hat{\psi}^\dagger}\hat{\psi} + \hat{a}_-^\dagger\hat{\psi}\dagger e^{2\imath kr}\hat{\psi}\right)\hat{a}_+ + U_0\int d^3r\left(\hat{a}_+^{\dagger\hat{\psi}^\dagger}e^{-2\imath kr}\hat{\psi} + \hat{a}_-^\dagger\hat{\psi}\dagger\hat{\psi}\right)\hat{a}_- + h.c. \\ &= NU_0\left(\hat{a}_+^\dagger\hat{a}_+ + \hat{a}_-^\dagger\hat{a}_-\right) + U_0\hat{a}_+^\dagger\hat{a}_-\int d^3r\hat{\psi}^\dagger e^{-2\imath kr}\hat{\psi} + U_0\hat{a}_+\hat{a}_-^\dagger\int d^3r\hat{\psi}^\dagger e^{2\imath kr}\hat{\psi} + h.c. \\ &= 2NU_0\left(\hat{a}_+^\dagger\hat{a}_+ + \hat{a}_-^\dagger\hat{a}_-\right) + 2U_0a_+^\dagger\hat{a}_-\int d^3r\hat{\psi}^\dagger e^{-2\imath kr}\hat{\psi} + 2U_0\hat{a}_+\hat{a}_-^\dagger\int d^3r\hat{\psi}^\dagger e^{2\imath kr}\hat{\psi} \ . \end{aligned}$$

Finally,

$$\begin{aligned}\mathcal{H} &= \mathcal{H}_{atom} + \mathcal{H}_{atom-cav} + H_{cav} + H_{laser-cav} \\ &\simeq H_{bec} + (\hat{N}U_0 - \Delta_c)\left(\hat{a}_+^\dagger \hat{a}_+ + \hat{a}_-^\dagger \hat{a}_-\right) \\ &\quad + U_0 \hat{a}_+^\dagger \hat{a}_- \int d^3r \hat{\psi}^\dagger e^{-2\imath kz}\hat{\psi} + U_0 \hat{a}_+ \hat{a}_-^\dagger \int d^3r \hat{\psi}^\dagger e^{2\imath kz}\hat{\psi} - \imath \sum_\pm \eta_\pm(\hat{a}_\pm - \hat{a}_\pm^\dagger) \ .\end{aligned}$$

This adiabatically approximated Hamiltonian looks very similar to (42.26).
b. The Heisenberg equations yield,

$$\begin{aligned}\imath \frac{d\hat{\psi}(\mathbf{r})}{dt} &= [\hat{\psi}(\mathbf{r}), \mathcal{H}] \\ &= \left(\frac{\hat{\mathbf{p}}^2}{2m} + V(\mathbf{r}) + u\hat{n}(\mathbf{r}) + U_0(\hat{a}_+^\dagger \hat{a}_+ + \hat{a}_-^\dagger \hat{a}_-) + \hat{a}_+\hat{a}_- e^{-2\imath kz} + \hat{a}_+\hat{a}_- e^{2\imath kz}\right)\hat{\psi}(\mathbf{r}) \ ,\end{aligned}$$

and

$$\imath \frac{d\hat{a}_\pm}{dt} = [\hat{a}_\pm, \mathcal{H}] = (NU_0 - \Delta_c)\hat{a}_\pm + U_0 \hat{a}_\mp \int \hat{\psi}^\dagger(\mathbf{r}) e^{\mp 2\imath kz}\hat{\psi}(\mathbf{r}) d^3r + \imath\eta_\pm \ ,$$

c. The single atom limit can be expressed by $\int d^3r \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r}) = 1$.

47.5.5.4 Ex: BEC-CARL equations from the adiabatically approximated CARL Hamiltonian

Derive the BEC-CARL equations from the adiabatically approximated CARL Hamiltonian (47.148).

Solution: *The BEC-CARL equations are,*

$$\begin{aligned}\imath\hbar \frac{d\hat{\psi}(\mathbf{r})}{dt} &= [\hat{\psi}(\mathbf{r}), \mathcal{H}] \\ &= \left(\frac{-\hbar^2\nabla^2}{2m} + V_1(\mathbf{r}) + \imath\hbar U_0(\hat{a}_-^\dagger e^{-\imath\mathbf{k}\cdot\mathbf{r}} - \hat{a}_- e^{\imath\mathbf{k}\cdot\mathbf{r}}) + \hbar(\hat{a}_+^\dagger \hat{a}_+ + \hat{a}_-^\dagger \hat{a}_-)U_0\right)\hat{\psi}(\mathbf{r}) \\ \imath\hbar \frac{d\hat{a}}{dt} &= [\hat{a}, \mathcal{H}] \\ &= -\hbar\delta + \imath U_0 \int d^3r \hat{\psi}_1^\dagger(\mathbf{r}) e^{-\imath\mathbf{k}\cdot\mathbf{r}}\hat{\psi}_1(\mathbf{r}) \ ,\end{aligned}$$

where $U_0 \equiv g^2/\Delta_a$.

47.5.5.5 Ex: Origin of quantum correlations

The BEC-CARL Hamiltonian has been shown to generate quantum correlations between optical and matter wave modes [918, 1036]. Discuss whether they are a many-body effect (bosonic stimulation) or just due to coherences between motional states

of single atoms.

Solution: *CARL is not conditioned to bosonic stimulation and even works with fermions. ???*

47.5.5.6 Ex: Ultracold fusion

Derive from Eqs. (47.165) using the definitions (47.167) and (47.168) the Eqs. (47.168).

Solution: *Substituting the definitions (47.167) into (47.165) we find,*

$$\begin{aligned}
\sqrt{N_1}\varphi\imath\dot{\Phi}_1 e^{\imath\Phi_1} + \frac{\dot{N}_1}{2\sqrt{N_1}}\varphi e^{\imath\Phi_1} &= -\imath\left(\frac{-\nabla^2}{2m} + V + u_{11}N_1\varphi^2 + u_{12}N_2\varphi^2 + \hbar\Delta_{mw}\right)\sqrt{N_1}\varphi e^{\imath\Phi_1} \\
&\quad - \imath\left(\frac{\Omega_{mw}}{2} + g_{cv}a\right)\sqrt{N_2}\varphi e^{\imath\Phi_2} \qquad (47.232) \\
\sqrt{N_2}\varphi\imath\dot{\Phi}_2 e^{\imath\Phi_2} + \frac{\dot{N}_2}{2\sqrt{N_2}}\varphi e^{\imath\Phi_2} &= -\imath\left(\frac{-\nabla^2}{2m} + V + u_{22}N_2\varphi^2 + u_{12}N_1\varphi^2\right)\sqrt{N_2}\varphi e^{\imath\Phi_2} \\
&\quad - \imath\left(\frac{\Omega_{mw}}{2} + g_{cv}a^*\right)\sqrt{N_1}\varphi e^{\imath\Phi_1} \\
\dot{a} &= -\imath\int d^3r\; g_{cv}\sqrt{N_1N_2}\varphi^2 e^{\imath(\Phi_1-\Phi_2)} - (\imath\Delta_{cv} + \tfrac{\kappa}{2})a\;.
\end{aligned}$$

We may eliminate the normalized wavefunction φ by multiplication it with φ and integration $\int d^3r$. Exploiting the definition of the chemical potential, we get,

$$\begin{aligned}
N_1\imath\dot{\Phi}_1 + \tfrac{1}{2}\dot{N}_1 &= -\imath\left(\frac{\mu_1}{\hbar} + \Delta_{mw}\right)N_1 - \imath\left(\tfrac{1}{2}\Omega_{mw} + g_{cv}a\right)\sqrt{N_1N_2}e^{\imath(\Phi_2-\Phi_1)} \\
-N_2\imath\dot{\Phi}_2 + \tfrac{1}{2}\dot{N}_2 &= \imath\frac{\mu_2}{\hbar}N_2 + \imath\left(\tfrac{1}{2}\Omega_{mw} + g_{cv}a\right)\sqrt{N_1N_2}e^{-\imath(\Phi_1-\Phi_2)} \\
\dot{a} &= -\imath g_{cv}\sqrt{N_1N_2}e^{\imath(\Phi_1-\Phi_2)} - \left(\imath\Delta_{cv} + \tfrac{1}{2}\kappa\right)a\;. \qquad (47.233)
\end{aligned}$$

The real parts of the sum $\frac{1}{\imath N_1}$(47.233)(a)+$\frac{1}{\imath N_2}$(47.233)(b) and of the difference (47.233)(b)−(47.233)(a) yield introducing $\Phi \equiv \Phi_1 - \Phi_2$, $P_\Phi \equiv \frac{1}{2}(N_2 - N_1)$,

$$\begin{aligned}
\dot{\Phi} &= \frac{\mu_2 - \mu_1}{\hbar} - \Delta_{mw} - \frac{2P_\Phi}{\sqrt{N_1N_2}}\mathfrak{Re}\;\left(\tfrac{1}{2}\Omega_{mw} + g_{cv}c\right)e^{-\imath\Phi}\;, \qquad (47.234) \\
\dot{P}_\Phi &= -2\sqrt{N_1N_2}\mathfrak{Im}\;\left(\tfrac{1}{2}\Omega_{mw} + g_{cv}c\right)e^{-\imath\Phi} \\
\dot{c} &= -\imath g_{cv}\sqrt{N_1N_2}e^{\imath\Phi} - \left(\imath\Delta_{cv} + \tfrac{1}{2}\kappa\right)c\;.
\end{aligned}$$

Chapter 48

Bosons and fermions in optical lattices and reduced dimensions

48.1 Condensation in reduced dimensions

In highly anisotropic trapping potentials the behavior of condensates can be dramatically altered by freezing inaccessible dimensions. We consider, for example, a condensate with the chemical potential μ trapped in the harmonic potential,

$$V_{trp} = \sum_{k=1,2,3} \tfrac{m}{2}\omega_k^2 x_k^2 \ . \tag{48.1}$$

If one of the secular frequencies exceeds the chemical potential, $\omega_k \gg \mu$, the corresponding degree of freedom is inaccessible to elementary excitations of the condensate and can be regarded as frozen. We discuss, in the following, the cases of condensates in one- and two-dimensional potentials.

48.1.1 Condensation in $1D$

We first consider the case $\omega_x, \omega_y \gg \omega_z$, such that the condensate is strongly compressed in the radial direction (x and y), such that the condensate takes the shape of a *cigar*. Then, deeply in the Thomas-Fermi regime, we can assume a *radially homogeneous* density distribution, that is, we can make ansatz,

$$\hat{\psi}(\mathbf{r}) \equiv C\hat{\phi}(z) \ , \tag{48.2}$$

where the constant is fixed by,

$$\int_{\mathbb{R}^3} |\hat{\psi}(\mathbf{r})|^2 d^3r = C^2 2\pi r_\perp^2 \int_{-\infty}^{\infty} |\phi(z)|^2 dz = 1 \ . \tag{48.3}$$

Requiring that the new one-dimensional wavefunction be normalized also, we conclude $C = (2\pi r_\perp^2)^{-1/2}$. Inserting the ansatz (48.2) into the stationary Gross-Pitaevskii equation we find immediately,

$$\boxed{\left(-\frac{\hbar^2}{2m}\frac{d}{dz} + V_{trp}(z) + N g_{1D}|\hat{\phi}(z)|^2\right)\hat{\phi}(z) = \mu\hat{\phi}(z)} \ , \tag{48.4}$$

where we introduced the abbreviation,

$$g_{1D} \equiv \frac{g}{(2r_h)^2} \ . \tag{48.5}$$

This GPE describes a condensate called *one-dimensional*.

Now applying the Thomas-Fermi approximation to a harmonic potential, we obtain,

$$|\hat{\phi}(z)|^2 = \frac{\mu - \frac{m}{2}\omega_z^2 z^2}{g_{2D}} \ . \tag{48.6}$$

with

$$\mu = \left(\tfrac{9}{32} g_{2D}^2 m \omega_z^2\right)^{1/3} \ . \tag{48.7}$$

48.1.2 Condensation in $2D$

Now, we consider the case $\omega_x, \omega_y \ll \omega_z$, such that the condensate is strongly compressed in the axial direction (x and y), such that the condensate takes the shape of a*panqueca*. Then, deeply in the Thomas-Fermi regime, we can assume a *axially homogeneous* density distribution, that is, we can make ansatz,

$$\hat{\psi}(\mathbf{r}) \equiv C\hat{\phi}(x,y) \ , \tag{48.8}$$

where the constant is fixed by,

$$\int_{\mathbb{R}^3} |\hat{\psi}(\mathbf{r})|^2 d^3r = C^2 2z_\perp \int_{\mathbb{R}^2} |\phi(x,y)|^2 dz = 1 \ . \tag{48.9}$$

Requiring that the new one-dimensional wavefunction be normalized also, we concludes $C = (2z_\perp)^{-1/2}$. Inserting the ansatz (48.2) into the stationary Gross-Pitaevskii equation we find immediately,

$$\boxed{\left(-\frac{\hbar^2}{2m}\frac{d}{dx} - \frac{\hbar^2}{2m}\frac{d}{dy} + V_{trp}(x,y) + N g_{2D}|\hat{\phi}(x,y)|^2\right)\hat{\phi}(x,y) = \mu\hat{\phi}(x,y)} \ , \tag{48.10}$$

where we introduced the abbreviation,

$$g_{2D} \equiv \frac{g}{2z_\perp} \ . \tag{48.11}$$

This GPE describes a condensate called *two-dimensional*.

Now applying the Thomas-Fermi approximation to a harmonic potential, we obtain,

$$|\phi(x,y)|^2 = \frac{\mu - \frac{m}{2}\omega_r^2 r^2}{g_{2D}} \ . \tag{48.12}$$

with

$$\mu = \left(\frac{g_{2D}}{\pi} m \omega_r^2\right)^{1/2} \ . \tag{48.13}$$

We show a slightly stricter derivation of the results (48.4) and (48.10) in the Exc. 48.1.4.1.

48.1.3 Interacting gas in a cylindrical potential

Within a cylindrical potential $V(\mathbf{r}) = V(\rho, z)$ the wavefunction will be rotationally symmetrical. With the replacement,

$$\psi(\rho, z, \varphi) \equiv \frac{\phi(\rho, z)}{\rho} \ , \tag{48.14}$$

the Gross-Pitaevskii equation can be written in cylindrical coordinates as follows [626],

$$i\hbar \frac{\partial \phi(\rho,z)}{\partial t} = -\frac{\hbar^2}{2m}\left[\frac{\partial^2}{\partial \rho^2} - \frac{1}{\rho}\frac{\partial}{\partial \rho} + \frac{1}{\rho^2} + \frac{\partial^2}{\partial z^2}\right]\phi(\rho,z) + V_{trap}(\rho,z)\phi(\rho,z) + g\frac{|\phi(\rho,z)|^2}{\rho^2}\phi(\rho,z) \ , \tag{48.15}$$

with the normalization,

$$\int |\psi(\mathbf{r})|^2 d^3r = 2\pi \int_{-\infty}^{\infty}\int_0^{\infty} |\psi(\mathbf{r})|^2 \rho d\rho dz = 2\pi \int_{-\infty}^{\infty}\int_0^{\infty} \frac{|\phi(\rho,z)|^2}{\rho} d\rho dz = 1 \ . \tag{48.16}$$

48.1.4 Exercises

48.1.4.1 Ex: Derivation of the Gross-Pitaevskii equation in reduced dimensions

In general, due to the nonlinear term in the Gross-Pitaevskii equation, the wavefunction can not be factorized. However, when the potential is extremely anisotropic, we note that the dimensions of the wavefunction decouple: in the case of a cigar-shaped condensate, the radial diameter does not depend on z and in the case of a pancake-shaped condensate, the axial thickness does not depend on ρ.
Use this argument to derive the 1D and 2D Gross-Pitaevskii equations for cylindrical harmonic potentials.

Solution: *The Gross-Pitaevskii equation is in spherical coordinates,*

$$\left[-\frac{\hbar^2}{2m}\left(\frac{1}{\rho}\frac{\partial}{\partial \rho}\left(\rho\frac{\partial}{\partial \rho}\right) + \frac{1}{\rho^2}\frac{\partial^2}{\partial \varphi^2} + \frac{\partial^2}{\partial z^2}\right) + V(\rho,z) + g|\hat{\psi}(\rho,z)|^2\right] = \mu\hat{\phi}(\rho,z) \ .$$

With the given argument, we can make a separation ansatz,

$$\hat{\psi}(\mathbf{r}) \equiv \hat{\phi}_\rho(\rho)\phi_z(z) \ .$$

With this ansatz the GPE is,

$$-\frac{\hbar^2}{2m}\frac{1}{\phi_\rho(\rho)}\frac{1}{\rho}\frac{\partial}{\partial \rho}\left(\rho\frac{\partial}{\partial \rho}\right)\phi_\rho(\rho) + \frac{m}{2}\omega_\rho^2\rho^2 - \frac{\hbar^2}{2m}\frac{1}{\phi_z(z)}\frac{\partial^2}{\partial z^2}\phi_z(z) + \frac{m}{2}\omega_z^2 z^2 + g|\phi_\rho(\rho)\phi_z(z)|^2 = \mu \ .$$

48.2 Tonks-Girardeau gas in $1D$ potentials

Preliminary investigations have been carried out on two-step condensation and reversible condensation [**?**]. Normal condensates in $3D$ have so strong interactions and are trapped in so weak traps that $\hbar\omega_{trap} \ll \mu$, which is equivalent to $a_{trap} \gg \xi$. One may however realize very anisotropic traps where the above conditions are not satisfied in some dimensions of space, for example in $1D$ one could think of $\hbar\omega_z \ll \mu \ll \hbar\omega_\perp$. For $n = 10^{14}$ cm^{-3} a typical values for the chemical potential is $\mu = gn = 2\pi\hbar\times 800$ Hz. Contrary to thermal gases which are always isotropic, the condensate freezes out of the strongly confining dimensions [971, 1022, 536, 527, 200], i.e. the radial motion is tightly confined to zero point oscillations.

One can define a $1D$ scattering length by,

$$a_{1D} = -\frac{d_\perp^2}{2a}\left(1 - C\frac{a}{d_\perp}\right) , \tag{48.17}$$

where $C = -\zeta(\frac{1}{2}) \simeq 1.4603...$ and $d_\perp = \sqrt{\hbar/m\omega_\perp}$,

$$g_{1D} = -\frac{2\hbar^2}{ma_{1D}} = \frac{g}{\pi d_\perp^2\,(1 - Ca/d_\perp)} , \tag{48.18}$$

where $g = 4\pi\hbar^2 a/m$. Introducing an effective scattering length $a_{eff} \equiv a(1-Ca/d_\perp)^{-1}$, we may write,

$$g_{1D} = \frac{4\hbar^2 a_{eff}}{md_\perp^2} . \tag{48.19}$$

Or alternatively defining a $1D$ density via $n_{1D} \equiv \pi d_\perp^2 n$, we may write,

$$n_{1D}g_{1D} = \frac{gn}{1 - Ca/d_\perp} . \tag{48.20}$$

Such system are interesting for studying new phenomena like the expected phase domains in *quasi-condensates*, the continuous cross-over of bosons to fermions in *Tonks-Girardeau gas* [1312, 997, 998, 720]. Furthermore, some topological excitations are predicted to be more stable in lower dimensions such as solitons ind $1D$ and vortices in $2D$.

Homogeneous BECs only exist in $3D$. In $1D$ there is no finite transition temperature. In trapped BECs however condensation can take place. For a $1D$ Bose gas the degree of correlation depends on the ratio between the repulsive energy of uncorrelated atoms, $E_{unc} = g_{1D}n_{1D}$, and the quantum kinetic energy needed to correlate atoms by localizing them with respect to each other within the mean interparticle distance $d = n_{1D}^{-1}$, i.e. $E_{cor} = \hbar^2/2md^2$:

$$\gamma \equiv \frac{E_{unc}}{4E_{cor}} = \frac{mg_{1D}}{2n_{1D}\hbar^2} . \tag{48.21}$$

Or using the above relations,

$$\gamma = \frac{2a_{eff}}{n_{1D}d_\perp^2} = \frac{2a_{eff}}{\pi n d_\perp^4} \tag{48.22}$$

according to the *Lieb-Liniger model*. When $\gamma \gg 1$ the correlations overwhelm; it is the Tonks-Girardeau regime or the regime of *impenetrable bosons* or *fermionization*. In the other limit, $\gamma \ll 1$, the mean-field regime, the GP equation is good.

For our lithium experiment, we have in the micro-trap for rubidium, $\omega_\perp = 2\pi \times 5$ kHz and $\omega_\parallel = 2\pi \times 10\,\text{Hz}$. Thus $a_\perp = 0.15a_B$ with $a = 3.4a_B$ and $a_{eff} \simeq 1.06a$ and $\gamma \simeq 0.07$ for $n = 10^{14}\,\text{cm}^{-3}$.

48.2.1 Kosterlitz-Thouless transition in $2D$ potentials

bosonization, *Luttinger liquid*

Homogeneous BECs only exist in $3D$. In $2D$ occurs a *Kosterlitz-Thouless transition* into a superfluid state. This proves that noncondensed superfluid exist. On the other hand, nonsuperfluid condensates also exist, e.g. the Bose glass.

48.2.2 Mott insulator, Bose-Hubbard model

For a condensate in a periodic lattice superposed to an external potential V_{trap} (taking account of possible intensity gradients of the lattice beams) the *Bose-Hubbard model* predicts the following Hamiltonian [982, 537],

$$H = -J\sum_{(i,j)} \hat{a}_i^\dagger \hat{a}_j + \sum_i \varepsilon_i \hat{n}_i + \tfrac{1}{2}U\sum_i \hat{n}_i(\hat{n}_i - 1)\ , \tag{48.23}$$

where $J \equiv \int d^3\mathbf{x}\, w^*(\mathbf{x}-\mathbf{x}_i)\left[-\frac{\hbar}{2m}\Delta + V_0(\mathbf{x})\right] w^*(\mathbf{x}-\mathbf{x}_i)$ and $U \equiv \frac{4\pi a_s\hbar^2}{m}\int d^3\mathbf{x}\,|w^*(\mathbf{x})|^4$ and $\varepsilon_i \equiv \frac{4\pi a_s\hbar^2}{m}\int d^3\mathbf{x}\, V_{trap}(\mathbf{x})|w(\mathbf{x}-\mathbf{x}_i)|^2 \approx V_{trap}(\mathbf{x})$ and $w(\mathbf{x}) = w(x)w(y)w(z)$ are single-particle Wannier functions. Let us assume for now a homogeneous condensate. In the limit of strong tunneling and weak interactions, $J \gg U$, the matterwave function resembles a *Bloch state*,

$$|\psi_{SF}\rangle \sim \left(\sum_{i=1}^M \hat{a}_i^\dagger\right)^N |0\rangle\ . \tag{48.24}$$

The on-site particle number variance is Poissonian, $\sigma_{SF} \sim \sqrt{N_i}$, i.e. the on-site wavefunction is (quasi-)coherent. The total wavefunction is delocalized over all sites of the lattice, the (sub-)BECs have a rigid phase relation and there is long-range phase coherence. In the invers case, the matterwave function is a product of independent *Fock states*,

$$|\psi_{MI}\rangle \sim \prod_{i=1}^M (\hat{a}_i^\dagger)^n |0\rangle\ . \tag{48.25}$$

The atoms are localized in individual sites and there is a perfect correlation of the particle number in each site, known as *spin-squeezed state*, i.e. the variance tends to zero, $\sigma_{MI} \to 0$. The Mott transition is characterized by $\sigma = \frac{1}{2}$. In a given site, the

atom number and the phase of the wavefunction cannot be known simultaneously: $\Delta N \Delta\phi < 1$. Therefore, the on-site wavefunction loose their relative coherence and capability to interfere. They cannot be described by a single global wavefunction and do not follow the Gross-Pitaevskii equation. However, this state is not equivalent to a completely randomized ensemble. Rather the *coherence is transferred from inter-site correlations to inner-site correlations* (keep in mind that a Fock state is a complicated superposition of Glauber states). This is somehow analogous to collaps and revival in the Jaynes-Cummings model.

The Mott transition between the superfluid and the *Mott insulator* phase is a *quantum phase transition*, since it is driven by quantum fluctuations rather than themal noise. Thus it is a direct result of Heisenberg's incertainty relation.

These features make optical lattices in the Mott insulating phase interesting for spectroscopy at the *Heisenberg limit* and quantum computing.

Momentum distribution in terms of Wannier functions,

$$n(\mathbf{k}) = |w(\mathbf{k})|^2 \sum_{i,j} e^{i\mathbf{k}(\mathbf{r}_i - \mathbf{r}_j)} \langle \hat{a}_i^\dagger \hat{a}_j \rangle \ . \tag{48.26}$$

Practical Aspects Normal MOT loaded $3D$ lattices have filling factors of $1/10$ per site. Sophisticated Raman-sideband cooling schemes are necessary (*evtl.* aided by collisional cooling of optically uncooled dimensions). Alternatively, one may fill $1D$ or $3D$ lattices from a BEC, which offers low temperatures and high densities, so large filling factors, but quantum generacy is not a requirement (what matters is that only the lowest band is populated).

We may go to $1D$ configurations. In order to get good signal contrast despite the small number of sites, large filling factors are necessary. Even though spin-squeezing is possible, the weak lateral confinement makes it hard to reach the Mott insulating regime. An improvement could be the use of $1D$ arrays of annular traps, because of the tighter lateral confinement. Alternatively, we may fill a $3D$ lattice with 1 to 3 atoms per site and some 150000 sites. Low atom numbers make it easier to resolve the Mott transition. Typical numbers are $\nu_{trap} \approx 50$ Hz, $\nu_{Gauss} \approx 60$ Hz, $\nu_{lattice} \approx 30$ kHz $\approx 22 E_{recoil}$.

For quantum gate application, spin squeezing is important since the entangling pulse area depends on the on-site interaction energy $\frac{4\pi a_s \hbar^2}{m} n$, but it is not necessary to have only a single atom per site. What is the deeper relationship of the Mott spin-squeezing and the entanglement achievable by quantum gates [661]?

Probing is simply done by free expansion and observation of the interference patterns as the image of the momentum space distribution. The periodic structure of the density distribution causes a periodic pattern in momentum space, and since in the superfluid phase the ....

For inhomogeneous systems, superfluid and Mott insulating phases with different (integral atom number) populations may coexist. The Mott insulating phase is characterized by a gap in the excitation spectrum (precisely the one that inhibits the atomic mobility). This may be probed by applying potential gradients designed to overcome the gap.

The Mott insulating phase is not equivalent to random dephasing in the sites. The latter one causes a broadening of the interference patterns. If all atoms at all sites had

the same phase (which is possible in a single realization, but highly unlikely, because such a state cannot be generated on purpose since this would violate the uncertainty principle) they could constructively interfere.

An important signature of is the *incompressibility of a Mott insulator*. This distinguishes it from a superfluid. Even more fundamental [502] is the fact that particle-hole pairs are localized. The $\mu - J/U$ phase diagram is most significant...

48.3 Bose- and Anderson glasses

The Mott insulator *gap* plays quite a similar role as the photonic band gap. The collectivity (or long-range correlation) resides in the fact that the band gap is global. The particularity of Anderson localization and Bose glasses is that the *gapless localization* [325, 1093].

In the presence of disorder the superfluid to Mott-insulator transition is supplemented by additional insulating phases called *Bose glass* and *Anderson glass* [782, 877, 325]. It may also allow the study of *Anderson localization*. Note that there are links with Raizen's dynamical localization of chaos and strong localization in photonic bandgaps.

48.3.1 Condensates in speckle potentials

To generate disordered potentials optical speckles can be imaged into the trapping region. Alternatively, one may consider using the fragmentation observed close to microtraps. In any case the disordered potential must satisfy some conditions to make localization interesting. In particular their should be global correlations. I.e. either the atoms are condensed and form a coherent matter-wave; for example, $\mu > \langle V_{spckl} \rangle$. Then interesting effects occur for when the healing length exceeds the characteristic length of the disorder, $\langle z_{spckl} \rangle < \xi$ [829, 270]. Or the atoms are localized, $\mu < \langle V_{spckl} \rangle$, but exhibit long-range number correlations [782, 877, 325]. Than interesting effects are expected when the tunneling rate is sufficiently strong.

Let us first discuss the first case. The disorder is characterized in terms of an average potential depth $\langle V_{spckl} \rangle = \left(2\Gamma^2/6\delta\right)(\sigma_I/I_S)$ and the correlation length is of course diffraction limited $\langle z_{spckl} \rangle = 1.22\lambda l/D$, as compared to the chemical potential $\mu = (\hbar\omega_{trp}/2)\left(15N_0 a/a_{trp}\right)^{2/5}$ and the healing length, $\xi = (8\pi na)^{-1/2} = \hbar/\sqrt{2m\mu}$, respectively. In the experiment [270] a magnetically trapped BEC with $\mu = 5$ kHz and $\xi = 0.11$ μm is suddenly released into a $\langle V_{spckl} \rangle = 0..0.7\mu$ deep speckle. As the BEC expands it reduces its μ until the atoms get localized as soon as $\mu < \langle V_{spckl} \rangle$. Since the speckle is too coarse, $\langle z_{spckl} \rangle = 50\xi$, tunneling is not possible; this localization is thus not Anderson localization. The situation may be more interesting when the kinetic energy dominates the chemical potential.

A BEC in a pure deep speckle potential is not Bose glass: A Bose glass is not just *several uncorrelated BECs*, but rather *several uncorrelated BECs despite the presence of tunneling*, or *despite a large healing length*, where the tunnelling is compromised by interference, which because of disorder is destructive. The process must be reversible, since $T = 0$. Just like Mott insulator.

48.3.2 Bose glasses in mixtures of species

A possible realization implies double species: One species is trapped in a $3D$ optical lattice, the other one is weakly trapped in a magnetic potential. For example, we could load a cold ^{6}Li gas in a lattice and study transport phenomena and localization in a ^{87}Rb Bose gas, i.e. Bose glasses. Or the transport of a ^{6}Li Fermi gas in a ^{87}Rb lattice in analogy to solids [985].

In the case of Bose glass studies, to minimize the impact on ^{87}Rb, the lattice beams should be tuned close and red to the ^{6}Li line and be weak. The lattice will be blue-detuned for ^{87}Rb, so that they will be kept away from the ^{6}Li, if the potential modulation is too deep. This is not desired, especially because the interspecies scattering length is small. The scheme will not work when the ^{87}Rb chemical potential is lower than the trap depth. It might then be necessary to use a Feshbach resonance.

Concretely, we start cooling ^{6}Li and ^{87}Rb to a few μK. Then we load ^{6}Li into a $2D$ or $3D$ lattice produced at 680 nm. Estimate beam waists, powers, potential depths. Think about acustic noise. Calculate interspecies collision rates (time scale of the experiment), find signatures (interference with a reference BEC, inhibited transport....).

Using the quadrupolar magnetic fields it might be possible to address individual lattice sites [24], which is useful to create disorder.

The following experiments will provide signatures:

1. Let the ^{87}Rb BEC exposed to the ^{6}Li lattice interfere with a non exposed BEC [829, 270, 1093, 985].

2. Measure suppression of transport: Inhibited expansion (switch off magnetic trap for Rb), or inhibited displacement (shift the trap sideways).

Some ideas:

1. Load ^{6}Li into a 3D optical lattice, make it a band insulator or not, compare the behavior of the ^{87}Rb BEC for both cases.

48.3.3 Disorder in Mott-insulators

A more straightforward approach may thus be to directly localize the atoms, but nevertheless ensure global correlations. To sort out the various superfluid-insulator transitions, let us imagine a double potential $V = V_{lttc} + V_{spckl}$. The generalized Bose-Hubbard Hamiltonian reads,

$$H = -\sum_{(i,j)} \left(J_0^{lttc} + \delta J_{ij}^{spckl} \right) \hat{a}_i^\dagger \hat{a}_j + \tfrac{1}{2} U_0 \sum_i \hat{n}_i(\hat{n}_i - 1) + \sum_i \varepsilon_i \hat{n}_i \ , \qquad (48.27)$$

with $\varepsilon_i \equiv \frac{4\pi a_s \hbar^2}{m} \int d^3\mathbf{x}\ V_{spckl}(\mathbf{x}) |w(\mathbf{x} - \mathbf{x}_i)|^2$ and $\left\langle \delta J_{ij}^{spckl} \right\rangle = 0$ can be neglected. The dynamics is governed by the interplay between hopping (tunneling), J, interactions, U, and disorder, ε. Let us call CF the condensed fraction and SF the superfluid fraction. The onset of a small perturbation of the lattice potential may induce a dynamical quantum phase transition from a superfluid to a Bose or Anderson glass. This is studied [325] by preparing an ordinary superfluid BEC, transfering it into a regular optical lattice such as to drive it to the Mott phase, where in principle, $CF = SF \to 0$. However, chosing small (or non-integer) filling factors, $\Upsilon < 1$, there will be a fraction of atoms hopping around. Let's call this a pseudo-Mott insulator (Note that this prohibits the use of strong confining potentials, which support

the formation of various Mott insulator domains filled by different, but everywhere integer numbers of atoms.) This mobility corresponds to a delocalization and thus a superfluid fraction, $1 > CF = SF > 0$. This is the ideal situation to study the impact of additional disorder. With disorder both, the condensed and the superfluid fraction are dramatically reduced, however while SF tends to zero, CF stays finite, $0 \neq CF > SF \to 0$. This is what is interesting: Localization despite phase-coherence. In such Bose glasses interactions and disorder both work to localize.

	Mott insulator	pseudo Mott insulator	Bose glass
Hamiltonian	Bose-Hubbard		generalized Bose-Hubba
filling factor	$\Upsilon = 1, 2, ..$	$\Upsilon < 1$, (non-integer)	Υ
regime	$U_0 \gg J_0 > J_{ij}^{spckl}, V_{spckl} \to 0$		$U_0 \gg J_0 > J_{ij}^{spckl}, V_{spckl}$
behavior for $V_{lttc} \to \infty$	$CF = SF \to 0$	$1 > CF = SF > 0$	$0 \neq CF > SF \to 0$
potential	V_{lttc}, U_0		U_0 with V_{spckl}
excitation spectrum	gap		no gap
analogy	Fock states		

Two basic concepts must be distinguished: 1. Bose-condensation is understood as phase-coherence, i.e. the capability of matter wave interference. Condensates have a broken gauge symmetry, and thus a global phase. 2. Superfluidity is understood as mobility, i.e. delocalization. All localizing effects reduce the superfluid fraction. The two concepts are *not equivalent*. This is seen in the fact that there are non-condensed superfluids in reduced dimensions, and non-superfluid condensates. A Bose glass is such a non-superfluid condensate; it has a gapless excitation spectrum. A Mott-insulator is neither a condensate nor a superfluid; it has a gap in the excitation spectrum.

48.4 Fermi gases in optical lattices and reduced dimensions

48.4.1 Band insulator, Fermi-Hubbard model

The Pauli principle gives rise to an energy gap in a Fermi gas and makes it a *band insulator* [735], *antiferromagnetic phases*.

48.4.1.1 Fermi gas in an optical lattice

Transfer a pure Fermi gas in an optical lattice [624].

48.4.2 Fermionic superfluidity in polarized samples

In solids, mixtures of spin states tend to adjust their respective chemical potentials, e.g. at pn-junction or for Pauli paramagnetism [see Sec. 16.1.6]. In contrast, in polarized gases where the collisions are elastic, no spin-flips occur and a chemical potential imbalance can survive. Such polarized fermionic samples exhibit interesting superfluid effects such as phase separation [1441, 1000]. This is not possible in superconductors because of the Meissner effect for charged particles.

Experimentally one creates an unbalanced mixture of ^{6}Li $|1/2, \pm 1/2\rangle$ states. Above a critical polarization $P \propto (P_+ - P_-)(P_+ + P_-)$, the excess cloud forms a polarized shell around an unpolarized core of paired atoms. This occurs as a quantum phase transition between a homogeneous superfluid and a phase-separated superfluid-normal state.

The scattering length is (besides the polarization) a second important control parameter and can be varied via a Feshbach resonance. On the BEC side of the resonance (tight binding regime), $k_F a \gg 1$, the superfluid phase may coexist with the polarized normal phase. On the BCS side (highly correlated multiparticle system beyond mean-field) a Fermi sea is needed to stabilize the superfluid. There is a strong repulsion between atoms and molecules leading to a phase separation. The pairing gap Δ prevents unpaired atoms from entering the superfluid. However, even further on the BCS side, $\Delta < |\mu_2 - \mu_1|$ the gap reduces

Unpaired atoms can perturb and disrupt the BCS state, once $\Delta < |\mu_2 - \mu_1|$.

48.4.3 Luttinger liquids in $1D$ optical lattices

Strong correlated systems, may exhibit their atomic quantum optics features beyond mean-field physics better in reduced dimensions. The Kondo effect is in close relationship to a *Luttinger liquid* and the *Anderson model*.

A Luttinger liquid is a paramagnetic one-dimensional metal without Landau quasiparticle excitations [1341]. All physical properties can be calculated, e.g. by *bosonization*. The elementary excitations are collective charge and spin modes, leading to *charge-spin separation*. Although charge-spin separation has been observed in semiconductors [740], some particularities have been elusive in solid state systems. Luttinger liquids have been realized in ultracold gases [924, 1064]. This dilute system might be suitable to probe above particularities.

$1D$ BEC $\longrightarrow$ Luttinger liquid $\longrightarrow$ Lieb-Liniger, $V = 0$, or Mathieu, $g = 0$, or Tonks-Girardeau, $g = \infty$ [1077]. Repulsive interactions between the spin states of a two-component Fermi gas are treated by [1400, 1397]. For attractive interactions one obtains a *Luther-Emery liquid* characterized by atomic density waves through spin pairing [1399]. The complete phase diagram for a Fermi gas in a $1D$ optical lattice contains metallic, Mott insulating and band insulating phases [687, 1096, 688]. Disorder influences phase transitions [1398].

48.4.3.1 Bose metals

Superconductivity obtains when all Cooper pairs lock into a single quantum state. There are two cases: 1. The radius of gyration of the Cooper pairs is smaller than the interpair spacing. The pairs are then bosons, whose condensation is possible. The resulting phase coherence thwarts localization. Superconductivity can be thought of as BEC. 2. The Cooper pair radius is larger than the interpair spacing. The mapping of Cooper pairs and bosons then breaks down, nonetheless phase coherence exists.

A *metal* is characterized by mobile non-paired fermions. Theory predicts, [1029, 1172], that when fermions pair to bosons they loose their mobility, except if they condense and form a superfluid. The *Bose metal* remains elusive.

48.4.4 Kondo physics

The *Kondo effect* is known from solid state physics. It may also be investigated in optical gratings [1076, 997]. Take two $1D$ BECs, one is a quantum liquid, the other is in an optical lattice. Assume $a_s \ll a_{ho} = \sqrt{\hbar/m\omega}$. Then $g_{\beta\beta'} = 2\pi a_{\beta\beta'}/a_{ho}$. The grating trapped atoms are then immersed in a magnetically trapped Bose-liquid. Just like quantum dots immersed in a superconducting current of electrons.

48.4.5 Born-Oppenheimer systems

Keywords: ultracold *Born-Oppenheimer gas*, *gaseous solid*.

Idea: Mulding of a solid state consistent of bosons or fermions. Their quantum nature does not matter, because the distance is large and the interatomic interaction is strong. The crystal atoms are trapped in an optical lattice, evtl. a Mott insulator phase to control the lattice populations.

Let a gaseous atomic Fermi gas flow around the atoms. This should hold the atoms trapped together. Even if the optical lattice is turned down. There should form a self-determined self-consistent lattice structure.

To make the problem treatable, one must be able to make the Born-Oppenheimer approximation: $m_e \ll m_{latt}$. LiRb could be a good toy model for metals $m_{Li} \ll m_{Rb}$.

Which type of crystals will form? With an optical we may easily form not fcc, but bcc or sc cubes [Ashcroft and Mermin, "Solid states physics", p. 67] [1021, 798].

48.4.5.1 List of programs on thermalization of atomic clouds

- AtomicClouds1: Density in a harmonic potential.
- AtomicClouds2: Density in a quadrupole trap.
- AtomicClouds3: Sum and product density of two clouds in a quadrupole trap.
- AtomicClouds4: Thermalization of two clouds in a quadrupole trap.
- AtomicClouds5: Thermalization of two clouds in a quadrupole trap, collision rate depends on overlap.
- AtomicClouds6: Thermalization of two clouds in a the real LiRb Ioffe trap.

Chapter 49

Multicomponent BECs, mixed species and fermionic superfluids

49.1 Mixtures of boson condensates

49.1.1 Two-mode model

A quantum field can be composed of several distinguishable species, that is, species with different internal states, for example, hyperfine or Zeeman substates [939, 1261, 214, 858, 574, 573, 891, 1239, 775]. These states may be coupled by different means, for example, lasers in Raman configuration, microwaves, Feshbach resonances, Josephson tunneling, etc.. The Rabi frequency λ describes such coupling:

$$\imath\hbar\frac{\partial}{\partial t}\vec{\Psi}(\mathbf{r},t) = \hat{H}_\delta\vec{\Psi}(\mathbf{r},t) \qquad \text{with} \qquad \vec{\Psi} \equiv \begin{pmatrix}\psi_a\\ \psi_b\end{pmatrix}, \tag{49.1}$$

with the Hamiltonian,

$$\hat{H} = \frac{-\hbar^2\Delta}{2m} + V_{trap}(\mathbf{r}) + Ng\left[|\psi_a(\mathbf{r},t)|^2 + |\psi_b(\mathbf{r},t)|^2\right] \tag{49.2}$$

$$\text{where} \qquad \hat{H}_\delta = \begin{pmatrix}H & \lambda/2\\ \lambda/2 & H-\delta\end{pmatrix}.$$

Individual BECs or mixtures of uncoupled BECS called *spinors* exhibit U(1) symmetry (infinite cylinder). The components may interpenetrate, overlap and tunnel through each other. In contrast, BECs with many coupled species exhibit SU(2) (sphere) symmetry. This is important for creating vortices, since it is necessary to first implement a SU(2) symmetry.

49.1.2 Spinores

To observe *ferromagnetism*: prepare a $m_F = -1, 0$ BEC using B-field gradients and observe how they change positions.

At long distance the total spins of the two atoms couple as $(f_1 f_2)f$. The interaction potential, therefore, is

$$V(\mathbf{r}_1-\mathbf{r}_2)=\delta(\mathbf{r}_1-\mathbf{r}_2)\sum_{f=0,f\ \text{even}}^{f_1+f_2} g_f\hat{P}_f \tag{49.3}$$

$$\mathbf{f}_1\mathbf{f}_2=\sum_{f=0,f\ \text{even}}^{f_1+f_2}\frac{1}{2}\left[f(f+1)-f_1(f_1+1)-f_2(f_2+1)\right]\hat{P}_f\ ,$$

with $g_f=4\pi\hbar^2 a_f/m$ e $\sum_{f\ \text{even}}\hat{P}_f=1$ and $\hat{P}_f=|f\rangle\langle f|$.

With the Zeeman states [775]

$$V(\mathbf{r}_1-\mathbf{r}_2)=\delta(\mathbf{r}_1-\mathbf{r}_2)\sum_{f=0,f\text{even}}^{f_1+f_2} g_f\sum_{m_f=-f}^{f}\hat{P}_{f,m_f}\ . \tag{49.4}$$

49.1.2.1 $f=1$-states

For $f_j=1$

$$1=\hat{P}_0+\hat{P}_2 \tag{49.5}$$
$$\mathbf{f}_1\mathbf{f}_2=-2\hat{P}_0+\hat{P}_2\ .$$

we can express,

$$V(\mathbf{r}_1-\mathbf{r}_2)=\delta(\mathbf{r}_1-\mathbf{r}_2)\left(g_0\hat{P}_0+g_2\hat{P}_2\right) \tag{49.6}$$
$$=\frac{4\pi\hbar^2}{m}\delta(\mathbf{r}_1-\mathbf{r}_2)\left[\bar{a}+\mathbf{f}_1\mathbf{f}_2\Delta a\right]\ .$$

defining $\bar{a}=\frac{1}{3}(2a_2+a_0)$ and $\Delta a=\frac{1}{3}(a_2-a_0)$. Therefore, the many-body Hamiltonian is,

$$H=\int d^3\mathbf{r}\,()\ . \tag{49.7}$$

Elastic and inelastic scattering [1238]

$$\begin{aligned}
g_{|1,\pm 1t\rangle+|1,\pm 1\rangle}&=g_2 \quad , \quad a_{|1,\pm1\rangle+|1,\pm1\rangle}=\bar{a}+\Delta a \\
g_{|1,0\rangle+|1,0\rangle}&=\tfrac{1}{3}(2g_2+g_0) \quad , \quad a_{|1,0\rangle+|1,0\rangle}=\bar{a} \\
g_{|1,\pm1\rangle+|1,\mp1\rangle}&=\tfrac{1}{6}(g_2+2g_0) \quad , \quad a_{|1,\pm1\rangle+|1,\mp1\rangle}=\bar{a}-\Delta a \\
g_{|1,\pm1\rangle+|1,0\rangle}&=\tfrac{1}{2}g_2 \quad , \quad a_{|1,\pm1\rangle+|1,0\rangle}=\bar{a}+\Delta a \\
g_{|1,+1\rangle|1,-1\rangle\leftrightarrow|1,0\rangle|1,0\rangle}&=\tfrac{1}{3}(g_2-g_0) \quad , \quad a_{|1,+1\rangle|1,-1\rangle\leftrightarrow|1,0\rangle|1,0\rangle}=\Delta a\ .
\end{aligned} \tag{49.8}$$

49.1.2.2 $f=2$-states

Para $f_j=2$

$$1=\hat{P}_0+\hat{P}_2+\hat{P}_4 \tag{49.9}$$
$$\mathbf{f}_1\mathbf{f}_2=-6\hat{P}_0-3\hat{P}_2+4\hat{P}_4$$
$$(\mathbf{f}_1\mathbf{f}_2)^2=36\hat{P}_0+9\hat{P}_2+16\hat{P}_4\ .$$

$$\hat{P}_0 = -\frac{2}{15} - \frac{1}{90}\mathbf{f}_1\mathbf{f}_2 + \frac{1}{90}(\mathbf{f}_1\mathbf{f}_2)^2 \tag{49.10}$$
$$\hat{P}_2 = -\frac{8}{21} - \frac{8}{63}\mathbf{f}_1\mathbf{f}_2 - \frac{1}{63}(\mathbf{f}_1\mathbf{f}_2)^2$$
$$\hat{P}_4 = \frac{53}{35} + \frac{29}{210}\mathbf{f}_1\mathbf{f}_2 + \frac{1}{210}(\mathbf{f}_1\mathbf{f}_2)^2 \ .$$

we can express,

$$V(\mathbf{r}_1 - \mathbf{r}_2) = \delta(\mathbf{r}_1 - \mathbf{r}_2)\left(g_0\hat{P}_0 + g_2\hat{P}_2 + g_4\hat{P}_4\right) \tag{49.11}$$
$$= \frac{4\pi\hbar^2}{m}\delta(\mathbf{r}_1 - \mathbf{r}_2)\left[\left(-\frac{2}{15}a_0 - \frac{8}{21}a_2 + \frac{53}{35}a_4\right) + ..\right] \ .$$

49.2 Fermion-boson mixtures

Two-Species Mixture of Quantum Degenerate Bose and Fermi Gases [568]
Degenerate Atom-Molecule Mixture in a Cold Fermi Gas [736]
Mixture of ultracold lithium and cesium atoms in an optical dipole trap [928]
Quasi-pure Bose-Einstein Condensate Immersed in a Fermi Sea [1168]

49.2.1 Sympathetic cooling

According to [935] the reduction factor due to the mass difference of the collision partners is,

$$\xi = \frac{4m_1m_2}{(m_1+m_2)^2} \ . \tag{49.12}$$

About $3/\xi$ collisions per atom are needed for complete thermalization of a gas. For the *Rb-Li* combination this gives $3/\xi = 12.4$. The collision rate,

$$\Gamma_{coll} = \sigma_{12}\bar{v}\int n_1(\mathbf{r})n_2(\mathbf{r})d^3\mathbf{r} \ , \tag{49.13}$$

where the mean thermal relative velocity is,

$$\bar{v} = \sqrt{\frac{8k_B}{\pi}\left(\frac{T_1}{m_1} + \frac{T_2}{m_2}\right)} \ . \tag{49.14}$$

The instantaneous temperature is calculated via,

$$\gamma_{therm} = -\frac{1}{\Delta T}\frac{d\Delta T}{dt} \ , \tag{49.15}$$

or for simulations: $\Delta T(t+dt) = \Delta T(t) - \Delta T(t)\gamma_{therm}dt$. According to [346] the rethermalization rate is connected to the collision rate via,

$$\gamma_{therm} = \frac{\xi}{3}\left(\frac{\Delta E_{1\to2}}{N_1k_B\Delta T} + \frac{\Delta E_{2\to1}}{N_2k_B\Delta T}\right) = \frac{\xi}{3}\left(\frac{\Gamma_{coll}}{N_1} + \frac{\Gamma_{coll}}{N_2}\right) \ . \tag{49.16}$$

For an isotropic harmonic trap we can derive analytic solutions. With the potentials $V_j(r) = \frac{1}{2}m_j\omega_{rj}^2r^2 + \frac{1}{2}m_j\omega_{zj}^2r^2 = k_BT_j\ \left(r^2/2\bar{r}_j^2 + z^2/2\bar{z}_j^2\right)$ the densities read

$n_j(r) = n_{0j} e^{-r^2/2\bar{r}_j^2 - z^2/2\bar{z}_j^2}$, and the integral becomes [927],

$$\begin{aligned}\Gamma_{coll} &= \sigma_{12}\bar{v} n_{01} n_{02} \int e^{-r^2/2\bar{r}_1^2 - z^2/2\bar{z}_1^2 - r^2/2\bar{r}_2^2 - z^2/2\bar{z}_2^2}\, d^3r \\ &= \frac{\sigma_{12}\bar{v} n_{01} n_{02} (2\pi)^{3/2}}{\sqrt{(\bar{x}_1^{-2} + \bar{x}_2^{-2})(\bar{y}_1^{-2} + \bar{y}_2^{-2})(\bar{z}_1^{-2} + \bar{z}_2^{-2})}} \\ &= \frac{\sigma_{12}\bar{v} N_1 N_2}{(2\pi)^{3/2}\sqrt{(\bar{x}_1^2 + \bar{x}_2^2)(\bar{y}_1^2 + \bar{y}_2^2)\,(\bar{z}_1^2 + \bar{z}_2^2)}}\ ,\end{aligned} \tag{49.17}$$

setting $N = n_0(2\pi)^{3/2}\bar{x}\bar{y}\bar{z}$. Defining $m_2\omega_2^2 = \beta^2 m_1\omega_1^2$,

$$\Gamma_{coll} = \frac{(m_1\omega_1^2)^{3/2}\sigma_{12}\bar{v} N_1 N_2}{(2\pi k_B)^{3/2}(T_1 + T_2\beta^{-2})^{3/2}}\ . \tag{49.18}$$

Again according to [346] the rethermalization rate becomes,

$$\gamma_{therm} = \frac{\xi(N_1 + N_2)(m_1\omega_1^2)^{3/2}\sigma_{12}\sqrt{T_1/m_1 + T_2/m_2}}{3\pi^2 k_B (T_1 + T_2\beta^{-2})^{3/2}}\ . \tag{49.19}$$

For an anisotropic trap take $\omega_1 = \sqrt{\omega_{1x}\omega_{1y}\omega_{1z}}$ the geometric mean of the trap frequencies. Then the scattering length follows from,

$$|a_{12}| = \sqrt{\sigma_{12}/4\pi}\ . \tag{49.20}$$

49.2.1.1 Damped oscillations with two species

Damping is decribed by two coupled differential equations [439],

$$\begin{aligned}\ddot{z}_1 &= -\omega_1^2 z_1 - \frac{4}{3}\frac{m_2}{m}\frac{N_2}{N}\gamma_{therm}(\dot{z}_1 - \dot{z}_2) \\ \ddot{z}_2 &= -\omega_2^2 z_2 - \frac{4}{3}\frac{m_1}{m}\frac{N_1}{N}\gamma_{therm}(\dot{z}_2 - \dot{z}_1)\end{aligned} \tag{49.21}$$

or in matrix form,

$$\begin{pmatrix}\dot{y}_1 \\ \dot{z}_1 \\ \dot{y}_2 \\ \dot{z}_2\end{pmatrix} = \begin{pmatrix}-\frac{4}{3}\frac{m_2}{m}\frac{N_2}{N}\Gamma & -\omega_1^2 & \frac{4}{3}\frac{m_2}{m}\frac{N_2}{N}\Gamma & 0 \\ 1 & 0 & 0 & 0 \\ \frac{4}{3}\frac{m_1}{m}\frac{N_1}{N} & 0 & -\frac{4}{3}\frac{m_1}{m}\frac{N_1}{N}\Gamma & -\omega_2^2 \\ 0 & 0 & 1 & 0\end{pmatrix}\begin{pmatrix}y_1 \\ z_1 \\ y_2 \\ z_2\end{pmatrix}\ , \tag{49.22}$$

where $\gamma_{therm} = n_{12}\sigma_{12}v$ with $n_{12} = \left(\frac{1}{N_1} + \frac{1}{N_2}\right)\int n_1 n_2 d^3\mathbf{r}$. Thus,

$$\gamma_{therm} = \left(\frac{1}{N_1} + \frac{1}{N_2}\right)\Gamma_{coll}\ . \tag{49.23}$$

49.2.1.2 Gravitational sag

The potential force for a species is $|\mu|/\mu_B = g_F m_F$. For ${}^{87}Rb,{}^2S_{1/2}, |2,2\rangle$ we get 1, for $|1,-1\rangle$ we get $\frac{1}{2}$, for ${}^6Li,{}^2S_{1/2}, |\frac{3}{2},\frac{3}{2}\rangle$ we get 1, and for $|\frac{1}{2},-\frac{1}{2}\rangle$ we get $\frac{1}{3}$. The *gravitational sag* for a harmonic trap is,

$$\Delta y = g/\omega_y^2\ . \tag{49.24}$$

49.2.1.3 Heating

Trap loss rate,

$$\dot{N} = L - \gamma N - \beta \int n^2 d^3r - \beta_3 \int n^3 d^3r \ . \tag{49.25}$$

49.2.2 Cooling strategies

The Fermi exclusion principle introduces a cooling barrier at low temperatures between identical fermions. One strategies that circumvents the problem is the use of fermionic spin mixtures [347] such as ^{6}Li-^{7}Li or ^{40}K-^{41}K. Cooling of fermions in different HFS levels is limited to ~1 μK: If all states in the Fermi see are populated there are no more unoccupied states necessary for rethermalizing collisions!

49.2.2.1 Sympathetic cooling

Another method for cooling fermions is *sympathetic cooling* with an actively cooled bosonic cloud. Important issues are the optimum evaporation path, loss processes, ...

The *Fermi temperature* scales like the critical temperature, $T_c \propto T_F$, with,

$$T_F = \frac{\hbar\tilde{\omega}}{k_B}(6N_F)^{1/3} \qquad \text{and} \qquad T_c = \frac{\hbar\bar{\omega}}{k_B}\left(\frac{N_B}{g_3(1)}\right)^{1/3} \ , \tag{49.26}$$

where $g_3(1) = 1.202$. The secular frequencies for Li and Rb scale like $\tilde{\omega} = \bar{\omega}\sqrt{87/6}$ where $\bar{\omega} = (\omega_x\omega_y\omega_z)^{1/3}$. This means that the temperatures can only be tuned by controlling the relative atom numbers.

49.2.2.2 Degrading heat capacity

To reach the Fermi regime with sympathetic cooling several conditions must be satisfied: 1. The spatial overlap must be good. Large mass ratios lead to different cloud sizes and different gravitational sagging. 2. The interspecies collision rate must be high. 3. The Bose cloud should not be condensed, $T_F \gg T_c$. 4. The Bose cloud should have a much higher heat capacity than the Fermi cloud, $C_{87} \gg 0.1C_6$ [202].

In a magnetic trap the secular frequencies $\tilde{\omega}$ and $\bar{\omega}$ have a fixed ratio so that condition 3. implies,

$$\frac{T_F}{T_c} = \sqrt{87/6}\left(6g_3(1)\frac{N_6}{N_{87}}\right)^{1/3} \gg 1 \ , \tag{49.27}$$

or $400N_6 \gg N_{87}$. In contrast in optical traps the secular frequencies depend on the detuning from atomic resonances, and may be tuned.

How to achieve very low temperatures via sympathetic cooling [977], [1052], [202], [295]?

49.2.2.3 Losses

To quantitatively study the impact of $|2,1\rangle$ atoms on the Li cloud lifetime, we write,

$$\dot{n}_6 = -G_{inel} n_6 n_{87,|2,1\rangle} \tag{49.28}$$

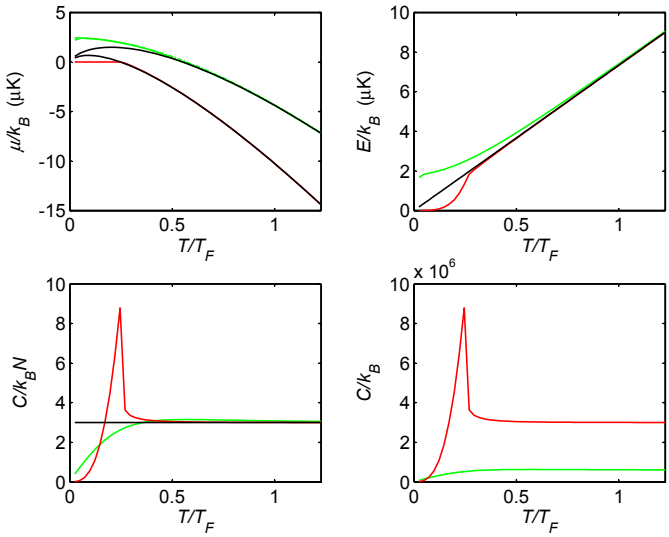

Figure 49.1: Density of states and chemical potential for a harmonic (dashed lines) and a Ioffe-Pritchard trap.

with the constraint $N_{87,|2,1\rangle} - N_{6,|3/2,3/2\rangle} = const$, we obtain the spin relaxation rate coefficient $G_{inel} = 1.2(3) \times 10^{-15}$ cm^2/s. Spin-relaxation, the only allowed collision-induced transitions are,

$$
\begin{aligned}
|2,1\rangle + |3/2,3/2\rangle &\rightarrow |2,2\rangle + |3/2,1/2\rangle \\
|2,1\rangle + |3/2,3/2\rangle &\rightarrow |2,2\rangle + |1/2,1/2\rangle + \nu_{6,hf} \\
|2,1\rangle + |3/2,3/2\rangle &\rightarrow |1,1\rangle + |3/2,3/2\rangle + \nu_{87,hf}
\end{aligned}
\tag{49.29}
$$

$$
\begin{aligned}
|1,-1\rangle + |3/2,3/2\rangle &\rightarrow |1,0\rangle + |3/2,1/2\rangle + \nu_{87,rf} + \nu_{6,rf} \\
|1,-1\rangle + |3/2,3/2\rangle &\rightarrow |1,0\rangle + |1/2,1/2\rangle + \nu_{87,rf} + \nu_{6,hf} \ .
\end{aligned}
$$

Three-body recombination,...

49.2.2.4 Dipolar relaxation of fully stretched ^{87}Rb

The dipolar relaxation of the $^{87}Rb, |2,2\rangle$ state is on the order of $G_{dip} = 2\times10^{-15}$ cm^3/s [159]. We establish the following rate equations,

$$
\begin{aligned}
\dot{N}_{|2,2\rangle} &= -G_{dip} \int n^2_{|2,2\rangle} d^3\mathbf{r} - G_{inel} \int n_{|2,2\rangle} n_{|2,1\rangle} d^3r \\
\dot{N}_{|2,1\rangle} &= G_{dip} \int n^2_{|2,2\rangle} d^3\mathbf{r} - G_{inel} \int n_{|2,2\rangle} n_{|2,1\rangle} d^3r \ .
\end{aligned}
\tag{49.30}
$$

Using $n_j = n_{0j} e^{-U_j/k_B T}$ with $U_{|2,2\rangle} = \frac{m}{2}\omega_r^2 r^2 + \frac{m}{2}\omega_z^2 z^2$ and $U_{|2,1\rangle} = \frac{1}{2}U_{|2,2\rangle}$, we get,

$$N_{|2,2\rangle} = \int n_{|2,2\rangle} d^3r = n_{0|2,2\rangle} \int e^{-m\omega_x^2 x^2/2k_B T} d^3r = n_{0|2,2\rangle} \sqrt{\frac{2\pi k_B T}{m\tilde{\omega}^2}}^3 \tag{49.31}$$

$$N_{|2,1\rangle} = \int n_{|2,1\rangle} d^3r = n_{0|2,1\rangle} \int e^{-m\omega_x^2 x^2/4k_B T} d^3r = n_{0|2,1\rangle} \sqrt{\frac{4\pi k_B T}{m\tilde{\omega}^2}}^3$$

$$\int n_{|2,2\rangle}^2 d^3r = \left(\frac{1}{2}\right)^{3/2} n_{0|2,2\rangle} N_{|2,2\rangle}$$

$$\int n_{|2,2\rangle} n_{|2,1\rangle} d^3r = \left(\frac{1}{3}\right)^{3/2} n_{0|2,2\rangle} N_{|2,1\rangle}$$

finally,

$$\dot{N}_{|2,2\rangle} = -G_{dip} \left(\frac{m\tilde{\omega}^2}{4\pi k_B T}\right)^{3/2} N_{2,2}^2 - G_{inel} \left(\frac{m\tilde{\omega}^2}{6\pi k_B T}\right)^{3/2} N_{2,2} N_{2,1} \tag{49.32}$$

$$\dot{N}_{|2,1\rangle} = G_{dip} \left(\frac{m\tilde{\omega}^2}{4\pi k_B T}\right)^{3/2} N_{2,2}^2 - G_{inel} \left(\frac{m\tilde{\omega}^2}{6\pi k_B T}\right)^{3/2} N_{2,2} N_{2,1} \ .$$

49.2.3 Mixed species experiments

The studied fermionic species are ^{40}K and ^{6}Li in combination with various other fermionic or bosonic species to allow for cooling. Both species exhibit Feshbach resonances: ^{40}K has one between $|9/2, -9/2\rangle$ and $|9/2, -7/2\rangle$ at 202 G [1081]. ^{6}Li has a broad $|1/2, \pm 1/2\rangle$ interstate Feshbach resonance at 850 G [679, 311].

49.2.3.1 Bragg scattering at BECs in the Lamb-Dicke limit

Make very deep traps such as [1168] or optical confinement, such that $\omega_{vib} \gg \varepsilon$. Bragg scattering off such BECs should not destroy them. How steep can we make the lithium surface trap? Everybody goes to the lower states: ^{7}Li, $|1, -1\rangle$-^{6}Li, $|1/2, -1/2\rangle$ or ^{23}Na, $|1, -1\rangle$-^{6}Li, $|1/2, -1/2\rangle$. How can we do this? Temperature determined from spatial extend of bosonic cloud in-situ.

49.2.4 Collapse and demixing of mixed species

49.2.4.1 Collapse

The collisional properties of ultracold K-Rb mixtures may lead to the collapse of a degenerate Fermi Gas [439, 905, 8, 262]. Until now we have neglected mean-field interactions between fermions and bosons. With interspecies interaction $g_{mx} = 2\pi\hbar^2 a_{mx}/m_{rd}$ where $m_{rd}^{-1} = m_6^{-1} + m_{87}^{-1}$ the GPEs read,

$$\left[-\frac{\hbar^2\nabla^2}{2m_{87}} + V_{87}(\mathbf{r}) + g|\phi_{87}|^2 + g_{mx}|\phi_6|^2\right]\phi_{87} = \mu_{87}\phi_{87} \tag{49.33}$$

$$\left[-\frac{\hbar^2\nabla^2}{2m_6} + V_6(\mathbf{r}) + g_{mx}|\phi_{87}|^2\right]\phi_6 = \mu_6\phi_6 \ .$$

The solution of the fermionic density distribution at $T \to 0$ is now,

$$\begin{aligned} n_6 &= \kappa \left(\mu_6 - V_6 - g_{mx} n_{87}\right)^{3/2} \ , \\ |\nabla \phi_6|^2 &= k_6^2 = \left(6\pi^2 n_6\right)^{2/3} \ . \end{aligned} \tag{49.34}$$

with $\kappa = 2^{1/2} m_6^{3/2}/3\pi^2\hbar^3$. To get a temperature dependence [262] use the Sommerfeld approximation. According to this the effective bosonic Hamiltonian including boson-fermion interaction at $T \to 0$,

$$\begin{aligned} H_{eff} &= \int d\mathbf{r} \left\{ \frac{\hbar^2}{2m_{87}} |\nabla \phi_{87}|^2 + (V_{87}(\mathbf{r}) - \mu_{87})|\phi_{87}|^2 + \frac{g}{2}|\phi_{87}|^4 + (V_6(\mathbf{r}) - \mu_6)|\phi_6|^2 + g_{mx}|\phi_{87}|^2|\phi_6|^2) \right. \\ &= \int d\mathbf{r} \left\{ \frac{\hbar^2}{2m_{87}} |\nabla \phi_{87}|^2 + (V_{87}(\mathbf{r}) - \mu_{87})|\phi_{87}|^2 + \frac{g}{2}|\phi_{87}|^4 - \kappa^{-2/3} n_6^{5/3}) \right\} \ . \end{aligned} \tag{49.35}$$

We assume now that both species of atoms experience the same potential $V(\mathbf{r}) \equiv V_j(\mathbf{r}) = \frac{m_j}{2}\omega_{j,z}^2 z^2 + \frac{m_j}{2}\omega_{j,r}^2 \rho^2 = \frac{m_j}{2}\omega_j^2 \left(\lambda^2 z^2 + \rho^2\right)$. To find out the condition for collapse we first determine μ_6 via the normalization condition $N_6 = \int d\mathbf{r}\ n_6(\mathbf{r})$. This is done by numerically integration Eq. (49.40). μ_{87} gives an offset and may be set to zero. We now insert the ansatz of the wavefunction,

$$\begin{aligned} \phi_{87} &= \left(\frac{N_B \lambda}{w^3 a^3 \pi^{3/2}}\right)^{1/2} \exp\left(-\frac{\rho^2 + \lambda^2 z^2}{2w^2 a^2}\right) \\ |\nabla \phi_{87}|^2 &= \frac{\rho^2 + \lambda^4 z^2}{w^4 a^4} |\phi_{87}|^2 \end{aligned} \tag{49.36}$$

using $a = \sqrt{\hbar/m_{87}\omega_{87}}$ and a variational parameter w and integrate Eq. (49.41) numerically.

49.2.4.2 Demixing

While collapse occurs for $g_{mx} < 0$, for $g_{mx} > 0$ the components may demix. For homogeneous systems the condition for demixing is [232],

$$g_{mx}^2 > g_{87} g_{FF} \qquad \text{with} \qquad g_{FF} = \frac{2}{3\kappa^{2/3} n_6^{1/3}} \ , \tag{49.37}$$

so that,

$$\frac{g_{mx}}{g_{87}} > \left(\frac{\pi m_{87}}{2m_6 (6\pi^2 n_6)^{1/3} a}\right)^{1/2} \ . \tag{49.38}$$

49.2.5 Fermion-boson collapse and demixing of ^{7}Li-^{87}Rb

49.2.5.1 Analytic estimation

An expansion of the interaction term in g_{mx} up to third order,

$$g_{mx}|\phi_{87}|^2|\phi_6|^2 = \kappa(\mu_6 - V)^{3/2} g_{mx} n_{87} - \frac{3}{2}\kappa(\mu_6 - V)^{1/2} g_{mx}^2 n_{87}^2 + \frac{3}{8}\frac{\kappa}{(\mu_6 - V)^{1/2}} g_{mx}^3 n_{87}^3 \tag{49.39}$$

$$\approx -\frac{3}{2}\kappa\mu_6^{1/2} g_{mx}^2 n_{87}^2 + \frac{3\kappa}{8\mu_6^{1/2}} g_{mx}^3 n_{87}^3 \ ,$$

yields,

$$H_{eff} \equiv C + \int d\mathbf{r} \left\{ \frac{\hbar^2}{2m_{87}}|\nabla\phi_{87}|^2 + (V_{eff} - \mu_B)|\phi_{87}|^2 + \frac{g_{eff}}{2}|\phi_{87}|^4 + \frac{\kappa}{8\mu_6^{1/2}} g_{mx}^3 |\phi_{87}|^6 \right\} , \tag{49.40}$$

where we used the definition $V_{eff}(\mathbf{r}) \equiv V(\mathbf{r})\left(1 - \frac{3}{2}\kappa\mu_6^{1/2} g_{mx}\right)$ and $g_{eff} \equiv g_{87} - \frac{3}{2}\kappa\mu_6^{1/2} g_{mx}^2$. There is a problem with factor 3 in the last term as compared to [262]. This is due to the fact that they go back from $(\mu_6 - V_6 - g_{mx} n_{87})^{3/2}$ to $-\frac{5}{2}(\mu_6 - V_6 - g_{mx} n_{87})^{5/2}$ before doing the expansion and then neglect the zeroth order. We now insert the ansatz of the wavefunction (49.42),

$$H_{eff} = \frac{2N_{87}\lambda}{\pi^{1/2}} \int_0^\infty d\rho \int_{-\infty}^\infty dz \ \rho \left\{ \frac{\hbar^2}{2m_{87}} \frac{\rho^2 + \lambda^4 z^2}{w^2 a^2} e^{-\rho^2 - \lambda^2 z^2} + (V_{eff} - \mu_{87}) e^{-\rho^2 - \lambda^2 z^2} \right. \tag{49.41}$$

$$\left. + \frac{N_6\lambda}{w^3 a^3 \pi^{3/2}} \frac{g_{eff}}{2} e^{-2\rho^2 - 2\lambda^2 z^2} + \left(\frac{N_{87}\lambda}{w^3 a^3 \pi^{3/2}}\right)^2 \frac{\kappa}{8\mu_6^{1/2}} g_{mx}^3 e^{-3\rho^2 - 3\lambda^2 z^2} \right\} \ .$$

All integrals can be solved exactly, so that we get,

$$\frac{H_{eff}}{N_{87}\hbar\omega_{87}} = \frac{2+\lambda}{4w^2} + \frac{3}{4}\frac{V_{eff}}{V} w^2 - \frac{\mu_{87}}{\hbar\omega_{87}} + \frac{g_{eff}}{2} \frac{\lambda}{(2\pi)^{3/2}\hbar\omega_{87} a^3} \frac{N_{87}}{w^3} + \frac{\kappa}{8\mu_6^{1/2}} g_{mx}^3 \frac{\lambda^2}{3^{3/2}\pi^3 \hbar\omega_{87} a^6} \frac{N_{87}^2}{w^6} \ . \tag{49.42}$$

Using ^{40}K with $a_s = 99.2 a_B$ and $a_{mx} = -410 a_B$ and $\omega_{87,r} = 2\pi \times 215$ Hz and $N_{87} = 50000$ and $N_6 \to N_{40} = 20000$ this reproduces the results of [262]. For ^{6}Li with $N_{87} = 50000$ and $N_6 = 20000$, we expect instability for $a_{mx} < -240 a_B$.

49.2.6 Ions in BECs

The hybrid system consistent of individual ions and Bose-condensed clouds of neutral atoms opens up new horizons. Many novel phenomena, such as controlled atom-ion collisions, charge transfer processes, polarization and structuring of an ultracold atomic cloud by ions, etc. can be studied.

During elastic collisions between ions ant atoms electrons can be exchanged between the collision partners. This may lead to interesting effects, in particular when

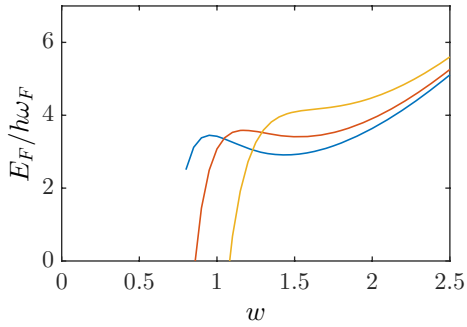

Figure 49.2: (code) Density of states and chemical potential for a harmonic (dashed lines) and a Ioffe-Pritchard trap.

the atoms are delocalized in a Bose-condensate. The ions polarize their surrounding atoms and induce an isotropic potential $\propto 1/r^4$, which has a much longer range than the $\propto 1/r^6$ interatomic van der Waals potential. Atoms are attracted by an ion and may be bound and form a giant *molecular atom*, whose nucleus is a single localized ion and whose shell is a Bose-condensate of several 100 neutral atoms.

49.2.7 Exercises

49.2.7.1 Ex: Instable fermion-boson mixtures

Solution: *InstableFermionBoson1: Analytic approximation from [Chui04] for 40-K.*
InstableFermionBoson1b: Analytic approximation from [Chui04] for 6-Li.
InstableFermionBoson2: Numerical integration, naive Hamiltonian.
InstableFermionBoson2b: Numerical integration, numerical integration, Hamiltonian from [Molmer98].
InstableFermionBoson2c: Numerical integration, numerical integration, Hamiltonian from [Capuzzi03].
InstableFermionBoson3: Numerical integration, instable 7-Li BEC.
InstableFermionBoson4: Numerical integration, repulsive mixtures.

49.3 Molecular BECs

49.3.1 Thermodynamics of trapped molecules

We consider a mixture of atomic fermions coupled to bosonic thermal molecules and condensed molecules via a Feshbach resonance. The molecular distribution function,

$$g_m(\epsilon) = \frac{1}{e^{\beta_m(\epsilon+\epsilon_{res}-\mu_m)}-1} \ , \tag{49.43}$$

takes into account the Feshbach-tunable internal energy of the molecules. It is now possible to set up a coupled thermodynamics and to calculate the atomic, molecular and condensed fractions as a function of ϵ_{res} and T [1379]. It also possible to determine trajectories in the phase diagrams for changes of ϵ_{res} starting at some given initial temperature T_i. The treatment of [1379] is however limited to ideal gases and probably will fails to quantitatively describe the BCS physics. The treatment is however useful to predict the conversion efficiency from a cold Fermi gas to molecules. This efficiency depends on the magnetic field ramp. *Adiabatic ramps* of ϵ_{res} are characterized by a constant total entropy, *sudden changes* conserve total energy. The conversion efficiency upon adiabatic ramps is much higher. Hence, the fact that molecular BECs have also been produced using fast ramps has been interpreted as a proof for the preexistence of BCS pairs before the ramp [1444, 1080, 1442].

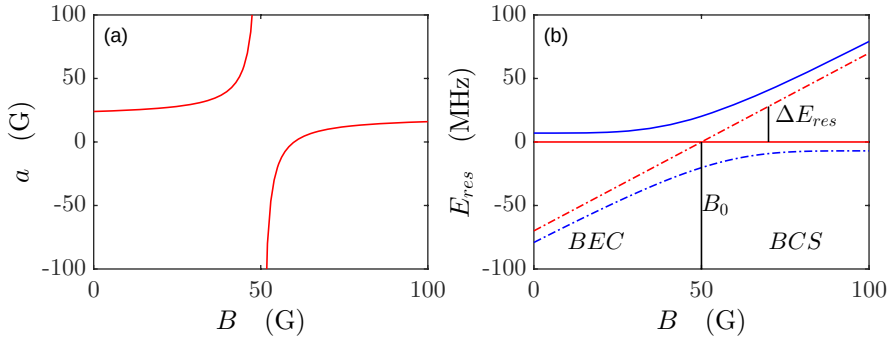

Figure 49.3: (code) (a) Scattering length as a function of magnetic field strength near a Feshbach resonance. (b) Energies of the bound state (solid) and the free channel (dashed). An avoided crossing introduces a pairing gap.

In contrast, [431]Phys Rev Lett/PRL92,130401 claims that the total wave function has molecular character even at detunings $\delta \gtrsim 0$. For $a(B) > 0$ the molecular binding energy is,

$$\epsilon_m \simeq \hbar^2/ma(B)^2 \ . \tag{49.44}$$

Cooper pairing and the *BCS transition*, analogous to electrons in solids, may be studied in optical traps. Long lifetimes up to 3 min can be achieved with careful control of the laser intensity [347, 966]. The absence of Coulomb interactions makes atomic systems very pure. But the transition temperatures are low. Currently, $T_{BCS} \simeq 0.2T_F$.

Note that a *molecular BEC* is unlike a *BCS pair*: in a molecular BEC, $k_F a < 1$, the molecules are delocalized in the BEC, but the atoms are localized within the molecule. For Cooper-pairs the two atoms forming the pair are delocalized within the BEC [1080, 1079].

49.3.2 Production of homonuclear BECs

Jin's group [538, 1081]. Using the Feshbach resonance on fermions, aided by the Pauli exclusion principle preventing relaxation, e.g. $^{40}K_2$ has a relaxation of only 0.5 s.

Production of Li_2 BECs, almost simultaneous detected at ENS, Innsbruck and MIT [678, 311, 1443].

Na_2 BECs were detected at MIT [1402] and Cs_2 BECs at Innsbruck [612].

49.3.3 Molecular solitons in BECs

While the self-interaction in BECs $\hat{\psi}_a^+\hat{\psi}_a^+\hat{\psi}_a\hat{\psi}_a$ corresponds to third-order nonlinearities $\chi^{(3)}$ in quantum optics, the second-harmonic generation of molecules $\hat{\psi}_m^+\hat{\psi}_a\hat{\psi}_a$ from atoms corresponds to second-order nonlinearities $\chi^{(2)}$. The single-species Gross-Pitaevski equation cannot produce solitons in three dimensions [391]. The free-bound coupling of atoms and molecules at low densities is particle-like and only forms individual dressed molecules similar to Cooper-pairs. At high densities, $\chi^{(3)}$ and $\chi^{(2)}$ interplay in such a way to make a coherent coupling between two BECs at the base of strong, coherent, non-linear and interactions giving rise to a *soliton matter wave*.

49.4 Cooper pairing mechanisms and transition temperatures

Valuable contribution to BCS theory for atomic Fermi gases have been made by [93, 92, 87, 995, 160, 627, 600, 88, 599, 899, 408, 86, 1234, 431, 1023, 369, 564, 1015, 719, 1288]. See also Sec. 21.4.

Dynamics of the BCS-BEC Crossover in a degenerate Fermi Gas, experimental work comes from [623, 539, 1078].

There are various options for Cooper pairing avoiding the Pauli principle:

49.4.1 BEC-BCS transition

The phenomena of superconductivity and superfluidity have fascinated physicists since the 20th century. In 1911, superconductivity was discovered when resistance of mercury was observed to vanish below a certain critical temperature [974]. In 1957 Bardeen, Cooper and Schrieffer (BCS) formulated the theory on superconductivity [93, 94], which predicts that, in fermionic systems below a certain temperature, there is formation of a *gap* of minimal excitation energy in the conductor. With this theory, many properties of superfluids and superconductors can be explained, as we will see in the following sections.

49.4.1.1 Pairing in a gas of fermionic atoms

Superfluids are fundamentally associated with the quantum properties of bosons. Therefore, to create a superfluid from a fermionic system, it is necessary to pair the fermions. The simplest way to imagine a pairing of fermions is to create a two-body bound state of two fermions. For example, two paired fermionic spin-1/2 particles form a single bosonic integer-spin particle. In recent experiments studying the BCS-BEC transition, the fermionic particles are atoms (e.g. ^{40}K) forced to form a diatomic molecule. These diatomic molecules, below a critical temperature, will form a BEC [1080]. Fig. 49.4(a) illustrates a superfluid containing such pairs.

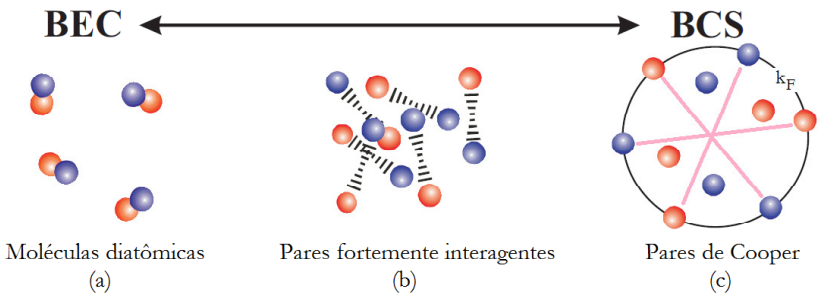

Figure 49.4: Illustration of fermion pairing in the BCS-BEC transition. The two colors represent fermions in two different spins states. Two states are required if the fermions are paired through s-wave ($\ell = 0$) interaction.

In the other pairing process, the Cooper pairing, the basic nature of the fermionic system is much more apparent. Cooper considered the problem of two fermions with equal-sized but and opposite momenta outside a perfect *Fermi sea* [290] [1] and noted that due to the Pauli exclusion principle, these two fermions are prevented from occupying momentum states inside the so-called Fermi sea, that is $k < k_F$ where k_F is the Fermi wavevector. This fermion pair, which is prevented from penetrating the Fermi sphere is called *Cooper pair*.

Now if only one electron pair were free to pair outside the Fermi sea, this would not lead to superconductivity, since all fermions must be allowed to participate in the pairing process. The superconductivity theory of Bardeen-Cooper-Schrieffer (BCS) was able to link the many-body theory to this problem and succeeded in describing the phenomenon of superconductivity [93, 94].

Qualitatively the BCS state results from a loss of correlations between fermions on the Fermi surface in momentum space [see Fig. 49.4(c)]. Spatially, the pairs are highly overlapping and can not simply be considered as bosons. Close to the BCS limit the momentum distribution only changes to the usual Fermi sea, that is, an exponentially small region near the Fermi surface.

It is interesting to consider what happens if diatomic molecules become increasingly weakly bound, that is, when the binding energy E_b of the molecules becomes smaller than the Fermi energy E_F. We may also consider the increase in the interaction energy of a Cooper-paired state up to E_F. The essence of the BCS-BEC transition is that these two possibilities describe the same physical state. As the interaction between fermions is increased, there will be a continuous change (or transition) between a BCS state of a BEC state of diatomic molecules. The point where two fermions in vacuum would have zero binding energy is considered the apex of the transition. The pairing of such a state is represented in Fig. 49.4(b). These pairs share some properties with diatomic molecules and some properties with Cooper pairs.

[1] The energy of the two fermions turns out to be smaller than the expected value of $2E_F$ for attractive and weak interactions. This finding contrasts with the behavior of two fermions in vacuum; in this case, a bound state can not exist until the interaction strength reaches a certain value. The main difference between the two situations arises from Pauli's exclusion principle which, in the case of Cooper pairs prevents the two fermions from occupying momentum states $k < k_F$.

49.4.1.2 Varying the interaction strength

It is instructive to consider a physical situation that allows for the pairing (see Fig. 49.5). Suppose that we start with an attractive potential between two atomic fermions in vacuum, e.g. a hard-core potential with characteristic length r_0 shown in Fig. 49.5. If this potential is very shallow, there will be a weak attractive interaction between the fermions. As we deepen the potential, the interaction between the fermions becomes stronger and, when the attraction is strong enough, a bound molecular state will appear. This molecule will become increasingly tightly bound as the potential becomes deeper.

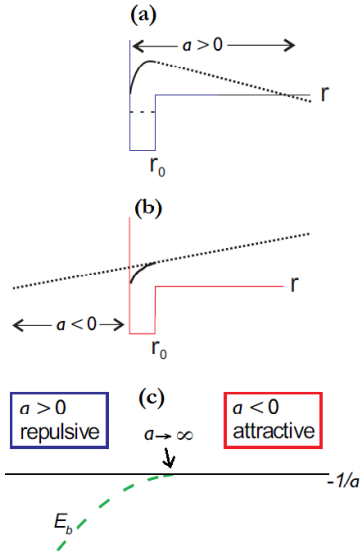

Figure 49.5: Scattering wavefunction in the presence of an attractive potential (b) and a deeper attractive potential (a) in the regime where the potential of the bound state (dashed line) is close to the *threshold*. Note that the scattering length changes sign when the bound state moves through the threshold.

The interaction in this system can be characterized by the scattering length a. The sign of a determines whether the interaction is attractive ($a < 0$) or repulsive ($a > 0$). The quantity a is related to the collision cross-section through $\sigma = 4\pi a^2$. Figs. 49.5(a) and 49.5(b) show a pictorial representation of a. Before the bound state appears, a is large and negative, which corresponds to a strong attractive interaction. As the bound state passes through the threshold the value of a diverges and, beyond the threshold, becomes larger and positive, which corresponds to a strong repulsive interaction. When a is much greater than r_0, the interaction independs on the shape of the potential, and when $a > 0$, it is related to the two-body binding energy through $E_b = \frac{\hbar^2}{ma^2}$, where m is the mass of one fermion [1129].

Now, if we consider an ensemble of many fermions under the situation depicted in Fig. 49.5, we have a system that can be changed from BCS to BEC, by simply tuning the attractive potential. To the far right of Fig. 49.5(c) we have a small and negative a and, hence, we are in a BCS state. On the opposite side of the figure, we

have an ensemble of diatomic molecules and therefore a BEC state. It is important to note that although the interaction between fermion pairs is stronger in the BEC limit, from the point of view of collisions in molecular gas, the BEC boundary is weakly interacting because the molecule-molecule interaction is weak.

49.4.1.3 Simplified theory

The BCS theory was originally applied to the regime where the interaction energy is extremely small compared to the Fermi energy. In this case, the chemical potential μ can be set to E_F, which simplifies the calculations reasonably. Leggett pointed out that, examining the equation describing the BCS gap upon varying μ, this equation becomes precisely the Schrödinger equation for a diatomic molecule in the limit where μ dominates [784].

Let us consider a homogeneous Fermi system at $T = 0$ in three dimensions consistent of a mixture with the same quantity of atoms in the two states. Applying the usual BCS theory results in an equation for the *gap*,

$$\Delta_k = -\sum_{\mathbf{k}'} U_{kk'} \frac{\Delta_{k'}}{2E_{k'}} \ , \tag{49.45}$$

where $E_k = \sqrt{\xi_k^2 + \Delta^2}$, $\xi_k = \epsilon_k - \mu$, and $\epsilon_k = \frac{\hbar^2 k^2}{2m}$. $U_{kk'} < 0$ is the attractive interaction for the scattering of fermions with momenta k' and $-k'$ to momenta k and $-k$. We can also obtain the equation for the total number of fermions in both states, N_{tot},

$$\langle N_{tot} \rangle = \sum_{\mathbf{k}} \left(1 - \frac{\xi_k}{E_k} \right) \ . \tag{49.46}$$

To solve Eq. (49.45) in the BCS limit the standard approach is to assume that the potential is constant with a value $U < 0$, which means that the gap is constant, i.e., $\Delta_k = \Delta$. In this case, the equation of the gap (49.45) becomes,

$$-\frac{1}{U} = \sum_{\mathbf{k}} \frac{1}{2E_k} \ . \tag{49.47}$$

We can see that this equation may diverge. In the BCS limit we also have $\mu = E_F$ and, given that there is the Debye energy limit $\hbar\omega_D \ll E_F$, the density of states is constant with the value $N(\xi = 0)$. The equation for the gap now becomes,

$$-\frac{1}{N(0)U} = \int_{-\hbar\omega_D}^{\hbar\omega_D} \frac{d\xi}{2\sqrt{\xi_k^2 + \Delta^2}} \ . \tag{49.48}$$

Solving Eq. (49.48) we produce the BCS result: $\Delta \approx 2\hbar\omega_D e^{-1/N(0)|U|}$.

Extending this calculation to the transition in atomic systems, we can no longer apply the cut-off $\hbar\omega_D$. The solution to the divergence problem, in this case, is not trivial and requires a renormalization procedure, which can be found in the reference [**?**].

The result of this procedure is a renormalized equation for the gap:

$$-\frac{m}{4\pi\hbar^2 a} = \frac{1}{V} \sum_{\mathbf{k}} \left(\frac{1}{2E_k} - \frac{1}{2\epsilon_k} \right) \ , \tag{49.49}$$

where the interaction is now described by the s-wave scattering length a instead of U, and V is the volume of the system. In addition, for the transition we can not assume $\mu = E_F$; instead, we must solve simultaneously the equation of the gap (49.49) and the equation of the number (49.46) in order to get μ and the gap Δ. This can be done resolving as a function of the dimensionless parameter $k_F a$, where $\hbar k_F = \sqrt{2mE_F}$, as done in Ref. [846].

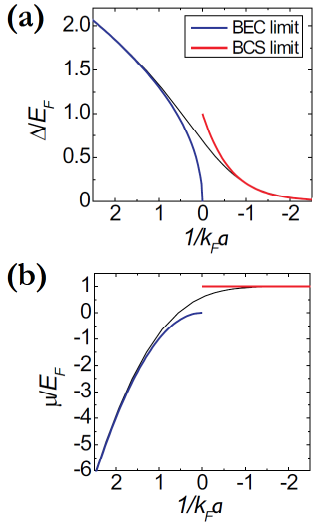

Figure 49.6: The gap, Δ, and the chemical potential, μ, of a homogeneous Fermi gas at $T = 0$, as determined via the NSR theory. The red and blue lines show the BCS and BEC theory. Note that the theories only deviate significantly from the complete theory inside the interval $-1 < \frac{1}{k_F a} < 1$ [1082].

The black lines in Fig. 49.6 show the result of the calculations of Δ and μ. Also are plotted the values of these two parameters calculated in the BCS and BEC limits, where we find that the BCS-BEC transition occurs in a relatively small region of the parameter $1/k_F a$, that is, between $-1 < \frac{1}{k_F a} < 1$. In typical experiments studying this transition (with ^{40}K or ^{6}Li) this interval corresponds to a ranging from $-2000a_0$, crossing the divergence ($a \to \infty$), until $2000a_0$, where a_0 is the Bohr radius.

It is useful to understand explicitly the value and meaning of both Δ and μ in these two limits. μ is equal to E_F in the BCS limit and equal to $-E_b/2 = -(\frac{1}{k_F a})^2 E_F$ in the BEC limit. Δ is equal to $E_F e^{-\frac{\pi}{k_F |a|}}$ in the BCS limit and equal to $E_F \sqrt{\frac{16}{3\pi} \frac{1}{k_F a}}$ in the BEC limit [846].

49.4.1.4 Beyond $T = 0$

A very important parameter for any superfluid system is the so-called phase transition temperature T_c. In the BCS-BEC transition T_c increases as the interaction is increased, that is, it is lower in the BCS regime and higher in the BEC regime. For a homogeneous system in the BCS regime $T_c/T_F = \frac{8}{\pi} e^{\gamma - 2} e^{-\frac{\pi}{2k_F |a|}}$, where $\gamma = 0.58$

[588]. In the BEC regime $T_c/T_F = 0.22$ [1017]. Note that in the BCS regime T_c can be extremely small due to the exponential dependence on $1/k_F a$.

In the BCS regime pairing and phase transition to a superfluid state occur at the same temperature. In the BEC regime this is not the case. It is natural to expect that there should be a cross-over between these two behaviors in the BCS-BEC transition, i.e. there should be a point in the transition, where the pairing temperature T^* is distinct from T_c, but not much different.

The above discussions and calculations, while providing a basic introduction to the BCS-BEC transition theory, are far from the current situation of this theory. For example, the result for the chemical potential at the singularity (where $1/k_F a = 0$) is significantly different from the result of more accurate calculations based on Monte Carlo simulations [234, 59]. Thus, it is clear that the addition of higher order correlations in the theory of the BCS-BEC transition theory is required.

The BCS-BEC transition was studied in laboratory [1083] using ^{40}K as the fermionic sample, prepared in two hyperfine states $|F = 9/2, m_F = 9/2\rangle$ and $|F = 9/2, m_F = 7/2\rangle$. Other group also studied this transition in different fermionic species. Many studies involving the BCS-BEC transition have been made, such as studies on the change of momentum distribution in this transition [1078], studies of collective oscillations [428], the modification of the expansion of ultracold clouds [1426], and the change of the critical velocity of the superfluid flow throughout the transition [894].

49.4.2 s- and p-wave pairing

Cooper pairing can occur between two fermions being in different spin states [87, 160]. For pure two-component Fermi systems the critical temperature follows to first order from [995, 600],

$$g_F \int_0^\infty \frac{p^2 dp}{2\pi^2\hbar^3} \frac{1}{\varepsilon_p} \frac{1}{e^{\varepsilon_p/k_B T^0_{BCS}} + 1} = 1 \ , \tag{49.50}$$

with $\varepsilon_p = p^2/2m_F - \mu$ i.e.,

$$k_B T^0_{BCS} = \frac{e^{C_E}}{\pi} \frac{8}{e^2} \varepsilon_F \exp\left(-\frac{\pi}{2k_F|a_s|}\right) \ . \tag{49.51}$$

However, spin- and density fluctuations in the Fermi cloud mediate an interaction between the fermions, which reduces T^0_{BCS} by a factor 2.2 in the case of two components and increases T^0_{BCS} for several components. The critical temperature is then,

$$k_B T_{BCS} \simeq 0.3\varepsilon_f \exp\left(-\frac{\pi}{2k_F|a_s|}\right) \ , \tag{49.52}$$

where $\varepsilon_F = \hbar^2 k_F^2/2m$. Therefore transfer half the population into an different Zeeman state, e.g. state ^{6}Li, $|1/2, 1/2\rangle|1/2, -1/2\rangle$ or ^{40}K, $|9/2, -9/2\rangle|9/2, -7/2\rangle$. This is only possible with optical traps. The s-wave scattering length for ^{6}Li is $a_s \simeq -2160 a_B$, even in this channel.

Use p-wave collisions as pairing mechanism [408]. The critical temperature is then,

$$k_B T_{BCS} \simeq \varepsilon_F \exp\left(-\frac{\pi}{2(k_F|a_p|)^3}\right) \ . \tag{49.53}$$

The p-wave scattering length for ^{6}Li is $a_p \simeq -35 a_B$.

49.4.3 Resonance superfluidity and boson-induced interactions

In general $k_F|a| \ll 1$, so that the pairing temperature is way too low. There are however two approaches to rise the critical temperature:

1. Increase the s-wave or the p-wave scattering length by a Feshbach resonance [1426, 1084] (see also Sec. 33.4.2).

2. For a Fermi gas embedded in a Bose condensate, there can be boson-mediated interaction, similar to phonon-mediated interaction in ^{3}He-^{4}He [144, 600]. This can give rive to an effective fermion-fermion scattering length, i.e. a Rb Bose gas may catalyse an enhancement of ^{6}Li-^{6}Li interactions. For a discussion on how to reach very cold temperatures via sympathetic cooling see Sec. 49.2.2.

All experiments used s-wave pairing of spin-mixtures enhanced by Feshbach resonances. BCS pairing has been observed in experiments by various methods: 1. Radio frequency spectroscopy probes the excitations spectrum [539], which should show a pairing gap [101, 256]. 2. Superfluidity is seen as the occurrence of vortices in a Fermi gas [1444].

49.5 Controlling the interatomic interaction

Collisions play an important role in all areas of atomic physics. By *elastic collisions*, an atom exchanges only kinetic energy, which is important, for example, for the thermalization of atomic clouds upon evaporative cooling. During a collision, the interatomic forces deform the electronic orbitals and displace energy levels and resonances. This is a hindrance to applications in frequency standards (such as atomic fountains), where the accuracy of the measurement of narrow resonances is limited by these effects. On the other hand, *controlled* elastic collisions are the essential ingredient of some quantum computer schemes [661]. An *inelastic collision* involves the internal degree of freedom of atoms, that is, the atoms modify their excitation levels. The excess excitation energy is transferred to the atomic motion as kinetic energy, which in turn, provided it is sufficiently high, can expel the atoms out of the trap.

Collisions can be classified by their energy: A *cold collision* is characterized by an interaction time, which is so long, that absorption and photon emission processes can occur during this period. This allows the manipulation of the collisions by irradiation of resonant laser beams [1279]. A collision is called *ultra-cold collision*, when the kinetic energy of the atoms lies below the photon recoil limit. At these temperatures, only partial s-waves contribute to the collision. In general, ultra-cold collisions are influenced by quantum statistics (bosonic or fermionic), whereas 'cold only' collisions can often be treated by classical theory.

49.5.1 Detection of Feshbach resonances

The spin structure of alkaline atoms is complex and results from a combination of electron-exchange energy, hyperfine spin coupling and Zeeman interactions. This gives rise to a multiplicity of energy levels, which increases the likelihood of an occurrence of Feshbach resonances. There are several ways to detect a Feshbach resonance. An

experiment done at the University of Texas at Austin used *photoassociation spectroscopy with resolved Zeeman structure* to prove the first Feshbach resonance in a thermal cloud of ^{85}Rb atoms [300]. An alternative method measures the influence of the Feshbach resonance on the elastic collision section [1108]. A third detection method, which proves the impact of a Feshbach resonance on a BEC, has been used for ^{23}Na [648]. Other Feshbach resonances were later found in ^{133}Cs [1349] and many other species or combinations of species [**?**].

49.5.2 Free-bound coupling by Feshbach resonances

First theoretical studies have been carried out by [1308, 391, 627]. The simplistic image of the scattering length (see Sec. **??**) is a good approximation for isolated atoms, very diluted clouds or condensates far away from a Feshbach resonance, $B - B_{FB} \to \infty$. However, the divergence of the condensate's mean field energy at $B \to B_{FB}$ is not a realist concept. In fact, the molecular state represents a separate species of particles and a new thermodynamic fraction which, when the Feshbach resonance is excited in a BEC, is expected to form a *molecular condensate* [1308]. The atomic BEC and the molecular BEC are coupled by tunneling of atom pairs between them. This coupling is described by the following contribution to the Hamiltonian:

$$H \sim \hat{\psi}^2_{atom}\hat{\psi}^\dagger_{mol} + (\hat{\psi}^\dagger_{atom})^2\hat{\psi}_{mol} \ . \tag{49.54}$$

The signature of this new type of quantum tunneling can be observed in Josephson-like oscillations as a response to an abrupt modification of the scattering length induced by a sudden change of the magnetic field.

One problem with the mixed atomic-molecular system is the rapid relaxation of the molecular states. In fact, bound states have high vibrational energy and can easily relax by inelastic collisions with atoms or other molecules. Relaxation may make it difficult to detect molecular condensates.

The coherent free-bound coupling has been studied in a series of theoretical and experimental publications [1314, 668, 391, 1307, 1308, 648, 1108, 1349, 293]. The chemical potential of a BEC in the Thomas-Fermi approximation depends on the scattering length via $\mu = gn$. The relationship may be useful to (a) study the collapse of BECs and to make BECs with new species, (b) to study the phase separation of BECs in different internal states tuning between miscible and non-miscible BECs, (c) to study Josephson oscillations adjusting the difference of the chemical potentials of two species, and (d) to study the dynamics of BECs.

But the physics of the BECs are considerably richer than that of a modified scattering length, due to the possibility of a free-bound coupling to a vibrational molecular state. Josephson oscillations far away from resonance between states of molecular and atomic BECs can be excited in response to an abrupt change of detuning. Near resonance, the production of molecules induces a self-stabilization and a minimum in energy dependence of the density. Consequently, the density is self-determined, which is a property of *rarefied liquid*s. Gases and liquids are both fluid. Their viscosity is much lower than that of a solid. Gases are distinguished from liquids by their self-diffusion and much greater compressibility, gases do not form surfaces. For liquids we have almost $(\partial n_{lq}/\partial P) \approx 0$, or in harmonic traps $(\partial n_{lq}/\partial \omega_{trap}) \approx 0$.

The treatment of the free-bound coupling introduced in the preceding section leads to non-physical phenomena when applied in BECs. Therefore, we reformulate the many-body problem allowing for the emergence of a separate molecular condensate coherently coupled to the atomic one:

$$
\begin{aligned}
H &= \int_{R^3} u(\mathbf{r}) d^3\mathbf{r} \ , \qquad (49.55)\\
n(\mathbf{r}) &= |\hat{\psi}_a|^2 + \tfrac{1}{2}|\hat{\psi}_m|^2, \\
u_{kin}(\mathbf{r}) &= \hat{\psi}_a^+ \left(\tfrac{-\hbar^2}{2M}\Delta + V_a(\mathbf{r}) \right) \hat{\psi}_a + \hat{\psi}_m^+ \left(\tfrac{-\hbar^2}{4M}\Delta + V_m(\mathbf{r}) + \Delta E \right) \hat{\psi}_m \ , \\
u_{self}(\mathbf{r}) &= \hat{\psi}_a^+ \left(g_{aa}|\hat{\psi}_a|^2 \right) \hat{\psi}_a + \hat{\psi}_m^+ \left(g_{mm}|\hat{\psi}_m|^2 \right) \hat{\psi}_m \ , \\
u_{mutual}(\mathbf{r}) &= g_{am}|\hat{\psi}_a|^2|\hat{\psi}_m|^2 \ , \\
u_{conv}(\mathbf{r}) &= \frac{\alpha}{\sqrt{2}} \left(\hat{\psi}_a^2 \hat{\psi}_m^\dagger + (\hat{\psi}_a^\dagger)^2 \hat{\psi}_m \right) \ ,
\end{aligned}
$$

where M denotes the atomic mass, α the atom-molecule coupling $\alpha\delta_{\mathbf{K},\mathbf{k}+\mathbf{k}'} = \sqrt{\Omega}\langle \mathbf{K}, m|V_{hfs}|\mathbf{k},\mathbf{k}'\rangle$. The contribution u_{conv} can be interpreted as *second harmonic generation* (SHG). With the commutation rules:

$$
\begin{aligned}
\left[\hat{\psi}_j^\dagger(\mathbf{r},t), \hat{\psi}_k(\mathbf{r}',t)\right] &= \delta_{jk}\delta^3(\mathbf{r}-\mathbf{r}') \ , \qquad (49.56)\\
\left[\hat{\psi}_j(\mathbf{r},t), \hat{\psi}_k(\mathbf{r}',t)\right] &= 0 \ ,
\end{aligned}
$$

and the Heisenberg equations,

$$
\left[H, \hat{\psi}_j(\mathbf{r},t)\right] = i\hbar\partial_t \hat{\psi}_j^+(\mathbf{r},t) \ , \qquad (49.57)
$$

we can calculate the dynamics of this coupled system.

The equilibrium situation is described by the atomic and molecular chemical potentials to be balanced, $\mu = \mu_a = \mu_m$. Expressing the BEC as a c-number and defining $n \equiv \phi^2$:

$$
\begin{aligned}
\mu\phi_a(\mathbf{r}) &= \left[\tfrac{-\hbar^2}{2M_a}\Delta + V_a(\mathbf{r}) + g_{aa}n_a(\mathbf{r}) + g_{am}n_m(\mathbf{r}) \right] \phi_a(\mathbf{r}) + \sqrt{2}\alpha\phi_m(\mathbf{r})\phi_a(\mathbf{r}) \ , \qquad (49.58)\\
2\mu\phi_m(\mathbf{r}) &= \left[\tfrac{-\hbar^2}{4M_m}\Delta + V_m(\mathbf{r}) + g_{mm}n_m(\mathbf{r}) + g_{am}n_a(\mathbf{r}) \right] \phi_m(\mathbf{r}) + \tfrac{1}{\sqrt{2}}\alpha\phi_a^2(\mathbf{r}) \ .
\end{aligned}
$$

49.5.2.1 Bose-Einstein condensation of ^{85}Rb

The scattering length of the isotope ^{85}Rb in the ground state $F = 2, m_F = -2$ is negative, $a_{|2,-2\rangle} \approx -400a_B$, which prevents the formation of stable condensates with this atomic species. However, in the vicinity of a Feshbach resonance, the scattering length is very sensitive to ambient magnetic fields B (see Fig. 33.30), and can change its amplitude and even its sign.

Consequently, quantum degeneration was reached with ^{85}Rb [293] operating in a region, where the scattering length is positive. The evaporative cooling of a gas

from this isotope is troubled by a minimum in the temperature dependence of the cross section for elastic collisions around 350 μK, which is a peculiarity of ^{85}Rb. In addition, inelastic two- or three-body collisions of are very common in some regimes of the scattering length. Nevertheless, these difficulties can be avoided [293] using relatively weak confinement potential to reduce the density of the atomic cloud. Also, via a temporal control of the scattering length through a magnetic field $a(B(t))$, it is possible to design a sophisticated evaporation trajectory avoiding the critical regimes.

The active control of the scattering length also allows to push a ^{85}Rb condensate into the ideal gas regime, $a(B) \to 0$, or toward the Thomas-Fermi limit of a strongly interacting gas, $a(B) > 10000 a_B$, where the assumption of a very dilute gas, (46.3), starts to fail and effects beyond the mean field approximation are expected. Since the volume and shape of a condensate depend on its self-energy, their measurement yields information about the actual value of the scattering length.

Near a Feshbach resonance, at an amplitude of the magnetic field of $B = 166.8$ G, the scattering length changes from positive to negative (see Fig. 33.30). Crossing this point, we observe a catastrophic dynamic behavior [1109]: The BEC tries to reduce its self-energy by compressing its density until it succumbs emitting a jet of hot atoms.

49.5.2.2 Production of molecules inside condensates

The complicated ro-vibrational structure of molecules prevents their efficient cooling by optical means. Nevertheless, some alternative techniques, such as supersonic expansion, cryogenic cooling [387] and magnetic trapping [1365] managed to cool molecular samples to temperatures around one Kelvin.

Photoassociation (PA) can be used [82] as a tool to convert a large number of atoms to ultra-cold molecules. Based on this technique, molecules were synthesized in the rotational ground state at temperatures of 100 μK, but distributed over a large number of highly excited vibrational states [445]. Alternatively, it is possible to consider a coupling of atomic states to a single ro-vibrational molecular state using two lasers in Raman configuration. This scheme is known as *two-photon photoassociation* (see Fig. 49.7). In equilibrium, the production of molecules by this method depends on the entropies of the coupled system [668]. In a thermal atomic gas, the (quasi-[2]) continuum of dissociated atomic states has a much greater entropy than the discrete spectrum of bound vibrational molecular states. The equilibrium of the free-bound coherent coupling, therefore, is biased toward the side of the continuum, that is, molecules dissociate faster than they associate, and the molecular production is negligible. However, when the atomic cloud approaches the quantum degeneracy regime, the phase space is considerably reduced (a condensate has zero entropy), and the free-bound coherent coupling can transform a considerable amount of condensed atoms to a *molecular condensate*. The formation of molecules within a condensate can be interpreted as a chemical process, where bosonic stimulation plays the role of a catalyst. The dynamics of this process is induced by quantum statistics rather than chemical forces between atoms.

The experimental procedure for synthesizing ^{87}Rb is quite simple: A condensate of some 10^5 atoms in the electronic ground state $^2S_{1/2}$ ($f = 1, m_f = -1$) and two laser

[2]The atoms are still confined to the trapping potential.

beams in the Raman configuration are irradiated for some 100 ms. As shown on the left side of Fig. 49.7, the first laser excites the transition between the ground state of free atoms and a vibrational state of the excited interatomic interaction potential 0_g^-. Its frequency is tuned $\Delta_1 = -150$ MHz below resonance. The second laser couples the molecular state of the interatomic ground state potential (in this case, it is the second vibrational state below the ionization threshold, $v = -2, \ell = 0$) and the excited molecular state of the 0_g^- potential (chosen for its large Franck-Condon overlap with the molecular ground state). This laser is tuned to $\Delta_2 = \Delta_1 + 636\,\text{MHz}$. Since the two frequencies are derived from a single laser using an acousto-optical modulator, their phases are coherent, that is, the Raman frequency $\Delta_1 - \Delta_2$ is sufficiently stable to couple only a single ro-vibrational state connected through a dark resonance to the collision channel. The molecules are not directly detected, but at the end of the Raman laser pulse, condensate losses due to the formation of molecules are measured by time-of-flight imaging. The dark resonance is detected by repeating the sequence with different laser detunings.

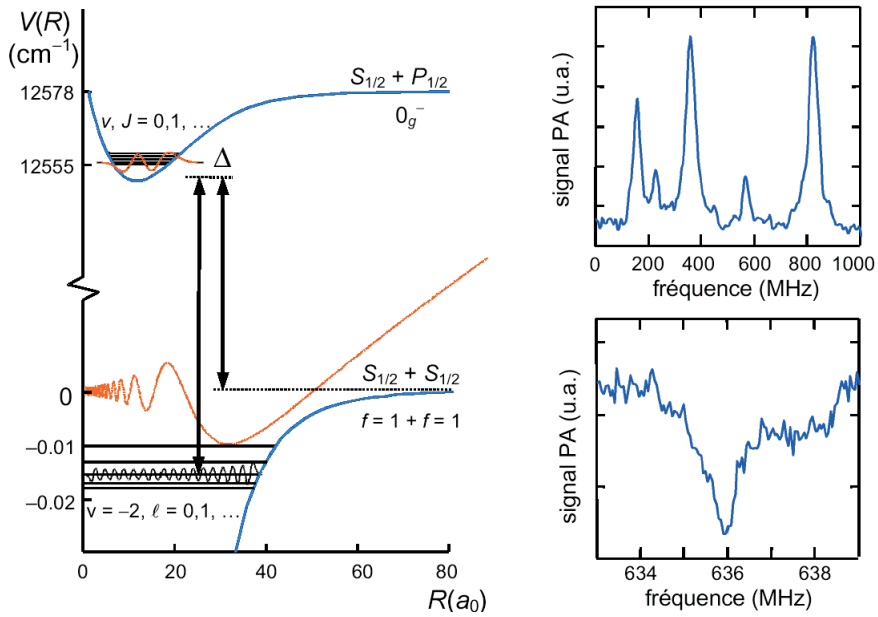

Figure 49.7: Free-bound-bound two-photon photoassociation in ^{87}Rb. During the collision of two atoms in their lower hyperfine level of the ground state, $^2S_{1/2}, f = 1, m_f = -1$, collide, they undergo a photoassociative Raman transition to the bound vibrational state $v = -2, l = 0, F = 2, m_F = -2$ located 636.0094 MHz below the ionization threshold. The intermediate excited state is $v, J = 0$ at $12555\,\text{cm}^{-1}$ of the 0_g^- potential connecting to the asymptote $^2S_{1/2} - ^2P_{1/2}$. The levels are chosen for their large Franck-Condon overlap.

While in a thermal cloud, two-photon photoassociation resonances have widths of some MHz (see Fig. 49.7 top right), the dark resonances measured in BECs have widths less than 2 kHz, which clearly shows the coherence of the coupling in the latter case. The narrowness of the dark resonance allows to measure the ionization energy of

the molecular ground state, $E = 2\pi\hbar \times 636.0094$ MHz, with unprecedented resolution, only limited by the spatially inhomogeneous distribution of the condensate's self-energy. Molecules are created in a specific state and preselected: They are at rest because the Raman process does not transfer momentum, the molecular state chosen in this experiment [1396] has no rotation, but the energy of the vibrational excitation is large (Rydberg's molecular states).

It is natural to ask in what situation the molecules should form an molecular condensate. In principle, for each ro-vibrational molecular state the lowest molecular state of the confining potential can accommodate a molecular BEC. However, the width of the dark resonance should be lower than the secular frequencies of the trap, to selectively populate a single (fundamental) motional state. In addition, the molecules should be reasonably stable. Unfortunately, molecules with highly excited vibrations undergo inelastic collisions with atoms (or other molecules if their density is high), which converts the vibrational excitation energy to kinetic energy for the atom and the molecule resulting in losses for the confined cloud [77]. Fast inelastic relaxation toward lower vibrational states limits the lifetime of the molecular Rydberg states to some 100 μs [1396]. We might think of coupling lower vibrational states of the molecular potential, provided the Franck-Condon overlap is sufficient. However, the energies of these vibrational levels are so far apart, that the frequencies of the Raman beams must be produced by different lasers. These lasers must be extremely stable, that is, their spectral emission bandwidth must be less than the desired resolution of the dark resonance.

49.6 Feshbach resonances in BECs

The equilibrium situation is described by the atomic and molecular chemical potentials being balanced $\mu = \mu_a = \mu_m$. If we express the BECs as c-numbers defining $n \equiv \phi^2$:

$$\mu\phi_a(\mathbf{r}) = \left[\tfrac{-\hbar^2}{2M_a}\Delta + V_a(\mathbf{r}) + g_{aa}n_a(\mathbf{r}) + g_{am}n_m(\mathbf{r})\right]\phi_a(\mathbf{r}) + \sqrt{2}\alpha\phi_m(\mathbf{r})\phi_a(\mathbf{r}) \ , \tag{49.59}$$

$$2\mu\phi_m(\mathbf{r}) = \left[\tfrac{-\hbar^2}{4M_m}\Delta + V_m(\mathbf{r}) + g_{mm}n_m(\mathbf{r}) + g_{am}n_a(\mathbf{r})\right]\phi_m(\mathbf{r}) + \tfrac{1}{\sqrt{2}}\alpha\phi_a^2(\mathbf{r}) \ .$$

49.6.1 Thomas-Fermi limit

For weak coupling strength $\alpha \to 0$, the contributions of a *single* atom and a *single* molecule to the total energy are:

$$1H = \int_{R^3} \left(U_a(\mathbf{r})n_a(\mathbf{r}) + U_m(\mathbf{r})n_m(\mathbf{r})\right) d^3\mathbf{r} \ , \tag{49.60}$$

$$1U_a(\mathbf{r}) = \tfrac{-\hbar^2}{2M_a}\Delta + V_a(\mathbf{r}) + g_{aa}n_a(\mathbf{r}) + g_{am}n_m(\mathbf{r}) \ ,$$

$$U_m(\mathbf{r}) = \tfrac{-\hbar^2}{2M_m}\Delta + V_m(\mathbf{r}) + g_{mm}n_m(\mathbf{r}) + g_{am}n_a(\mathbf{r}) \ .$$

For small molecular condensates, in the Thomas-Fermi limit:

$$U_a(\mathbf{r}) = V_a(\mathbf{r}) + g_{aa} n_a(\mathbf{r}) \ , \tag{49.61}$$
$$U_m(\mathbf{r}) = V_m(\mathbf{r}) + g_{am} n_a(\mathbf{r}) \ .$$

The elastic cold collision of two particles, atoms or molecules, $i, j = a, m$, can be described by the real part of the scattering length $a_{ij} = a'_{ij} - i a''_{ij}$, which is related to the interparticle interaction strength $g_{ij} = 4\pi\hbar^2 a'_{ij}/M_{ij}$, where we used the reduced mass $M_{ij}^{-1} = M_i^{-1} + M_j^{-1}$ of particle pairs, i.e. $M_{aa} = M/2$, $M_{am} = 2M/3$ and $M_{mm} = M$. Similarly, inelastic collisions are described by the imaginary part $K_{ij}^{(inel)} = 4\pi\hbar^2 a''_{ij}/M_{ij}$. Additionally we have the interspecies coupling strength α.

49.6.2 Off-resonant and resonant limit

Far from the Feshbach resonance, $\Delta E \longrightarrow \infty$, in the Thomas-Fermi limit, $g \equiv 2g_a \equiv g_m$. The minimum energy density is,

$$u_{\min} = \phi_a^+ \left(\tfrac{g_a}{2} - \tfrac{\alpha^2}{\Delta E} \right) n \phi_a \ , \tag{49.62}$$

and the equations (49.58) reduce to the well-known single-species GPE where the scattering has changed to,

$$a_{eff} = a_0 - \frac{M}{4\pi\hbar^2} \frac{2\alpha^2}{2\mu_a - \mu_m} \frac{1}{B - B_{FB}} \ . \tag{49.63}$$

Tuning a from *positive side* into resonance, i.e. driving the scattering length from positive values to 0 reduces the self-energy $4\pi\hbar^2 a/M \cdot n_a \longrightarrow 0$, so that the BEC must collaps according to the a_{eff} description, unless it is stabilized by a confining trap allowing a certain maximum n_a. However, in the correct two-species description, the atoms can tunnel into molecular states thus reducing n_a to a number that can actually be balanced by the confining trap. This effect stabilizes the BEC.

The a_{eff} description also suggests unphysical divergences.

49.6.2.1 Decay

Collisions will induce a fast relaxation of highly excited *molecular Rydberg states*. We have two competing time scales. Fast relaxation of high vibrational states by inelastic (molecule-atom) 3-body collisions typically happens for $n = 10^{14}$ cm^{-3} and $\Gamma_{typical}$ within $\tau_{relax} = 1$ μs..1 ms. The condensate dynamics governed by self-energy $i\hbar\partial_t\psi = \frac{4\pi\hbar^2 1}{m} n\psi$ which happens within τ_{cond} =several 100 ms. It seems, that adiabatic tuning into FBR may be barely feasible.

The decay gives rise to an irreversibility and thus to a dependence of the state on history which is not included in the a_{eff} description.

49.7 Raman photoassociation in BECs

49.7.1 Molecule production

Complicated ro-vibrational structure of molecules inhibits efficient laser cooling. Supersonic expansion internally cold but translationally hot, cryogenic cooling [387] and

magnetic trapping [1365] works down to K. Incoherent photoassociation has produced molecules rotationally as cold as 100 μK, but still populates many excited vibrational states and has a large energy spread [445]. Other work has been done by [82], [690], [832], [669], [1396], [638].

In a BEC we can state-selectively (here: no rotation, high vibration, weakly bound) create ^{87}Rb molecules at rest (no motion). Raman dark resonance width of 1.5 kHz influenced by molecule- atomic BEC interactions. The molecular binding energy is precisely measurable $\varepsilon = 2\pi \times 636.0094$ MHz. Is useful for determining the potentials even more accurately.

Procedure is very simple: Make a BEC of a few 10^5 atoms in the ground state ^{87}Rb $5^2S_{1/2}(f = 1, m_f = -1)$ with variable densities $n_0 = 0.8...2.7$ cm^{-3}. Then irradiate a collinear pair of laser beams for $\tau = 150...550$ ms with $\Delta_1 = 2\pi \times -150$ MHz and detuned from an upper 0_g^- long range molecular state and $\Delta_2 = \Delta_1 + 636$ MHz phase coherent to Δ_1 within 1 kHz. The momentum transfer is neglegible, because $\mathbf{k}_1 \approx \mathbf{k}_2$. Neighboring atoms interact via $V_g(R)$, the Raman beams couple the free collisional channel via a dark resonance to a single ro-vibrational bound state. Finally measure the losses $N(\tau)/N_0$ from the BEC via fluorescence TOF. The dark resonance is probe by repeating the sequence with various detunings.

The width and shift of the resonance depends on the laser intensities I_1 and I_2 and detuning Δ_1 and on the peak density of the condensate. AC-Stark shift and *power*-broadening due to spontaneous Raman scattering of molecules removing them from the BEC. The dependence on the laser parameter can be removed by extrapolation to 0.

The Doppler broadening is not important, because $E_{kin} \approx 6$ nK and $E_{pot} \approx 100$ nK. Zeeman brodening is neglegible, because $\vec{\mu}_{mol} = 2\vec{\mu}_{atom}$ so that it is smaller than1.5 kHz/G. No radiative decay? In the Thomas-Fermi limit the energy width of the atomic BEC is strongly reduced, because of the large coordinate distribution and the uncertainty relation. The resonance width is therefore attributed to molecule-atom interactions.

To treat the problem, we can use equations (49.58), and set $u_{kin} \to 0$ and $u_{conv} \to 0$. In analogy to equation (49.60), we get,

$$\begin{aligned} H &= \int_{R^3} \left(U_a(\mathbf{r})n_a(\mathbf{r}) + U_m(\mathbf{r})n_m(\mathbf{r})\right) d^3\mathbf{r} \qquad (49.64) \\ U_a(\mathbf{r}) &= V_a(\mathbf{r}) + g_{aa}n_a(\mathbf{r}) = const \\ U_m(\mathbf{r}) &= V_m(\mathbf{r}) + g_{am}n_a(\mathbf{r}) \ , \end{aligned}$$

where $g_{aa} = 4\pi\hbar^2 a'_{aa}/M$ and $g_{am} = 3\pi\hbar^2 a'_{am}/M$ and $V_m(\mathbf{r}) = 2V_a(\mathbf{r})$. We know from earlier experiments that $a'_{aa} = 104a_B$ and $a''_{aa} \approx 0$. When converting a pair of atoms into a molecule, we have to cross the energy gap $\Delta U(\mathbf{r}) \equiv U_m(\mathbf{r}) - 2U_a(\mathbf{r}) = (g_m - 2g_a)n_a(\mathbf{r})$. The coordinate dependence broadens the transition. A crude model for the photoassociative loss rate $\dot{n}_a(\mathbf{r}, t)$ permits a rough estimate of $a'_{am} \approx -180a_B$ and $a''_{am} < 110a_B$, or equivalently g_{am} and $K_{am}^{(inel)} < 8 \cdot 10^{-11}$cm^3/s. That means that at $n_a(0) = 10^{14}$cm^3 peak density the lifetime of the molecules lies at about $\tau_{inel} = 0.1...0.5$ms and much faster than the trap secular frequency, so that the molecules can be considered at rest during the whole process. For longer vibrational lifetimes, the inhomogeneous broadening transforms into an oscillator spectrum which

could be resolved by the Raman transition. The lowest trap oscillation level for each vibrational state can, in principle, accommodate a molecular ground state BEC.

Vibrationally excited molecules collide inelastically with atoms (or other molecules if the density is high enough) converting their vibrational energy into kinetic energy for the atom and the molecule resulting in trap loss. This process is very strong for high vibrational excitation [77]. This process is also the reason for the observed strong inelastic losses near Feshbach resonances. The analogy to Feshbach resonances comes from the fact that they can be interpreted as coming from a transient intermediate molecular state in a 2-atom collision. Both schemes of controlled molecule production may be useful only if the lowest vibrational levels are populated or a level with inhibited decay.

However, if the lifetime of the vibrational state τ_{vib} is long enough, both schemes are not simply collision resonances (resonant modification of the scattering length), but a separate population of the molecular state builds up and the *cm-* degree of freedom interacts with the atomic BEC.

Outlook on reversible creation of molecular BECs with exotic phenomena provided the vibrational relaxation by molecule-atom and molecule-molecule collisions can be overcome. Molecular laser may be feasible by choosing laser geometries different from parallel beams, so that the momentum transfer expulses the molecules from the atomic BEC.

49.8 Production of heteronuclear molecules

Our main goal is the production of LiRb molecules. Two ways are possible: Using Feshbach resonances or via Raman-Photoassociation. Stability issues: They might be much more unstable then fermionic species molecules. Molecules may be short-lived due to inelastic or *reactive losses* [315].

49.8.1 General production schemes

49.8.1.1 Photoassociation

Mixed species collisions have no resonant dipole-dipole interaction [707, 837]. Therefore excited state collisions of different species are purely short-ranged. This makes free-bound *photoassociation* more difficult, but enhanced bound-bound transitions towards deeply bound vibrational states. For reasonable rates laser intensities on the order of 100 W/cm^2 are required. High densities more than 10^{11} cm^{-3} are desired. The lowest fine structure dissociation limit is good to prevent predissociation [706]: Li($2s$)-Rb($5p_{1/2}$).

The ground state $^3\Sigma$ potential supports around 60 vibrational levels. It is 300 cm^{-1} deep (or 20 nm at 795 nm).

49.8.1.2 Two-color photoassociation

For a coherent coupling via *stimulated Raman photoassociation* of those states stable lasers are necessary. Phase-locked stabilization either requires photonic fibres or locking to a common cavity. The free-bound laser must be very strong.

49.8.1.3 Feshbach resonance

Proposal for heteronuclear molecules via Feshbach resonances stem from [738, 1274]. Also *heteronuclear Feshbach resonance* has been observed for ^{6}Li^{7}Li [1327], ^{6}Li^{23}Na, [1242], and ^{40}K^{87}Rb [**?**].

49.8.2 LiRb molecules

The LiRb sytem is interesting for its large permanent electric dipole moment. Also, the combination LiRb has been shown advantageous for reaching low temperatures due to the large mass difference (see Sec. 49.2.2). E.g. try boson-mediated s-wave or p-wave Cooper pairing without no ^{6}Li^{6}Li Feshbach resonance enhancement. In contrast, the ^{6}Li^{87}Rb interaction can be tuned by an interspecies Feshbach resonance (tuning both resonances simultaneously does not work anyway). The predicted pairing temperatures are very low [408], $T \ll 1$ nK for $a_{bf} \gg 200a_B$ and $n_f \gg 10^{14}$ cm^{-3}.

The idea for their production is to cool ^{6}Li and ^{87}Rb atoms down, excite a Feshbach resonance and simultaneously a Raman transition.

49.8.2.1 Production scheme for LiRb molecules

- Step 1: Transfer atoms from the triplet scattering channel $|2,-2\rangle|3/2,3/2\rangle$ towards $|1,-1\rangle|1/2,-1/2\rangle$ via a combination of microwave pulses driving the hyperfine resonance and adiabatic radiofrequency sweeps, carefully designed to populate the desired states.

- Step 2: The colliding channel is coupled to a low-lying bound vibrational level via a Raman transition. An appropriate scheme has to be found, satisfying the selection rules for radiative transitions, maximizing the Franck-Condon overlaps and working at convenient transition wavelengths. The Raman transition must be driven by a stabilized system of two lasers; their relative stability should be high enough to allow for a resolution of the secular frequencies of the trapping potential [3].

- Exciting Raman transitions, Scheme 1: The atoms collide in their fully stretched $|2,2\rangle|3/2,3/2\rangle$ channel which only connects to the $a^3\Sigma^+$ potential. The amplitude of the scattering wavefunction is enhance by a Feshbach resonance. A laser at 1700 nm excites close to the outer turning point a level of the $(1)^3\Pi$ potential, which mixes via spin-orbit coupling with the $(2)^1\Sigma^+$ potential to give rise to a 0^+ level structure. The inner turning point has a good Franck-Condon overlap with low-lying vibrational levels of the $X^1\Sigma^+$ ground state potential.

- Exciting Raman transitions, Scheme 2: The atoms collide in a channel which has admixtures of the $X^1\Sigma^+$ ground state potential.

[3] Is PA coupling strong enough even in presence of spontaneous decay? What are the selection rules for bound-bound transitions to deeply bound levels?

49.8.3 Stability of LiRb Rydberg molecules

The heteronuclear ^{6}Li^{87}Rb molecules will be unstable against collisions with Li and in particular bosonic Rb atoms, whose density is very high. However sufficiently deep bound LiRb molecules are fermionic and thus stable against ultra-slow inelastic collisions. In contrast, this is not true for highly excited vibrational states. Close to dissociation the quantum statistics of the constituents is expected to dominate the collision process, which leads to accelerated decay. How deep must the binding be for stable LiRb clouds? What loss mechanisms are possible [44]?

49.8.3.1 Tuning the binding energy

There are two contradictory pictures. In a 'single-channel picture', close to a FR the bound states of potential V_b interacts with the collisional channel of another potential V_c. This interaction deepens (or flattens) V_c and causes a continuum state of V_c to move into a bound state of V_c. The binding energy then increases with the detuning.

In a two-channel picture, have [1242].

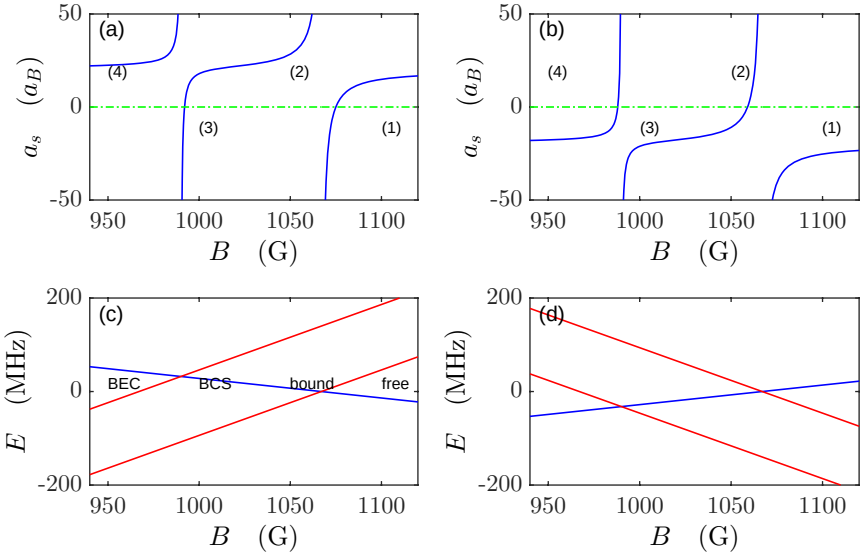

Figure 49.8: (code) Tuning of scattering length (a,b) and bound state energies (c) near Feshbach resonances for (a) $a_s(0) > 0$, (b) $a_s(0) < 0$. Here (1,3) $a_s > 0$, (2,4) $a_s < 0$.

49.8.4 Removing Li and Rb molecules

Nocif Li and Rb atoms can be removed by *Stern-Gerlach separation*. This may work if the goal is separate imaging of atoms and molecules. It may however be too slow to prevent collisions. Another option is resonant excitation of the atoms. But this requires GHz far-detuned lasers.

We want to separate Rb atoms and LiRb molecules in time-of-flight. The clouds are 7 µK hot. We want to apply a $b = 40\,\mathrm{G/cm}$ gradient force for less than $\Delta t = 500\,\mu\mathrm{s}$.

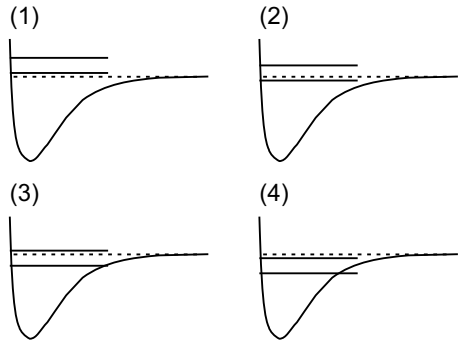

Figure 49.9: (code) (1,3) $a_s < 0$, (2,4) $a_s > 0$.

Hence, the thermal expansion velocity,

$$\bar{v} = \sqrt{\frac{k_B T}{m_{87}}} \simeq \sqrt{\frac{k_B T}{m_{93}}} \simeq 2.5\,\mathrm{cm/s} \tag{49.65}$$

must be smaller than the separation velocity,

$$\Delta v = \int \frac{F_{87}}{m_{87}} dt - \int \frac{F_{93}}{m_{93}} dt \simeq 2\frac{F_{87}}{m_{87}}\Delta t \simeq 2\frac{\mu_B b}{m_{87}}\Delta t \simeq 2.6\,\mathrm{cm/s}\ . \tag{49.66}$$

49.8.4.1 Optical transitions in the Paschen-Goudsmith regime

There are cycling transitions out of the absolute ground state in the Paschen-Back regime. For ^{87}Rb the $^2S_{1/2}$ ground state $|F = 1, m_F = 1\rangle$ connects to $|m'_J = -\frac{1}{2}, m'_I = \frac{3}{2}\rangle$. From here laser light can reach the excited $^2P_{3/2}$ state $|m'_J = -\frac{3}{2}, m'_I = \frac{3}{2}\rangle$, which connects to $|F' = 0, m'_F = 0\rangle$. For ^{6}Li the $^2S_{1/2}$ ground state $|F = \frac{1}{2}, m_F = \frac{1}{2}\rangle$ connects to $|m'_J = -\frac{1}{2}, m'_I = 1\rangle$. From here laser light can reach the excited $^2P_{3/2}$ state $|m'_J = -\frac{3}{2}, m'_I = 1\rangle$, which connects to $|F' = \frac{1}{2}, m'_F = -\frac{1}{2}\rangle$. Note the latter transitions would be forbidden in the Zeeman regime, because $\Delta > 1$.

49.8.5 Detecting molecules

49.8.5.1 Ramping through a Feshbach resonance

A procedure could be

1. Create an ultracold mixture of atomic Li and Rb.
2. Quickly tune the magnetic field to 1080 nm above the Feshbach resonance at 1070 nm.
3. Ramp the magnetic field across the Feshbach resonance to 1060 nm such that the binding energy ΔE_B is increased, thus creating up to 40000 LiRb molecules.

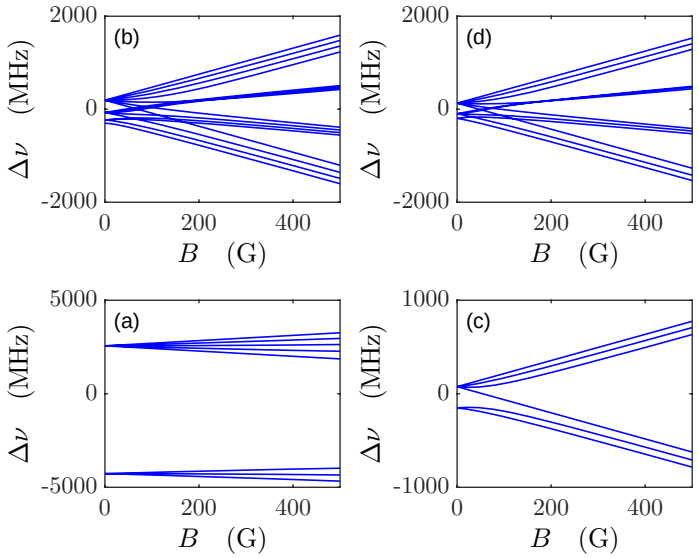

Figure 49.10: Zeeman splitting in the Paschen-Back regime. (a) ^{87}Rb $^2S_{1/2}$, (b) ^{87}Rb $^2P_{3/2}$, (c): ^{6}Li $^2S_{1/2}$, and (c): ^{6}Li $^2P_{3/2}$. The cycling transitions are marked by thick lines.

4. Immediately switch off the dipole trap to reduce the density and diminish the collision rate between LiRb molecules and Rb atoms.

5. Ramp the homogeneous magnetic field back through the Feshbach resonance to 1080 nm, thus reconverting the molecules into atoms.

6. Switch off the homogeneous magnetic field.

7. Immediately absorption image the Li atoms. The visible Li atoms are those that have been bound to Rb atoms previously.

8. Repeat the sequence 1. to 7. now skipping step 5. In this case no Li atoms should be visible, because they are all bound to Rb atoms.

If the Li signal is too weak because the steps 5. and 6. take too much time, it may be possible to watch the Rb cloud. In order to separate those Rb atoms which have not been bound to a Li atom from those who have, one could apply a gradient field to Stern-Gerlach separate LiRb from Rb. In this case the following sequence might work:

1.-4. as above.

5. Apply a gradient field. It can be superposed to the homogeneous field provided both are chosen collinear.

6. Ramp the homogeneous magnetic field back through the Feshbach resonance to 1080 nm, thus reconverting the molecules into atoms.

7. Switch off all magnetic fields.

8. Immediately absorption image the Rb atoms. A bimodal distribution of Rb atoms should be visible [402].

49.8.5.2 Radiofrequency spectroscopy of molecules

Following [983] we could try to excite molecular resonances without any hope of detecting them. It's just an additional loss channel. It could reveal precious information on the size of the scattering length.

How to predict the location of the binding energy peak? If we assume that the measure trap loss width corresponds to the real width of the Feshbach resonance, we can calculate the profile of the scattering length and the binding energy from $E_b = \frac{\hbar^2}{2ma_s^2}$.

1. Transfer Li atoms into $|1/2, -1/2\rangle$ state (i.e. $|m_J, m_I\rangle = |1/2, -1/2\rangle$).
2. Tune close to the Feshbach resonance of the $|1/2, 1/2\rangle$ state.
3. Populate the $|1/2, 1/2\rangle$ state by rf-spectroscopy.
4. Near the Feshbach resonance a second peak blue-detuned from the resonant energy for the population transfer should appear due to the formation of molecules with a certain binding energy.
5. Image the atoms remaining in the $|1/2, 1/2\rangle$ state.
6. Image the atoms in the $|1/2, -1/2\rangle$ state together with the molecules.
7. The molecular decay is expected to be fast leading to important losses in the image 6.. In contrast, it should not matter for the image 5.

The transition frequency is about 50 MHz. Note that the $\Delta m_I \neq 0$ transition may be very weak. Alternatively, one could probe from the ^{6}Li$|F = 3/2, m_F = 3/2\rangle$ state with a transition frequency of 500 MHz or from the ^{87}Rb$|F = 2, m_F = 2\rangle$ state with a frequency of 6.8 GHz.

49.8.6 Binding energy in the harmonic trap

One expects resonances of trap-assisted binding [219, 983, 360]. However, our weak scattering length and the (relatively) weak trap mitigates this behavior. The spectrum is given by,

$$\frac{\Gamma(-E_b/2\hbar\omega_{ho} + 3/4)}{\Gamma(-E_b/2\hbar\omega_{ho} + 1/4)} = \frac{a_{ho}}{2a_s} \ , \tag{49.67}$$

where $a_{ho} = \sqrt{\hbar/m\omega_{ho}}$. Making use of $\lim_{x\leftarrow\infty} \frac{\Gamma(-x+3/4)}{\Gamma(-x+1/4)} \to \sqrt{x}$, we find for large scattering lengths,

$$-E_b = \frac{\hbar}{2\mu a_s} \ . \tag{49.68}$$

Within the Feshbach resonance $|B - B_0| \ll \Delta B$,

$$E_b = -\frac{\hbar^2}{2ma_{bg}^2 \left(1 - \frac{\Delta B}{B - B_0}\right)^2} \simeq -\frac{\hbar^2}{2ma_{bg}^2} \left(\frac{B - B_0}{\Delta B}\right)^2 \ . \tag{49.69}$$

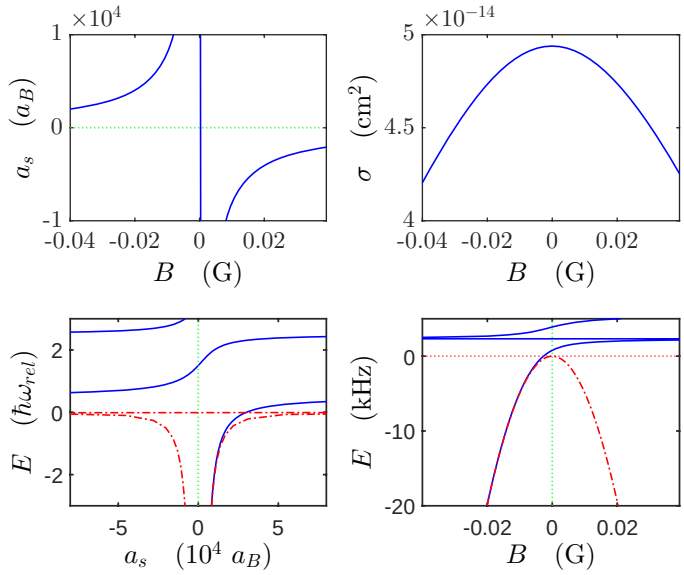

Figure 49.11: Trap binding.

E.g. let us choose a detuning of $B - B_0 = -0.1\Delta B$, where $E_b = h \times 8$ MHz. Then a magnetic field noise of $dB \approx 1$ mG causes an inhomogeneous broadening of the transition by $dE_b \simeq -\frac{\hbar^2}{ma_{bg}^2}\frac{B-B_0}{\Delta B^2}dB \approx h \times 20$ kHz. The broadening increases linearly with detuning.

Thermal broadening may reduce the production efficiency of LiRb atoms. At 7 μK the broadening is 146 kHz. It is recommended to have at least one species condensed [623, 996].

49.8.7 Dipolar relaxation and three-body decay in mixed species

The rate equations for the collisional decay of a Li-Rb mixture are,

$$\dot{N}_6 = \int d^3\mathbf{r}\ \left(-\gamma_6 n_6 - G_{6,6}n_6^2 - G_{6,87}n_6 n_{87} - K_{6,6,6}n_6^3 - K_{6,6,87}n_6^2 n_{87} - K_{6,87,87}n_6 n_{87}^2\right) \tag{49.70}$$

$$\dot{N}_{87} = \int d^3\mathbf{r}\ \left(-\gamma_{87} n_{87} - G_{87,87}n_{87}^2 - G_{6,87}n_6 n_{87} - K_{87,87,87}n_{87}^3 - K_{6,87,87}n_6 n_{87}^2 - K_{6,6,87}n_6^2 n_{87}\right)\ .$$

For a harmonic trap the densities are Gaussian function, $n_j = n_{0,j}e^{-U_j/k_BT_j}$ with $U_j = \frac{m_j}{2}\omega_{r,j}^2 r^2 + \frac{m_j}{2}\omega_{z,j}^2 z^2$. The masses, the trapping potentials and the temperatures for the clouds may differ. We will however assume that the trap have identical shapes, $\omega_{r,87}/\omega_{z,87} = \omega_{r,6}/\omega_{z,6}$, so that the traps may be decribed by isotropic potentials with an averaged secular frequencies, $U_j = \frac{m_j}{2}\omega_j^2 x^2$ with $\omega_j = \left(\omega_{r,j}^2\omega_{z,j}\right)^{1/3}$. We define $\xi \equiv m_6\omega_6^2 T_{87}/m_{87}\omega_{87}^2 T_6$ and the effective volumes $V_{87} \equiv \left(\frac{2\pi k_B T_{87}}{m_{87}\tilde{\omega}_{87}^2}\right)^{3/2} = \xi^{3/2}V_6$. The

integrals can analytically be evaluated,

$$N_j = \int n_j d^3\mathbf{r} = n_{0,j} \int e^{-m_j\omega_j^2 x^2/2k_B T_j} d^3\mathbf{r} = n_{0,j} \sqrt{\frac{2\pi k_B T_j}{m_j\omega_j^2}}^3 = n_{0,j} V_j \tag{49.71}$$

$$\int n_j^k d^3\mathbf{r} = k^{-3/2} n_{0,j}^k V_j$$

$$\int n_{87}^k n_6^l d^3\mathbf{r} = (k + l\xi)^{-3/2} n_{0,87}^k n_{0,6}^l V_{87}$$

finally,

$$\frac{\dot{N}_6}{N_6} = -\gamma_6 - \frac{G_{6,6}}{2^{3/2}}\frac{N_6}{V_6} - \frac{\xi^{3/2} G_{6,87}}{(1+\xi)^{3/2}}\frac{N_{87}}{V_{87}} - \frac{K_{6,6,6}}{3^{3/2}}\frac{N_6^2}{V_6^2} - \frac{\xi^{3/2} K_{6,6,87}}{(1+2\xi)^{3/2}}\frac{N_{87}N_6}{V_{87}V_6} - \frac{\xi^{3/2} K_{6,87,87}}{(2+\xi)^{3/2}}\frac{N_{87}^2}{V_{87}^2} \tag{49.72}$$

$$\frac{\dot{N}_{87}}{N_{87}} = -\gamma_{87} - \frac{G_{87,87}}{2^{3/2}}\frac{N_{87}}{V_{87}} - \frac{G_{6,87}}{(1+\xi)^{3/2}}\frac{N_6}{V_6} - \frac{K_{87,87,87}}{3^{3/2}}\frac{N_{87}^2}{V_{87}^2} - \frac{K_{6,87,87}}{(2+\xi)^{3/2}}\frac{N_{87}N_6}{V_{87}V_6} - \frac{K_{6,6,87}}{(1+2\xi)^{3/2}}\frac{N_6^2}{V_6^2} .$$

Trap loss due to collisions with the background gas is negligible, $\gamma \approx 0$. Two-body relaxation is impossible in the energetic ground state, $G_{x,y} \simeq 0$. $K_{x,y,z}$ are the rate coefficients for losses due to collisions involving atoms of species xyz. The Rb density is overwhelming, $n_6 \ll n_{87}$. Hence the rate equations can be simplified. The terms in $K_{6,6,87}n_6^2$ are explicitly retained, although they are small, in order to permit a modeling of a resonant enhancement of $K_{6,6,87}$ near a ^{6}Li p-wave Feshbach resonance. Else we may set $K_{6,6,87} = 0$. Approximating $V \simeq 3{\times}10^{-15}$ m^3. Setting the initial atom numbers to $N_6 = 50000$ and $N_{87} = 200\,000$ and assuming $K_{87-87-87} \simeq K_{87-87-6} \approx 2.8 \times 10^{-28}$ cm^6/s [984], we get the following curves,

$$\dot{N}_6 V_{87}^2 = -\frac{\xi^3 K_{6,6,6}(B)}{3^{3/2}} N_6^3 - \frac{\xi^3 K_{6,6,87}(B)}{(1+2\xi)^{3/2}} N_{87} N_6^2 - \frac{\xi^{3/2} K_{6,87,87}(B)}{(2+\xi)^{3/2}} N_{87}^2 N_6 \tag{49.73}$$

$$\dot{N}_{87} V_{87}^2 = -\frac{K_{87,87,87}(B)}{3^{3/2}} N_{87}^3 - \frac{\xi^3 K_{6,6,87}(B)}{(1+2\xi)^{3/2}} N_{87} N_6^2 - \frac{\xi^{3/2} K_{6,87,87}(B)}{(2+\xi)^{3/2}} N_{87}^2 N_6 .$$

Now we develop full rate equation model considering all possible processes, try the ansatz $K_{6,6,87} \simeq 10\hbar/m\ a_{6,6}^{8/3} a_{6,87}^{4/3}$ and $K_{6,87,87} \simeq 10\hbar/m\ a_{6,6}^{4/3} a_{6,87}^{8/3}$, calculate rate equations across Feshbach resonances,

$$\dot{N}_6 = -\frac{10\hbar\ a_{6,6}^{8/3} a_{6,87}^{4/3}}{mV^2} N_6^2 N_{87} - \frac{10\hbar\ a_{6,6}^{4/3} a_{6,87}^{8/3}}{mV^2} N_6 N_{87}^2 \tag{49.74}$$

$$\dot{N}_{87} = -\frac{10\hbar\ a_{87,87}^{4}}{mV^2} N_{87}^3 - \frac{10\hbar\ a_{6,6}^{4/3} a_{6,87}^{8/3}}{mV^2} N_6 N_{87}^2 - \frac{10\hbar\ a_{6,6}^{8/3} a_{6,87}^{4/3}}{mV^2} N_6^2 N_{87} .$$

49.8.8 ^{6}Li^{87}Rb $X^1\Sigma^+(v = 0)$ ground state molecules

According to [1274] it should be possible to with heteronuclear dimers to convert free atoms via a Feshbach resonance to a molecular BEC of weakly bound $a^3\Sigma^+$ molecules.

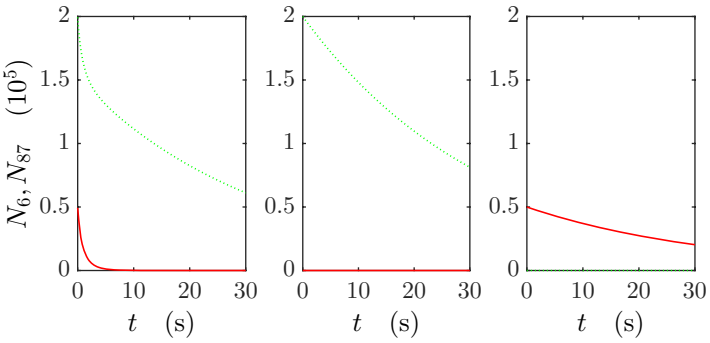

Figure 49.12: (a) Simultaneous decay of Li and Rb, (b) decay of Rb when Li is absent from the trap, (c) and decay of Li when Rb is absent from the trap.

Those are then excited to the outer turning point of the $(1)^3\Pi$ level, which mixes with the $A^1\Sigma^+$ level to form a 0^+ potential, which has 4 turning points. The molecules are then deexcited at the inner turning point towards the absolute ground state $X^1\Sigma^+$. Unfortunately, the laser wavelengths are difficult. For the pump at 1700 nm and for the dump at 830 nmm (Fig. 49.13, left) or 693 nm and 495 nm (Fig. 49.13, right).

Other more sophisticated transitions towards higher levels or using more intermediate steps are possible.

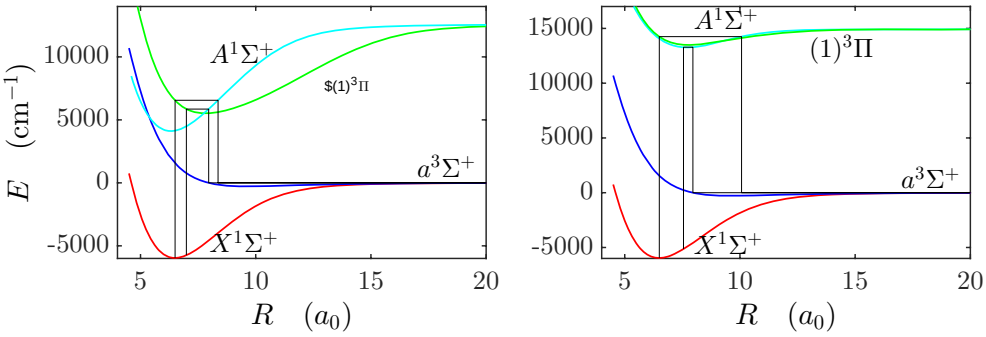

Figure 49.13: Scheme for deexciting ^{6}Li^{87}Rb molecules to low-lying vibrational states. Left: $\lambda_{pump} = 1707.592$ nm and $\lambda_{dump} = 862.4407$ nm. Right: $\lambda_{pump} = 701.7544$ nm and $\lambda_{dump} = 500.2802$ nm.

Chapter 50

Quantum theory of non-relativistic fields

50.1 Quantizing the scalar field

50.1.1 States of individual atoms in a gas

To introduce the physical situation, we consider an external potential $U(\mathbf{r})$ representing a cubic box of length L and volume $V = L^3$. Introducing periodic boundary conditions, $\phi(x+L, y+L, z+L) = \phi(x, y, z)$, the Schrödinger equation for the spatial motion of a single atom in the box can be written as,

$$-\frac{\hbar^2}{2m}\nabla^2\phi_{\mathbf{k}}(\mathbf{r}) = \varepsilon_{\mathbf{k}}\phi_{\mathbf{k}}(\mathbf{r}) \ , \tag{50.1}$$

where the eigenfunctions and corresponding eigenvalues are given by

$$\phi_{\mathbf{k}}(\mathbf{r}) = \tfrac{1}{\sqrt{V}}e^{\imath\mathbf{k}\cdot\mathbf{r}} \qquad \text{and} \qquad \varepsilon_{\mathbf{k}} = \frac{\hbar^2k^2}{2m} \ . \tag{50.2}$$

The wavefunctions $\phi_k(\mathbf{r})$ represent *plane wave solutions*, normalized to the volume of the box, with $\mathbf{k}$ the wave vector of the atom, $k = |\mathbf{k}| = 2\pi/\lambda_{dB}$ the wave number, and λ_{dB} the de Broglie wavelength. The periodic boundary conditions give rise to a discrete set of wavenumbers, $k_\alpha = (2\pi/L)n_\alpha$ with $n_\alpha \in \{0, \pm1, \pm2, ...\}$ and $\alpha \in \{x, y, z\}$.

50.1.2 Wave functions for pairs

The Hamiltonian for the motion of two atoms with interatomic interaction $\mathcal{V}(\mathbf{r}_{12})$ and confined by the cubic box potential $\mathcal{U}(\mathbf{r})$ defined above is given by

$$\mathcal{H} = \sum_{i=1,2}\left(-\frac{\hbar^2}{2m_i}\nabla_i^2 + \mathcal{U}(\mathbf{r}_i)\right) + \mathcal{V}(\mathbf{r}_{12}) \ . \tag{50.3}$$

When the cubic box $\mathcal{U}(\mathbf{r})$ is macroscopically large, the pair is in the extreme collisionless limit and the dynamics may be described accurately by neglecting the interaction $\mathcal{V}(\mathbf{r}_{12})$, i.e., the Schrödinger equation takes the form

$$\left(-\frac{\hbar^2}{2m_1}\nabla_1^2 - \frac{\hbar^2}{2m_2}\nabla_2^2\right)\psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) = E_{\mathbf{k}_1,\mathbf{k}_2}\psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) \ . \tag{50.4}$$

In this limit we have complete separation of variables so that the pair solution can be written in the form of a product wavefunction

$$\psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2) = \tfrac{1}{V} e^{i\mathbf{k}_1\cdot\mathbf{r}_1} e^{i\mathbf{k}_2\cdot\mathbf{r}_2} \ , \tag{50.5}$$

with $\mathbf{k}_i$ the wavevector of atom i, quantized as $k_{i\alpha} = \frac{2\pi}{L} n_{i\alpha}$ with $n_{i\alpha} \in \{0, \pm 1, \pm 2, ...\}$. This wavefunction is normalized to unity (one pair). The energy eigenvalues are

$$E_{\mathbf{k}_1,\mathbf{k}_2} = \frac{\hbar^2 k_1^2}{2m_1} + \frac{\hbar^2 k_2^2}{2m_2} \ . \tag{50.6}$$

Note that in this case

$$E_{\mathbf{k}_1,\mathbf{k}_2} \neq E_{\mathbf{k}_2,\mathbf{k}_1} \qquad \text{for} \qquad \mathbf{k}_1 \neq \mathbf{k}_2 \ . \tag{50.7}$$

Importantly, only for pairs of *unlike* atoms the product wavefunctions (7.5) represent uniquely defined quantum mechanical eigenstates for the eigenvalues $E_{\mathbf{k}_1,\mathbf{k}_2}$. By unlike we mean that the atoms may be distinguished from each other because they are of different species. For *identical* atoms, i.e., atoms of the same isotopic species, the situation is fundamentally different. In this case the product wavefunctions (7.5) are degenerate with pair wavefunctions in which the atoms are exchanged,

$$E_{\mathbf{k}_1,\mathbf{k}_2} = E_{\mathbf{k}_2,\mathbf{k}_1} \qquad \text{also for} \qquad \mathbf{k}_1 \neq \mathbf{k}_2 \ . \tag{50.8}$$

This implies that any linear combination of the type

$$\psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2) = \frac{1}{V}\frac{1}{|c_1|^2+|c_2|^2} c_1 e^{i\mathbf{k}_1\cdot\mathbf{r}_1} e^{i\mathbf{k}_2\cdot\mathbf{r}_2} + c_2 e^{i\mathbf{k}_2\cdot\mathbf{r}_2} e^{i\mathbf{k}_1\cdot\mathbf{r}_1} \tag{50.9}$$

represents a properly normalized energy eigenstate of the pair. This is called *exchange degeneracy*. As we shall see in the next section, this degeneracy gives rise to *quantum correlations* in the motion of the atoms that depend on the quantum statistical nature of the atoms as well as on their internal state.

50.1.3 Identical particles and exchange operator

Before starting the subject of many-body wavefunctions, we first recall the consequences of the indistinguishability of identical particles in quantum mechanics. Particles are called identical if there is no physical way to establish whether or not two particles have been exchanged. To describe the exchange we introduce the *exchange operator* $\mathcal{P}$. For two identical particles in an arbitrary pair state $\psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2)$ the operator $\mathcal{P}$ is defined by

$$\mathcal{P}\psi(\mathbf{r}_1,\sigma_1;\mathbf{r}_2,\sigma_2) \equiv \psi(\mathbf{r}_2,\sigma_2;\mathbf{r}_1,\sigma_1) \ , \tag{50.10}$$

where $\mathbf{r}_1$ and $\mathbf{r}_2$ are the *position coordinates* and σ_1 and σ_2 the *spin coordinates* of the particles 1 and 2, respectively. The effect of this operator is to exchange the particle labels. Because $\mathcal{P}$ is a norm-conserving operator, $\langle\psi|\mathcal{P}^\dagger\mathcal{P}|\psi\rangle = 1$, we have

$$\mathcal{P}^\dagger\mathcal{P} = 1 \ . \tag{50.11}$$

Furthermore, exchanging the particles twice must leave the pair state unchanged. Therefore, we have

$$\mathcal{P}^2 = 1 \ . \tag{50.12}$$

and writing $\mathcal{P} = \mathcal{P}^\dagger \mathcal{P}\mathcal{P} = \mathcal{P}$, we see that $\mathcal{P}^\dagger$ is *hermitian*, i.e., the eigenvalues are real and have to ± 1 for the norm to be conserved.

Any pair state $\psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2)$ can be written as the sum of a *symmetric* $(+)$ and an *antisymmetric* $(-)$ part (see Problem 7.1). Therefore, the eigenstates of $\mathcal{P}$ span the full Hilbert space of the pair and $\mathcal{P}$ is not only hermitian but also an *observable*. Remarkably, in nature particles of a given species are found to show always the same symmetry under exchange, corresponding to *only one* of the eigenvalues of $\mathcal{P}$. This important observation means that for *identical* particles the pair wavefunction *must* be an eigenfunction of the exchange operator. In other words: linear combinations of symmetric and antisymmetric pair wavefunctions (like the simple product wavefunction) violate experimental observation. When the wavefunction is symmetric under exchange of two particles the particles are called *bosons*, when antisymmetric the particles are called *fermions*. We do not enter in the relation between spin and statistics except from mentioning that the bosons turn out to have *integral* total spin and the fermions *half-integral* total spin.

> **Example 294 (*Symmetry of wavefunctions*):** Any pair wavefunction can be written as the sum of a part symmetric under exchange and a part antisymmetric under exchange of the pair. To see this we write a pair wavefunction as $|\psi\rangle = \frac{1}{2}(1+\mathcal{P})|\psi\rangle + \frac{1}{2}(1-\mathcal{P})|\psi\rangle$, where $\mathcal{P}$ is the exchange operator, $\mathcal{P}^2 = 1$. The first term is symmetric, $\mathcal{P}(1+\mathcal{P})|\psi\rangle = (\mathcal{P}+\mathcal{P}^2)|\psi\rangle = (1+\mathcal{P})|\psi\rangle$, and the second term is antisymmetric, $\mathcal{P}(1-\mathcal{P})|\psi\rangle = (\mathcal{P}-\mathcal{P}^2)|\psi\rangle = -(1-\mathcal{P})|\psi\rangle$.

50.1.4 Fermions and Pauli principle

Let us turn to the case of two fermions in the pair state $\psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2)$. As we are dealing with fermions we know that P must have the eigenvalue -1,

$$\mathcal{P}\psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) = -\psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) \ . \tag{50.13}$$

Combining with the definition (7.10) we obtain the condition

$$\psi(\mathbf{r}_2, \sigma_2; \mathbf{r}_1, \sigma_1) = -\psi(\mathbf{r}_1, \sigma_1; \mathbf{r}_2, \sigma_2) \ . \tag{50.14}$$

For fermions in the same spin state ($\sigma_1 = \sigma_2 = \sigma$) and at the same position ($\mathbf{r}_1 = \mathbf{r}_2 = \mathbf{r}$) this condition can only be satisfied if $\psi(\mathbf{r}, \sigma; \mathbf{r}, \sigma) = -\psi(\mathbf{r}, \sigma; \mathbf{r}, \sigma)$. Hence, two fermions in the same spin state have *zero probability* to be found at the same position. Therefore, the fermions show correlated motion. Importantly, these *kinematic correlations* occur irrespective of the presence or absence of forces between the particles.

As the fermions are identical particles the pair hamiltonian $\mathcal{H}$ is invariant under exchange of the two particles, i.e., the exchange operator $\mathcal{P}$ commutes with the hamiltonian and $\mathcal{P}$ and $\mathcal{H}$ share a complete set of eigenstates. Thus also the eigenfunctions of the hamiltonian must be antisymmetric under exchange of the fermions.

We first look at the symmetry of the spin states. With a $(s_1 \times s_1)$ Clebsch-Gordan decomposition,

$$|S, M_S\rangle = \sum_{m_{S_1}, m_{S_2}} |s_1, m_{s_1}; s_2, m_{s_2}\rangle\langle s_1, m_{s_1}; s_2, m_{s_2}|S, M_S \tag{50.15}$$

we find for the case $(1/2 \times 1/2)$, i.e., for two $s = 1/2$ fermions the spin states,

$$\left.\begin{array}{l} |1,+1\rangle = |\uparrow\uparrow\rangle \\ |1,0\rangle = \frac{1}{2}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle) \\ |1,-1\rangle = |\downarrow\downarrow\rangle \end{array}\right\} \quad (S=1)$$
$$|0,0\rangle = \frac{1}{2}(|\uparrow\downarrow\rangle - |\uparrow\downarrow\rangle) \qquad (S=0) \tag{50.16}$$

Hence, presuming the fermion to be in a symmetric spin state, for instance the state $|1,1\rangle$, the orbital wavefunction must be antisymmetric,

$$\psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2) = \frac{1}{V}\sqrt{\frac{1}{2}}(e^{i\mathbf{k}_1\cdot\mathbf{r}_1}e^{i\mathbf{k}_2\cdot\mathbf{r}_2} - e^{i\mathbf{k}_1\cdot\mathbf{r}_2}e^{i\mathbf{k}_2\cdot\mathbf{r}_1})|\uparrow\uparrow\rangle \ . \tag{50.17}$$

If the fermions are in different orbital states ($\mathbf{k}_1 \neq \mathbf{k}_2$) this gives rise to the above mentioned *kinematic correlations*. For two fermions in the same orbital state ($\mathbf{k}_1 = \mathbf{k}_2 = \mathbf{k}$) Eq. (7.17) yields identically zero,

$$\psi^-_{\mathbf{k},\mathbf{k}}(\mathbf{r}_1,\mathbf{r}_2)|1,1\rangle \equiv 0 \ . \tag{50.18}$$

Table 7.1: In the ortho and para isomers of the hydrogen and deuterium molecule the distribution over the rotational levels is affected by quantum statistics (only even or odd levels).

			symmetry				
species	J	I	ψ_{nucl}	ψ_{rot}	ψ_{vib}	$^1\Sigma_g^+$	ψ_{tot}
ortho-H_2	1,3,5,..	1	S	A	S	A	S
ortho-D_2	0,2,4,..	1	A	S	S	A	A
para-H_2	0,2,4,..	0	A	S	S	A	S
para-D_2	1,3,5,..	0,2	S	A	S	A	A

(50.19)

Thus, also its norm $|\psi^-_{\mathbf{k},\mathbf{k}}(\mathbf{r}_1,\mathbf{r}_2)|^2$ is zero. Apparently two (identical) fermions cannot occupy the same state; such a coincidence is *entirely* destroyed by interference. Hence, the Pauli exclusion principle, holds for all fermionic particles and not only for fermions. Starting from an anti-symmetric spin state the orbital part should symmetric. An example is given by the state

$$\psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|0,0\rangle = \frac{1}{V}\sqrt{\frac{1}{2}}e^{i\mathbf{k}_1\cdot\mathbf{r}_1}e^{i\mathbf{k}_2\cdot\mathbf{r}_2}(|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle) \ . \tag{50.20}$$

In this case no restriction is found for the relative positions of the fermions.

We found that the quantum mechanical *indistinguishability* of *identical* particles affects the distribution of particles over the single-particle states. For fermions this is

made explicit by the Pauli principle. Also the distribution in configuration space is affected. Remarkably, these kinematic correlations happen in the complete absence of forces between the particles: it is a purely quantum statistical effect. A consequence of such correlations can be observed in the rotational properties of homonuclear diatomic molecules: depending on the total spin of the molecules either the even or the odd rotational levels are observed. This is illustrated in Table 7.1 for the ortho and para isomers of hydrogen (bosonic atoms) and deuterium (fermionic atoms).

50.1.5 Spinorbitals and Slater determinants

Eq. (7.17) can be written in the form of a determinant,

$$\psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|1,1\rangle = \sqrt{\frac{1}{2}}\begin{vmatrix}\phi_{\mathbf{k}_1\uparrow}(1) & \phi_{\mathbf{k}_2\uparrow}(1)\\ \phi_{\mathbf{k}_1\uparrow}(2) & \phi_{\mathbf{k}_2\uparrow}(2)\end{vmatrix}\,, \tag{50.21}$$

where,

$$\phi_{\mathbf{k}_j\uparrow}(i) = \tfrac{1}{V^{1/2}}e^{i\mathbf{k}_1\cdot\mathbf{r}_i}\chi_\uparrow(\sigma_i) \tag{50.22}$$

are called *spin orbitals*. Similarly, the symmetric spin state $|1,0\rangle$ in combination with the antisymmetric orbital state $\psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)$ can be written as the sum of two determinants,

$$\psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|1,0\rangle = \frac{1}{2}\begin{vmatrix}\phi_{\mathbf{k}_1\uparrow}(1) & \phi_{\mathbf{k}_2\downarrow}(1)\\ \phi_{\mathbf{k}_1\uparrow}(2) & \phi_{\mathbf{k}_2\downarrow}(2)\end{vmatrix} + \frac{1}{2}\begin{vmatrix}\phi_{\mathbf{k}_1\downarrow}(1) & \phi_{\mathbf{k}_2\uparrow}(1)\\ \phi_{\mathbf{k}_1\downarrow}(2) & \phi_{\mathbf{k}_2\uparrow}(2)\end{vmatrix}\,, \tag{50.23}$$

where $\phi_{\mathbf{k}_j\downarrow}(i) = \phi_{\mathbf{k}_j}(i)\chi_\downarrow(\sigma_i)$ with $i = 1, 2$. The two-body state (7.19) consisting of an antisymmetric spin state and a symmetric orbital state ($\mathbf{k}_1 = \mathbf{k}_2$) takes the form

$$\psi^-_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1,\mathbf{r}_2)|0,0\rangle = \sqrt{\frac{1}{2}}\begin{vmatrix}\phi_{\mathbf{k}_1\uparrow}(1) & \phi_{\mathbf{k}_2\uparrow}(1)\\ \phi_{\mathbf{k}_1\uparrow}(2) & \phi_{\mathbf{k}_2\uparrow}(2)\end{vmatrix}\,. \tag{50.24}$$

Indeed, the property of determinants to vanish when two columns or two rows are equal assures that the wavefunction vanishes when two fermions are in the same state α or share the same (position and spin) coordinates $(i) = (\mathbf{r}_i, \sigma_i)$, while exchanging two rows or two columns yields the minus sign required for anti-symmetric wavefunctions. One can easily show that any two-body fermion state can be expressed as a linear combination of determinantal spin-orbital states.

Slater generalized this approach to antisymmetrize N-fermion systems,

$$\psi_\alpha(\mathbf{r}_1,\sigma_1;...;\mathbf{r}_N,\sigma_N) = \sqrt{\frac{1}{N!}}\begin{vmatrix}\phi_{\alpha_1}(\mathbf{r}_1,\sigma_1) & \cdots & \phi_{\alpha_N}(\mathbf{r}_1,\sigma_1)\\ \vdots & \ddots & \vdots\\ \phi_{\alpha_1}(\mathbf{r}_N,\sigma_N) & \cdots & \phi_{\alpha_N}(\mathbf{r}_N,\sigma_N)\end{vmatrix}\,. \tag{50.25}$$

In this form the determinant is called a *Slater determinant*. It is the simplest generalization of the product wavefunction with the proper symmetry under interchange of any two fermions and consistent the Pauli principle. It is a true milestone

in many-body physics. In Dirac notation the antisymmetrized form of N fermions in states $\alpha_1, ..., \alpha_N$ is given by

$$|\alpha_1, ..., \alpha_N\rangle \equiv \tfrac{1}{N!} \sum_P (-1)^p P|\alpha_1, ...\alpha_N) \ , \tag{50.26}$$

where $|\alpha_1, ..., \alpha_N) \equiv |\alpha_1\rangle_1 \otimes |\alpha_2\rangle_2 \otimes ...|\alpha_N\rangle_N$ is the N-body product state of the single-particle states $|\alpha_\kappa\rangle_i$, where $\kappa = 1, .., N$ is the *state index* and $i = 1, .., N$ is the *particle index*. The sum runs over all permutations P of the particles, p being the *parity* (number of transpositions; i.e., binary interchanges) required to realize the permutation starting from an initial ordering fixed by convention. As the sum runs over all permutations, it makes no difference whether we permute all particles or permute all states of the particles. We choose the permutation operator P to *act on the state index* (κ) *and not on the particle index* (i). With this choice, the interchange of the states of particles 1 and 2 is written as

$$P|\alpha_1, ...\alpha_N) = |\alpha_1, ...\alpha_N) = |\alpha_1\rangle_1 \otimes ...|\alpha_N\rangle_N \ . \tag{50.27}$$

To assure a uniquely defined sign of the Slater determinants we shall adopt the standard ordering convention of atomic configurations (see below). The state labeling $\alpha_1, ...\alpha_N$ represents both the orbital and the spin quantum numbers, e.g. $\phi_{\alpha_\kappa}(\mathbf{r}_i, \sigma_i) = \phi_{\mathbf{k}_1\uparrow}(\mathbf{r}_i, \sigma_i)$. These functions are called *spinorbitals*.

50.1.6 Bosons and normalization

For bosons the energy eigenfunctions must be symmetric under exchange of the atoms. For spinless bosons (like ^{4}He atoms) or boson in symmetric spin states this suggests to use Eq.(7.9) in the form

$$\Psi_{\mathbf{k}_1,\mathbf{k}_2}(\mathbf{r}_1, \mathbf{r}_2) = \tfrac{1}{V}\sqrt{\tfrac{1}{2!}}(e^{i\mathbf{k}_1\cdot\mathbf{r}_1}e^{i\mathbf{k}_2\cdot\mathbf{r}_2} + e^{i\mathbf{k}_1\cdot\mathbf{r}_2}e^{i\mathbf{k}_2\cdot\mathbf{r}_1}) \ . \tag{50.28}$$

For $\mathbf{k}_1 \neq \mathbf{k}_2$ this form is appropriate because it is symmetric and also has the proper normalization of unity, $\langle\mathbf{k}_1, \mathbf{k}_2|\mathbf{k}_1, \mathbf{k}_2\rangle = 1$ (cf. Problem 7.2). For $\mathbf{k}_1 = \mathbf{k}_2 = \mathbf{k}$ the situation is different. Eq. (7.28) yields norm 2 rather than the physically required value unity. In this case the properly symmetrized and normalized wavefunction is the product wavefunction

$$\Psi_{\mathbf{k},\mathbf{k}}(\mathbf{r}_1, r_2) = \tfrac{1}{V}e^{i\mathbf{k}_1\cdot\mathbf{r}_1}e^{i\mathbf{k}_2\cdot\mathbf{r}_2} \ , \tag{50.29}$$

with $\langle\mathbf{k}, \mathbf{k}|\mathbf{k}, \mathbf{k}\rangle = 1$. Explicit symmetrization is superfluous because the product wavefunction is symmetrized to begin with. The general form (7.28) may still be used *provided the normalization is corrected for the degeneracy of occupation* (in this case we have to divide by an extra factor $\sqrt{2}$). For bosons in antisymmetric spin states we require the motional wavefunction to be also antisymmetric. Like in the fermion case this gives rise to kinematic correlations.

Example 295 (): Show that Eq. (7.28) has unit normalization for $\mathbf{k}_1 \neq \mathbf{k}_2$,

$$\mathcal{N} = \sqrt{\tfrac{1}{2}}\langle\mathbf{k}_1, \mathbf{k}_2|\mathbf{k}_1, \mathbf{k}_2\rangle = 1 \ .$$

By definition the norm is given by

$$\mathcal{N} = \sqrt{\tfrac{1}{2}}\{(\mathbf{k}_1,\mathbf{k}_2| + (\mathbf{k}_2,\mathbf{k}_1|\}\sqrt{\tfrac{1}{2}}\{|\mathbf{k}_1,\mathbf{k}_2) + |\mathbf{k}_2,\mathbf{k}_1)\}$$
$$= \tfrac{1}{2}\{(\mathbf{k}_1,\mathbf{k}_2|\mathbf{k}_1,\mathbf{k}_2) + (\mathbf{k}_1,\mathbf{k}_2|\mathbf{k}_2,\mathbf{k}_1) + (\mathbf{k}_2,\mathbf{k}_1|\mathbf{k}_1,\mathbf{k}_2) + (\mathbf{k}_2,\mathbf{k}_1|\mathbf{k}_2,\mathbf{k}_1)\} = 1 \ .$$

Here we used $(\mathbf{k}_1,\mathbf{k}_2|\mathbf{k}_2,\mathbf{k}_1) = 0 = (\mathbf{k}_2,\mathbf{k}_1|\mathbf{k}_1,\mathbf{k}_2)$ because $k_1 \neq \mathbf{k}_2$. Further we have $(\mathbf{k}_1,\mathbf{k}_2|\mathbf{k}_1,\mathbf{k}_2) = 1 = (\mathbf{k}_2,\mathbf{k}_1|\mathbf{k}_2,\mathbf{k}_1)$.

50.1.7 Generalization of the symmetrization to many-body states

We found from the analysis of two-body systems that the quantum mechanical *indistinguishability* of identical particles affects the distribution of particles over the single-particle states. For fermions (antisymmetric under exchange) this is made explicit by the Pauli principle, which excludes double occupation of the same state. For bosons (symmetric under exchange) double occupation affects the normalization of the state. In both cases the distribution in configuration space is affected; kinematic correlations happen between the particles in the complete absence of interatomic forces: it is a purely quantum statistical phenomenon. The analysis of systems of two identical particles can be extended to many-body systems of identical particles.

For each particle i we can define a Hilbert space $\mathcal{H}_i$ spanned by a basis consisting of a complete orthonormal set of states $\{|\mathbf{k}_s\rangle_i\}$,

$$_i\langle\mathbf{k}_{s'}|\mathbf{k}_s\rangle_i = \delta_{\mathbf{k}_s,\mathbf{k}_{s'}} \qquad \text{and} \qquad \sum_{\mathbf{k}_s} |\mathbf{k}_s\rangle_{ii}\langle\mathbf{k}_s| = 1 \ . \tag{50.30}$$

where $s \in \{1,...,N\}$ is the state index and $i \in \{1,...,N\}$ the particle index. In principle $|\mathbf{k}_s\rangle_i$ stands for the full description of the eigenstates of the particle i, including the internal state (for instance the hyperfine state in the case of atoms). The wavefunctions of the Schrödinger picture areobtained as the probability amplitude to find the particle at position $\mathbf{r}_i$,

$$\psi_{\mathbf{k}_s}(\mathbf{r}_i) = \langle\mathbf{r}_i|\mathbf{k}_s\rangle \equiv \langle\mathbf{r}_i|\mathbf{k}_s\rangle_i \ . \tag{50.31}$$

For spinless particles (like ^{4}He atoms) in the box potential $U(\mathbf{r})$ introduced earlier, these wavefunctions are best chosen to be the plane waves given by Eq. (7.2); for harmonic trapping potentials they will be harmonic oscillator eigenstates; for electrons in the Coulomb field of the nucleus they are the atomic spinorbitals, etc.. Also in the presence of interactions such wavefunctions remain a good basis set but the simple interpretation as single-particle eigenstates is lost.

For the N-body system we can define a Hilbert space as the tensor product space

$$\mathbf{H}^N = \mathbf{H}_1 \otimes \mathbf{H}_2 \otimes ... \otimes \mathbf{H}_N \tag{50.32}$$

of the N single-particle Hilbert spaces Hi and represented by the orthonormal basis $\{|\mathbf{k}_1,...,\mathbf{k}_N)\}$ where

$$\{|\mathbf{k}_1,...,\mathbf{k}_N)\} \equiv |\mathbf{k}_1\rangle_1 \otimes |\mathbf{k}_2\rangle_2 \otimes ... \otimes |\mathbf{k}_N\rangle_N \tag{50.33}$$

is the N-body tensor product state of the single-particle states $|\mathbf{k}_s\rangle i$ with normalization condition $(\mathbf{k}'_1, ..., \mathbf{k}'_N|\mathbf{k}_1, ..., \mathbf{k}_N) = \delta_{\mathbf{k}_1,\mathbf{k}'_1}...\delta_{\mathbf{k}_N,\mathbf{k}'_N}$ and closure,

$$\sum_{\mathbf{k}_1,...,\mathbf{k}_N} |\mathbf{k}_1, ..., \mathbf{k}_N)(\mathbf{k}_1, ..., \mathbf{k}_N| = \prod_{i=1}^{N} \left(\sum_{\mathbf{k}_s} |\mathbf{k}_s\rangle_i i\langle \mathbf{k}_s| \right) = 1 \ . \tag{50.34}$$

The notation of curved brackets $|\mathbf{k}_1, ..., \mathbf{k}_N)$ is reserved for unsymmetrized many-body states; i.e. product states written with the convention of referring always in the same order from left to right to the states of particle 1 through N. Sometimes we shall use an implicit definition of the N-body state $|N_\gamma)$ by specifying the index γ as an array of state indices,

$$|N_\gamma) = |\mathbf{k}_1, ..., \mathbf{k}_N) \qquad \text{for} \qquad \gamma = \{1, ..., N\} \ . \tag{50.35}$$

To deal with the indistinguishability of particles in the many-body case, we argue that all dynamical properties must remain unchanged under an arbitrary permutation P of these particles. This means that all operators representing a dynamical variable of the system must be invariant under these permutations. This holds in particular for the Hamilton operator and implies that P commutes with the hamiltonian, just as we found for the exchange operator in the two-body case. This is of course not surprising because any permutation can be realized by a sequence of binary interchanges of particles. A many-body state $|\psi^{(S)}\rangle$ is called symmetric (bosonic) if it is invariant under all permutations P,

$$P|\psi^{(S)} = |\psi^{(S)} \ . \tag{50.36}$$

Similarly, a many-body state $|\psi^{(A)}\rangle$ is called antisymmetric (fermionic) if it satisfies the property,

$$P|\psi^{(A)} = (-)^p|\psi^{(A)} \ . \tag{50.37}$$

where $(-)^p = 1$ for all even permutations and $(-)^p = -1$ for all odd permutations, p being the number of binary interchanges required to realize the permutation. We thus can identify two orthogonal subspaces within the product space $\mathcal{H}^{(N)}$: the symmetric subspace $\mathcal{H}^{(S)}$ (for bosons) and the antisymmetric subspace $\mathcal{H}^{(A)}$ (for fermions),

$$\mathcal{H}^{(A)} \oplus \mathcal{H}^{(A)} \in \mathcal{H}^{(A)} \ . \tag{50.38}$$

50.1.7.1 Fermions

For identical fermions in states $\mathbf{k}_1, ..., \mathbf{k}_N$ the N-body state has to be antisymmetrized. This is done by summing over all permutations using a plus sign for all even permutations and a minus sign for all odd permutations,

$$|\mathbf{k}_1, ..., \mathbf{k}_N\rangle \equiv \sqrt{\frac{1}{N!}} \sum_P (-1)^p P|\mathbf{k}_1, ..., \mathbf{k}_N\rangle \ . \tag{50.39}$$

Note that this expression represents a Slater determinant and therefore satisfies the condition (7.36). As the sum runs over all permutations, it makes no difference whether we permute all particles or permute all states of the particles. We choose the permutation operator P *to act on the state index (s) and not on the particle index*

(i) as this allows us to conserve the *ordering convention of the particle index*. With this choice, the interchange of the states of particles 1 and 2 is written as,

$$\mathcal{P}|\mathbf{k}_1, \mathbf{k}_2, ..., \mathbf{k}_N\rangle = |\mathbf{k}_2, \mathbf{k}_1, ..., k_N\rangle = -|\mathbf{k}_2\rangle_1 \otimes |\mathbf{k}_1\rangle_2 \otimes .. \otimes |\mathbf{k}_N\rangle_N\rangle \ . \tag{50.40}$$

To assure a uniquely defined sign of the Slater determinants we need to define the non-permuted state by adopting an *ordering convention of the states*. The quantity

$$\mathcal{A} \equiv \sqrt{\frac{1}{N!}} \sum_P (-1)^p P \tag{50.41}$$

can be interpreted as the antisymmetrization operator that projects an arbitrary unsymmetrized state $|\mathbf{k}_1, ..., \mathbf{k}_N\rangle$ onto the antisymmetric subspace $\mathcal{H}^{(A)}$.

50.1.7.2 Bosons

For identical bosons the N-body state has to be symmetrized. This is done by summing over all permutations while correcting for the degeneracy of occupation (just like in the two-body case) in order to maintain unit normalization. For a N-body system with n_1 particles in state $\mathbf{k}_1$, n_2 particles in state $\mathbf{k}_2$, ... and n_l particles in state $\mathbf{k}_l$ we obtain [1],

$$|\mathbf{k}_1, \mathbf{k}_1, ..., \mathbf{k}_N\rangle \equiv \sqrt{\frac{1}{N! n_1! ... n_l!}} \sum_P P|\mathbf{k}_1, \underset{n_1}{\mathbf{k}_2}, ..., \underset{n_2}{\mathbf{k}_2}, ..., \underset{n_l}{...}, \mathbf{k}_N\rangle \ , \tag{50.42}$$

where $N = n_1 + n_2 + ... + n_l$. In view of the symmetric form, in the bosonic case there is no significance in the order in which the states are written. The quantity,

$$\mathcal{S} \equiv \sum_P P \tag{50.43}$$

can be interpreted as the symmetrization operator that projects an arbitrary unsymmetrized state $|\mathbf{k}_1, ..., \mathbf{k}_N)$ onto the symmetric N-body subspace $\mathcal{H}^{(S)}$.

As an example we consider the special case of N bosons in the same state, $|\mathbf{k}_s, ..., \mathbf{k}_s)$. Here all $N!$ permutations leave the unsymmetrized wavefunction unchanged and we obtain $N!$ identical terms with normalization coefficient $1/N!$, reflecting the feature that the wavefunction was symmetrized to begin with; i.e. $|\mathbf{k}_s, ..., \mathbf{k}_s\rangle = |\mathbf{k}_s, ..., \mathbf{k}_s)$.

Problem 7.3. Show that for $N > 2$,

$$\mathcal{S} + \mathcal{A} \neq \mathcal{I} \ .$$

50.1.7.3 Anderson's orthogonality theorem

Consider a system of N fermions in its ground state; i.e., all single-particle levels are occupied up to the highest level (Fermi level). Let us denote the states of the

[1] We use the convention in which all classically defined permutations are included in the summation. In an alternative convention the permutations of atoms in identical states are omitted. This results in a different normalization factor in the definition of the same symmetrized state.

fermions by $|\alpha_i\rangle$, with $i \in \{1, ..., N\}$. Next we introduce an impurity in the system. This changes both the energies and the wavefunctions of all the fermions. These distorted wavefunctions are denoted by $|\beta_i\rangle$. Anderson pointed out that the many-body states $|\varphi_\alpha\rangle = |\alpha_1, ..., \alpha_N\rangle$ and $|\varphi_\beta\rangle = |\beta_1, ..., \beta_N\rangle$ are essentially orthogonal; i.e., $\langle\varphi_\alpha|\varphi_\beta\rangle \ll 1$ *irrespective of the strength of the perturbation.* This feature is fundamental because it represents a situation where perturbation theory works at the two-body level but fails at the many-body level.

To demonstrate the validity of this theorem, we start by expressing the symmetrized states in terms of the unsymmetrized states,

$$\langle\varphi_\alpha|\varphi_\beta\rangle = \frac{1}{N!}\sum_{P_\alpha}(-1)^{p_\alpha}P_\alpha\sum_{P_\beta}(-1)^{p_\beta}P_\beta(\alpha_1, ..., \alpha_N|\beta_1, ..., \beta_N) \ , \tag{50.44}$$

where P_α and P_β are the permutation operators of the bra and ket states, respectively, To evaluate this expression we note that the perturbed states $|\beta_i\rangle_n$ of particle n, with $n \in \{1, ..., N\}$, can be decomposed with respect to the unperturbed basis $\{|\beta_i\rangle_n\}$,

$$|\beta_i\rangle_n = \sum_i |\alpha_i\rangle_n \ {}_n\langle\alpha_i|\beta_j\rangle_n \ , \tag{50.45}$$

where the states $|\alpha_i\rangle_n$, with $i \leq N$, correspond to the occupied levels. Taking this into account and using the orthonormality of the basis $\{|\alpha_i\rangle\}$, we find,

$$(\alpha_1, ..., \alpha_N|\beta_1, ..., \beta_N) = \sum_{i_1=1}^{N}\cdots\sum_{i_N=1}^{N}(\alpha_1, ..., \alpha_N|\alpha_{i_1}, ..., \alpha_{i_N})\langle\alpha_{i_1}|\beta_1\rangle_1...\langle\alpha_{i_N}|\beta_N\rangle_N = \langle\alpha_1|\beta_1\rangle...\langle\alpha_N|\beta \tag{50.46}$$

Note that the particle indices have been eliminated because the inner products are independent of the particle considered. Thus, the inner product $\langle\varphi_\alpha|\psi_\beta\rangle$ can be written as,

$$\langle\varphi_\alpha|\varphi_\beta\rangle = \frac{1}{N!}\sum_{P_\alpha}(-1)^{p_\alpha}P_\alpha\sum_{P_\beta}(-1)^{p_\beta}P_\beta\langle\alpha_1|\beta_1\rangle...\langle\alpha_N|\beta_N\rangle \ . \tag{50.47}$$

Importantly, as the particle index has been removed the result of the second summation is not affected by the action of the operator $(-1)^{p_\alpha}P_\alpha$. Hence, as there $N!$ possible permutations, the expression for $\langle\varphi_\alpha|\psi_\beta\rangle$ simplifies to,

$$\langle\varphi_\alpha|\varphi_\beta\rangle = \sum_{P_\beta}(-1)^{p_\beta}P_\beta\langle\alpha_1|\beta_1\rangle...\langle\alpha_N|\beta_N\rangle \ , \tag{50.48}$$

which can be written as the determinant of the single-particle overlap matrix,

$$\langle\varphi_\alpha|\psi_\beta\rangle = \begin{vmatrix} \langle\alpha_1|\beta_1\rangle & \cdots & \langle\alpha_1|\beta_N\rangle \\ \vdots & \ddots & \vdots \\ \langle\alpha_N|\beta_1\rangle & \cdots & \langle\alpha_N|\beta_N\rangle \end{vmatrix} \ . \tag{50.49}$$

Specializing to the case $|\alpha_i\rangle = |\beta_i\rangle$ and using the orthonormality of the basis $\{|\alpha_i\rangle\}$ we readily verify the normalization of the many-body state $|\varphi_\alpha\rangle$,

$$\langle\varphi_\alpha|\varphi_\alpha\rangle = \begin{vmatrix} 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{vmatrix} = 1 \ . \tag{50.50}$$

On the other hand, if the two states are only approximately equal, $|\alpha_i\rangle \simeq |\beta_i\rangle$; we have $\langle\alpha_i|\beta_i\rangle = 1 - \varepsilon$ with $\varepsilon \ll 1$, and $\langle\alpha_i|\beta_i\rangle \ll 1$. In this case $\langle\varphi_\alpha|\psi_\beta\rangle \longrightarrow 0$ for $N \longrightarrow \infty$.

50.1.8 Occupation number representation

50.1.8.1 Introduction

The notation of the previous section calls for simplification. This is realized by introducing construction operators which satisfy an algebra that enforces the quantum statistics. The first construction operators were introduced by Paul Dirac in 1927 [371]. Starting from Maxwell's equations, Dirac quantized the electromagnetic field by treating the eigenmodes of the field as independent harmonic oscillators. The excitation level of the oscillator represents the mode occupation of the field. The raising (lowering) operators of the oscillator serve to construct the field by creation (annihilation) of photons, the quanta of the radiation field, which occupy the modes. The commutation relations between the operators define the algebra that enforces the Bose statistics of the field. This marks the start of quantum field theory. In the same year Pascual Jordan and Oskar Klein showed that the method could be extended to describe quantum many-body systems of bosons satisfying the Schrödinger equation [683]. Adapting the algebra, Jordan and Wigner further extended the method to describe quantum many-body systems of interacting fermionic particles [684]. The above sequence of seminal papers is not complete without the name of Vladimir Fock, who emphasized in 1932 the use of field operators (construction operators for configuration space) [459]. This approach leads to an operator identity resembling the Schrödinger equation, which explains the unfortunate name second quantization for the construction operator formalism. In following sections we give a concise introduction in the construction operator formalism for quantum many-body systems. For a systematic introduction the lecture notes of Jan de Boer are recommended [335].

50.1.8.2 Number states in the N-body Hilbert space

The notation of the properly symmetrized states can be further compacted by listing only the occupations of the states,

$$|\tilde{n}_\gamma\rangle = |n_1, n_2, ..., n_l\rangle \equiv |\underbrace{\mathbf{k}_1, \mathbf{k}_1, ...}_{n_1}, \underbrace{\mathbf{k}_2, \mathbf{k}_2, ...}_{n_2}, \underbrace{..., \mathbf{k}_l}_{n_l}\rangle \ , \tag{50.51}$$

where $\gamma = \{1, 1, ..., 2, 2, ..., n_l\}$ with $l \lesssim N$. In this way the states take the shape of *number states*, which are the basis states of the occupation number representation (see next section). For the case of N bosons in the same state $|\mathbf{k}_s\rangle$ the number state

is given by $|n_s\rangle \equiv |\mathbf{k}_s, ..., \mathbf{k}_s\rangle$; for a single particle in state $|\mathbf{k}_s\rangle$ we have $|1_s\rangle \equiv |\mathbf{k}_s\rangle$. Note that the Bose symmetrization procedure puts no restriction on the value or order of the occupations $n_1, ..., n_l$ as long as they add up to the total number of particles, $n_1 + n_2 + ... + n_l = N$. For fermions the notation is the same but because the wavefunction changes sign under permutation the order in which the occupations are listed becomes subject to convention (for instance in order of growing energy of the states). Up to this point and in view of Eqs. (50.42) and (50.40) the number states (50.51) have normalization,

$$\langle n_1', n_2', ...|n_1, n_2, ...\rangle = \delta_{n_1', n_1}\delta_{n_2', n_2}... \tag{50.52}$$

and closure

$$\sum_{n_1, n_2, ...}{}' |n_1, n_2, ...\rangle\langle n_1, n_2, ...| = \mathbb{I} \ , \tag{50.53}$$

where the prime indicates that the sum over all occupations equals the total number of particles, $n_1 + n_2 + ... + n_l = N$. This is called closure within $\mathcal{H}^N$.

50.1.8.3 Number states in Grand Hilbert space - construction operators

An important generalization of number states is obtained by interpreting the occupations $n_s, n_t, ...$ as the eigenvalues of number operators $\hat{n}_s, \hat{n}_t, ...$ defined by

$$\hat{n}_s|n_s, n_t, ..., n_l\rangle = n_s|n_s, n_t, ..., n_l\rangle \ . \tag{50.54}$$

With this definition the expectation value of $\hat{n}_s$ is exclusively determined by the occupation of state $|s\rangle$; it is independent of the occupation of all other states. Therefore, the number operators may be interpreted as acting in a Grand Hilbert space, also known as Fock space, which is the direct sum of the Hilbert spaces of all possible atom number states of a gas cloud, including the vacuum,

$$\mathcal{H}^{Gr} = \mathcal{H}^0 \oplus \mathcal{H}^1 \oplus ... \oplus \mathcal{H}^N \oplus ... \ . \tag{50.55}$$

By adding an atom we shift from $\mathcal{H}^N$ to $\mathcal{H}^{N+1}$, analogously we shift from $\mathcal{H}^N$ to $\mathcal{H}^{N-1}$ by removing an atom. As long as this does not affect the occupation of the single-particle state $|s\rangle$ the operator $\hat{n}_s$ yields the same result. Hence, the *number states* $|n_s, n_t, ..., n_l\rangle$ from $\mathcal{H}^N$ may be reinterpreted as number states $|n_s, n_t, ..., n_l, 0_a, 0_b, ..., 0_z\rangle$ within $\mathcal{H}^{Gr}$ by specifying — in principle — the occupations

50.1.9 Field operators

Let us write the total number operator (7.98) in the position representation. Using the closure relation $\mathbb{I} = \int dr|\mathbf{r}\rangle\langle\mathbf{r}|$ we obtain,

$$\hat{N} = \int d^3r \sum_{s,s'} \hat{a}_{s'}^\dagger \langle s'|\mathbf{r}\rangle\langle\mathbf{r}|s\rangle\hat{a}_s = \int d^3r \sum_{s'} \phi_{s'}^*(\mathbf{r})\hat{a}_{s'}^\dagger \sum_{s,s'} \phi_s(\mathbf{r})\hat{a}_s \ , \tag{50.56}$$

where the $\mathbf{r}|s\rangle = \psi_s(\mathbf{r})$ are the wavefunctions of an arbitrary single-particle basis $\{|s\rangle\}$. With this transformation we introduced two operator densities,

$$\hat{\psi}(\mathbf{r}) \equiv \sum_s \psi(\mathbf{r})\hat{a}_s \qquad \text{and} \qquad \hat{\psi}^\dagger(\mathbf{r}) \equiv \sum_s \psi^*(\mathbf{r})\hat{a}_s^\dagger \ , \tag{50.57}$$

which are called field operators in view of their dependence on position. In terms of these field operators the total number operator takes the form,

$$\hat{N} = \int d^3r \hat{\psi}^\dagger(\mathbf{r})\hat{\psi}(\mathbf{r}) = \int d^3r \hat{n}(\mathbf{r}) \ , \tag{50.58}$$

where we defined the density operator $\hat{n}(\mathbf{r})$ as the diagonal part of the density matrix operator. The field operators are construction operators that create or annihilate particles at a given position. Let us demonstrate this for $\hat{\psi}(\mathbf{r})$: This field operator is a creation operator because it is defined in terms of creation operators,

$$\hat{\psi}^\dagger(\mathbf{r})|0\rangle = \sum_s \psi_s^*(\mathbf{r})\hat{a}_s^\dagger|0\rangle = \sum_s |s\rangle\langle s|\mathbf{r}\rangle = |\mathbf{r}\rangle \ . \tag{50.59}$$

Using the closure relation, we found that $\hat{\psi}^\dagger(\mathbf{r})$ creates from the vacuum a particle in state $|\mathbf{r}\rangle$; i.e., a particle at position $\mathbf{r}$. Similarly we can show that $\hat{\psi}(\mathbf{r})$ is the corresponding annihilation operator,

$$\hat{\psi}(\mathbf{r})|0\rangle = |0\rangle \ . \tag{50.60}$$

The field operators are important quantities because (at least in principle) the positions of the particles can be measured to arbitrary accuracy in any many-body system, also when the concept of stationary single-particle states has lost meaning due to coupling by the interactions.

50.1.9.1 Position representation

50.1.10 Exercises

50.1.10.1 Ex: Atom-field coupling

We determine here the coupling Hamiltonian for an atom in a classical field under two equivalent forms (we have only considered the quantum case in the course). We consider the case of the simplest hydrogen atom, with a single electron (reduced mass m, charge $q = -e$) bound to a proton by the Coulomb potential U. This atom interacts also with a laser wave, whose potential and scalar vectors are $\mathbf{V}(\mathbf{r}, t)$ and $\mathbf{A}(\mathbf{r}, t)$.

1. Derive the complete classical Hamiltonian of the atom from the standard form of the classical Lagrangian of a charge in a field: $L = T - q(V + U) + q\mathbf{v} \cdot \mathbf{A}$. What is the link between the electron's velocity and its momentum (conjugate with its position)?

2. Show that the quantum hamiltonian is thus:

$$H = \frac{1}{2m}(\mathbf{P} - q\mathbf{A}(\mathbf{R}, t))^2 + qU(\mathbf{R}) + qV(\mathbf{R}) \ .$$

3. Show that in the Coulomb gauge, $\nabla \cdot \mathbf{A} = 0$, V can be set to zero without loss of generality.

4. Show that in the Coulomb gauge, $\mathbf{A} \cdot \mathbf{P} = \mathbf{P} \cdot \mathbf{A}$. Develop accordingly the full Hamiltonian.

5. Under which hypotheses does H reduce to $H = H_0 - (q/m)\mathbf{P} \cdot \mathbf{A}(0, t)$, where H_0 is the free atomic Hamiltonian?// We now transform the Hamiltonian under the more

standard dipole form using the Göppert-Mayer transformation. We restart from the full Hamiltonian, with all terms including $V(\mathbf{r}, t)$.
6. We neglect the terms quadratic in $\mathbf{A}$. The atom being small compared to the optical wavelength, give the Hamiltonian obtained by expanding $\mathbf{A}$ and $\mathbf{V}$ to the lowest relevant order. Use the notation $\mathbf{D} = q\mathbf{R}$.
7. Show that a proper gauge transformation cancels $\mathbf{A}(0, t)$.
8. Show that in this new gauge, the Hamiltonian reads $H = H_0 - \mathbf{D} \cdot \mathbf{E}(0)$. Is this result gauge-dependent?

Solution: *1. From classical dynamics (see Landau or Goldstein):*

$$L = T - q(V + U) + q\mathbf{v} \cdot \mathbf{A} \ ,$$

where $V + U$ is the total scalar potential seen by the electron. We use the standard analytical mechanics approach to derive the Hamliltonian. The momentum is defined as

$$\mathbf{p} = \nabla_v L = m\mathbf{v} + q\mathbf{A} \ ,$$

and the Hamiltonian as:

$$H = \mathbf{v} \cdot \nabla_v L - L = \tfrac{m}{2} v^2 + q(V + U) = \tfrac{1}{2m}(\mathbf{p} - q\mathbf{A})^2 + q(U + V) \ .$$

2. The quantum Hamiltonian follows by replacing all positions and momenta by non-commuting operators.
3. Follows directly from the properties of the Fourier-transformed fields,

$$\mathbf{A}(r, t) = \frac{1}{4\pi} \int \mathcal{A}(\mathbf{k}, \omega) e^{i(\mathbf{k}\cdot\mathbf{r} - \omega t)} d\mathbf{k} d\omega \ .$$

Longitudinal and transverse potentials w.r.t. k:

$$\mathcal{A}(\mathbf{k}, \omega) = \mathcal{A}(\mathbf{k}, \omega)_{\|} + \mathcal{A}_{\perp} \qquad \textit{hence} \qquad \mathbf{A}(\mathbf{r}, t) = \mathbf{A}_{\|} + \mathbf{A}_{\perp} \ .$$

The Fourier transform of $\mathbf{r} \cdot \mathbf{A}$ is $i\mathbf{k} \cdot \mathcal{A}$ hence $\mathbf{A}_{\|} = 0 = \mathcal{A}_{\|}$. The electric field is transverse also and hence $V = 0$ since ∇V is longitudinal (proportional to $\mathbf{k}$ in Fourier space).
4. We have,

$$[P_i, f(\mathbf{R})] = -i \frac{\partial f}{\partial R_i} \qquad \textit{for} \qquad i \in x, y, z$$

$$\sum_i [P_i, A_i] = -i\hbar \sum_i \frac{\partial A_i}{\partial R_i} = -i\hbar \nabla \cdot \mathbf{A} = 0$$

$$\mathbf{P} \cdot \mathbf{A} = \sum_i P_i A_i = \sum_i A_i P_i = \mathbf{A} \cdot \mathbf{P} \ .$$

And finally,

$$H = \frac{p^2}{2m} + qU(\mathbf{R}) - \frac{q}{m} \mathbf{P} \cdot \mathbf{A} + \frac{q^2}{2m} \mathbf{A} \cdot \mathbf{A} \ .$$

5. Hypotheses:

- *Weak field (much lower than atomic field unit, 10^{11} V/m), A $\mathbf{A}\cdot\mathbf{A}$ quadratic term negligible compared to first order contribution.*
- *Radiation wavelength: about 1μ m; Atomic size: about 100 pm : Neglect spatial variation of the vector potential across atomic orbit: $\mathbf{A}(\mathbf{R},t)=\mathbf{A}(0,t)$ (dipole approximation),*

$$H = H_0 - \frac{q}{m}\mathbf{P}\cdot\mathbf{A}(0,t)\ .$$

6. Restart from full Hamiltonian

$$H = \frac{1}{2m}(\mathbf{P}-q\mathbf{A}(\mathbf{R},t))^2 + qU(\mathbf{R}) + qV(\mathbf{R},t)\ ,$$

and perform dipole approximation first. For the vector potential

$$\mathbf{A}(\mathbf{R},t) = \mathbf{A}(0,t)\ ,$$

and (keeping first order)

$$V = V(0,t) + \mathbf{R}\cdot\nabla V(0,t)\ ,$$

The space-independent term in V has no effect

$$H = H_0 - \frac{q}{m}\mathbf{P}\cdot\mathbf{A}(0,t) + \mathbf{D}\cdot\nabla V(0,t)\ ,$$

with

$$\mathbf{D} = q\mathbf{R}\ .$$

7. Perform a gauge transformation:

$$\mathbf{A}\to\mathbf{A}' = \mathbf{A}+\nabla\chi(\mathbf{r},t)$$
$$V\to V' = V - \frac{\partial\chi}{\partial t}$$

and choose

$$\chi(\mathbf{r},t) = -\mathbf{r}\cdot\mathbf{A}(0,t)\ ,$$

so that $\mathbf{A}'(0,t)=0$. Then

$$V' = V + \mathbf{r}\cdot\frac{\partial\mathbf{A}(0,t)}{\partial t}$$
$$\nabla V'(0) = V(0) + \frac{\partial\mathbf{A}(0,t)}{\partial t} = -\mathbf{E}(0)\ .$$

8. We got,

$$H = H_0 - \mathbf{D}\cdot\mathbf{E}(0)\ .$$

50.1.10.2 Ex: Atom and classical field

We consider a two-level atom coupled to a classical field $\mathbf{E} = \mathbf{E}_0 exp[-i(\omega t + \phi)]$. We examine the Rabi oscillation and the Ramsey separated oscillatory field spectroscopic method. We use the two-level atom model (ground state $|g\rangle$ and excited state $|e\rangle$) with a transition angular frequency ω_{eg} and the Pauli matrices notations. We note $\Delta \equiv \omega_{eg} - \omega$. The atom is initially in $|g\rangle$.
1. Show that the atom-field Hamiltonian is $H = H_0 + H_1$, where $H_0 = \hbar\omega_0\sigma_z/2$ is the free Hamiltonian and $H_1 = -\hbar\Omega\cos(\omega t+\phi)\sigma_x$, where the Rabi frequency $\Omega = \mathbf{d}\cdot\mathbf{E}_0/\hbar$ is assumed real.
2. Switch to an interaction representation with respect to $H_0' = \hbar\omega\sigma_z/2$. Show that the Hamiltonian contains four terms and that two of them are negligible (RWA approximation).
3. Show finally that the new Hamiltonian is $H = \frac{\hbar\Omega'}{2}\sigma_{\mathbf{n}}$, where $\mathbf{n}$ is a unit vector whose expression will be given.
4. Show that H generates a rotation of the Bloch vector around $\mathbf{n}$. Discuss the interesting limit cases. Give at resonance the probability p_e for finding the atom in $|e\rangle$ as a function of time.
5. Give the atomic state transformations performed by a resonant $\pi/2$-pulse such that $t = \pi/2\Omega$.
6. The atom is submitted to two very short nearly resonant $\pi/2$-pulses both with a duration τ a phase $\phi = -\pi/2$, separated by a long time interval T. In which condition can we assume that these pulses are resonant?
7. Show that at the end of the second pulse, $p_e = (1 + \cos\Delta T)/2$. Comment.
8. We assume that the detection noise is only of statistical origin. Show that two ω values can be distinguished provided their angular frequency difference obeys $\delta > \frac{\sqrt{2}}{T\sqrt{N}}$, where N is the total number of atoms detected.

Solution:

50.1.10.3 Ex: Optical Bloch equations

We consider the interaction of a damped two-level atom with a classical field. Show that the evolution equations for the atomic density matrix read:

$$\frac{d\rho_{ee}}{dt} = \frac{d}{\hbar}\text{Im}\ (\rho_{eg}E_1^*) - \Gamma\rho_{ee}$$
$$\frac{d\rho_{eg}}{dt} = -i\Delta\rho_{eg} - \frac{d}{2\hbar}E_1(\rho_{ee} - \rho_{gg}) - \gamma'\rho_{eg}\ ,$$

where Γ is the spontaneous emission rate, $\gamma' = \gamma + \Gamma/2$, γ being the transverse relaxation rate and $E_1 = E_0 e^{-i\phi}$ (plus the notations of the previous exercise). Deduce the evolution equations for the coordinates x, y and z of the Bloch vector. Give the steady state solution of these equations in the simple situation when E_1 is real and atom and field are at resonance for an atom initially in $|g\rangle$. Consider simple limit cases.

Solution:

50.1.10.4 Ex: Field algebra

We demonstrate here a few simple properties of the annihilation and creation operators, as well as of the coherent state. In the following, $f(N)$ (e.g. $\sin(N)$ or $\sqrt{N}$) represents an operator function of the photon number operator. We assume that f can always be expanded in a power series. Results of questions 1-4 are used in the problem.
1. Show that the eigenstates of $f(N)$ are the Fock states $|n\rangle$ with eigenvalues $f(n)$.
2. Show that $\frac{1}{N}\hat{a}^\dagger|n\rangle = |n+1\rangle$.
3. Show that $\hat{a}\frac{1}{N}\hat{a}|n\rangle = |n-1\rangle$.
4. Show that $\hat{a}f(N) = f(N+1)\hat{a}$ and $f(N)\hat{a}^\dagger = a^\dagger f(N+1)$.
5. Show that the coherent states are an overcomplete basis of the single mode Hilbert space: $\mathbb{1} = \frac{1}{\pi}\int d^2\alpha\ |\alpha\rangle\langle\alpha|$. **Hint:** Use Fock state expansion and integration in polar coordinates.
6. We couple a classical current at frequency ω with a field mode a frequency ω_0. Give the amplitude of the created coherent field as a function of time.

Solution:

50.1.10.5 Ex: Phase space distributions

1. Compute the three characteristic functions for the coherent state $\alpha\rangle$. 2. Show that $Q^{[\rho]}(\alpha) = \frac{1}{\pi}\langle 0|D(-\alpha)\rho D(\alpha)|0\rangle = \frac{1}{\pi}\mathrm{Tr}[|0\rangle\langle 0|D(-\alpha)\rho D(\alpha)|0\rangle]$. **Hint:** use linearity of the trace, the closure relations of coherent states.
3. Compute the Q function of a coherent state and of a Fock state.
4. **Difficult:** Show that $W(x,p) = \frac{1}{\pi}\int du\langle\frac{u}{2}|D(-\alpha)\rho D(\alpha)\mathcal{P}|\frac{u}{2}\rangle = \frac{2}{\pi}\mathrm{Tr}[D(-\alpha)\rho D(\alpha)\mathcal{P}]$.

Solution:

50.1.10.6 Ex: Construction operators and occupation number representation

Many body quantum systems are described by symmetrized or antisymmetrized wavefunctions. To keep the calculations manageable this is done in the occupation number representation. Below follows a series of questions with regard to the properties of construction operators. Nota bene: With $\{a,b\}$ we refer to anticommutator of a and b. We presume that the standard ordering is represented by the alphabetic ordering of the state indices.
1. For an arbitrary normalized one-body eigenstate $|s\rangle$, i.e. $\langle s'|s\rangle = \delta_{s,s'}$, we have by definition $|s\rangle \equiv |1_s\rangle \equiv |\bar{1}_s\rangle = \hat{a}_s^\dagger|0\rangle$. Comment of the differences of notation.
2. Give the definition of the creation operator $\hat{a}_s^\dagger$ acting on the number state $|n_s, n_t, ..., n_l\rangle$ for bosons.

3. Give the definition of the annihilation operator $\hat{a}_s$ acting on the number state $|n_s, n_t, ..., n_l\rangle$ for bosons.
4. Evaluate $\hat{a}_s^\dagger|0_q, 0_s, ...\rangle$ for fermions.
5. Evaluate $\hat{a}_s^\dagger|1_q, 0_s, ...\rangle$ for fermions.
6. Evaluate $\hat{a}_s^\dagger|1_q, 1_s, ...\rangle$ for fermions.
7. Show that also the vacuum state $|0\rangle$ is normalized.
8. Calculate the norm $\langle 2_s|2_s\rangle$ for bosons and fermions without using the fermion rule $\hat{a}_s^\dagger|1_q, 1_s, ...\rangle = 0$.
9. Derive $[\hat{a}_q^\dagger, \hat{a}_s^\dagger] = 0$ for bosons.
10. Derive $\{\hat{a}_q^\dagger, \hat{a}_s^\dagger\} = 0$ for fermions.
11. Derive $\{\hat{a}_q, \hat{a}_s^\dagger\} = \delta_{q,s}$ for fermions.
12. Show that $[\hat{n}_q, \hat{a}_s^\dagger] = +\hat{a}_s^\dagger\delta_{q,s}$ for both bosons and fermions.

Solution: *1. By the ket $|1_s\rangle$ one means the number state in which one particle occupies the state $|s\rangle$. By the ket $|\tilde{1}_s\rangle$ one means the number state in Grand Hilbert space consisting of only a single particle, a particle in state $|s\rangle$.*
2. The definition of the creation operator is $\hat{a}_s^\dagger|n_s, n_t, ..., n_l\rangle \equiv \sqrt{n_s+1}|n_s{+}1, n_t, ..., n_l\rangle$.
3. The definition of the annihilation operator is $\hat{a}_s|n_s, n_t, ..., n_l\rangle \equiv \sqrt{n_s}|n_s{-}1, n_t, ..., n_l\rangle$.
4. $\hat{a}_s^\dagger|0_q, 0_s, ...\rangle = |0_q, 1_s, ...\rangle$.
5. $\hat{a}_s^\dagger|1_q, 0_s, ...\rangle = -|0_q, 1_s, ...\rangle$.
6. $\hat{a}_s^\dagger|1_q, 1_s, ...\rangle = 0$.
7. The normalization of the vacuum state is $\langle 0|0\rangle = \langle 1_s|\hat{a}_s^\dagger\hat{a}_s|1_s\rangle = \langle 1_s|\hat{n}_s|1_s\rangle = \langle 1_s|1_s\rangle = \langle s|s\rangle = 1$.
8. The normalization of the state $\langle 2_s|2_s\rangle$ is for bosons:

$$\langle 2_s|2_s\rangle = \tfrac{1}{2}\langle 1_s|\hat{a}_s\hat{a}_s^\dagger|1_s\rangle = \tfrac{1}{2}\langle 1_s|\hat{a}_s^\dagger\hat{a}_s + 1|1_s\rangle = \tfrac{1}{2}\langle 1_s|\hat{n}_s + 1|1_s\rangle = \langle 1_s|1_s\rangle = 1 \ .$$

For fermions (not using the fermion rule $\hat{a}_s^\dagger|1_q, 0_s, ...\rangle = 0$):

$$\langle 2_s|2_s\rangle = \tfrac{1}{2}\langle 1_s|\hat{a}_s\hat{a}_s^\dagger|1_s\rangle = \tfrac{1}{2}\langle 1_s|\hat{a}_s^\dagger\hat{a}_s - 1|1_s\rangle = \tfrac{1}{2}\langle 1_s|\hat{n}_s - 1|1_s\rangle = 0 \ .$$

9. First we consider $q \neq s$:

$$[\hat{a}_q^\dagger, \hat{a}_s^\dagger]|n_s, n_q, ..., n_l\rangle = ...$$

Next we consider the case $q = s$:

$$[\hat{a}_q^\dagger, \hat{a}_s^\dagger]|n_s, n_q, ..., n_l\rangle = ...$$

10. First we consider $q \neq s$. The creation operators can only yield a nonzero result if $n_s = 0$ and $n_q = 0$. Thus we have:

$$\{\hat{a}_q^\dagger, \hat{a}_s^\dagger\}|0\rangle = ...$$

In the case $q = s$ the anwer is trivially zero because no two fermions can occupy the same state.
11. 12.

50.1.10.7 Ex: Important commutation relations for boson field operators

Consider a many-body system of particles confined by on external potential $\mathcal{U}(\mathbf{r})$. At sufficiently low densities this system may be described by the hamiltonian for a pairwise interacting system,

$$\mathcal{H} = \sum_i \mathcal{H}^{(i)} + \tfrac{1}{2}\sum_{i,j} \mathcal{H}^{(i,j)} \ ,$$

where

$$\mathcal{H}^{(i)} = \frac{\mathbf{p}_i^2}{2m} + \mathcal{U}(\mathbf{r}_i)$$

is the free particle contribution of particle i and $\mathcal{H}^{(i,j)} = \mathcal{V}(\mathbf{r}_i, \mathbf{r}_j)$ represents the potential energy of interaction between the particles i and j. At sufficiently low temperatures this potential may be approximated by the expression

$$\mathcal{V}(\mathbf{r}_i, \mathbf{r}_j) = g\delta(\mathbf{r}_i - \mathbf{r}_j) \ ,$$

where $g = (4\pi\hbar^2/m)a$ and a is called the s-wave scattering length. In the occupation number representation for a system of identical particles the hamiltonian takes the form

$$\hat{H} = \hat{H}^{(1)} + \hat{H}^{(2)} \ ,$$

where

$$\hat{H}^{(1)} = \sum_{s,s'} \hat{a}^\dagger_{s'} \langle s'|\mathcal{H}^{(1)}|s\rangle \hat{a}_s \ ,$$

and

$$\hat{H}^{(2)} = \tfrac{1}{2}\sum_{t,t'}\sum_{s,s'} \hat{a}^\dagger_{s'}\hat{a}^\dagger_{t'}\langle s', t'|\mathcal{H}^{(1,2)}|s,t\rangle \hat{a}_t\hat{a}_s \ ,$$

Here $|s\rangle, |s'\rangle \in \{|s\rangle\}$, and $|t\rangle, |t'\rangle \in \{|t\rangle\}$ represent single particle eigenstates of the Hamiltonians $\mathcal{H}^{(1)}$ and $\mathcal{H}^{(2)}$, respectively. Rewriting the hamiltonian in terms of field operators we obtain

$$\hat{H}^{(1)} = \int d\mathbf{r}\hat{\psi}^\dagger(\mathbf{r})\mathcal{H}_0\hat{\psi}(\mathbf{r})$$

with $\mathcal{H}_0 = p^2/2m + \mathcal{U}(\mathbf{r})$ and

$$\hat{H}^{(2)} = \tfrac{1}{2}\int d\mathbf{r}d\mathbf{r}'\hat{\psi}^\dagger(\mathbf{r})\hat{\psi}^\dagger(\mathbf{r}')\mathcal{V}(\mathbf{r},\mathbf{r}')\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r}) \ .$$

Here $\mathbf{r}$ is the position coordinate of a single particle and $\mathbf{r}, \mathbf{r}'$ are the position coordinates of a pair of particles. The total number operator is defined as the integral over the density operator

$$\hat{N} = \int d\mathbf{r}\hat{n}(\mathbf{r}) \ .$$

Three commutation relations for boson field operators are crucial for the understanding of the ground state of an interacting bosonic superfluid:

$$[\hat{\psi}(\mathbf{r}), \hat{H}^{(1)}] = \mathcal{H}_0(\mathbf{p}, \mathbf{r})\hat{\psi}(\mathbf{r})$$
$$[\hat{\psi}(\mathbf{r}), \hat{H}^{(2)}] = g\hat{n}(\mathbf{r})\hat{\psi}(\mathbf{r})$$
$$[\hat{\psi}(\mathbf{r}), \hat{N}] = \hat{\psi}(\mathbf{r}) \ .$$

Derive the above commutation relations.

Solution: *a. First we recall* $\hat{N} = \int d\mathbf{r}' \hat{n}(\mathbf{r}')$ *and write the commutator in the form,*

$$[\hat{\psi}(\mathbf{r}), \hat{N}] = \int d\mathbf{r}' [\hat{\psi}(\mathbf{r}), \hat{n}(\mathbf{r}')] \ ,$$

where $\hat{n}(\mathbf{r}')$ *is the number-density operator. Using the commutation relation* $[\hat{n}(\mathbf{r}), \hat{\psi}(\mathbf{r}')] = -\hat{\psi}(\mathbf{r}')\delta(\mathbf{r} - \mathbf{r}')$ *we find by integration over* $\mathbf{r}'$*,*

$$\int d\mathbf{r}' [\hat{\psi}(\mathbf{r}), \hat{n}(\mathbf{r}')] = \int d\mathbf{r}' \hat{\psi}(\mathbf{r}')\delta(\mathbf{r} - \mathbf{r}') = \hat{\psi}(\mathbf{r}) \ .$$

b. First we write the commutator in the form,

$$[\hat{\psi}(\mathbf{r}), \hat{H}^{(2)}] = \int d\mathbf{r}' [\hat{\psi}(\mathbf{r}), \hat{H}^{(2)}(\mathbf{r}')] \ ,$$

where $\hat{H}^{(2)}(\mathbf{r}') = \frac{g}{2}\hat{\psi}^\dagger(\mathbf{r}')\hat{(}\mathbf{r}')\hat{\psi}(\mathbf{r}')$ *is the construction operator density for the two-body interaction* $\mathcal{V}(\mathbf{r}_1, \mathbf{r}_2) = g\delta(\mathbf{r}_1 - \mathbf{r}_2)$*. Using the commutation relations* $[\hat{\psi}(\mathbf{r}), \hat{\psi}^\dagger(\mathbf{r}')] = \delta(\mathbf{r} - \mathbf{r}')$*,* $[\hat{\psi}(\mathbf{r}), \hat{\psi}(\mathbf{r}')] = 0$*, and* $[\hat{n}(\mathbf{r}), \hat{\psi}(\mathbf{r}')] = -\hat{\psi}(\mathbf{r}')\delta(\mathbf{r} - \mathbf{r}')$ *we find after integration over* $\mathbf{r}'$*,*

$$\begin{aligned}
\int d\mathbf{r}' [\hat{\psi}(\mathbf{r}), \hat{H}^{(2)}(\mathbf{r}')] &= \tfrac{g}{2} \int d\mathbf{r}' [\hat{\psi}(\mathbf{r})\hat{\psi}^\dagger(\mathbf{r}')\hat{n}(\mathbf{r}')\hat{\psi}(\mathbf{r}') - \hat{\psi}^\dagger(\mathbf{r}')\hat{n}(\mathbf{r}')\hat{\psi}(\mathbf{r}')\hat{\psi}(\mathbf{r})] \\
&= \tfrac{g}{2} \int d\mathbf{r}' [\hat{\psi}^\dagger\hat{\psi}(\mathbf{r})(\mathbf{r}')\hat{n}(\mathbf{r}')\hat{\psi}(\mathbf{r}') - \hat{\psi}^\dagger(\mathbf{r}')\hat{\psi}(\mathbf{r})\hat{n}(\mathbf{r}')\hat{\psi}(\mathbf{r}') + 2\delta(\mathbf{r} - \mathbf{r}')\hat{n}(\mathbf{r}')\hat{\psi}(\mathbf{r}')] \\
&= g\hat{n}(\mathbf{r})\hat{\psi}(\mathbf{r}) \ .
\end{aligned}$$

50.1.10.8 Ex: Amplitude and phase of the order parameter

To analyze the deviations from the stationary state we write the order parameter in a form separating the fluctuations of the amplitude from those of the phase,

$$\Psi(\mathbf{r}, t) = |\Psi(\mathbf{r}, t)|e^{-i\mu t/\hbar + i\Phi(\mathbf{r},t)} \ .$$

Using the Bogolubov ansatz the amplitude takes the form

$$|\Psi(\mathbf{r}, t)| = \sqrt{n_0(\mathbf{r}, t)} \ .$$

The overall phase $\phi(\mathbf{r}, t)$ is a real quantity defined as

$$\phi(\mathbf{r}, t) \equiv \mu t - \Phi(\mathbf{r}, t) \ .$$

The phase $\Phi(\mathbf{r}, t)$ is called the *fluctuating phase* and represents the *deviation* from the dynamical phase evolution $\mu t/\hbar$ of the stationary state $\Psi_0(\mathbf{r}, t)$. The current density is defined as

$$\mathbf{j}(\mathbf{r}, t) = \frac{i\hbar}{2m}(\Psi\nabla\Psi^* - \Psi^*\nabla\Psi) \ .$$

a. Derive the following expression for the current density,

$$\mathbf{j}(\mathbf{r},t) = \frac{\hbar}{m} n_0(\mathbf{r},t)\nabla\Phi(\mathbf{r},t) \ .$$

b. Show that the time dependence of the phase of the order parameter can be expressed in the form,

$$-\hbar\frac{\partial\phi}{\partial t} = \frac{\hbar^2}{2m}(\nabla\Phi)^2 + \mathcal{U}(\mathbf{r}) + g|\Psi|^2 - \frac{\hbar^2}{2m}\frac{1}{|\Psi|}\nabla^2|\Psi| \ .$$

Hint: Use the difference of time-dependent GP equation and its complex conjugate.

Solution:

50.2 Quantum statistics

To describe the time evolution of an isolated quantum gas, in principle, all we need to know is the many-body wavefunction plus the hamiltonian operator. Of course, in practice, these quantities will be known only to limited accuracy. Therefore, just as in the case of classical gases, we have to rely on statistical methods to describe the properties of a quantum gas. This means that we are interested in the occupation probability of quantum many-body states. In view of the convenience of the occupation number representation we ask in particular for the occupation probability P_γ of the number states $|\tilde{n}_\gamma\rangle$. The canonical ensemble introduced in Section 1.2.4 is not suited for this purpose because it presumes a fixed number of atoms N, whereas the ensemble of number states $\{|\tilde{n}_\gamma\rangle\}$ is defined in Grand Hilbert space in which the number of atoms is not fixed. This motivates us to introduce an important variant of the canonical ensemble which is known as the grand canonical ensemble.

50.2.1 Grand canonical distribution

In the grand canonical approach we consider a small system which can exchange not only heat but also atoms with a large reservoir. Like in the canonical case a small system is split off as a part of a one-component gas of N_{tot} identical atoms at temperature T (total energy $_{tot}$). We can visualize the situation as a cloud of trapped atoms connected asymptotically to a homogeneous gas at very low density, a bit reminiscent of the conditions for evaporative cooling (see Section 1.4.1). We are interested in conditions in which the quantum resolution limit is reached in the center of the cloud and the cloud has to be treated as an interacting quantum many-body system. In the reservoir the density can be made arbitrarily low, so the reservoir atoms may be treated quasi-classically.

According to the statistical principle, the probability $P_0(E,N)$ that the trapped gas (the subsystem) has total energy between E and $E+\delta E$ and consists of a number of trapped atoms between N and $N+\delta N$ is proportional to the number $\Omega^{(0)}(E,N)$ of

states accessible to the total system in which the subsystem matches the conditions for E and N,

$$P_0(E,N) = C_0\Omega^{(0)}(E,N) \ , \tag{50.61}$$

where C_0 is a normalization constant. Because the atoms of the subsystem do not interact with the atoms of the reservoir (except for a vanishingly fraction of the atoms near the edge of the trap) the probability $P_0(E,N)$ can be written as the product of the number of quantum mechanical N-body states $\Omega_N(E)$ with energy near E with the number of microstates $\Omega(E^*,N^*)$ with energy near $E^* = E_{tot} - E$ accessible to the $N^* = N_{tot} - N$ atoms of the rest of the gas,

$$P_0(E,N) = C_0\Omega(E,N)\Omega(E_{tot}-E, N_{tot}-N) \ , \tag{50.62}$$

If the total number of atoms is very large ($N_{tot} \gg 1$) the trapped number will always be much smaller than the number in the remaining gas, $N \lll N^*$. Similarly, the amount of heat involved is small, $E \lll E^*$. Thus the distribution $P_0(E,N)$ can be calculated by treating the remaining gas as both a heat reservoir and a particle reservoir for the small system. The ensemble of subsystems with energy near E and atom number near N is called the grand canonical ensemble.

The probability P_γ that the small system is in a specific, properly symmetrized, many-body energy eigenstate $|\tilde{n}_\gamma\rangle$ is given by

Instrumentation of a Quantum Optics Lab

Chapter 51

Gaussian optics and the polarization of light

The objective of this part of the course is to introduce the student into the basics of *Gaussian optics* and *polarizations optics*. The student will learn how to transform the diameter and the divergence of a Gaussian beam using lenses and telescopes and to analyze and manipulate the polarization of a laser beam.

51.1 Some more basic notions

51.1.1 Definition of photometric quantities

The *radiant energy* W is the total energy emitted from a source. The *radiant power* P (or radiant flux) is the total energy emitted per second. The *radiance* $L(\Omega)$ is defined as the power radiated (emitted, reflected, transmitted or received) under an angle θ through a surface element $d\mathbf{A}$ into a solid angle element $d\Omega = \sin\theta d\theta d\phi$. It is a directional quantity indicating how much of the power will be received by an optical system looking at that surface from a specified angle of view,

$$\boxed{P = \int L(\Omega) dA_n d\Omega} \,. \tag{51.1}$$

Spectral densities are denoted by an index ν, e.g. $P = \int P_\nu(\nu) d\nu$. In (51.1), $dA_n \equiv \hat{\mathbf{n}} \cdot d\mathbf{A} = dA \cos\theta$ is the projection of the surface element onto the surface normal. The quantity,

$$I^* = \int L(\Omega) d\Omega \tag{51.2}$$

is called *radiant intensity*.

> **Example 296 (*Angular distribution of thermal radiation*):** In a blackbody in thermal equilibrium with its surroundings (e.g the walls of a cavity) the radiation is isotropic with a spectral energy distribution given by Planck's law. This means that at any point of the volume of the blackbody radiator an imaginary volume element radiates energy in all directions of space, such that the radiance into a specific solid angle element is,
>
> $$L(\Omega) = \bar{u} \frac{c}{4\pi} \,. \tag{51.3}$$

Radiation passing under an angle θ through a hole of size $dA = dA_n/\cos\theta$ into a specific solid angle element $d\Omega$ generates the radiance,

$$\frac{\partial^2 P}{\partial\Omega\partial A} = L(\Omega)\cos\theta \ . \tag{51.4}$$

In *any* direction we get,

$$\frac{\partial P_\nu}{\partial A} = \int_{\text{half sphere}} L_\nu(\Omega)\cos\theta d\Omega = \bar{u}\frac{c}{4\pi}\int_0^{2\pi} d\phi \int_0^{\pi/2} \cos\theta\sin\theta d\theta = \frac{c\bar{u}}{4} \ . \tag{51.5}$$

Summing up over all surface elements of a sphere of radius R,

$$P = \int \frac{\partial P}{\partial A} dA = \frac{c\bar{u}}{4} R^2 \int_0^{2\pi} d\phi \int_0^{\pi} \sin\theta d\theta = \pi R^2 c\bar{u} \ . \tag{51.6}$$

Accordingly, the spectral distribution is, using Planck's law,

$$P_\nu = P\frac{8\pi h\nu^3}{c^3}\frac{1}{e^{\beta\hbar\omega}-1} = \frac{8\pi^2 R^2 h\nu^3}{c^2}\frac{1}{e^{\beta\hbar\omega}-1} \ . \tag{51.7}$$

A detector covers itself a finite solid angle $d\Omega = \frac{dA'\cos\theta'}{r^2}$. The radiant flux for $r^2 \gg dA, dA'$ can then be expressed as,

$$d\Phi = L(\Omega)dA\cos\theta d\Omega = L(\Omega)dA\cos\theta\frac{dA'\cos\theta'}{r^2} \tag{51.8}$$

$$\text{that is} \qquad \Phi = \int_A\int_{A'} \frac{L(\Omega)}{r^2}\cos\theta\cos\theta' dA dA' \ .$$

Note that for isotropic sources (51.8) is symmetric upon interchanging emitter and detector with regard to θ and θ' or dA and dA'. Furthermore, the formula demonstrates that the radiant flux emitted into the unit solid angle is proportional to $\cos\theta$ (Lambert's law). An example for such a source is a hole with the area dA in a blackbody radiation cavity (see Fig. 51.1). Solve Excs. 51.1.2.1 and 51.1.2.2.

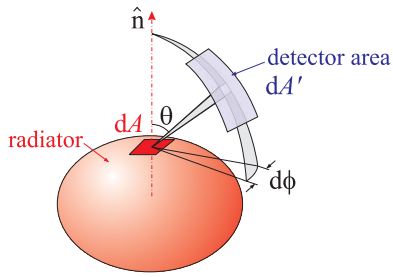

Figure 51.1: Illustration of the radiance.

Note that it is impossible to increase the radiance of a source by any sophisticated imaging optics [352]. This means that the image dA^* of a radiation source dA never has a larger radiance than the source itself. It is true that the flux density can be increased by focussing the radiation. The solid angle, however, into which radiation

from the image dA^* is emitted is also increased by the same factor. Therefore, the radiance does not increase. In fact, because of inevitable reflection, scattering, and absorption losses of the imaging optics, the radiance of the image dA^* is, in practice, always less than that of the source. A strictly parallel light beam would be emitted into the solid angle $d\Omega = 0$. With a finite radiant power this would imply an infinite radiance L, which is impossible. This illustrates that such a light beam cannot be realized. The radiation source for a strictly parallel beam anyway has to be a point source in the focal plane of a lens. Such a point source with zero surface cannot emit any power.

Example 297 (*Radiance of the sun*): An area $A = 1\,\mathrm{m}^2$ of the Earth's surface receives at normal incidence from the sun about $P/A = 1.35\,\mathrm{kW/m}^2$ of intensity. Since the sun covers an angle of $\theta = 0.53°$ seen from the Earth, we can estimate the sun's radiance as,

$$L = \frac{P}{A\Omega} = \frac{P}{A\int_0^{2\pi}\int_0^{\theta}\sin\theta d\theta d\phi} \simeq \frac{P}{A\pi\theta^2} \approx 2\cdot 10^4\,\mathrm{kW\ m^{-2}\ ster^{-1}}\ .$$

The total power received by the Earth is $\frac{P}{A}\pi R_{Earth}^2$. The total power emitted by the sun is $\frac{P}{A}4\pi d_{sun-Earth}^2$.

Example 298 (*Radiance of a HeNe laser*): We consider a HeNe laser emitting $P = 1\,\mathrm{mW}$ of power from a $w_0 = 1\,\mathrm{mm}$ beam waist into an angle of $2\theta = 0.067°$. With a typical emission bandwidth of $\Delta\nu = 1\,\mathrm{MHz}$ the spectral radiance is,

$$L_\nu = \frac{P_\nu}{A\Omega} \simeq \frac{P}{\pi w_0^2\ \pi\theta^2\ \Delta\nu} \approx 1\,\mathrm{kWsm^{-2}\ ster^{-1}}\ .$$

For comparison, the sun's radiance at it's surface ($T = 6000\,\mathrm{K}$) at the same wavelength as the HeNe laser is,

$$L_\nu = \frac{Lu_\nu}{\bar{u}} \approx 5\,\mathrm{nWsm^{-2}\ ster^{-1}}\ .$$

51.1.2 Exercises

51.1.2.1 Ex: Emission of an argon laser

The angular divergence of the output from a $P = 1\,\mathrm{W}$ argon laser is assumed to be $\alpha = 4\cdot 10^{-3}\,\mathrm{rad}$.
a. Calculate the radiance L and the radiant intensity I_1 of the laser beam and the irradiance I (intensity) at a surface 1 m away from the output mirror, when the laser beam diameter at the mirror is $2w_s = 2\,\mathrm{mm}$.
b. What is the spectral power density $u(\nu)$ if the laser bandwidth is 1 MHz?

Solution: *a. The spot size on the output mirror is* $A = \pi w_s^2 \approx 3.1\cdot 10^{-2}\,\mathrm{cm}^2$. *The radiant intensity at the mirror is then,*

$$I_1 = \frac{P}{A} \approx 32\,\mathrm{W/cm}^2\ .$$

The solid angle Ω into which the laser beam is emitted is,

$$\Omega = \int d\Omega = \int_0^{2\pi} \int_0^{\alpha} \sin\theta d\theta d\phi = 2\pi(1-\cos\alpha) \simeq \pi\alpha^2 \ .$$

The radiance L of the laser is then,

$$L = \frac{P}{A\Omega} = \frac{P}{\pi w_s^2 \ \pi\alpha^2} \approx 6.4 \cdot 10^9 \, \mathrm{Wm^{-2}} \ \mathrm{sr^{-1}} \ .$$

At a surface a distance $z = 1$ m from the mirror, the spot size is:

$$A_2 = dA + z^2 d\Omega \approx 0.53 \, \mathrm{cm}^2 \ .$$

The intensity at the surface is:

$$I_2 = \frac{P}{A_2} \approx 1.9 \, \mathrm{W/cm}^2 \ .$$

b. For a spectral width $\Delta\nu = 1\,\mathrm{MHz}$, the spectral power density at the distant surface is:

$$u_2(\nu) = \frac{I_2/c}{\Delta\nu} \approx 6.3 \cdot 10^{-11} \, \mathrm{Ws}^2 \ \mathrm{m}^3 \ .$$

This should be compared with the visible part of the solar radiation on Earth ($I \approx 10^3 \, \mathrm{W/m}^2$ and $\Delta\nu \approx 3 \cdot 10^{16} \, \mathrm{s^{-1}}$), yielding $u_{RS}(\nu) = 10^{-22} \, \mathrm{Ws}^2/\mathrm{m}^3$, which is smaller by 13 orders of magnitude.

51.1.2.2 Ex: Photosynthetically active radiation

The photon flux density and the photosynthetically active radiation (PAR) are defined as,

$$\eta_{photon} \equiv \frac{\int_{\lambda_1}^{\lambda_2} u(\lambda,T) \frac{\lambda}{hcN_A} d\lambda}{\int_{\lambda_1}^{\lambda_2} u_{Pl}(\lambda,T) d\lambda} \qquad \text{and} \qquad \eta_{PAR} = \frac{\int_{\lambda_1}^{\lambda_2} u(\lambda,T) d\lambda}{\int_0^{\infty} u(\lambda,T) d\lambda} \ ,$$

where $\lambda_1 = 400\,\mathrm{nm}$ and $\lambda_2 = 700\,\mathrm{nm}$ delimit the range, where photosynthesis takes place. Calculate both quantities for a blackbody at $T = 5800\,\mathrm{K}$ temperature. Plot them as a function of temperature in the range $T = 300..6000\,\mathrm{K}$.

Solution: *The photon energy density in the case of blackbody radiation is,*

$$u_{Pl}(\lambda,T)d\lambda = -\frac{8\pi ch}{\lambda^5} \frac{1}{e^{\beta hc/\lambda} - 1} d\lambda \ .$$

With this we find $\beta h\nu_1 \approx 5.99$, and $\beta h\nu_2 \approx 3.43$, and,

$$\eta_{photon} = \frac{\int_{\lambda_1}^{\lambda_2} u_{Pl}(\lambda,T) \frac{\lambda}{hcN_A} d\lambda}{\int_{\lambda_1}^{\lambda_2} u_{Pl}(\lambda,T) d\lambda} = \frac{\beta}{N_A} \frac{\int_{\beta h\nu_1}^{\beta h\nu_2} \frac{x^2}{e^x - 1} dx}{\int_{\beta h\nu_1}^{\beta h\nu_2} \frac{x^3}{e^x - 1} dx} \approx 0.394 \, \mathrm{mol/(day \ W)} \ .$$

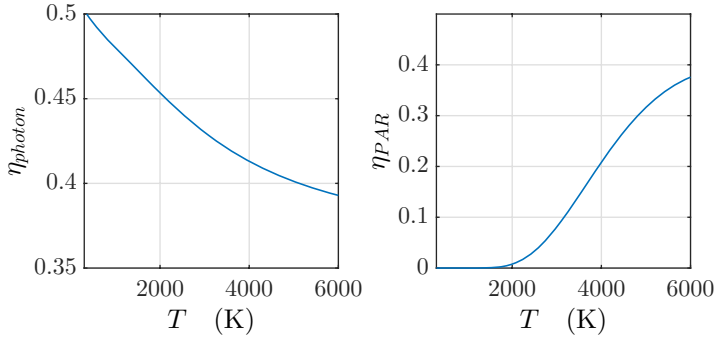

Figure 51.2: Temperature dependence of photosynthetically active radiation.

Now,

$$\eta_{PAR} = \frac{\int_{\lambda_1}^{\lambda_2} u_{Pl}(\lambda,T)d\lambda}{\int_0^{\infty} u_{Pl}(\lambda,T)d\lambda} = \frac{\int_{\beta h\nu_1}^{\beta h\nu_2} \frac{x^2}{e^x-1}dx}{\int_0^{\infty} \frac{x^3}{e^x-1}dx} = \frac{15}{\pi^4}\int_{\beta h\nu_1}^{\beta h\nu_2} \frac{x^2}{e^x-1}dx \approx 0.0878 \ .$$

The graphs are shown in Fig. 51.2.

51.2 Introduction to Gaussian optics

51.2.1 Wave equation and beam parameters

At first sight, one might think that the propagation of laser light is well described by the laws of geometrical optics. On closer inspection it turns out, however, that laser beams behave in many respects more like plane waves with their energy is concentrated near an optical axis. The electro-magnetic fields satisfy the *wave equation*,

$$k^2 u + \nabla^2 u = 0 \ . \tag{51.9}$$

For waves propagating in z direction, $u = \psi(x,y,z)e^{-\imath kz}$, one obtains a Schrödinger-like equation [734],

$$2\imath k\frac{\partial\psi}{\partial z} - \frac{\partial^2\psi}{\partial x^2} - \frac{\partial^2\psi}{\partial y^2} = 0 \ , \tag{51.10}$$

where $\partial^2\psi/\partial z^2$ has been neglected.

To describe a *Gaussian beam*, we choose an exponential ansatz and introduce two parameters, which can vary along the propagation axis z: $P(z)$ is a complex phase shift and $q(z)$ a complex parameter, whose imaginary part describes the diameter of the beam. The ansatz,

$$\psi = e^{-\imath\left[P(z)+k(x^2+y^2)/2q(z)\right]} \tag{51.11}$$

leads to [1],

$$0 = (q'-1)\frac{\imath k(x^2+y^2)}{q^2} - 2\imath P' + \frac{2}{q} \ . \tag{51.12}$$

[1] See script on *Electrodynamics* (2023), Sec. 7.4.2..

In order for Eq. (51.12) to hold for all x and y, we need $q' = 1$ and $P' = \frac{-\imath}{q}$. Integrating q', we find

$$q = q_0 + z \ . \tag{51.13}$$

It is useful to introduce real beam parameters,

$$\frac{1}{q} \equiv \frac{1}{R} - \imath \frac{\lambda}{\pi w^2} \ . \tag{51.14}$$

Inserting these into Eq. (51.10),

$$\psi = e^{-\imath P - \imath \frac{k(x^2+y^2)}{2R} - \frac{(x^2+y^2)}{w^2}} \ , \tag{51.15}$$

it becomes clear that $R(z)$ is the radius of curvature and $w(z)$ the beam diameter. Evaluating q_0 at the position of the focus (waist of the beam), where $R = \infty$, we obtain from (51.13) and (51.14)

$$w^2(z) = w_0^2 \left[1 + \left(\frac{\lambda z}{\pi w_0^2} \right)^2 \right] \qquad \text{and} \qquad R(z) = z \left[1 + \left(\frac{\pi w_0^2}{\lambda z} \right)^2 \right] \ . \tag{51.16}$$

Normalizing the intensity to the total power, we may write the radial intensity distributions as,

$$I_z(x,y) = \frac{2P}{\pi w(z)^2} e^{-2(x^2+y^2)/w(z)^2} \ . \tag{51.17}$$

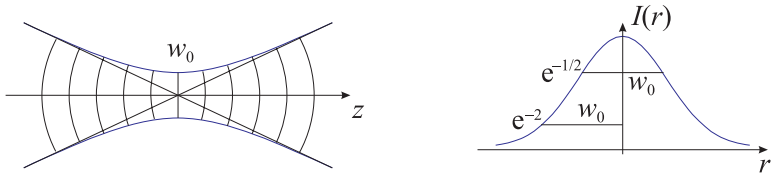

Figure 51.3: (Left) Propagation of the beam along the optical axis. (Right) Cross section of a Gaussian laser beam.

51.2.2 Transfer matrices

For the practical work with Gauss beams it is helpful to introduce transfer matrices, which describe the transformation of a Gauss beam through optical components along the optical axis. The matrix

$$\mathbf{M} = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \tag{51.18}$$

transforms the beam parameter q in the following way:

$$q(z) = \frac{aq(0) + b}{cq(0) + d} \ . \tag{51.19}$$

Transfer matrices allow to calculate, how the parameters R and w transform along the optical axis across the optical elements or in free space. The most common optical elements are lenses, crystals, prisms, mirrors and cavities. For example, the matrix for propagation in free space of a beam over a distance d is,

$$\mathbf{M} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \tag{51.20}$$

and the matrix for transformation through a thin lens with focal distance f,

$$\mathbf{M} = \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix} . \tag{51.21}$$

It is interesting to note that the transfer matrices are the same as those, which in classical beam optics transform the vector, whose components are the distance of the beam from the optical axis y and its divergence $y'(z)$:

$$\begin{pmatrix} y(z) \\ y'(z) \end{pmatrix} = \mathbf{M} \begin{pmatrix} y(0) \\ y'(0) \end{pmatrix} . \tag{51.22}$$

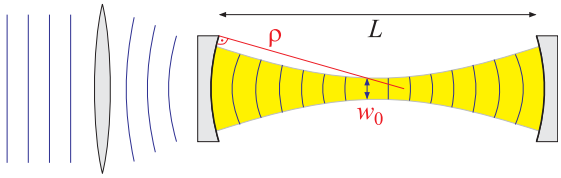

Figure 51.4: Coupling a Gaussian beam of light into cavity requires matching of the phase fronts.

Fig. 51.4 shows that coupling a Gaussian beam of light into a cavity requires matching of the phase fronts. Solve the Excs. 51.2.3.1 to 51.2.3.16 [352, 734, 1364].

51.2.3 Exercises

51.2.3.1 Ex: Imaging through a thin lens

In classical ray optics the equations describing the focusing of a thin lens are given by,

$$\frac{1}{f} = \frac{1}{g} + \frac{1}{b} \quad \text{and} \quad \frac{b}{g} = \frac{B}{G} ,$$

where f is the focal distance of the lens, g the distance between the object and the lens, b the distance between the image and the lens, G the size of the object, and B the size of the image.
At what distance from an object of size $G = 1$ mm do you have to place a thin lens with focal distance $f = 100$ mm in order to obtain a ten times larger image? Test your result in practice.

Solution: *From the lens equations,*

$$\frac{1}{f} = \frac{1}{g} + \frac{1}{b} = \frac{1}{g} + \frac{G}{B}\frac{1}{g} = \frac{1}{g} + \frac{1}{10g} = \frac{11}{10g} \ .$$

Hence, $g = 1.1f$.

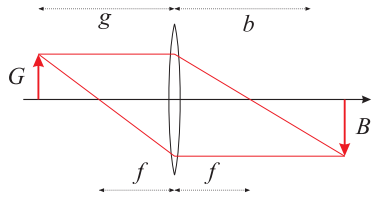

Figure 51.5: Ray optics.

51.2.3.2 Ex: Image of a convex lens

Show that with a convex lens of focal distance f the smallest distance between object and image should be $s = 4f$.

Solution: *The lens equation postulates,*

$$\frac{1}{f} = \frac{1}{b} + \frac{1}{g} \ ,$$

such that

$$b + g = b + \frac{1}{\frac{1}{f} - \frac{1}{b}} = \frac{b^2}{b - f} \ .$$

Minimizing the distance between object and image,

$$0 = \frac{\partial(b+g)}{\partial b} = \frac{\partial}{\partial b}\frac{b^2}{b-f} = b\frac{b-2f}{(b-f)^2} \ ,$$

we get $b = 2f = g$ *and hence,* $b + g > 4f$.

51.2.3.3 Ex: Telescope with ray optics

In classical optics the transfer matrix for the propagation of a beam through free space and through a thin lens are given, respectively, by

$$M_{free} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \qquad \text{and} \qquad M_{lens} = \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix} \ .$$

The transfer between a point z_0 of the optical axis and a point z_1 is described by

$$\begin{pmatrix} y(z_1) \\ y'(z_1) \end{pmatrix} = M_{free} \begin{pmatrix} y(z_0) \\ y'(z_0) \end{pmatrix} \ .$$

Here, y is the distance of a beam ray from the optical axis and $y' = \frac{dy}{dx}$ its divergence. Use this formalism to design a 3 times magnifying telescope with two lenses have, respectively, the focal lengths $f_1 = 100\,\text{mm}$ and $f_2 = 300\,\text{mm}$.

Solution: *The total optical system is a concatenation of 3 matrices,*

$$M_{tot} = M_{lens,2} M_{free} M_{lens,1} = \begin{pmatrix} 1 & 0 \\ -1/f_2 & 1 \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -1/f_1 & 1 \end{pmatrix} = \begin{pmatrix} 1 - \frac{d}{f_1} & d \\ \frac{d}{f_1 f_2} - \frac{1}{f_1} - \frac{1}{f_2} & 1 - \frac{d}{f_2} \end{pmatrix} .$$

The variable parameter is the distance d between the two lenses, the condition of a telescope is that a coaxial input ray, $y'(z_0) = 0$, is transformed into a coaxial output ray, $y'(z_1) = 0$. Hence,

$$\begin{pmatrix} y(z_1) \\ 0 \end{pmatrix} = M_{tot} \begin{pmatrix} y(z_0) \\ 0 \end{pmatrix} = \begin{pmatrix} \left(1 - \frac{d}{f_1}\right) y(z_0) \\ \left(\frac{d}{f_1 f_2} - \frac{1}{f_1} - \frac{1}{f_2}\right) y(z_0) \end{pmatrix} .$$

This can only be true if

$$d = f_1 + f_2 \ .$$

The magnification is then

$$\frac{y(z_1)}{y(z_0)} = 1 - \frac{d}{f_1} = \frac{f_2}{f_1} \ .$$

51.2.3.4 Ex: Ray tracing

Simulate the trajectory of a ray of light traversing under an angle a layer of a material with a refraction index characterized by a Gaussian profile.

Solution: *The simulation is shown in Fig. 51.6.*

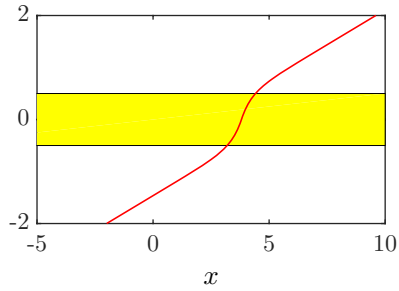

Figure 51.6: (code) Trajectory of a ray of light with 15° angle of incidence.

51.2.3.5 Ex: The eye

The effective distance between the cornea and the lens of the eye is 2.5 cm, and the lens is in contact with the eye. To resolve two very close points, their images on the retina must be on two non-adjacent cone cells (i.e. there must be at least one non-activated cone cell between the images). The cone cells are about 1 μm apart.
a. What is the smallest angle ϵ under which two points are still separately perceptible? Assume that the direct beams P, P' are not refracted.
b. How close can the two points P_1 and P_2 be, at a distance of 20 m from the eye, so that they are still separately perceptible?

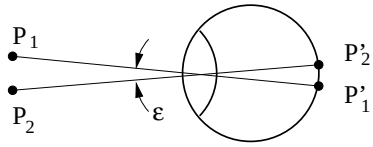

Figure 51.7: The eye.

Solution:

51.2.3.6 Ex: Microscope

A simple homemade microscope consists of two convex lenses, each one with a diffractive power of 20 dpt, fixed at the extremities of a 30 cm long tube.
a. Wie groß ist die Tubuslänge dieses Mikroskops?
b. Wie groß ist der Abbildungsmaßstab des Mikroskops?
c. Welche Vergrößerung erreicht das Mikroskop? Gehen Sie davon aus, dass die deutliche Sehweite 25 cm beträgt.
d. Wie weit muss sich der Gegenstand vor dem Objektiv befinden, damit er im Auge des Betrachters scharf abgebildet wird?

Solution:

51.2.3.7 Ex: Classical cloaking with four lenses

Can you design a system of four lenses (focal distances f_1, f_2, $f_3 = f_2$, and $f_4 = f_1$) separated by three distances $t_1 = f_1 + f_2$, t_2, and $t_3 = t_1$, such that the system appears to be invisible for an observer looking through the lenses [258]?

Solution: *The transfer matrix of this system is,*

$$M = \begin{pmatrix} 1 & 0 \\ -\frac{1}{f_1} & 1 \end{pmatrix} \begin{pmatrix} 1 & f_1+f_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{1}{f_2} & 1 \end{pmatrix} \begin{pmatrix} 1 & t_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{1}{f_2} & 1 \end{pmatrix} \begin{pmatrix} 1 & f_1+f_2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -\frac{1}{f_1} & 1 \end{pmatrix}$$
$$= \begin{pmatrix} 1 & -f_1 \frac{2f_1f_2+2f_2^2-t_2f_1}{f_2^2} \\ 0 & 1 \end{pmatrix} .$$

In order to obtain, that this matrix is equal to,

$$M = \begin{pmatrix} 1 & L \\ 0 & 1 \end{pmatrix} ,$$

with $L = t_1 + t_2 + t_3$, the distance t_2 be chosen such that,

$$t_2 = 2f_2 \frac{f_1+f_2}{f_1-f_2} .$$

Choosing, for instance, $2f_2 = f_1$ we get $t_2 = 3f_1$.
Comment: *Works in practice with $f_1 = 2f_2 = 2f_3 = f_4 = 50\,\mathrm{mm}$, $t_1 = t_3 = 75\,\mathrm{mm}$, and $t_2 = 150\,\mathrm{mm}$. However, lens aberrations spoil the visibility of the effect.*

51.2.3.8 Ex: Diameter of a Gaussian beam

You are blocking part of a laser beam with a razor blade mounted on a translation stage allowing you to vary the horizontal position. At the same time, you observe the transmitted power P. You observe that, for varying the power between 16% and 84%, you need to vary the translation by 140 µm. What is the diameter of the Gaussian beam?

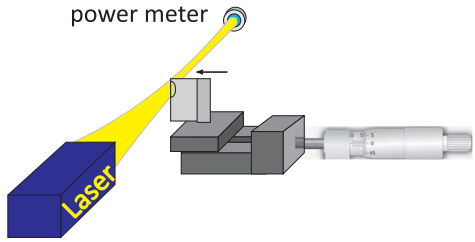

Figure 51.8: Diameter of a Gaussian beam.

Solution: *We calculate,*

$$\frac{\tilde{P}(\tilde{x})}{P} = \int_{-\infty}^{\tilde{x}} \int_{-\infty}^{\infty} \frac{2}{\pi w_0^2} e^{-2r^2/w_0^2} dx dy = \frac{1}{\pi} \int_{-\infty}^{\infty} e^{-\theta^2} d\theta \int_{-\infty}^{\tilde{\xi}} e^{-\xi^2} d\xi = \tfrac{1}{2} \operatorname{erf}\left(\tfrac{\tilde{x}\sqrt{2}}{w_0}\right) + \tfrac{1}{2} .$$

Hence, $\tilde{P}(-w_0/2) = P \cdot 16\%$ and $\tilde{P}(w_0/2) = P \cdot 84\%$, which means that the value of the translation corresponds precisely to the waist.

51.2.3.9 Ex: Diffraction of a Gaussian beam at a slit

a. Determine the power loss suffered by a Gaussian beam passing through a one-dimensional slit, assuming that the beam hits the slit in its center.
b. Calculate the diffraction pattern produced by the slit.
c. A laser beam ($\lambda = 633\,\text{nm}$) looses 50% of its power after being passed through a slit. At a distance of $L = 1\,\text{m}$ behind the slit appear diffraction patterns exhibiting first minima at $\Delta x = 1\,\text{mm}$ to both sides of the central peak. Determine the diameter of the Gaussian beam.

Solution: *a. We have,*

$$P_{tr} = \int_{-\infty}^{\infty}\int_{-d/2}^{d/2} I(x,y)dxdy = \int_{-\infty}^{\infty}\int_{-d/2}^{d/2} \frac{2P}{\pi w^2} e^{(-2x^2-2y^2)/w^2} dxdy = P\,erf\left(\frac{d}{w\sqrt{2}}\right) .$$

b. We let the slit be oriented in x-direction. The field is then obtained by Fourier transformation,

$$u(\theta_x,\theta_y) \propto F[\chi_{[-d/2,d/2]}] = \int_{-\infty}^{\infty}\int_{-d/2}^{d/2} dxdy e^{\imath k_x x + \imath k_y y} = 2\pi\delta(k_y)\frac{2}{k_x}\sin\frac{k_x d}{2} ,$$

where the diffraction angle is, $\theta_x \simeq \sin\theta_x = \frac{k_x}{k}$. *The intensity is just the square,*

$$I(\theta_x) = \left(2\pi d \frac{\sin\frac{kd}{2}\theta_x}{\frac{kd}{2}\theta_x}\right)^2 .$$

We normalize via,

$$\int I(\theta_x)d\theta_x = \int \left(2\pi d \frac{\sin\frac{kd}{2}\theta_x}{\frac{kd}{2}\theta_x}\right)^2 d\theta_x = (2\pi d)^2 \frac{2}{kd}\int_{-\infty}^{\infty}\frac{\sin^2 x}{x^2}dx = (2\pi d)^2\frac{2}{kd}\pi ,$$

such that

$$I(\theta_x,\theta_y) = \frac{I_0}{(2\pi d)^2\frac{2}{kd}\pi}\left(2\pi d\frac{\sin\frac{kd}{2}\theta_x}{\frac{kd}{2}\theta_x}\right)^2 = I_0\frac{kd}{2\pi}\left(\frac{\sin\frac{kd}{2}\theta_x}{\frac{kd}{2}\theta_x}\right)^2 .$$

c. From

$$\frac{P_{tr}}{P} = 50\% = \text{erf}(0.477) = \text{erf}\left(\tfrac{d}{w\sqrt{2}}\right) ,$$

we get

$$w = \frac{d}{0.477\sqrt{2}} .$$

The diameter of the slit can be determined by observing the interference fringes. The first minimum is observed under the diffraction angle $\theta_x \simeq \tan\theta_x = \frac{\Delta x}{L}$, *corresponding to a zero passage of the diffraction function at* $\frac{kd}{2}\theta_x = \pi$. *Hence,*

$$w = \frac{d}{0.477\sqrt{2}} = \frac{1}{0.477\sqrt{2}}\frac{2\pi}{k\theta_x} = \frac{1}{0.477\sqrt{2}}\frac{\lambda}{\Delta x}L \approx 938\,\mu\text{m} .$$

51.2.3.10 Ex: Diffraction of a Gaussian beam at a pinhole

a. Determine the power loss suffered by a Gaussian beam passing through the center of a a pinhole of radius R.
b. A laser beam ($\lambda = 633\,\text{nm}$) looses 50% of its power after being passed through a slit. At a distance of $L = 1\,\text{m}$ behind the slit appear diffraction patterns exhibiting a first minimum at a distance $\Delta b = 1\,\text{mm}$ from the optical axis. Determine the diameter of the Gaussian beam. Help: The first ring of destructive interference occurs under an angle of $\sin\theta = 1.22\frac{\lambda}{2R}$.

Solution: *a. For a pinhole,*

$$P_{tr} = 2\pi \int_0^R I(x,y) r dr = 2\pi \int_0^R \frac{2P}{\pi w^2} e^{-2r^2/w^2} r dr = P(1 - e^{-2R^2/w^2}) \ .$$

b. From

$$\frac{P_{tr}}{P} = 50\% = 1 - e^{-2R^2/w^2}$$

we get,

$$w = R\sqrt{\frac{-2}{\ln\left(1 - \frac{P_{tr}}{P}\right)}} = 1.7R \ .$$

With $R = \frac{1.22\lambda}{2\sin\theta} \simeq \frac{1.22\lambda}{2\theta}$ *we get,*

$$w = 1.7 \cdot \frac{1.22\lambda}{2\theta} = 1.7 \cdot \frac{1.22\lambda L}{2\Delta b} = 656\,\mu\text{m} \ .$$

51.2.3.11 Ex: Focusing a HeNe laser

The output beam from an HeNe laser with a confocal resonator ($\rho = L = 30\,\text{cm}$) is focused by a lens of $f = 30\,\text{cm}$, 50 cm away from the output mirror. Calculate the location of the focus, the Rayleigh length, and the beam waist in the focal plane.

Solution: *The transfer matrix for half a round trip in a confocal cavity,* $\rho = L$, *starting from the waist is,*

$$\mathcal{M}_{cav} = \begin{pmatrix} 1 & L/2 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -2/\rho & 1 \end{pmatrix} \begin{pmatrix} 1 & L/2 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & L/2 \\ -2/L & 0 \end{pmatrix} \ .$$

Self-consistency of the beam parameter $\frac{1}{q_0} = \frac{1}{R_0} - \imath\frac{\lambda}{\pi w_0^2} = -\imath/z_{R0}$ *requires,*

$$\imath z_{R0} = q_0 = \frac{M_{11}q_0 + M_{12}}{M_{21}q_0 + M_{22}} = -\frac{L}{2} - \frac{L^2}{4q(0)} = -\frac{L}{2} - \frac{L^2}{4\imath z_{R0}} \ .$$

The imaginary part of this equation yields the waist and Rayleigh length,

$$w_0 = \sqrt{\frac{\lambda L}{2\pi}} \approx 174\,\mu\text{m} \qquad \textit{and} \qquad z_{R0} = \frac{\pi w_0^2}{\lambda} \approx 15\,\text{cm} \ .$$

The beam diameter at the surfaces of the laser mirrors is,

$$w_{mir} = w_0\sqrt{1+\left(\frac{\lambda z}{\pi w_0^2}\right)^2} \approx 246\,\mu\text{m} \ .$$

To obtain the beam parameters at the location of the exterior focus we set up the transfer matrix,

$$\mathcal{M}_{ext} = \begin{pmatrix} 1 & d_2 \\ 0 & 1 \end{pmatrix}\begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix}\begin{pmatrix} 1 & d_1 \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1-d_2/f & d_1 - d_1d_2/f + d_2 \\ -1/f & 1-d_1/f \end{pmatrix} \ ,$$

with $d_1 = z_1 + L/2$ where $z_1 = 50\,\text{cm}$. The beam parameter is now,

$$q_2 = \frac{M_{11}q_0 + M_{12}}{M_{21}q_0 + M_{22}} = \frac{(f-d_2)q_0 + fd_1 - d_1d_2 + fd_2}{-q_0 + f - d_1} = \frac{(f-d_2)\imath z_{R0} + fd_1 - d_1d_2 + fd_2}{\imath z_{R0} + f - d_1} \ ,$$

with the real part,

$$0 = \mathfrak{Re}\ q_2 = \frac{(f-d_2)\imath z_{R0}\imath z_{R0} + (fd_1 - d_1d_2 + fd_2)(f-d_1)}{z_{R0}^2 + (f-d_1)^2}$$
$$\Longrightarrow d_2 = f\frac{z_{R0}^2 + d_1(d_1-f)}{z_{R0}^2 + (d_1-f)^2} \approx 51.72\,\text{cm} \ ,$$

and the imaginary part,

$$z_{R2} = \mathfrak{Im}\ q_2 = \frac{1}{\imath}\frac{(f-d_2)\imath z_{R0}(f-d_1) + (fd_1 - d_1d_2 + fd_2)\imath z_{R0}}{z_{R0}^2 + (f-d_1)^2} = \frac{f^2 z_{R0}}{z_{R0}^2 + (f-d_1)^2} \approx 9.3\,\text{cm}$$
$$\Longrightarrow w_2 = \sqrt{\frac{\lambda z_{R2}}{\pi}} \approx 137\,\mu\text{m} \ .$$

Note that classical ray optics would have predicted,

$$0 \simeq \frac{1}{d_1} + \frac{1}{d_2} - \frac{1}{f} \qquad \textit{and} \qquad w_2 \simeq w_1\frac{d_2}{d_1} \ ,$$

giving with $d_1 = z_1 + L/2$,

$$d_2 \simeq \frac{1}{\frac{1}{f} - \frac{1}{z_1 + L/2}} \approx 55.7\,\text{cm} \qquad \textit{and} \qquad w_2 = w_1\sqrt{\frac{d_2 - f}{d_1 - f}} \simeq w_1\frac{d_2}{d_1} \approx 149\,\mu\text{m}$$
$$\textit{and} \qquad z_R = \frac{\pi w_2^2}{\lambda} \approx 11\,\text{cm} \ .$$

51.2.3.12 Ex: Spatial filtering

A nearly parallel Gaussian beam with $\lambda = 500\,\text{nm}$ is expanded by a telescope with two lenses of focal lengths $f_1 = 1\,\text{cm}$ and $f_2 = 10\,\text{cm}$, illustrated in the figure. The

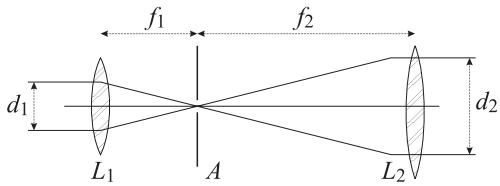

Figure 51.9: Beam-expanding telescope with an aperture in the focal plane.

spot size at the entrance lens is $w = 1\,\text{mm}$.
a. Why does an aperture in the focal plane improve the quality of the wave fronts in the expanded beam by eliminating perturbations due to diffraction effects by dust and other imperfections on the lens surfaces?
b. What is the diameter of this aperture, if 95% of the intensity is transmitted?

Solution: *a. Dust particles on the lens L_1 cause scattering of light in all directions. This light is not focused by L_1, and therefore only a tiny fraction can pass through the aperture. The same is true for imperfections of lenses or mirror surfaces. Without the aperture the superposition of scattered light or light with deformed wavefronts with the incident light causes interference patterns. The aperture therefore 'cleans' the Gaussian laser beam.*
b. The beam waist at the focus is

$$w_0 = \frac{f\lambda}{\pi w} = 1.59\,\mu\text{m} \ .$$

The power transmitted through the aperture with radius a is $P_t = P_i(1 - e^{-2a^2/w_0^2})$. For $P_t/P_i = 0.95$ we obtain $a = 1.95\,\mu\text{m} = 1.22 w_0$.

51.2.3.13 Ex: Transverse mode selection in an Ar laser

An argon laser oscillating at $\lambda = 488\,\text{nm}$ with resonator length $d = 100\,\text{cm}$ and two mirrors with radius $R_1 = \infty$ and $R_2 = 400\,\text{cm}$ has an intracavity circular aperture close to the spherical mirror to prevent oscillation on transversal modes. Estimate the maximum diameter of the aperture that introduces losses $\gamma_{diffr} < 1\%$ for the TEM_{00} mode, but prevents oscillation of higher transverse modes, which without the aperture have a net gain of 10%.

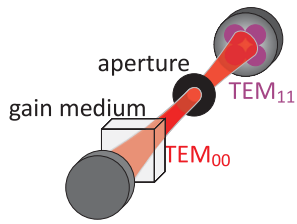

Figure 51.10: Transverse mode selection in an Ar laser.

Solution: *The transfer matrix for the resonator,*

$$\mathcal{M} = \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -2/\rho & 1 \end{pmatrix} \begin{pmatrix} 1 & d \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} 1 - \frac{2d}{\rho} & 2d\left(1 - \frac{d}{\rho}\right) \\ -\frac{2}{\rho} & 1 - \frac{2d}{\rho} \end{pmatrix}$$

transforms the beam parameter like,

$$q(0) = \frac{M_{11}q(0) + M_{12}}{M_{21}q(0) + M_{22}} = \frac{\left(1 - \frac{2d}{\rho}\right)\imath z_{R0} + 2d\left(1 - \frac{d}{\rho}\right)}{-\frac{2}{\rho}\imath z_{R0} + 1 - \frac{2d}{\rho}} = \imath z_{R0} = \imath\frac{\pi w_0^2}{\lambda} \ .$$

The imaginary part of this equation yields,

$$z_{R0}^2 = \rho d\left(1 - \frac{d}{\rho}\right)$$

or

$$w_0 = \sqrt{\frac{\lambda}{\pi}\sqrt{\rho d\left(1 - \frac{d}{\rho}\right)}} \approx 519\,\mu\text{m}$$

for the beam waist. The beam diameter at the exit mirror is then,

$$w_1 = w_0\sqrt{1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2} \approx 599\,\mu\text{m} \ .$$

The power transmitted through an aperture located at the exit mirror is,

$$P_{tr} = \int_0^{r_0} 2\pi I(r) r dr = 2\pi\frac{2P}{\pi w_1^2}\int_0^{r_0} e^{-2r^2/w_1^2} r dr = P\left(1 - e^{-2r_0^2/w_1^2}\right) \equiv P \cdot 99\% \ .$$

This gives $r_0 > w_1\sqrt{-\frac{1}{2}\ln 0.01} \approx 909\,\mu\text{m}$. *According to Demtröder, Fig. 5.12 the Fresnel number* N_F *should be smaller than* 0.8, *in order to increase the losses of the* TEM_{10} *mode above 10%. The Fresnel number is defined as,*

$$N_F = \frac{1}{\pi}\frac{\pi a^2}{\pi w_s^2} \ ,$$

where w_s *is the beam waist of the fundamental mode. Therefore,*

$$a^2 < 0.8 \cdot \pi w_s^2 \ ,$$

Yielding $a \leq 944\,\mu\text{m}$. *The radius of the aperture therefore must lie between* $a \in [904, 944]\,\mu\text{m}$.

51.2.3.14 Ex: Anamorphic prism

A prism can be used for expansion of a laser beam if the incident beam is nearly parallel to the prism surface. Calculate the angle of incidence α for which a laser beam transmitted through a rectangular glass prism with an $\varepsilon = 45°$ base angle is expanded tenfold.

Solution: *From the figure we see,*

$$\cos\varepsilon = \frac{d_2}{D} \qquad \textit{and} \qquad \cos\alpha = \frac{d_1}{D} \ .$$

Hence,

$$\frac{d_2}{d_1} = \frac{\cos\varepsilon}{\cos\alpha} \equiv 10 \ ,$$

or, for $\varepsilon = 45°$*,*

$$\alpha = \arccos\frac{\cos\varepsilon}{10} \approx 85.9° \ .$$

The incident beam has an angle of $90° - \alpha$ *against the prism surface. From this we can infer the required refractive index must be,*

$$n_{rfr} = \frac{\sin\alpha}{\sin\varepsilon} \approx 1.41 \ .$$

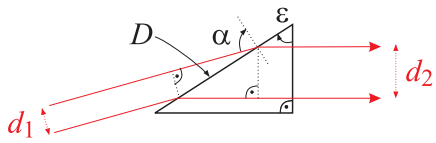

Figure 51.11: Beam expanding prism.

51.2.3.15 Ex: Anamorphic prism pair

An *anamorphic prism* pair is a setup consisting of two prisms through which a laser beam is passed under specific angles. The angles can be chosen such as to change the beam diameter only in the p-plane.
a. Calculate, for a single prism with refractive index $n = 1.5$, the beam expansion for an incidence angle of $\theta_1 = 57°$ and an exit angle of $0°$. How large must the base angle β of the prism be for this to be possible?
b. How must the second prism be aligned in order for the beam transmitted to this second prism to remain parallel to the incident beam? Note, that an anamorphic prism pair does not allow to correct for astigmatism. This requires cylindrical lenses.

Solution: *a. From Snell's law,*

$$n_{rfr} = \frac{\sin\theta_1}{\sin\theta_2} \ ,$$

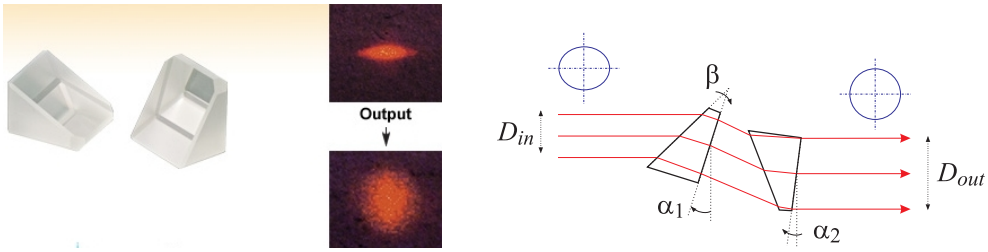

Figure 51.12: (Left) Anamorphic prisms (Thorlabs, PS870). (Right) Geometry of the beam transformation. The entrance side of a prism is often chosen close to the Brewster angle, while the exit side treated carries an anti-reflexion coating.

we derive,

$$\frac{d_2}{d_1} = \frac{\cos\theta_2}{\cos\theta_1} = \frac{\sqrt{1-\sin^2\theta_1/n_{rfr}^2}}{\sqrt{1-\sin^2\theta_1}} \approx 1.5 \ .$$

The base angle under the given condition should be,

$$\beta = \theta_2 = \arcsin(\sin\theta_1/n_{rfr}) \approx 34^\circ \ ,$$

which can be derived geometrically.
b. The incidence angle on the second (identical) prism is,

$$\theta_1' = 90^\circ - \alpha_2 - \beta \ .$$

From this xxx.

51.2.3.16 Ex: Beam steering with two wedged substrates

The wavevector of a laser beam is generally aligned with one or more adjustable reflective mirrors. Alternatively, one may use a pair of rotatable transmissive wedged substrates. Calculate the wave vector of a laser beam after its transmission through two $\epsilon = 3^\circ$ wedged, 2 mm thick, AR-coated substrates with the refraction index $n_{rfr} = 1.5134$ at 689 nm, each one rotated by $\theta_{1,2}$ from some normal position.

Solution: *We assume the incident beam parallel to the optical axis,* $\mathbf{k}_0 = k\hat{\mathbf{e}}_z$. *The normal vectors of the wedges (wedge angle* $\varepsilon = 3^\circ$*) are,*

$$\hat{\mathbf{e}}_{\perp 1} = \begin{pmatrix} \cos\theta_1 & \sin\theta_1 & 0 \\ -\sin\theta_1 & \cos\theta_1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \cos\varepsilon & 0 & \sin\varepsilon \\ 0 & 1 & 0 \\ -\sin\varepsilon & 0 & \cos\varepsilon \end{pmatrix} \begin{pmatrix} 0 \\ 0 \\ -1 \end{pmatrix} = \begin{pmatrix} -\sin\varepsilon\cos\theta_m \\ \sin\varepsilon\sin\theta_m \\ -\cos\varepsilon \end{pmatrix}$$

and $\hat{\mathbf{e}}_{\perp 2} = \begin{pmatrix} -\sin\varepsilon\cos\theta_2 \\ \sin\varepsilon\sin\theta_2 \\ \cos\varepsilon \end{pmatrix}$.

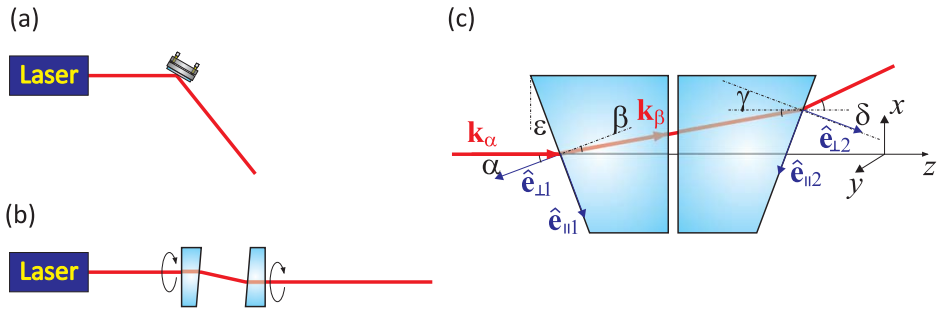

Figure 51.13: Beam steering with two rotatable wedged substrates (see Thorlabs, PS810).

We also define normal vectors in the direction where the refraction plane cuts the wedge surface,

$$\hat{\mathbf{e}}_{\parallel 1} = \frac{\hat{\mathbf{e}}_{\perp 1} \times (\hat{\mathbf{e}}_{\perp 1} \times \mathbf{k}_\alpha)}{|\hat{\mathbf{e}}_{\perp 1} \times (\hat{\mathbf{e}}_{\perp 1} \times \mathbf{k}_\alpha)|} \qquad \textit{and} \qquad \hat{\mathbf{e}}_{\parallel 2} = \frac{\hat{\mathbf{e}}_{\perp 2} \times (\hat{\mathbf{e}}_{\perp 2} \times \mathbf{k}_\gamma)}{|\hat{\mathbf{e}}_{\perp 2} \times (\hat{\mathbf{e}}_{\perp 2} \times \mathbf{k}_\gamma)|} \ .$$

The refraction of a wavevector at a tilted interface between air and a dielectric with

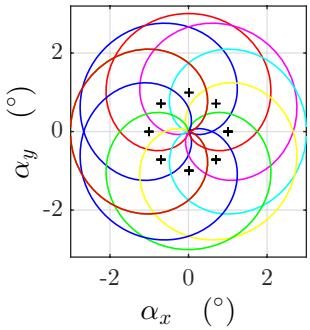

Figure 51.14: (code) Refraction angles that can be reached.

refractive index n_{rfr} follows Snell's law,

$$n_{rfr} = \frac{\sin\alpha}{\sin\beta} = \frac{\sin\delta}{\sin\gamma} \ ,$$

where the angles are given by,

$$\begin{aligned} \mathbf{k}_\alpha \cdot \hat{\mathbf{e}}_{\perp 1} &= -k\cos\alpha \quad , \quad \mathbf{k}_\beta \cdot \hat{\mathbf{e}}_{\perp 1} = -k\cos\beta \\ \mathbf{k}_\gamma \cdot \hat{\mathbf{e}}_{\perp 2} &= k\cos\gamma \quad , \quad \mathbf{k}_\delta \cdot \hat{\mathbf{e}}_{\perp 2} = k\cos\delta \ . \end{aligned}$$

With this we can derive coordinate-free notation,

$$\mathbf{k}_\beta = -\hat{\mathbf{e}}_{\perp 1} k\cos\beta - \hat{\mathbf{e}}_{\parallel 1} k\sin\beta \qquad \textit{where} \qquad \sin\beta = \frac{\sin\alpha}{n_{rfr}} = \frac{1}{n_{rfr}}\sqrt{1 - \frac{(\mathbf{k}_\alpha \cdot \hat{\mathbf{e}}_{\perp 1})^2}{k^2}} \ .$$

Concatenating two wedges by $\mathbf{k}_\gamma = \mathbf{k}_\beta$ *and,*

$$\mathbf{k}_\delta = -\hat{\mathbf{e}}_{\perp 2} k \cos\delta + \hat{\mathbf{e}}_{\parallel 2} k \sin\eta_2 \qquad \textit{where} \qquad \sin\delta = n_{rfr}\sin\gamma \equiv n_{rfr}\sqrt{1 - \frac{(\mathbf{k}_\gamma \cdot \hat{\mathbf{e}}_{\perp 2})^2}{k^2}}\,.$$

Fig. 51.14 shows the angles that can be reached after the first wedge by rotating θ_1 *(black curve) and after the second wedge by rotating* $\theta_{1,2}$ *(colored curves).*

51.2.4 *Experiment: Measuring the diameter of a Gaussian laser beam*

Most laser beams exhibit a Gaussian shape transverse intensity distribution, as we will study in this experiment.

1. Measure the phase profile of a helium-neon laser. To this end fix a razor blade on a translation stage and move it sideways into the beam. From the power of the partially blocked beam $\int_F I(x,y)dxdy$, where F is the cross section of the unblocked part of the beam, $w(z)$ can be determined (see Excs. 51.2.3.8 to 51.2.3.10).

Example 299 (*LOGaussian01*): Example for the experimental determination of a Gaussian beam. We fit the integral,

$$\frac{\tilde{P}}{P} = \int_{-\infty}^{\tilde{x}}\int_{-\infty}^{\infty} \frac{2}{\pi w(z)^2} e^{-2r^2/w(z)^2}\,dxdy \qquad (51.23)$$
$$= \frac{2}{\sqrt{\pi}w(z)^2}\int_{-\infty}^{\tilde{x}\sqrt{2}/w(z)} e^{-\xi^2}\,d\xi = \tfrac{1}{2}\left[\mathrm{erf}\left(\tfrac{\tilde{x}\sqrt{2}}{w(z)}\right)+1\right]$$

to the measured data by varying only $w(z)$.

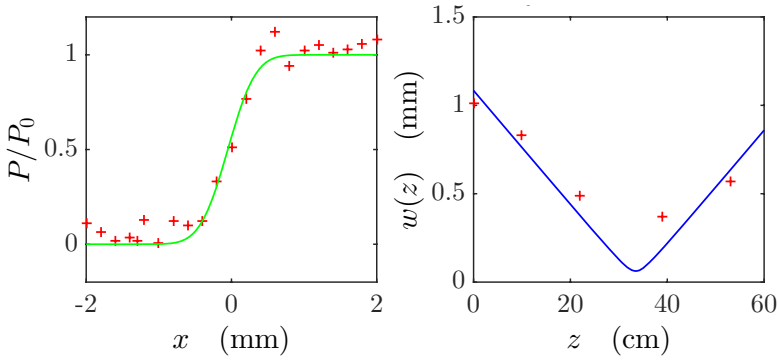

Figure 51.15: (code) (a) Adjustment of an error function for a measured beam profile. (b) Adjustment of a laser beam propagation using Gaussian optics.

51.2.5 *Experiment: Measuring the parameters of a Gaussian laser beam*

Once a Gaussian beam has been characterized at a given position z, the transfer matrix formalism allows us to calculate its shape at any position along the optical axis. In this experiment, we will study the propagation of a Gaussian beam through free space [see Eqs. (51.16)] and its transformation through a thin lens with focal distance f. For the latter one, we obtain directly after the lens,

$$\frac{1}{R(z \searrow 0)} = \frac{1}{R(z \nearrow 0)} - \frac{1}{f} \,. \tag{51.24}$$

1. Focus the beam with a lens. Measure the beam diameter at 3 different locations. Compare with the prediction of Gaussian optics.

2. Set up a 1:3 telescope and verify that the outgoing beam is collimated.

51.2.6 *Experiment: Spatial filtering with a pinhole*

Laser light emitted from diode lasers is often astigmatic and has an irregular beam profile. The beam profile can be purified by passing it through an optical fiber or a pinhole, however, at the price of losing power.

1. Focus the beam of a HeNe laser with a lens of $f = 100\,\text{mm}$ focal distance onto a pinhole. Observe the interference fringes and, from their distance from the optical axis, infer the diameter of the pinhole.

2. Remove the higher-order diffraction rings with an iris and compare the beam profile with that of a Gaussian beam. What are the divergence and the waist of the spatially filtered beam (see Exc. 51.2.3.10)?

51.3 Introduction to polarization optics

A laser usually has a well-defined polarization, e.g. , linear or circular. The polarizations can be transformed into one another through a *quarter waveplate* ($\lambda/4$) or a *half waveplate* ($\lambda/2$) by a Fresnel rhomb or other birefringent elements. Superpositions of polarizations can be separated by a *polarizing beam splitter*.

Waveplates consist of thin sheets of *birefringents crystal*s, which are transparent material characterized by anisotropic refraction indices. Cut in a particular way, a birefringent crystal can exhibit a polarization-dependent refraction index, allowing to control the retardation of a light beam as a function of its polarization. The thickness of a waveplate determines the retardation of one polarization axis with respect to the other.

In practice, the degree of freedom of polarization is often used for separating counterpropagating light fields, e.g. in ring lasers, by means of elements called *optical diode* or *optical isolator*, which consist of a Faraday rotator and $\lambda/2$ waveplate. Another practical example is the use of $\lambda/4$ in double passage. An incoming beam can be separated from a returning beam by using a $\lambda/4$ waveplate and a polarizing beam splitter.

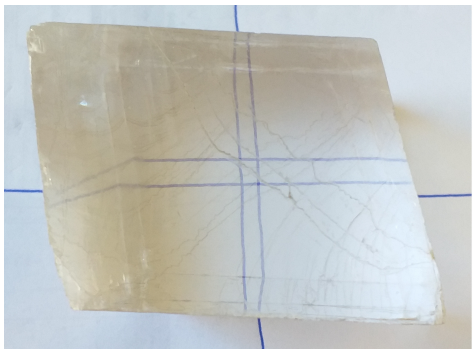

Figure 51.16: (Left) Transmission through a birefringent crystal. (Right) $\lambda/2$-waveplate mounted in a rotation stage.

51.3.1 Jones matrices

The term *polarization* is defined in relation to a fixed coordinate system, while the term *helicity* denotes the direction of rotation of the polarization vector with respect to the direction of propagation of the light beam. The polarization of a beam propagating in z-direction can easily be expressed by a vector of complex amplitude,

$$\vec{\mathcal{E}}(\mathbf{r},t) = \begin{pmatrix} a \\ b \\ 0 \end{pmatrix} e^{\imath kz - \imath\omega t} = \begin{pmatrix} 1 \\ e^{-\imath\phi}|b|/|a| \\ 0 \end{pmatrix} |a| e^{\imath kz - \imath\omega t} \ . \tag{51.25}$$

The angle $\phi = \arctan \frac{\mathfrak{Im}\ ab^*}{\mathfrak{Re}\ ab^*}$ determines the polarization of the light beam. A polarization is linear when $\phi = 0$ and circular when $\phi = \pi/2$. $|b|/|a|$ is, hence, the degree of ellipticity. A polarization rotator for linearly polarized light (e.g., a sugar solution) is described by the following *Jones matrix* (we will restrict to the x-y-plane)

$$M_{rotator}(\phi) = \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \ , \tag{51.26}$$

where ϕ is the rotation angle. For the Faraday rotator the sign of the rotation angle depends on the propagation direction of the laser beam. A *polarizer* projects the polarization onto a specific axis. In the case of the x-axis Jones matrix is,

$$M_{polarizer} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \ . \tag{51.27}$$

If the rotation angle is ϕ,

$$M_{polarizer}(\phi) = \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix}^{-1} \ . \tag{51.28}$$

Other components, such as electro-optical modulators or phase plates are birefringent crystals, which act only on one of the two optical axes. If only the y axis is optically

active, the Jones' matrix is,

$$M_{\theta\text{-waveplate}} = \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} . \tag{51.29}$$

For $\theta = 2\pi/n$ we obtain a λ/n-waveplate. When we rotate the waveplate and therefore the optically inactive axis to an angle ϕ, the Jones matrices are,

$$\begin{aligned} M_{\theta\text{-waveplate}}(\phi) &= \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix}^{-1} \\ &= \begin{pmatrix} \cos^2\phi + e^{\imath\theta}\sin^2\phi & -\sin\phi\cos\phi + e^{\imath\theta}\sin\phi\cos\phi \\ -\sin\phi\cos\phi + e^{\imath\theta}\sin\phi\cos\phi & \sin^2\phi + e^{\imath\theta}\cos^2\phi \end{pmatrix} . \end{aligned} \tag{51.30}$$

In most cases, we use quarter waveplates $\lambda/4$,

$$M_{\lambda/4}(\phi) = \begin{pmatrix} \cos^2\phi + \imath\sin^2\phi & (-1+\imath)\sin\phi\cos\phi \\ (-1+\imath)\sin\phi\cos\phi & \sin^2\phi + \imath\cos^2\phi \end{pmatrix} \tag{51.31}$$

and half waveplates $\lambda/2$,

$$M_{\lambda/2}(\phi) = \begin{pmatrix} \cos 2\phi & -\sin 2\phi \\ -\sin 2\phi & -\cos 2\phi \end{pmatrix} . \tag{51.32}$$

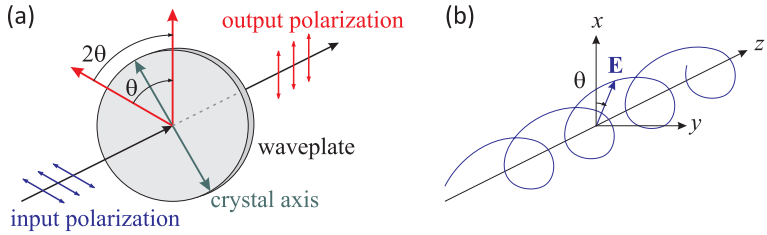

Figure 51.17: (a) Rotation of the polarization by a birefringent waveplate. (b) Illustration of a circularly polarized light wave.

Combinations of $\lambda/2$ waveplates and *Faraday rotator*s are used as *optical isolator*, also called *optical diode*.

51.3.2 Fresnel formulae

Reflection and transmission of a beam of light at a surface depend on the polarization of the light and the angle of incidence. They are described by the *Fresnel formula*:

$$\begin{aligned}
\left(\frac{I_{0t}}{I_{0i}}\right)_s &= T_s = \left(\frac{2\sin\theta_t\cos\theta_i}{\sin(\theta_i+\theta_t)}\right)^2 \\
\left(\frac{I_{0r}}{I_{0i}}\right)_s &= R_s = \left(-\frac{\sin(\theta_i-\theta_t)}{\sin(\theta_i+\theta_t)}\right)^2 \\
\left(\frac{I_{0t}}{I_{0i}}\right)_p &= T_p = \left(\frac{2\sin\theta_t\cos\theta_i}{\sin(\theta_i+\theta_t)\cos(\theta_i-\theta_t)}\right)^2 \\
\left(\frac{I_{0r}}{I_{0i}}\right)_p &= R_p = \left(\frac{\tan(\theta_i-\theta_t)}{\tan(\theta_i+\theta_t)}\right)^2 .
\end{aligned} \tag{51.33}$$

The angles of incidence and transmission are related by Snell's law: $n_1\sin\theta_i = n_2\sin\theta_t$.

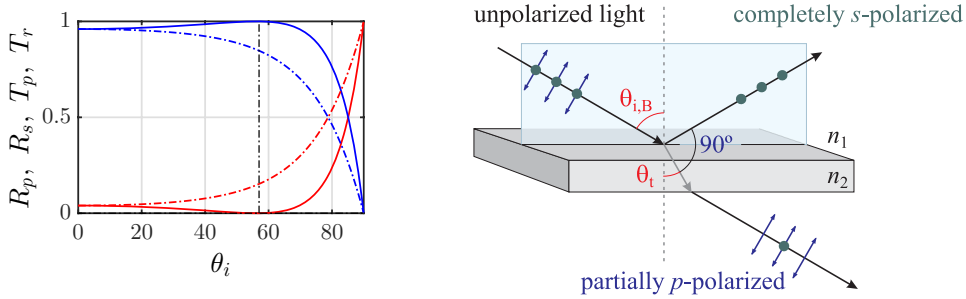

Figure 51.18: (code) (Left) Fresnel formulae showing the angular dependence of t_s (red solid), r_s (green dash-dotted), t_p (blue dashed), and r_p (cyan dotted) for reflection from and transmission through a piece of glass-air interface. (Right) Interfaces between optical media with different reflection indices can act like polarizers: Light reflected from a glas surface under the Brewster angle is completely s-polarized, while the transmitted light is partially p-polarized. The notation s comes from *senkrecht*, i.e. perpendicular to the plane spanned by the incident and reflected light beams, while p means *parallel* to this plane.

The *Brewster angle* $\theta_{i,B}$ is reached, when $\theta_{i,B}+\theta_t = 90°$, i.e., when following Snell's law,

$$n_1\sin\theta_{i,B} = n_2\sin(90°-\theta_{i,B}) = n_2\cos\theta_{i,B} . \tag{51.34}$$

Hence, the Brewster angle is given by,

$$\tan\theta_{i,B} = \frac{n_2}{n_1} . \tag{51.35}$$

Resolve the exercises 51.3.4.1 to 51.3.4.5.

51.3.3 Stokes parameters

In quantum mechanics the *Stokes parameters* of a light beam with horizontal and vertical polarizations, $\hat{a}_h$ and $\hat{a}_v$, satisfying,

$$[\hat{a}_k, \hat{a}_m^\dagger] = \delta_{km} \ , \tag{51.36}$$

with $k, m = h, v$ are defined by,

$$\boxed{\begin{aligned} \hat{S}_0 &\equiv \hat{a}_h^\dagger \hat{a}_h + \hat{a}_v^\dagger \hat{a}_v \\ \hat{S}_1 &\equiv \hat{a}_h^\dagger \hat{a}_h - \hat{a}_v^\dagger \hat{a}_v \\ \hat{S}_2 &\equiv \hat{a}_h^\dagger \hat{a}_v e^{\imath\theta} + \hat{a}_v^\dagger \hat{a}_h e^{-\imath\theta} \\ \hat{S}_3 &\equiv -\imath(\hat{a}_h^\dagger \hat{a}_v e^{\imath\theta} - \hat{a}_v^\dagger \hat{a}_h e^{-\imath\theta}) \end{aligned}} \ . \tag{51.37}$$

The Stokes parameters exhaustively describe the polarization state of a light beam. It is interesting, that the vector $\hat{\mathbf{S}}$ with components S_j with $j = 1, 2, 3$ satisfies the SU(2) spin algebra,

$$[\hat{S}_k, \hat{S}_m] = 2\imath\epsilon_{kmn}\hat{S}_n \qquad \text{and} \qquad \hat{\mathbf{S}}^2 = \hat{S}_0^2 + 2\hat{S}_0 \ , \tag{51.38}$$

as will be shown in Exc. 51.3.4.6. It is conveniently pictured on a Poincaré sphere or as a polarization ellipse. In the classical limit we get,

$$\begin{aligned} \hat{S}_0 &= I \\ \hat{S}_1 &= Ip\cos 2\psi \cos 2\chi \\ \hat{S}_2 &= Ip\sin 2\psi \cos 2\chi \\ \hat{S}_3 &= Ip\sin 2\chi \ , \end{aligned} \tag{51.39}$$

with I the light intensity (eventually normalized to the single-photon light intensity), the degree of polarization p. Obviously,

$$\hat{S}_1^2 + \hat{S}_2^2 + \hat{S}_3^2 = p^2 \hat{S}_0^2 \ . \tag{51.40}$$

51.3.4 Exercises

51.3.4.1 Ex: Light power control using polarization optics

The power of a laser beam can be regulated by a combination of a half-wave plate and a polarizing beam splitter. By how many degrees do you have to rotate the waveplate in order to reduce the light power by a factor of 2? Use the Jones matrices to justify your response. **Advice:** Look up the Jones matrices (51.32) and (51.27). Test your result in practice.

Solution: *The action of the optical components on the polarization is described by,*

$$\begin{pmatrix} E_x(z_1) \\ E_y(z_1) \end{pmatrix} = M_{pol} M_{\lambda/2}(\phi) \begin{pmatrix} E_x(z_0) \\ E_y(z_0) \end{pmatrix}$$
$$= \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \cos 2\phi & -\sin 2\phi \\ -\sin 2\phi & -\cos 2\phi \end{pmatrix} \begin{pmatrix} E_x(z_0) \\ E_y(z_0) \end{pmatrix} = \begin{pmatrix} \cos 2\phi & -\sin 2\phi \\ 0 & 0 \end{pmatrix} \begin{pmatrix} E_x(z_0) \\ E_y(z_0) \end{pmatrix} .$$

We assume an initially linear polarization $\mathbf{E}(z_0) = E_x(z_0)\hat{\mathbf{e}}_x$*, so that the initial intensity is* $I(z_0) \propto E_x(z_0)^2$*,*

$$\begin{pmatrix} E_x(z_1) \\ E_y(z_1) \end{pmatrix} = \begin{pmatrix} \cos 2\phi & -\sin 2\phi \\ 0 & 0 \end{pmatrix} \begin{pmatrix} E_x(z_0) \\ 0 \end{pmatrix} = \begin{pmatrix} E_x(z_0)\cos 2\phi \\ 0 \end{pmatrix} .$$

The final intensity is $I(z_1) = E_x^2(z_1) + E_y^2(z_1)$*. Hence,*

$$\frac{I(z_1)}{I(z_0)} = \cos^2 2\phi \equiv \frac{1}{2} ,$$

gives $\phi = 22.5°$*.*

51.3.4.2 Ex: Jones matrices

Consider a linearly polarized laser beam passing twice through a $\lambda/4$, first in direction of the optical axis, the second time in opposite direction. Calculate the final polarization.

Solution: *The propagation direction of the beam doesn't matter for the retardation. We can show* $M_{\lambda/4}(\phi)^2 = M_{\lambda/2}(\phi)$ *and* $M_{\lambda/4}(\pi/4) = \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}$.

51.3.4.3 Ex: Intensity transmitted through a polarizer

Unpolarized light of intensity I_0 is transmitted through a polarizer with thickness $d = 1\,\text{mm}$. Calculate the transmitted intensity when the absorption coefficients for the two polarizations are $\alpha_\parallel = 100\,\text{cm}^{-1}$ and $\alpha_\perp = 5\,\text{cm}^{-1}$.

Solution: *Using the Lambert-Beer law,* $I = I_0 e^{-\alpha d}$*, we have* $I_\parallel \approx 4.5 \cdot 10^{-5} I_0$ *and* $I_\perp \approx 0.6 I_0$*.*

51.3.4.4 Ex: Thickness of a half-waveplate

A birefringent quartz crystal is characterized by different refraction indices of the ordinary beam $n_o = 1.544$ and the extraordinary beam $n_e = 1.553$. Calculate the necessary thickness of a quartz waveplate to be used as a $\lambda/2$ retarder at 633 nm. Choose an appropriate waveplate from the Thorlabs catalogue. How thick would a

calcite waveplate ($n_o = 1.658$, $n_e = 1.486$)?

Solution: *The phase difference is,*

$$\phi = \frac{2\pi d(n_o - n_e)}{\lambda} \stackrel{!}{=} \pi \ .$$

Hence for quartz,

$$d = \frac{\lambda}{2(n_o - n_e)} \approx 35.2\,\mu\text{m} \ .$$

The waveplate WPHSM05-633 would be a good choice. For calcite we would have,

$$d = \frac{\lambda}{2(n_o - n_e)} \approx 1.84\,\mu\text{m} \ .$$

51.3.4.5 Ex: Faraday isolator

A Faraday rotator is a device exploiting the Faraday effect to rotate the polarization of a light beam according to the Jones matrix,

$$M_{Faraday}(\phi) = \begin{pmatrix} \cos\phi & -\mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi \\ \mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi & \cos\phi \end{pmatrix} \ , \tag{51.41}$$

where $\mathbf{k}$ is the wavevector of the light beam. An optical diode is composed by a $\phi = 45°$ Faraday rotor sandwiched between two polarizers rotated by $\phi = 45°$ with respect to each other.
a. How is the polarization of a light beam changed after a double passage (back and forth) through a Faraday rotator?
b. Calculate what happens to a light beam upon a single passage through a Faraday rotator in either direction $\mathbf{k}$ and $-\mathbf{k}$?

Solution: *a. The polarization is unchanged, since,*

$$\begin{pmatrix} \cos\phi & -\mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi \\ \mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} \cos\phi & \mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi \\ -\mathbf{k}\cdot\hat{\mathbf{e}}_z \sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} a \\ b \end{pmatrix} = \begin{pmatrix} a \\ b \end{pmatrix} \ .$$

b. We assume the entrance polarizer oriented along the $\hat{\mathbf{e}}_x$ axis and the exit polarizer rotated by 45°,

$$M_{in} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \qquad with \qquad M_{rot}(\phi) = \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix} \ ,$$

such that,

$$M_{out} = M_{rot}(\tfrac{\pi}{4}) M_{in} M_{rot}(\tfrac{\pi}{4})^{-1} = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix} \ .$$

Without loss of generality we assume the light to be initially polarized as $\hat{\varepsilon} = \hat{\mathbf{e}}_x$ *and the entrance polarizer transmissive. Then for a propagation in* $\mathbf{k}$*-direction,*

$$M_{out}M_{Faraday}M_{in}\begin{pmatrix}1 & 0\end{pmatrix} = \begin{pmatrix}\frac{1}{2} & \frac{1}{2}\\ \frac{1}{2} & \frac{1}{2}\end{pmatrix}\begin{pmatrix}\cos\frac{\pi}{4} & -\sin\frac{\pi}{4}\\ \sin\frac{\pi}{4} & \cos\frac{\pi}{4}\end{pmatrix}\begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}\begin{pmatrix}1\\ 0\end{pmatrix} = \begin{pmatrix}\frac{1}{\sqrt{2}}\\ \frac{1}{\sqrt{2}}\end{pmatrix} .$$

And for a propagation in $-\mathbf{k}$*-direction,*

$$M_{in}M_{Faraday}^{-1}M_{out}\begin{pmatrix}a\\ b\end{pmatrix} = \begin{pmatrix}1 & 0\\ 0 & 0\end{pmatrix}\begin{pmatrix}\cos\frac{\pi}{4} & \sin\frac{\pi}{4}\\ -\sin\frac{\pi}{4} & \cos\frac{\pi}{4}\end{pmatrix}\begin{pmatrix}\frac{1}{2} & \frac{1}{2}\\ \frac{1}{2} & \frac{1}{2}\end{pmatrix}\begin{pmatrix}a\\ b\end{pmatrix} = \begin{pmatrix}0\\ 0\end{pmatrix} .$$

51.3.4.6 Ex: Stokes parameters

For the Stokes parameters defined in (51.43) prove the following relationships,

$$[\hat{S}_k, \hat{S}_m] = 2\imath\epsilon_{kmn}\hat{S}_n \qquad \text{and} \qquad \hat{\mathbf{S}}^2 = \hat{S}_0^2 .$$

Solution: *We calculate using* $[\hat{a}_h, \hat{a}_h^\dagger] = 1 = [\hat{a}_v, \hat{a}_v^\dagger]$ *and* $[\hat{a}_v, \hat{a}_h^\dagger] = 0$*,*

$$\begin{aligned}[\hat{S}_1, \hat{S}_2] &= (\hat{a}_h^\dagger\hat{a}_h - \hat{a}_v^\dagger\hat{a}_v)(\hat{a}_h^\dagger\hat{a}_v e^{\imath\theta} + \hat{a}_v^\dagger\hat{a}_h e^{-\imath\theta}) - (\hat{a}_h^\dagger\hat{a}_v e^{\imath\theta} + \hat{a}_v^\dagger\hat{a}_h e^{-\imath\theta})(\hat{a}_h^\dagger\hat{a}_h - \hat{a}_v^\dagger\hat{a}_v)\\ &= \hat{a}_h^\dagger(\hat{a}_h\hat{a}_h^\dagger - \hat{a}_h^\dagger\hat{a}_h)\hat{a}_v e^{\imath\theta} + (\hat{a}_h^\dagger\hat{a}_h - \hat{a}_h\hat{a}_h^\dagger)\hat{a}_h\hat{a}_v^\dagger e^{-\imath\theta}\\ &\quad + \hat{a}_h^\dagger\left(\hat{a}_v\hat{a}_v^\dagger - \hat{a}_v^\dagger\hat{a}_v\right)\hat{a}_v e^{\imath\theta} + \hat{a}_h\hat{a}_v^\dagger e^{-\imath\theta}(\hat{a}_v^\dagger\hat{a}_v - \hat{a}_v\hat{a}_v^\dagger)\\ &= 2\hat{a}_h^\dagger\hat{a}_v e^{\imath\theta} - 2\hat{a}_h\hat{a}_v^\dagger e^{-\imath\theta} = 2\imath\hat{S}_3 ,\end{aligned}$$

and similarly for the other commutators. Also,

$$\begin{aligned}\hat{\mathbf{S}}^2 &= (\hat{a}_h^\dagger\hat{a}_h - \hat{a}_v^\dagger\hat{a}_v)^2 + (\hat{a}_h^\dagger\hat{a}_v e^{\imath\theta} + \hat{a}_v^\dagger\hat{a}_h e^{-\imath\theta})^2 - (\hat{a}_h^\dagger\hat{a}_v e^{\imath\theta} - \hat{a}_v^\dagger\hat{a}_h e^{-\imath\theta})^2\\ &= (\hat{a}_h^\dagger\hat{a}_h - \hat{a}_v^\dagger\hat{a}_v)^2 + 2\hat{a}_h^\dagger\hat{a}_v\hat{a}_v^\dagger\hat{a}_h + 2\hat{a}_v^\dagger\hat{a}_h\hat{a}_h^\dagger\hat{a}_v\\ &= (\hat{a}_h^\dagger\hat{a}_h + \hat{a}_v^\dagger\hat{a}_v)^2 + 2\hat{a}_h^\dagger\hat{a}_h + 2\hat{a}_v^\dagger\hat{a}_v = \hat{S}_0^2 + 2\hat{S}_0 .\end{aligned}$$

51.3.5 *Experiment: Polarization of a helium-neon laser*

We will now analyze and manipulate the polarization of a laser beam in practice.

1. Pass the beam of a helium-neon laser through a polarizer and a quarter- resp. half-waveplate. Analyze the polarization using a rotatable second polarizer for various rotation angles of the waveplate. Sketch the transmitted intensity as a function of the rotation angle of the beamsplitter in a polar diagram. How good can you achieve linear and circular polarization?

2. Characterize the polarization of a helium-neon laser by sketching the transmitted intensity through a polarizing beamsplitter as a function of the rotation angle of the beamsplitter in a polar diagram. Now couple the laser beam to a Fabry-Pérot interferometer. What do you observe? Place a quarter-waveplate at the output of the helium-neon laser and characterize again the polarization. What do you observe at the Fabry-Pérot interferometer?

3. Use a quarter-waveplate to separate a beam of light from a counterpropagating beam according to Fig. 51.19.

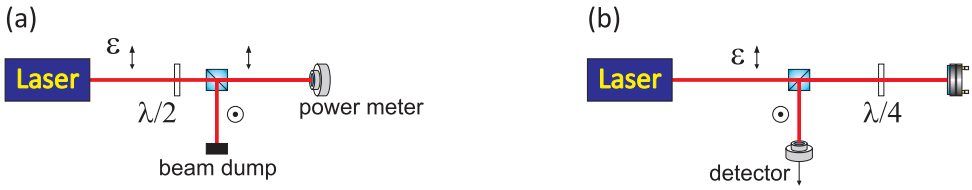

Figure 51.19: (a) Power control of a light beam and (b) separation of counterpropagating beams through polarization optics.

4. Characterize an optical insulator. Optimize its extinction.

51.3.6 *Experiment: Measuring the Brewster angle*

Any interface between two transparent materials with different refraction indices reflects a part of incident light depending on the polarization and the angle of incidence, as predicted by Fresnels formulae (51.33).

1. Measure the transmission by a glass plate as a function of the angle of incidence for two orthogonal polarizations and determine the Brewster angle.

2. Mirrors can change the polarization of a light beam and, for example, transform a linear polarization into elliptical. Determine the degree of ellipticity for a given mirror.

3. How does a mirror transform the polarization and the helicity of a reflected laser beam?

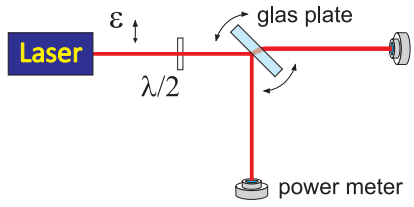

Figure 51.20: Measuring the Brewster angle by varying the tilt of a glas plate.

51.3.7 *Experiment: Pockels cell*

Pockels cells are birefringent crystals allowing to manipulate the polarization of a laser beam by application of a voltage.

1. Prepare a laser beam by passing it through a polarizer followed by a half-waveplate and a second polarizer. Observe the intensity transmitted and reflected through the last polarizer as a function of the rotation angle of the half-waveplate.

2. Use the EOM as a Pockels cell by placing it between the half-waveplate and the second polarizer. Supply a voltage between 0 V and 350 V to the EOM. Measures the intensity of reflected and transmitted light as a function of the supplied voltage and prepare a diagram. What do you observe when you rotate either the half-waveplate or the EOM?

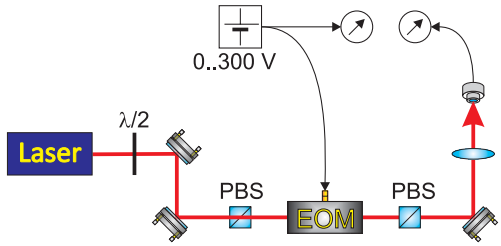

Figure 51.21: Scheme for using an EOM as a Pockels cell.

51.4 Laguerre-Gaussian light modes

Light beams not only possess polarization, but can also have orbital angular momentum. This property of light can impressively demonstrated at the so-called *Laguerre-Gaussian mode*s.

These modes can be produced by means of masks resembling *Fresnel zone plate*. Fresnel zone plates are masks consisting of concentric sequences of bright (transmitting) and dark (absorbing) rings. The diameters of the rings are selected in such a way that the diameters of the rings defined by the bright rings interfere constructively at a certain distance f_1 on the optical axis and form a 'focus' there. For this purpose, the distance d_n of the n^{th} ring must satisfy the condition,

$$d_n = \sqrt{(f_1 + n\lambda)^2 - f_1^2} \simeq \sqrt{2 f_1 n \lambda}\ . \tag{51.42}$$

For a given zone plate there are other focuses at smaller distances,

$$f_k = \frac{d_n^2 - k^2 n^2 \lambda^2}{2kn\lambda} \simeq \frac{d_n^2}{2kn\lambda} = \frac{f_1}{k}\ . \tag{51.43}$$

In order to separate the beams diffracted by the zone plate into a given focus from those diffracted into other focuses or not being diffracted at all, we pass the beam

through an iris diaphragm localized at the desired focus and recollimate the beam by means of a lens, as shown in Fig. 51.22.

The phase profile of the beam can be viewed interferometrically (see Fig. 51.22) by overlapping a plane wave laser beam. With a *neutral density filter* the intensities of the overlapping beams can be adjusted to maximize the contrast.

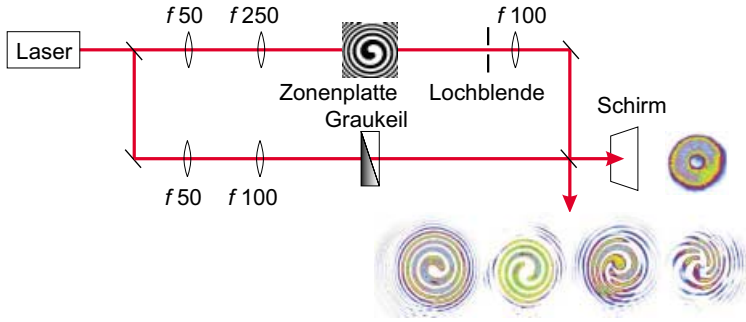

Figure 51.22: Creation of Laguerre-Gaussian modes.

Now, for realizing Laguerre-Gaussian light modes, we use Fresnel zone plates with spiral patterns, instead of concentric rings. In contrast to the Gaussian mode, the Laguerre-Gauß modes exhibit an intensity minimum on the optical axis (doonat mode). Their phase profiles can be viewed by interferometry [21].

51.4.1 *Experiment: Generating a Laguerre-Gaussian mode*

In this experiment, we will...

1. Construct the interferometer sketched in Fig. 51.22 using adequate Fresnel zone plates. What do you observe in the diffracted beam and in the interferogram, when instead of filtering the principal focus f_1 you filter a higher order focus?

2. Pass a Laguerre-Gauß laser beam through a $\lambda/2$ waveplate. How does the angular orbital momentum change when you change the rotation? What happens upon reflection from a mirror?

3. Slightly misalign the mode-matching between the Laguerre-Gauß beam and the Gaussian reference beam until you observe multiple fringes. What do you observe?

Chapter 52

Electronics and radiofrequency

For the control and regulation of important quantum optical devices, such as EOMs, AOMs, laser diodes, photodiodes, piezos etc., *electronic circuit*s are necessary. The aim of this chapter is to provide practical know-how in the basics of electronics.

52.1 Introduction to electronic circuits

52.1.1 Passive electronic components

Electronic components which are characterized by a fixed impedance are called *passive*. The most common devices are resistors, capacitors, and inductances. For their handling, it is useful to be able to identify their impedance from their labeling.

The values of the resistances of resistors are generally codified by colored rings. The first ring to be considered is the one closest to a terminal. In case of 4 rings, the first two rings are to be considered as digits, the third ring gives the exponent 10. With five rings, the first three are digits and the forth gives the exponent of 10. The last ring, in both cases specifies the tolerance of the value of the resistance.

There are various types of capacitors depending on the employed materials for the dielectric medium (paper, ceramics, polyester, electrolyte made of aluminum and electrolyte made of tantalum). Electrolyte capacitors have a defined polarity, and an reversion of their voltage supply can result in their explosion. The value of the capacitance is generally written on their body, as well as their maximum allowed operating voltage. Also the polarity of electrolyte capacitors is always indicated (although there can be some confusion with regard to the physical and technical direction of the current flow). Ceramic and polyester capacitors can have their values either written in letters or color coded. The color code sequence is similar to that of resistors, with the first two digits devoted to the digits, the third to the multiplier exponent, the forth to the tolerance, and the fifth for the maximum voltage. In case of printed numbers, the first two numbers represent the first two digits, and the third one represents the numbers of 0 before the decimal point. In all cases (colors or digits), the value is given in picoFarads. With more modern serigraphic techniques, some capacitors have their values printed directly in Farads (micro, nano and pico). In these cases, the letter denoting the unit also serves to mark the decimal point. For example, 2n2 means 2.2 nF.

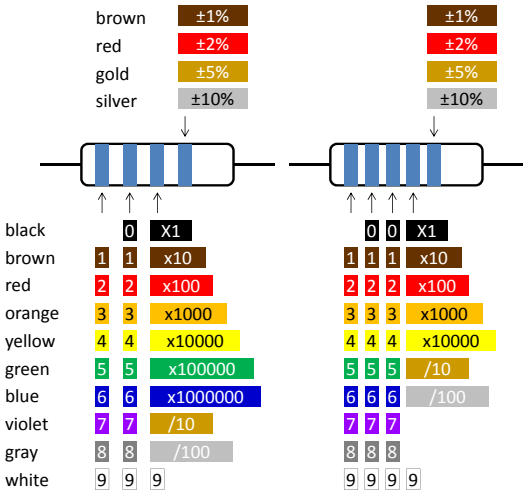

Figure 52.1: Color code for resistors with 4 and 5 rings.

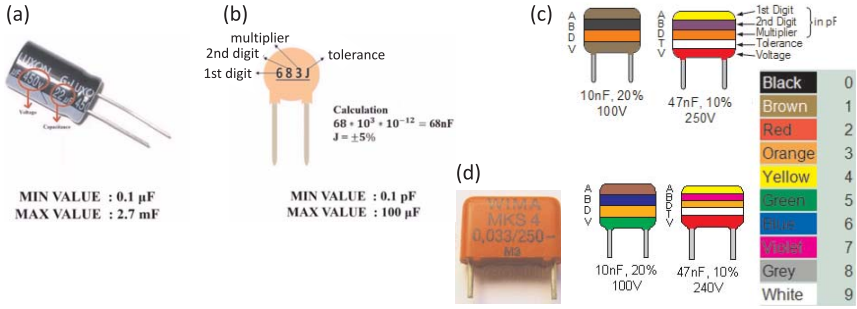

Figure 52.2: (Left) Electrolyte aluminum capacitors. (Center) Polyester capacitor and color code. (Right) Ceramic capacitor.

52.1.2 Active electronic components and the *pn*-junction

Diodes, transistors, photodiodes, operational amplifiers are called *active components*, because their current-to-voltage curve is non-linear, their response $I = I(U)$ cannot be described by a single constant value, but depends on the applied voltage.

During this course we will work a lot with *operational amplifiers* (OpAmp), which are integrated circuits designed to amplify input signals with characteristics that are entirely determined by external components. This feature makes them easy to use and extremely versatile.

OpAmps are generally found encapsulated in DIL type housings (dual in line), which means that they have two lines of 4 pins. The sequence of pins is numerated in counter-clockwise orientation, and they have a mark on the side of pin 1. It is always recommend to obtain the datasheet of the OpAmp since, despite a usual pin compatibility ensured by the various OpAmp manufacturers, deviations are frequent.

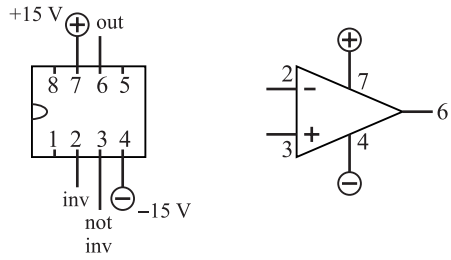

Figure 52.3: (Left) Schematic symbol of an OpAmp; (Right) Pin layout of a standard OpAmp.

52.1.3 Electronic circuits

Amplification or control circuits are nowadays mostly realized with *operational amplifiers* (*OpAmp*). The advantage of an OpAmp compared to circuits based on transistors is, that their properties are almost independent of their internal structure. Hence, their properties can be personalized via an external feedback realized with external components. The input of an OpAmp does not require current. OpAmps amplify the voltage difference between the non-inverting input (+) and the inverting (-). For most practical matters we can assume, that the OpAmp has infinite amplification and negligible input impedance.

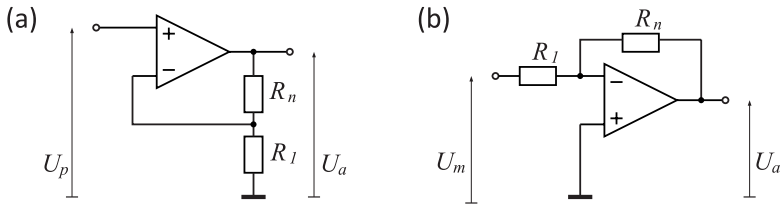

Figure 52.4: (Left) Principle scheme of a standard OpAmp. (Center) Non-inverting amplifier. (Right) Inverting amplifier.

OpAmps can be used as *inverting amplifiers* or *non-inverting amplifiers*. Using *Kirchhoff's rules* for the *loops* and *nodes* of the circuit, we find for a non-inverting amplifier,

$$\frac{U_e}{R_1} = -\frac{U_a}{R_1 + R_n} \quad , \quad G = 1 + \frac{R_n}{R_1} \; . \tag{52.1}$$

This becomes clear noting that, since no voltage is dropped between the inputs (+) and (-), the input voltage must be equal to the voltage drop at R_1. And since the non-inverting input does not deliver current, the currents traversing the resistances R_n and R_1 must be equal. For the inverting amplifier, we find,

$$\frac{U_a}{R_n} = -\frac{U_e}{R_1} \quad , \quad G = -\frac{R_n}{R_1} \; . \tag{52.2}$$

This becomes clear noting that, since the input (-) does not drag current, the currents traversing the resistances R_n and R_1 must cancel each other.

Changing the resistances R to inductances L or capacitances C, it becomes possible to influence the frequency response of the amplifying circuit. The impedance are,

$$Z_L = \imath L\omega \quad , \quad Z_C = \frac{1}{\imath C\omega} \ . \tag{52.3}$$

For the calculation of the amplification wit complex impedances, we just take the absolute value of the gain G.

52.1.4 The thermoelectric effect

52.1.4.1 Seebeck effect

The Seebeck effect is a classic example of an electromotive force (EMF) and leads to measurable currents or voltages in the same way as any other EMF. The local current density is given by,

$$\mathbf{J} = \sigma(-\nabla V + \mathbf{E}_{emf}) \ , \tag{52.4}$$

where V is the local voltage, and σ is the local conductivity. In general, the Seebeck effect is described locally by the creation of an electromotive field,

$$\mathbf{E}_{emf} = -S\nabla T \ , \tag{52.5}$$

where S is the Seebeck coefficient (also known as thermopower), a property of the local material, and ∇T is the temperature gradient.

The Seebeck coefficients generally vary as function of temperature and depend strongly on the composition of the conductor. For ordinary materials at room temperature, the Seebeck coefficient may range in value from $-100\,\mu\text{V/K}$ to $+1000\,\mu\text{V/K}$.

If the system reaches a steady state, where $\mathbf{J} = 0$, then the voltage gradient is given simply by the emf:

$$-V = S\Delta T \ . \tag{52.6}$$

This simple relationship, which does not depend on conductivity, is used in the thermocouple to measure a temperature difference; an absolute temperature may be found by performing the voltage measurement at a known reference temperature. A metal of unknown composition can be classified by its thermoelectric effect if a metallic probe of known composition is kept at a constant temperature and held in contact with the unknown sample that is locally heated to the probe temperature. It is used commercially to identify metal alloys. Thermocouples in series form a *thermopile*. Thermoelectric generators are used for creating power from heat differentials.

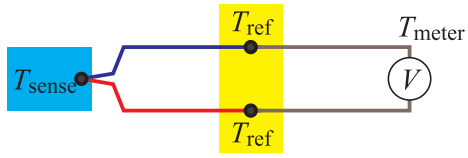

Figure 52.5:

52.1.4.2 Peltier effect

When an electric current is passed through a circuit of a thermocouple, heat is evolved at one junction and absorbed at the other junction. This is known as Peltier Effect and is named after a physicist. The Peltier effect is the presence of heating or cooling at an electrified junction of two different conductors. When a current is made to flow through a junction between two conductors, A and B, heat may be generated or removed at the junction. The Peltier heat generated at the junction per unit time is,

$$\dot{Q} = (\Pi_A - \Pi_B)I \ , \tag{52.7}$$

where Π_A and Π_B are the Peltier coefficients of conductors A and B, and I is the electric current (from A to B). The total heat generated is not determined by the Peltier effect alone, as it may also be influenced by Joule heating and thermal-gradient effects (see below).

The Peltier coefficients represent how much heat is carried per unit charge. Since charge current must be continuous across a junction, the associated heat flow will develop a discontinuity if Π_A and Π_B are different. The Peltier effect can be considered as the back-action counterpart to the Seebeck effect (analogous to the back-EMF in magnetic induction): if a simple thermoelectric circuit is closed, then the Seebeck effect will drive a current, which in turn (by the Peltier effect) will always transfer heat from the hot to the cold junction. The close relationship between Peltier and Seebeck effects can be seen in the direct connection between their coefficients [635, 1306]:

$$\Pi = TS \ . \tag{52.8}$$

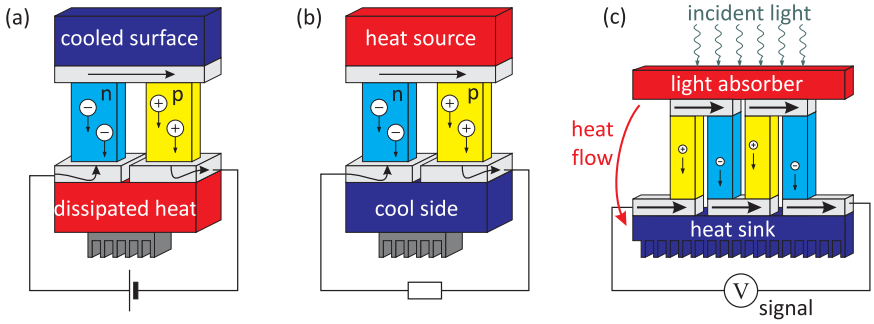

Figure 52.6: (a) Peltier cooler, (b) voltage generator or heat sensor, and (c) heat or radiation sensor with thermocouples connected in parallel.

52.1.5 Exercises

52.1.5.1 Ex: Integrator with operational amplifier

Based on the two golden rules for operational amplifiers, (1) $I_+ = I_- = 0$ A and (2) $U_+ = U_-$, show that the output voltage U_a at the integrated circuit shown in the figure is: $U_a = \frac{1}{RC} \int U_e dt$.

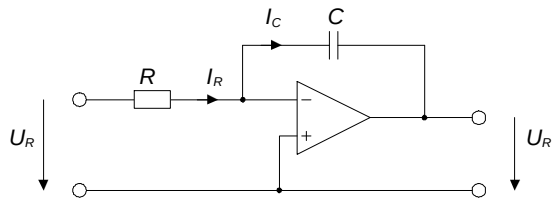

Figure 52.7: Integrator with operational amplifier.

Solution: *Using the golden rule, we get:*

$$U_e = RI_R \qquad \textit{and} \qquad I_R = I_C \qquad \textit{and} \qquad U_a = \frac{1}{C}\int I_C \; dt \; .$$

From this follows,

$$U_a = \frac{1}{RC}\int U_e \; dt \; .$$

52.1.5.2 Ex: Low-pass filter using an OpAmp

Using an inverting operational amplifier design a simple low-pass filter with a constant amplification of 10 at low frequencies and diminishing gain above 10 kHz. Calculate the Bode diagram (i.e. the frequency-dependent gain and phase-shift of your circuit. What is the gain reduction per octave?

Solution: *Choosing a circuit like in Fig. 52.3(b) with an impedance in parallel* $R_n = R_2 \parallel 1/\imath C\omega$*, we find a gain curve of,*

$$G(\omega) = -\frac{1}{\frac{1}{R_2} + \imath C\omega}\frac{1}{R_1} \; ,$$

that is,

$$|G(\omega)| = \frac{R_2}{R_1}\sqrt{\frac{1}{1+(R_2C\omega)^2}} \qquad \textit{and} \qquad \arctan\phi = \frac{\mathrm{Im}\;\; G(\omega)}{\mathrm{Re}\;\; G(\omega)} = -R_2C\omega \; .$$

The reduction per octave is,

$$\left|\frac{G(2\omega)}{G(\omega)}\right| = \sqrt{\frac{1+(2\omega R_2C)^2}{1+(\omega R_2C)^2}} \overset{\omega\to\infty}{\longrightarrow} 3\,\mathrm{dB} \; .$$

52.1.6 *Experiment: Amplifiers and active filters*

Here, we will learn how to use OpAmps: We will start mounting a 10-fold inverting amplifier on a breadboard and then modify the external passive components, such as to build a low-pass filter.

1. Assemble on a breadboard a simple inverting amplifier using an OpAmp. Use 10 kΩ resistors at the input aim for an amplification factor of 10.

2. Test the circuit with a frequency generator and an oscilloscope.

3. Modify the circuit such as to obtain a low-pass filter with $f_g = 50$ kHz bandwidth and test the circuit again.

52.1.7 *Experiment: Peltier element and thermistor*

Here, we will learn how to use a Peltier element and a thermistor. A *thermistor* is nothing else than a well-calibrated resistor with temperature-dependent resistance (see Fig. 52.9).

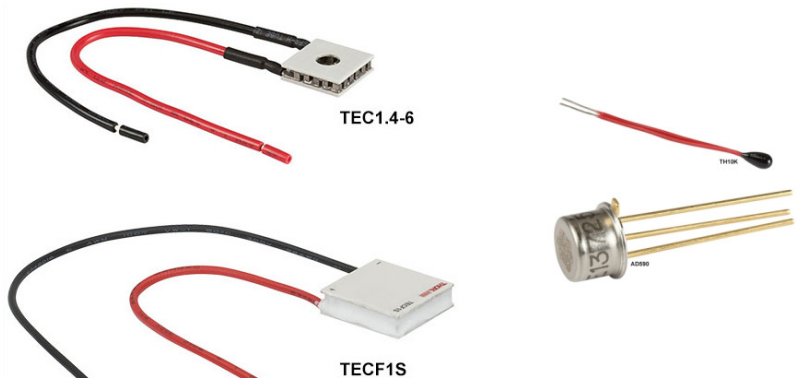

Figure 52.8: Pictures of Peltier elements, a thermistor, and an AD590 temperature transducer.

1. Connect a Peltier element to a 1 A current source and bring one of the two surfaces of the Peltier element into thermal contact with a heat sink. What do you observe?

2. Bring a 10 kΩ thermistor in thermal contact with either of the two surfaces of the Peltier element and measure its resistance. What do you observe?

3. Can you imagine a feedback logic evaluating the measured resistance in order to control the current applied to the Peltier element such as to maintain constant the temperature of the surface not connected to the heat sink.

52.2 Detectors

52.2.1 Photodiodes

Most active components are many of *semiconductor* characterized by a relatively large band gap between the valence band and the conduction band. By appropriate doping of the material with donors (p-type) or acceptors (n-type) a semiconductor can be made conductive. The most basic semiconductor element, which is the *diode* consists of a junction of two types of semiconductors, as shown in Fig. 52.10.

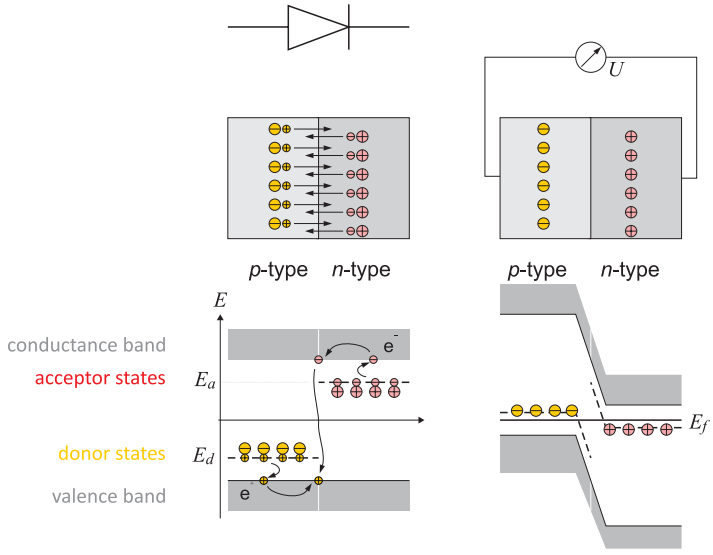

Figure 52.10: Joining a p-type and a n-type doped semiconductor (left) one observes a charge carrier redistribution across the pn transition (right).

Our first task will be to construct a *photo detector*. The central part of a photodetector is the photodiode. We have at our disposal silicium *pin*-photodiodes of the type C30822E of the company Perkin Elmer and of the type FFD100.

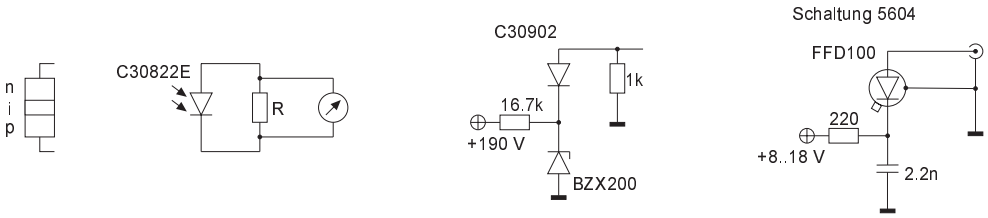

Figure 52.11: Circuit with photodiode.

Photodiodes exploit an intrinsic photoeffect of semiconductor *pn*-junctions. In the transition region, free electrons of the *n*-type semiconductor and excess holes of the *p*-type semiconductor are drifting into the respective opposite semiconductor, where they recombine. The consequence is a transition zone with a charge carrier depletion, which acts as a barrier and has an intrinsic capacitance. The charge carrier imbalance gives rise to an electric field across the junction. The energy liberated during the recombination process can be dissipated via emission of light.

The reverse process is also possible: Via the intrinsic photoeffect, light irradiated into the *pn*-junction can lift electrons from the valence into the conduction band, thus generating pairs of charge carriers. Under the influence of the electric field across the junction, the holes flow to the edge of the p domain and the electrons flow to the n domain. This part of the current is called *drift current*. A smaller part, called the *diffusion current*, has its origin in the diffusion of the electron-hole pairs formed in the edge regions. Since these minority charge carriers have only a limited lifetime before they recombine, only the part of the current generated within a few units of the diffusion lengths near the charge carrier zone contributes. This results in an external photovoltaic voltage at the electrodes of the photodiode. If the photodiode is connected to a load, a photocurrent will flow, which is composed, as mentioned above, by the drift current of the charge carrier zone and the diffusion current from its edges.

The principal scheme of a pin diode is illustrated in Fig. 52.12(left): A weakly doped intrinsic layer separates the p and the n conductor. This reduces the capacity of the barrier. The current at short circuit is proportional to the light power. A photodiode is always operated in blocking direction. A negative offset voltage reduces the capacity of the *pn*-junction.

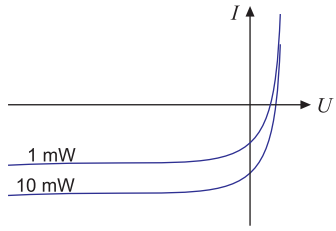

Figure 52.12: (code) U-I dependence of a photodiode.

Despite all measures the *pn*-junction capacity remains finite. One can model the impact of the *pn*-junction capacity via a replacement diagram. The voltage drop is

$$\frac{U(\omega)}{U_0} = \frac{R_L||\frac{1}{\imath\omega C}}{R_i + \left(R_L||\frac{1}{\imath\omega C}\right)} = \frac{\frac{R_i||R_L}{R_i}}{1+\imath\omega C(R_i||R_L)} \ . \tag{52.9}$$

For high load resistances the frequency response obviously becomes load-independent. For small loads, $R_L < R_i$, the band width of the photodiode is dramatically increased to $\omega_g = 1/R_L C$. In the same time, however, the amplification drops to $V = R_L/R_i$.

52.2.2 Exercises

52.2.2.1 Ex: Photomultiplier

The anode of a photomultiplier tube is connected by a resistor of $R = 1\,\mathrm{k\Omega}$ to ground. The stray capacitance is 10 pF, the current amplification 10^6, and the anode rise time 1.5 ns. What is the peak amplitude and the halfwidth of the anode output pulse produced by a single photoelectron? What is the dc output current produced by 10^{-12} W cw radiation at $\lambda = 500\,\mathrm{nm}$, if the quantum efficiency of the cathode is $\eta = 0.2$ and the anode resistor $R = 10^6\,\Omega$? Estimate the necessary voltage amplification of a preamplifier (a) to produce 1 V pulses for single-photon counting; and (b) to read 1 V on a dc meter of the cw radiation?

Solution: *The anode voltage pulse is,*

$$U_a(t) = \frac{Q(t)}{C} = \left(\frac{1}{C}\int_0^{\Delta t} i_{ph}(t)dt\right)\cdot e^{-t/RC} \ .$$

a. The time constant $\tau = RC = 10^{-8}\,\mathrm{s}$, which governs the decay of the voltage at C, is long compared with the rise time $\Delta t = 1.5\,\mathrm{ns}$. Therefore we can neglect the decay during the rise time and obtain for the pulse maximum,

$$U_a = \frac{1}{C}\cdot 10^6 e = \frac{1}{C}\cdot 1.6\cdot 10^{-13}\,\mathrm{C}$$

with $C = 10^{-11}\,\mathrm{F}$ we obtain $U_a(t) = 1.6\cdot 10^{-2}\cdot e^{-t\cdot 10^8}\,\mathrm{V}$. The peak amplitude is $U_{max} = 16\,\mathrm{mV}$. The halfwidth of the pulse is obtained from $e^{-10^8 t} = \frac{1}{2}$, yielding $\Delta t_1 = 6.9\cdot 10^{-9}\,\mathrm{s}$.
b. For $P = 10^{-12}\,\mathrm{W}$ cw radiation power at $\lambda = 500\,\mathrm{nm}$, the number of photoelectrons per second is,

$$n_{PE} = \eta\frac{P}{h\nu} = 4.5\cdot 10^5\,\mathrm{s^{-1}} \ .$$

With an amplification factor M, the anode current is: $i_a = n_{PE}\cdot e\cdot M$. The voltage across the anode resistor R is $U_a = i_a R = R n_{PE} e M = 72\,\mu\mathrm{V}$. Note that for cw measurements, a larger resistance of $R \approx 1\,\mathrm{M\Omega}$ is used, because the time resolution is not important here. For $R = 10^6\,\Omega$, we get $U_a = 72\,\mathrm{mV}$. In order to produce 1 V output pulses for single photoelectrons, an amplification of $M_2 \approx 62$ of the preamplifier is required.

52.2.2.2 Ex: Optical image intensifier

A manufacturer of a two-stage optical image intensifier states that incident intensities of $10^{-17}\,\mathrm{W}$ at $\lambda = 500\,\mathrm{nm}$ can still be 'seen' on the phosphor screen of the output state. Estimate the minimum intensity amplification, if the quantum efficiency of the cathodes and the conversion efficiency of the phosphor screens are both 0.2 and the collection efficiency of light emitted by the phosphor screens is 0.1. The human eye needs at least 20 photons/s to observe a signal.

Solution: *For* $10^{-17}\,\mathrm{W}$ *at* $\lambda = 500\,\mathrm{nm}$, $25\,\mathrm{photons/s}$ *fall onto the first cathode. The human eye can see* $20\,\mathrm{photons/s}$, *which corresponds to* $8 \cdot 10^{-18}\,\mathrm{W}$. *With a collection efficiency of* 0.1 *the last phosphor screen has to emit at least* $8 \cdot 10^{-17}\,\mathrm{W}$. *With a conversion efficiency of 0.2, the intensity amplification has to be*

$$V_I = \frac{8 \cdot 10^{-17}}{1 \cdot 10^{-17} \cdot 0.23} = 1000 \ .$$

52.2.2.3 Ex: Photovoltaic detector

Estimate the maximum output voltage of an open photovoltaic detector at room temperature under $10\,\mu\mathrm{W}$ irradiation when the photocurrent of the shortened output is $50\,\mu\mathrm{A}$ and the dark current is $50\,\mathrm{nA}$.

Solution: *With* $I_{ph} = 50\,\mu\mathrm{A}$ *and* $I_d = 50\,\mathrm{nA}$ *we get,*

$$U_{ph}(I = 0) = \frac{k_B T}{e}\left[\ln\left(\frac{I_{ph}}{I}\right) + 1\right] = 0.2\,\mathrm{V} \ .$$

52.2.3 *Experiment: Taking the response function of a photodiode*

In this part of the lab course, we will learn to solder and set up simple electronic circuits. We will also learn how to identify the connections of a photodiode and mount into a case with BNC connectors. Finally, we will characterize the photodiode for use in future applications. Initially, we will work without offset voltage, later we will apply a voltage and identify its impact [1].

1. Connect an LED to a function generator and make it blink at low frequencies adjusting the offset and the amplitude of the output voltage. Shine the light onto your photodiode and monitor the signal on an oscilloscope. Explain your observations.

[1] Datasheet for the Photodiode FFD100 see appendix Fig. 56.21,
data sheet for the Photodiode C30822E see appendix Fig. 56.22.

2. Reduce the amplitude and adjust the offset until you observe a sinusoidal signal. Increase the frequency and explain your observations. (Note that the response of LEDs is extremely fast (MHz).) Determine the bandwidth of your detector.

3. Measure the current at short circuit. Connect a $R = 10\,\mathrm{k\Omega}$ resistive load in parallel to the photodiode output and measure the voltage drop into this load.

4. Characterize the photodetector with respect to its sensitivity (in A/W) by varying the load.

5. How is the frequency response of the photodiode modified by the load? Measure bandwidth as a function of the load. Adjust the load until the detector (circuit including photodiode and resistor) has a bandwidth of 10 kHz (which is sufficient for many applications).

6. Apply a 10 V voltage in reverse direction and analyze again the sensitivity and the bandwidth of your photodetector. Note that the blinking LED can be replaced by a rotating chopper wheel.

Example of a measured characterization of a photodiode.

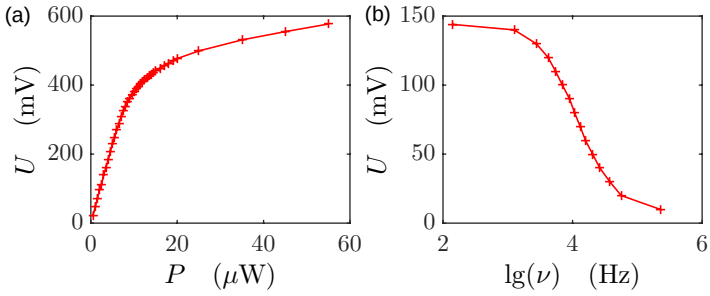

Figure 52.13: (a) Calibration of a photodiode, measured voltage as a function of the incident light power. (b) Low-pass behavior of a resistive charge of 90 kΩ.

52.3 Introduction to radiofrequency components

52.3.1 VCOs and the generation of rf-sidebands

Voltage-controlled oscillators (*VCO*) serve to generate variable radiofrequencies. They are the basis for most function generators. A useful particularity of VCOs is the possibility modulate the frequency and phase of an optical carrier wave by modulating the control voltage of a VCO at low frequency.

The modulation of the carrier wave generates sidebands. This can be seen by expanding the signal which carries the phase modulation into a Fourier series,

$$Ae^{\imath\omega t+\imath\beta\sin\Omega t} = Ae^{\imath\omega t}\sum_{k=-\infty}^{\infty} J_k(\beta)e^{\imath k\Omega t} \simeq Ae^{\imath\omega t} + J_1(\beta)Ae^{\imath\omega t+\imath\Omega t} + J_{-1}(\beta)Ae^{\imath\omega t-\imath\Omega t} \tag{52.10}$$

when the *modulation index* β is small. Here, $J_{-k}(\beta) = (-1)^k J_k(\beta)$ are the Bessel functions. This is in contrast to amplitude modulation, which is described by only two symmetric sidebands,

$$A(1 + \beta \sin \Omega t)e^{\imath\omega t} = Ae^{\imath\omega t}\left(1 + \frac{\beta}{2\imath}(e^{\imath\Omega t} - e^{-\imath\Omega t})\right) . \tag{52.11}$$

For *amplitude modulation* (*AM*) the beat signals between the carrier frequency and the two sidebands are in phase, i.e.,

$$\left|e^{\imath\omega t} + e^{\imath(\omega\pm\Omega)t}\right|^2 = 2 + e^{\imath\Omega t} + e^{-\imath\Omega t} . \tag{52.12}$$

For *phase modulation* (*PM*) the beat signal are in counter-phase, i.e.,

$$\left|e^{\imath\omega t} + e^{\imath(\omega\pm\Omega)t+\imath\pi/2}\right|^2 = 2 + \imath e^{\pm\imath\Omega t} - \imath e^{\mp\imath\Omega t} . \tag{52.13}$$

In the case of AM, the amplitude is blurred, but the phase at zero-crossing is well defined. In the case of PM, the amplitude in the antinode is sharp, but the phase of the zero-crossing is blurred.

It is not easy to transform AM into PM, and vice versa. In fact, the phase between carrier and sidebands can be varied, for example by adding an AC voltage, $\sqrt{2}e^{\imath\omega t+3\imath\pi/4}$ to the signal; however, it is not easy to transform synchronized phases into opposite phases.

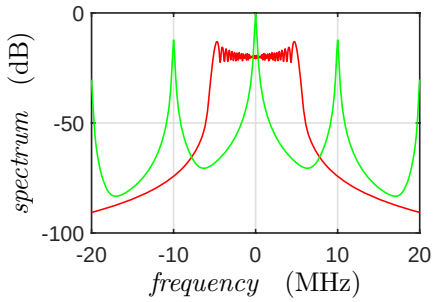

Figure 52.14: (code) Frequency spectra of a phase-modulated carrier frequency for $\Delta\omega = 5\,\text{MHz}$ modulation excursion and (red) $\omega = 100$ kHz modulation frequency ($\beta = \frac{\Delta\omega}{\Omega} = 50$) and (green) $\omega = 10\,\text{MHz}$ modulation frequency ($\beta = 0.5$). Furthermore, a $\gamma = 100\,\text{kHz}$ resolution linewidth is assumed.

As shown in Eq. (52.10), the spectrum of a signal with phase modulation (PM) consists of discrete lines, called sidebands, whose amplitudes are given by Bessel functions,

$$S(\omega) = \sum_{k=-\infty}^{\infty} |A\mathcal{J}_k(\beta)|^2 \delta(\omega + k\Omega) . \tag{52.14}$$

In real systems, the sidebands have finite widths γ due to frequency noise or the finite resolution of the detectors. In the case of Lorentzian line profiles, we have,

$$S(\omega) = \sum_{k=-\infty}^{\infty} |A\mathcal{J}_k(\beta)|^2 \frac{\beta^2}{(\omega - k\Omega)^2 + \beta^2} . \tag{52.15}$$

52.3.2 Mixers

A *frequency mixer* is a nonlinear electrical circuit that creates new frequencies from two input signals, e.g. the sum and difference of the input frequencies. A device that has a non-linear (e.g. exponential) characteristic can act as a mixer. Passive mixers use one or more diodes and rely on their non-linear relation between voltage and current. Active mixers use an amplifying device (such as a transistor) to increase the strength of the product signal.

Mixers may be classified by their topology: An unbalanced mixer, in addition to producing a product signal, allows both input signals to pass through and appear as components in the output. A single-balanced mixer is arranged with one of its inputs applied to a balanced (differential) circuit so that either the local oscillator (LO) or signal input (RF) is suppressed at the output, but not both. A double-balanced mixer has both its inputs applied to differential circuits, so that neither of the input signals and only the product signal appears at the output. Double balanced mixers are more complex and require higher drive levels than unbalanced and single-balanced designs.

In practice, mixers are widely used to shift signals from one frequency range to another, a process known as *heterodyning*, in order to facilitate signal transmission or further signal processing. Frequency mixers are also used to modulate a carrier signal in radio transmitters, as product detectors, phase detectors, or frequency multipliers.

52.3.2.1 Diode

The non-linearity (or non-Ohmic behavior) of a diode can be used to create a simple unbalanced mixer producing the original frequencies as well as their sum and their difference. The current I through an ideal diode as a function of the voltage U across it is given by an exponential function,

$$I = I_0(e^{qU/k_BT} - 1) \ . \tag{52.16}$$

The exponential can be expanded as $e^x - 1 \simeq x + \frac{x^2}{2}$. Suppose that the sum of the two input signals $U_1 + U_2$ is applied to a diode, and that an output voltage is generated that is proportional to the current through the diode [e.g. by providing the voltage that is present across a resistor in series with the diode, as shown in Fig. 52.15(a)]. Then, disregarding the constants in the diode equation, the output voltage will have the form,

$$\begin{aligned} U_0 &= (U_1 + U_2) + \tfrac{1}{2}(U_1 + U_2)^2 + ... \\ &= (U_1 + U_2) + \tfrac{1}{2}(U_1^2 + 2U_1U_2 + U_2^2) + ... \ . \end{aligned} \tag{52.17}$$

The ellipsis represents all the higher powers of the sum which we assume to be negligible for small signals.

Suppose that two input sinusoids of different frequencies, $U_1 = \sin\omega_1 t$ and $U_2 = \sin\omega_2 t$ are fed into the diode. The signal U_0 becomes:

$$U_0 = (\sin\omega_1 t + \sin\omega_2 t) + \tfrac{1}{2}(\sin^2\omega_1 t + 2\sin\omega_1 t \sin\omega_2 t + \sin^2\omega_2 t) + ... \ . \tag{52.18}$$

Ignoring all terms except for the $\sin\omega_1 t \sin\omega_2 t$ term we get,

$$U_0 = 2\sin\omega_1 t \sin\omega_2 t + ... = \cos(\omega_1 t - \omega_2 t) - \cos(\omega_1 t + \omega_2 t) + ... \ , \tag{52.19}$$

demonstrating how new frequencies are created from the mixer.

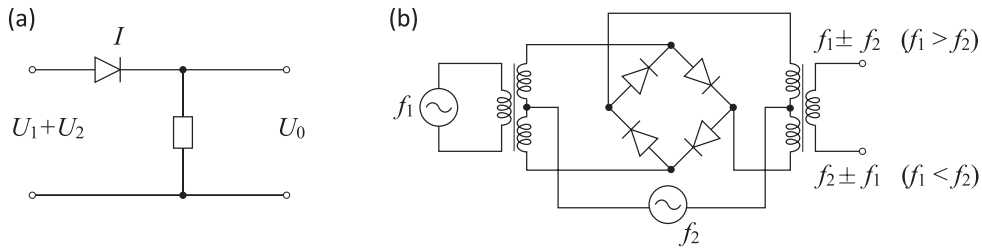

Figure 52.15: (a) Mixing two signal at a diode. (b) Schematic diagram of a double-balanced passive diode mixer (also known as a ring modulator). There is no output unless both f_1 and f_2 inputs are present, though f_2 (but not f_1) can be DC.

52.3.2.2 Switching

Another form of mixer operates by switching, with the smaller input signal being passed inverted or non-inverted according to the phase of the local oscillator (LO). This would be typical of the normal operating mode of a packaged double balanced mixer, with the local oscillator drive considerably higher than the signal amplitude.

The aim of a switching mixer is to achieve linear operation over the signal level by means of hard switching, driven by the local oscillator. Mathematically, the switching mixer is not much different from a multiplying mixer. Instead of the LO sine wave term, we would use the signum function. In the frequency domain, the switching mixer operation leads to the usual sum and difference frequencies, but also to further terms, e.g. $\pm 3f_{LO}$, $\pm 5f_{LO}$, etc.. The advantage of a switching mixer is that it can achieve (with the same effort) a lower noise figure and larger conversion gain. This is because the switching diodes or transistors act either like a small resistor (switch closed) or large resistor (switch open), and in both cases only a minimal noise is added. From the circuit perspective, many multiplying mixers can be used as switching mixers, just by increasing the LO amplitude.

52.3.2.3 Modulation and demodulation

Mixers are often used for modulation or demodulation purposes. Suppose we have on one hand a *carrier* signal, $U_{carrier} = \cos \omega t$, also called *local oscillator*. This may be a constant radiofrequency emitted by an antenna or a microwave. On the other hand, we have a reference signal which we want to transport somewhere else, $U_{ref} = \cos \Omega t$. Used as a modulator the mixer will simple multiply,

$$U_{mod} = U_{carrier} U_{ref} = \cos \omega t \cos \Omega t = \tfrac{1}{2} \cos[(\omega - \Omega)t] + \tfrac{1}{2} \cos[\omega + \Omega)t] \; . \qquad (52.20)$$

Thus the mixer output contains two frequencies, the sum and the difference. Supposing that ω is a frequency in a range that can be radiated by antenna and Ω an acoustic frequency, both frequency components $\omega \pm \Omega \simeq \omega$ will be radiated.

On the side of the receiver, who also has access to a synthesizer generating a signal $U_{carrier} = \cos \omega t$, we will use the mixer as a demodulator,

$$U_{demod} = U_{carrier} U_{mod} = \cos^2 \omega t \cos \Omega t = \tfrac{1}{2}(\cos 2\omega t + 1) \cos \Omega t \; . \qquad (52.21)$$

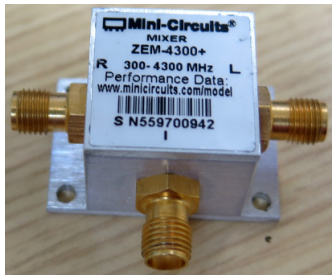

Figure 52.16: Picture of a radiofrequency mixer.

If $\omega \gg \Omega$, the carrier oscillation can easily be removed by a low-pass filter,

$$U_{filtered} = \tfrac{1}{2}\cos\Omega t \propto U_{ref} \ . \tag{52.22}$$

That is, we recover the original information. And this holds even when the reference signal is (slowly) varying in amplitude or frequency, such as in the case of an acoustic signal [2]. Resolve Exc. 52.3.3.1.

52.3.2.4 Filtering with a mixer

Suppose we have a signal containing many frequency components (which may vary slowly in time), $U_{noisy}(t) = \sum_n A(\omega_n)e^{\imath\omega_n t}$ in complex notation, and that the signal we are interested in is an amplitude at a known particular frequency ω_0. By demodulating,

$$U_{sig}(t) = U_{noisy}(t)e^{-\imath\omega_0 t} = \sum_n A(\omega_n)e^{\imath\omega_n t}e^{-\imath\omega_0 t} = \sum_n A(\omega_n)e^{\imath(\omega_n-\omega_0)t} \ , \tag{52.23}$$

and low-pass filtering the lowest frequency component, i.e. $\omega_n - \omega_0 \simeq 0$,

$$U_{filtered} = A(\omega_0) \ . \tag{52.24}$$

This even holds for continuous noise spectra, $U_{noisy}(t) = \int A(\omega)e^{\imath\omega t}d\omega$, since,

$$U_{sig}(t) = U_{noisy}(t)e^{-\imath\omega_0 t} = \int_{-\infty}^{\infty} A(\omega)e^{\imath\omega t}e^{-\imath\omega_0 t}d\omega = \int_{-\infty}^{\infty} A(\omega+\omega_0)e^{\imath\omega t}d\omega \ , \tag{52.25}$$

and low-pass filtering with a filter bandwidth $\Delta\omega$,

$$U_{filtered} = \int_{-\Delta\omega}^{\Delta\omega} A(\omega+\omega_0)e^{\imath\omega t}d\omega \simeq A(\omega_0)2\Delta\omega \ . \tag{52.26}$$

Such techniques are widely used in lock-in amplifiers (see Sec. 52.4.3).

[2] In complex notation, $U_{in} = e^{\imath\omega t}$, $U_{mod} = U_{in}e^{\imath\Omega t} = e^{\imath(\omega+\Omega)t}$, $U_{demod} = U_{mod}e^{-\imath\omega t} = e^{\imath\Omega t}$.

52.3.3 Exercises

52.3.3.1 Ex: Phase modulation

a. Show that it is not possible to construct a periodic phase modulation function such that the signal has only two sidebands.
b. Compare the spectra $\sum_{k=-\infty}^{\infty} J_k(M)e^{\imath k\Omega t} = e^{\imath M\sin\Omega t}$ and $\sum_{k=-\infty}^{\infty}|J_k(M)|e^{\imath k\Omega t}$. Can you detect phase modulation of a photodetector signal on a spectrum analyzer? How about amplitude modulation?

Solution: *a. The question is whether there is a periodic function $f(t)$ such that,*

$$e^{\imath\omega t+\imath f(t)} = e^{\imath\omega t} + Me^{\imath(\omega+\Omega)t} - Me^{\imath(\omega-\Omega)t}$$

or equivalently $e^{if(t)} = 1 + 2\imath M\sin\Omega t$. Such a function would have to satisfy,

$$1 = |1 + 2\imath M\sin\Omega t|^2 = 1 + 4M^2\sin^2\Omega t \ ,$$

which only holds for $M = 0$. In contrast, a sinusoidal phase modulation satisfies,

$$1 = |e^{\imath M\sin\Omega t}|^2 = \left|\sum_{k=-\infty}^{\infty} J_k(M)e^{\imath k\Omega t}\right|^2 = \sum_{k,m=-\infty}^{\infty} J_k(M)J_m(M)e^{\imath(k-m)\Omega t} = \sum_{k=-\infty}^{\infty}|J_k(M)|^2 \ .$$

b. Phase modulation cannot be seen by a spectrum analyzer, simply because the signal recorded by a photodetector is,

$$|E_{pm}|^2 = |e^{\imath\omega t+\imath M\sin\Omega t}|^2 = 1 \ .$$

On the other hand, amplitude modulation is visible, since,

$$|E_{am}|^2 = |(1 + M\cos\Omega t)e^{\imath\omega t}|^2 = 1 + \tfrac{M^2}{2} + 2M\cos\Omega t + \tfrac{M^2}{2}\cos 2\Omega t \ .$$

52.3.4 *Experiment: Creating sidebands on a radiofrequency*

In this exercise, we will understand the origin of sidebands as we'll see them emerge from a modulation spectrum when we gradually increase the modulation index [3].

1. Take a VCO, for example, ZOS-100+ from MiniCircuits. Study the datasheet and drive the VCO with an AC voltage. Vary the amplitude and the frequency of the voltage and observe the output signal of the VCO on a spectrum analyzer.

2. Try to understand the spectrum observing the limiting cases $\Omega \gg \Delta\omega$ and $\Omega \ll \Delta\omega$. How can you read Ω and Δf from the spectra in both cases?

3. Write a MATLAB program to simulate the spectrum.

[3] Datasheet for the VCO see appendix Fig. 56.16,
data sheet for the variable attenuator see appendix Fig. 56.17,
data sheet for the mixer see appendix data sheet Fig. 56.19.

52.4 Measurement instrumentation

52.4.1 Sample-and-hold circuit

sample-and-hold circuit Solder on euroboard

52.4.2 Box-car integrator

box-car integrator Solder on euroboard

52.4.3 Lock-in amplifier

An *lock-in amplifier* (also called a phase-sensitive rectifier or *mixer*) is an amplifier that can measure a weak electrical signal by modulating the signal by a reference signal with a known frequency and phase. The device represents a bandpass filter with an extremely narrow bandwidth and, therefore, improves the signal-to-noise ratio (SNR). DC or AC noise components are efficiently filtered.

Download an illustration of the working principle of a *lock-in amplifier* here.

52.4.4 *Experiment: Building a lock-in amplifier*

Let's now build a lock-in amplifier. The principle is illustrated in Fig. 52.17(a). The sinusoidal signal discriminated at a non-linear line is switched on and off in the lock-in by a switch. At the same time, the inverted signal (i.e., phase shifted by 180°) is turned off and on. Both signals are combined and low-pass filtered. As Fig. 52.17(b) shows, the sign of the filtered signal depends on the phase between the discriminator and the TTL signal controlling the switch [4]

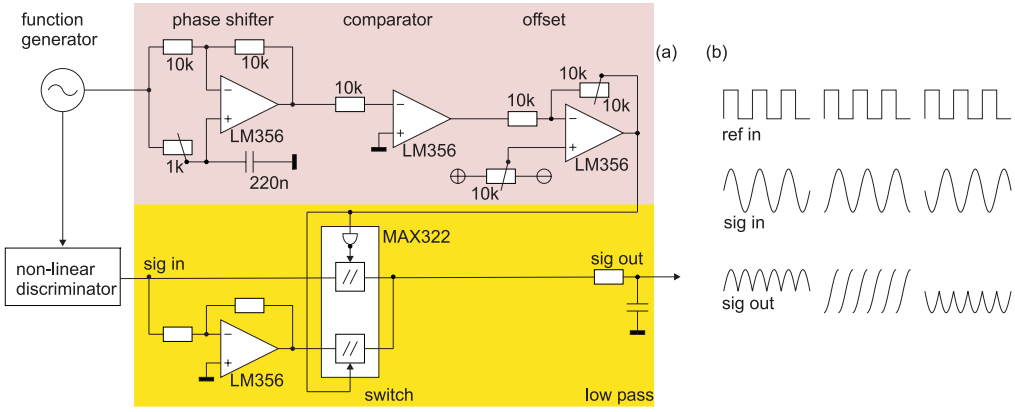

Figure 52.17: (a) Principal scheme of a lock-in amplifier. (b) Mode of operation.

[4] Datasheets for the operational amplifier see appendix Fig. 56.24, data sheet for the switch see appendix Fig. 56.23.

1. Create the circuit sketched in Fig. 52.17(a) on a circuit board and test it by varying the phase between the modulated output signal and the TTL signal provided by a function generator.

Chapter 53

Quantum optics and optical interferometry

The objective of this chapter is to introduce the basics of optical *interferometry*. We will see, how to match the light modes in optical cavities and fibers, and to phase-match the wavefronts of two laser beams in order to detect their frequency beating with a photodetector. Furthermore, he will learn how to handle essential tools of *quantum electronics*, such as a piezo-electric transducer, an electro-optic modulator, and an acousto-optic modulator, used in interferometry, as discussed in Secs. 53.4.1 to 53.4. Interferometers have versatile applications such as 1. for the detection of very small length variations (as for example caused by gravitational waves), 2. as vibration and inertial sensors, or in 3. the transmission of information (radio).

53.1 Introduction to interferometry

53.1.1 Beam splitter

The essential component of any interferometer is the (non-polarizing) *beam splitter*.

We consider a classical lossless beam splitter with electric fields incident at both its inputs. The two output fields E_c and E_d are linearly related to the inputs through

$$\begin{pmatrix} \mathcal{E}_c \\ \mathcal{E}_d \end{pmatrix} = \begin{pmatrix} r_{ac} & t_{bc} \\ t_{ad} & r_{bd} \end{pmatrix} \begin{pmatrix} \mathcal{E}_a \\ \mathcal{E}_b \end{pmatrix} , \tag{53.1}$$

where the 2×2 element is the beam splitter matrix. r and t are the reflectance and transmittance along a particular path through the beam splitter, that path being indicated by the subscripts.

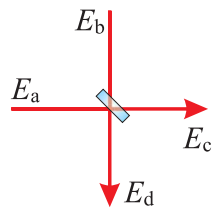

Figure 53.1: Beam splitter.

Assuming the beam splitter removes no energy from the light beams, the total output energy can be equated with the total input energy, reading

$$|\mathcal{E}_c|^2 + |\mathcal{E}_d|^2 = (|r_{ac}||\mathcal{E}_a| + |t_{bc}|\mathcal{E}_b|)^2 + (|t_{ad}||\mathcal{E}_a| + |r_{bd}||\mathcal{E}_b|)^2 = |\mathcal{E}_a|^2 + |\mathcal{E}_b|^2 \ . \quad (53.2)$$

This can only be true for any field amplitudes, if the following relationships between reflectance and transmittance are satisfied,

$$|r_{ac}|^2 + |t_{ad}|^2 = 1 = |r_{bd}|^2 + |t_{bc}|^2 \quad \text{and} \quad r_{ac}t^*_{bc} + t_{ad}r^*_{bd} = 0 \ . \quad (53.3)$$

We write each r and t as a complex number having an amplitude and phase factor accounting for possible phase shifts of a beam as it reflects or transmits at the beam splitting surface. From the second equation (53.3) we obtain,

$$\frac{|r_{ac}|}{|t_{ad}|} = -\frac{|r_{bd}|}{|t_{bc}|} e^{\imath(\phi_{ad}-\phi_{bd}+\phi_{bc}-\phi_{ac})} \quad (53.4)$$

which is true when $\phi_{ad} - \phi_{bd} + \phi_{bc} - \phi_{ac} = \pi$. Squaring both sides of the expression (53.4) and comparing this with the first equation (53.3) we obtain the result

$$|t_{ad}| = |t_{bc}| \equiv \sqrt{T} \quad \text{and} \quad |r_{ac}| = |r_{bd}| \equiv \sqrt{R} \ . \quad (53.5)$$

It follows that

$$\boxed{R + T = 1} \ . \quad (53.6)$$

The above result holds for any type of beam splitting device. For beam splitting at dielectric interfaces in particular we know that the electric field amplitude does not suffer phase shifts upon transmission and no phase shifts upon reflection at an optical more dilute medium. But it suffers a 180° phase shift upon reflection at an optical denser medium. For the situation depicted in Fig. 53.1, we conclude $\phi_{ac} = \phi_{bd} = \phi_{bc} = 0$ and $\phi_{ad} = \pi$. With this constraints the matrix describing a lossless beam splitter reads,

$$\boxed{\begin{pmatrix} \mathcal{E}_c \\ \mathcal{E}_d \end{pmatrix} = \begin{pmatrix} \sqrt{R} & \sqrt{T} \\ -\sqrt{T} & \sqrt{R} \end{pmatrix} \begin{pmatrix} \mathcal{E}_a \\ \mathcal{E}_b \end{pmatrix}} \ . \quad (53.7)$$

53.1.2 Piezo-electric actuator

The piezo-electricity effect describes the reciprocal action between mechanical pressure (from Greek: piézein - press) and electrical voltage in solids. It is based on the phenomenon that occurs in the regular deformation of certain piezoelectric materials: at the surface occur displacements of electric charges creating microscopic dipoles inside the unit cells. The sum over all the unit cells of the crystal leads to a macroscopically measurable electrical voltage. The deformation should be directed, which means, that the pressure is not applied from all sides on the crystal, but for example only on opposite sides.

On the other hand, by applying an electric voltage, a crystal (or piezo-ceramic element) may be deformed. Like any other solid body, piezo-electric crystals can execute mechanical vibrations. In a *piezo-electric actuator* (or piezo transducer PZT), these vibrations can be electrically excited. The frequency of the vibrations depend

only on the speed of sound (which is a constant of the material) and the dimensions of the actuator. Therefore, actuators are also suitable for realizing oscillators (for example, quartz crystals). The piezo-electric effect can only occur in non-conductive materials (e.g., lead titanate zirconate).

When a voltage is applied to the piezo-ceramic in the direction of polarization, we observe an expansion in this direction and a perpendicular contraction. Depending on the employed material and the coefficient for piezo-electric strain d, stretches up to $\Delta l/l = 0.15\%$ can be obtained:

$$\Delta l = d\mathcal{E} l_0 \ , \tag{53.8}$$

where l_0 is the length of the actuator and $E = U/l_0$ the amplitude of the electric field. The elongation effect is therefore proportional to the field strength and the overall length of the actuator. To achieve large stretches with manageable electrical voltages, actuator discs are often stacked (mechanical circuit in series and electric circuit in parallel).

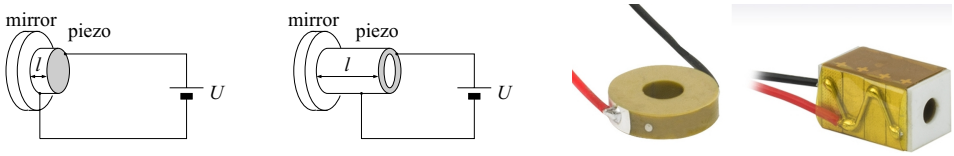

Figure 53.2: (Left) Scheme of mirrors mounted on a piezo actuator having the shape of a disc or a ring. (Right) Photos of a ring piezo and a piezo stack.

Negative voltages with respect to the orientation of the discs cause a contraction. However, negative voltages can also cause a change in the polarization state of the piezo and should therefore be avoided! In electrical circuits, piezoelectric actuators introduce a capacitance with a relative dielectric constant between 600 and 5000 and an internal resistance of about $10^8\ \Omega$ depending on the material. See Exc. 53.1.10.1.

53.1.3 Michelson and Mach-Zehnder interferometer

Interferometry is a technique exploiting the interference of waves coherently split and recombined by beam splitters. Sufficiently stable interferometers allow to visualize variations of the path lengths of two or more partial waves following different pathways as an alteration of constructive and destructive interference.

The two most common types of interferometers are the *Michelson interferometer* and the *Mach-Zehnder interferometer* are depicted in Fig. 53.3. The advantages of the Michelson interferometer are an easy alignment and the need of only one beamsplitter. The advantage of the Mach-Zehnder interferometer is a direct optical access to both output ports of the interferometer. The following treatment applies to both types.

The field amplitude of a laser beam, $\mathcal{E}_i$, with frequency, $\omega = ck$, is divided by a beam splitter (reflectivity $\sqrt{R}$) into a transmitted $\mathcal{E}_t$ and a reflected beam $\mathcal{E}_r$,

$$\mathcal{E}_r = \sqrt{R_1}\mathcal{E}_i \qquad \text{and} \qquad \mathcal{E}_t = \sqrt{1-R_1}\mathcal{E}_i \ , \tag{53.9}$$

where we disregard possible phase-shifts upon reflection at optically dilute interface. The energy is obviously conserved, $|\mathcal{E}_r|^2 + |\mathcal{E}_t|^2 = \mathcal{E}_i^2$.

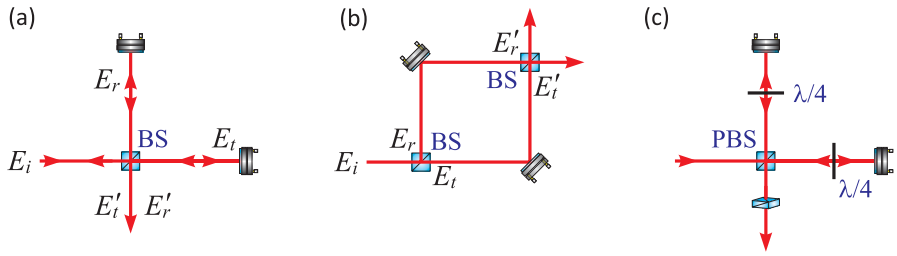

Figure 53.3: Principle of a two-beam interferometer: (a) Michelson interferometer and (b) Mach-Zehnder interferometer using non-polarizing beamsplitters. (c) Michelson interferometer using a polarizing beamsplitter.

We consider the Mach-Zehnder interferometer sketched in Fig. 53.3 with one arm of length L_r, which can be varied by a piezo, and the other arm of length L_t,

$$\mathcal{E}_r' = \mathcal{E}_r e^{2\imath k L_r} \qquad \text{and} \qquad \mathcal{E}_t' = \mathcal{E}_t e^{2\imath k L_t} \ . \tag{53.10}$$

The beams are recombined on a second beam splitter and sent to a photodetector, whose signal is,

$$\begin{aligned} I &\propto |\sqrt{R_2}\mathcal{E}_r' + \sqrt{1-R_2}\mathcal{E}_t'|^2 \\ &= |\sqrt{R_2}\sqrt{R_1}e^{2\imath k L_r} + \sqrt{1-R_2}\sqrt{1-R_1}e^{2\imath k L_t}|^2 \mathcal{E}_i^2 \ . \end{aligned} \tag{53.11}$$

Hence,

$$I \propto R_2 R_1 + (1-R_2)(1-R_1) + 2\sqrt{R_2}\sqrt{R_1}\sqrt{1-R_2}\sqrt{1-R_1}\cos[2k(L_t - L_r)] \ . \tag{53.12}$$

For reflectivities of $R_1 = R_2 = 50\%$, we get,

$$\boxed{I \propto \tfrac{1}{2} + \tfrac{1}{2}\cos[2k(L_t - L_r)]} \ . \tag{53.13}$$

It is important to realize that, while superpositions of light field amplitudes in the same mode interfere, *superpositions of light field amplitudes in different modes do not*. For example, the superposition of two plane waves with equal frequency and polarization interferes,

$$\left| \begin{pmatrix} \mathcal{E}_1 + \mathcal{E}_2 \\ 0 \end{pmatrix} \right|^2 = |\mathcal{E}_1 + \mathcal{E}_2|^2 \ , \tag{53.14}$$

while the superposition of two plane waves with equal frequency but different polarizations does not,

$$\left| \begin{pmatrix} \mathcal{E}_1 \\ 0 \end{pmatrix} + \begin{pmatrix} 0 \\ \mathcal{E}_2 \end{pmatrix} \right|^2 = |\mathcal{E}_1|^2 + |\mathcal{E}_2|^2 \ . \tag{53.15}$$

Solve the Excs. 53.1.10.2 to 53.1.10.4.

53.1.4 Coherence and spectrum of a light field

We have seen above that interferometers probe the electric field amplitude rather than the intensity. For this reason, they are suited to measure the first-order correlation function $g^{(1)}(\tau)$ and the emission spectrum, which are defined by,

$$g^{(1)}(\tau) \equiv \frac{\langle \mathcal{E}^-(t)\mathcal{E}^+(t+\tau)\rangle}{\langle \mathcal{E}^-(t)\mathcal{E}^+(t)\rangle} \qquad \text{and} \qquad S_{\mathcal{E}}(\omega) \equiv \mathcal{F}[g^{(1)}(\tau)] \ . \tag{53.16}$$

As an example, Fig. 53.4 shows the aurocorrelation function and spectrum of a simultaneously amplitude- and phase-modulated laser beam, $\mathcal{E}(t) = (1+n\cos\omega_n t)e^{\imath m \sin\omega_m t}$.

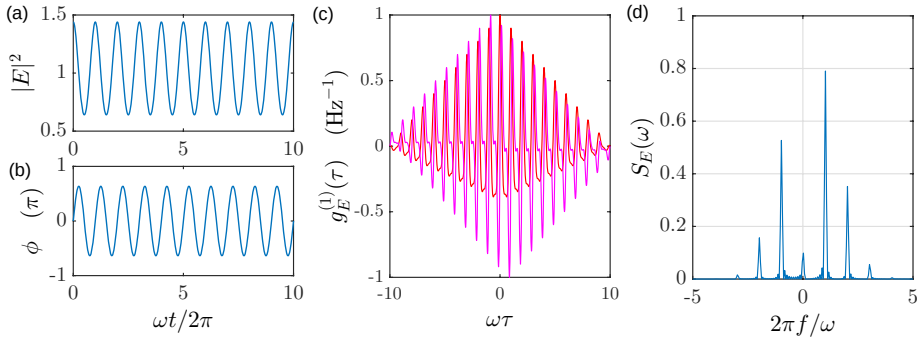

Figure 53.4: (code) (a) Amplitude and (b) phase of the electric field, with $n = 0.2$, $m = 1$, and $\omega_n = \omega_m = (2\pi)\ 1\,\mathrm{Hz}$. (c) Aurocorrelation function and (d) spectrum of the light field.

53.1.5 Birefringent interferometer

A *birefringent interferometer* or *Lyot filter* consists of one or more birefringent crystals mounted onto a rotation frame between two polarizers. Let n_o and $n_e = n_o + \Delta n$ be the refractive indices of the normal and the extraordinary axis, respectively. The corresponding Jones matrix is then,

$$\mathcal{M} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} e^{\imath k_0 L} & 0 \\ 0 & e^{\imath k_e L} \end{pmatrix} \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} , \tag{53.17}$$

Such that,

$$\begin{pmatrix} \mathcal{E}_{out} \\ 0 \end{pmatrix} = \mathcal{M} \begin{pmatrix} \mathcal{E}_{in} \\ 0 \end{pmatrix} = \begin{pmatrix} \left(e^{\imath k_0 L}\cos^2\phi + e^{\imath k_e L}\sin^2\phi\right)\mathcal{E}_{in} \\ 0 \end{pmatrix} . \tag{53.18}$$

By trigonometric transformations it is possible to show, that the transmission $T \equiv |\mathcal{E}_{out}/\mathcal{E}_{in}|^2$ is,

$$\boxed{T(\lambda,\phi) = |e^{\imath k_0 L}\cos^2\phi + e^{\imath k_e L}\sin^2\phi|^2 = 1 - \sin^2 2\phi \sin^2\tfrac{\pi L\Delta n}{\lambda}} \ . \tag{53.19}$$

For $\phi = 45°$ the transmission becomes simply,

$$T(\lambda, \tfrac{\pi}{4}) = \cos^2 \tfrac{\pi L \Delta n}{\lambda} \ . \tag{53.20}$$

In practice Lyot filters are often used, placed under the Brewster angle inside ring cavity lasers, as frequency selective elements. Frequently, birefringent plates of different thicknesses are stacked,

$$T(\lambda) = T_1(\lambda) T_2(\lambda) \ , \tag{53.21}$$

in order to increase the frequency selectivity. Furthermore, when the axis of the birefringent plates are rotated by fixed angles $\Delta\alpha$ with respect to each other,

$$T(\lambda, \alpha) = T_1(\lambda, \alpha) T_2(\lambda, \alpha + \Delta\alpha) \ , \tag{53.22}$$

the frequency of maximum transmission can be tuned by simply rotating the stack as a whole by an angle α. See 53.1.10.5.

A Lyot filter can be considered an interferometer, because it splits and recombines the polarization vector of a light beam in two parts following the ordinary and the extraordinary axis of the birefringent crystal. This is somewhat analogous to the Michelson interferometer depicted in Fig. 53.3(c).

53.1.6 Optical resonators

Optical cavities consist of an arrangement of mirrors reflecting the light beams in such a way, that they form a closed path. Since light that entered the cavity is performing there many round trips before it is transmitted again or absorbed, the light power is considerably enhanced, i.e. cavities can store light.

Light which is to resonate in the cavity must satisfy the boundary condition, that the mirror surfaces coincide with standing wave nodes. Therefore, in a cavity with length L only a discrete spectrum of wavelengths $N\frac{\lambda}{2} = L$ can be resonantly amplified, where N is a natural number. Because of this property, cavity are often used as frequency filters or optical spectrum analyzers: Only frequencies $\nu = N\delta_{fsr}$ are transmitted, where

$$\boxed{\delta_{fsr} = c/2L} \tag{53.23}$$

is the free spectral range of the cavity.

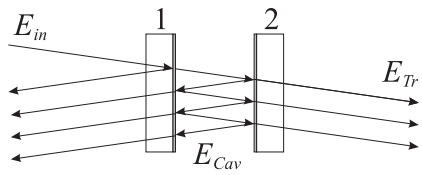

Figure 53.5: Multiple interference in an optical cavity.

Cavities are characterized on one hand by their geometry, i.e. the curvature and the distance of their mirrors, and on the other hand by their finesse, which is given by the reflectivity of their mirrors. Let us first study the finesse. Regarding the cavity as a multipass interferometer [351], we can derive expressions for the reflected and

transmitted intensity as a function of frequency [1]. The so-called *Airy formula* for transmission and reflection are,

$$\frac{\mathcal{E}_{refl}}{\mathcal{E}_{in}} = r_1 - \frac{t_1^2 r_2 e^{2\imath kL}}{1 - r_1 r_2 e^{2\imath kL}} \quad \text{and} \quad \frac{\mathcal{E}_{trns}}{\mathcal{E}_{in}} = \frac{t_1 t_2 e^{\imath kL}}{1 - r_1 r_2 e^{2\imath kL}} \ . \tag{53.24}$$

In terms of intensity, assuming identical mirrors, $r_1 = r_2 = \sqrt{R}$ and $t_1 = t_2 = \sqrt{T}$, and neglecting possible absorptive losses, $A = 1 - R - T = 0$,

$$\boxed{\frac{I_{refl}}{I_{in}} = \frac{(\frac{2F}{\pi})^2 \sin^2 \frac{\Delta}{2\delta_{fsr}}}{1 + (\frac{2F}{\pi})^2 \sin^2 \frac{\Delta}{2\delta_{fsr}}} \quad \text{and} \quad \frac{I_{trns}}{I_{in}} = \frac{1}{1 + (\frac{2F}{\pi})^2 \sin^2 \frac{\Delta}{2\delta_{fsr}}}} \ , \tag{53.25}$$

where R is the reflectivity of a mirror and $\delta = 4\pi L/\lambda = 2\pi\nu/\delta_{fsr}$. The transmission curve of a cavity has a finite transmission bandwidth $\Delta\nu$, which depends on the reflectivity of the mirrors. The finesse of a cavity is defined by

$$\boxed{F \equiv \frac{2\pi\delta_{fsr}}{\kappa} = \frac{\pi\sqrt{R}}{1-R}} \ . \tag{53.26}$$

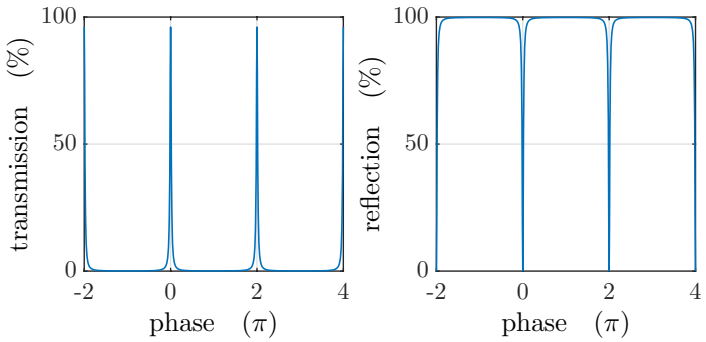

Figure 53.6: (code) Transmission and reflection through a resonator.

Note that factors others than the finite reflectivity may degrade the finesse of a cavity. For example, an imperfect mirror flatness (commonly specified as λ/F_{surf}) reduces the finesse to [351],

$$F_{tot} = \left(\frac{1}{F} + \frac{1}{F_{surf}} \right)^{-1} \ . \tag{53.27}$$

.

The geometry of a cavity must satisfy certain conditions, in order to be stable [734]. Besides the main longitudinal modes a cavity possesses transverse modes of the order TEM_{mn}, whose frequencies are given by [2],

$$\nu/\delta_{fsr} = (q+1) + \frac{m+n+1}{\pi} \arccos \sqrt{\left(1 - \frac{L}{\rho_1}\right)\left(1 - \frac{L}{\rho_2}\right)} \ . \tag{53.28}$$

[1] See script on *Electrodynamics* (2023), Exc. 7.3.6.16.
[2] See script on *Electrodynamics* (2023), Sec. 7.4.2.2.

A *confocal cavity* with degenerate transverse modes, $\rho_1 = \rho_2 = L$, is particularly suited as optical spectrum analyzer.

The diameter of the beam waist in the cavity is,

$$w_0 = \sqrt[4]{\left(\frac{\lambda}{\pi}\right)^2 \frac{L(\rho_1 - L)(\rho_2 - L)(\rho_1 + \rho_2 - L)}{(\rho_1 + \rho_2 - 2L)^2}} \,. \tag{53.29}$$

For an optimal coupling of the light into the cavity the Gaussian laser beam must be matched to the cavity's geometry of the cavity, i.e. diameter and divergence of the laser beam must be adapted to the cavity mode with a suitable arrangement of lenses [352, 734]. See Excs. 53.1.10.6 to 53.1.10.11.

53.1.7 Dielectric mirrors and filters

Dielectric mirrors and filters are multiple beam interferometers in a similar sense as Fabry-Pérot cavities. They consist of stacks of thin dielectric layers with alternating refraction indices [3].

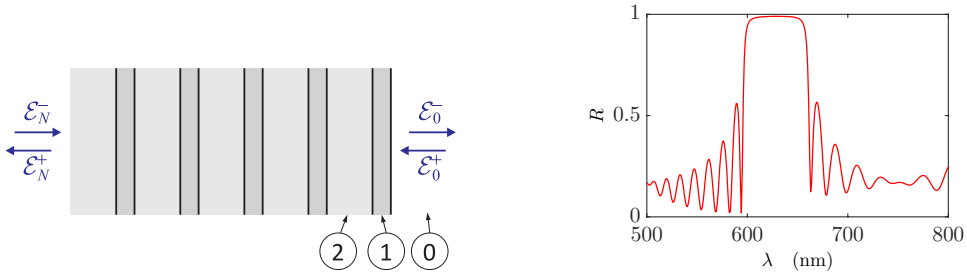

Figure 53.7: (code) Reflection by a high reflecting mirror made of 10 layers with $n_1 = 2.4$ and $\Delta z_1 = 80\,\text{nm}$ alternating with 10 layers with $n_2 = 1.5$ and $\Delta z_2 = 500\,\text{nm}$. The absorption coefficient for each layer is supposed to be $\alpha = 0.2\%$. The beam impinges from vacuum, $n_0 = 1$.

Reflections of $R = 99.999\%$ can be reached which, applied of superpolished mirrors, allow for the construction of cavities with finesse $F > 300000$. On the other anti-reflection coatings can be applied to surfaces reducing their reflections to below $R = 0.1\%$. See Excs. 53.1.10.12 and 53.1.10.13 [352, 800].

53.1.8 Optical fibers

An *optical fiber* is a waveguide in which light is guided by internal total reflection. The total reflection occurs between layers with different refractive indices called *fiber core* and *fiber cladding*. The core is the central region of the optical fiber where the light is guided. In order to create guiding conditions, the refractive index of the core must be higher than the one of the cladding. The cladding diameter is typically 8 to 10 times the *mode field diameter* (MFD) of the fundamental mode. In general, MFD

[3] See script on *Electrodynamics* (2023), Sec. 7.1.7.

is greater than the physical diameter of the fiber core, which means that some optical power is always guided by the fiber cladding as an evanescent wave.

The *cut-off wavelength* λ_{co} of an optical fiber is the wavelength above which a guided mode of a waveguide ceases to exist. For wavelength longer than λ_{co} an optical fiber becomes single-mode. At wavelengths shorter than λ_{co} several optical modes may propagate and the fiber becomes multi-mode. The cut-off wavelength is directly related to the core diameter of the fiber $\lambda_{co} \propto \emptyset$. For

$$\frac{\lambda}{2} < \emptyset < \lambda \qquad \text{or equivalently} \qquad \emptyset < \lambda < 2\emptyset \tag{53.30}$$

the fiber is single-mode. For $\lambda > 2\emptyset$ no guided mode exists and for $\emptyset > \lambda$ the fiber becomes multimode.

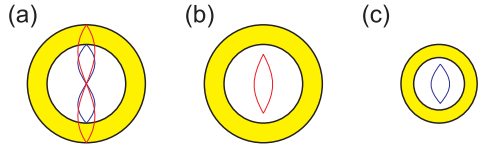

Figure 53.8: Mono-mode waveguiding by optical fibers.

The *numerical aperture* is a measure of the acceptance angle of the fiber. It is very important because it determines how strongly a fiber guides light, and so how resistant it is to bend-induced losses. The numerical aperture can be defined by the acceptance angle of the fiber, though as this is highly diverging in space it is rather complicated to reach a simple definition. It is most convenient to define the NA in terms of the relative indices of core and cladding glass forming the fiber waveguide:

$$NA = \sin\tfrac{\theta_a}{2} = \sqrt{n_{core}^2 - n_{clad}^2} \simeq \sqrt{2n_{core}^2 \delta n}\ , \tag{53.31}$$

where δn is the index difference between the core and cladding. An optical fiber with 'high' numerical aperture will confine light more strongly in the core, and so support guidance further above cut-off. This attribute has two important effects: (a) it will be single-mode over a greater range of wavelengths than is possible with a fiber with a 'low' numerical aperture fiber and (b) it will still guide a single-mode when coiled or bent to a smaller diameter.

53.1.8.1 Multi-mode, mono-mode, and polarization maintaining fibers

Many types of fibers are currently available for a large variety of applications.

53.1.9 Laser gyroscope and the Sagnac effect

Gyroscopes are based on the *Sagnac effect*. They are based on a ring cavity mounted on a rotating stage, as shown in Fig. 53.10(a). Let us, for simplicity first consider a circular path for the light beam (e.g. a fiber-based ring cavity) rotating at an angular velocity Ω. Then the time needed for the light beam to travel in either one of the two directions is,

$$t_\pm = \frac{(2\pi \pm \Omega t_\pm)r}{c} = \frac{2\pi r}{c \mp \Omega r}\ , \tag{53.32}$$

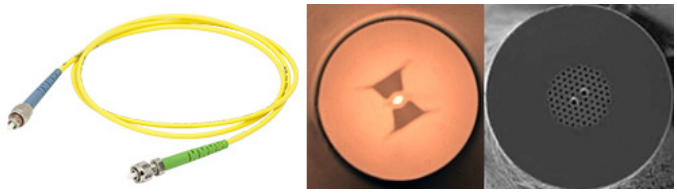

Figure 53.9: (Left) Fiber patch cord, (center) cross section of a bow-tie polarization maintaining fiber, and (right) cross section of a photonic crystal fiber.

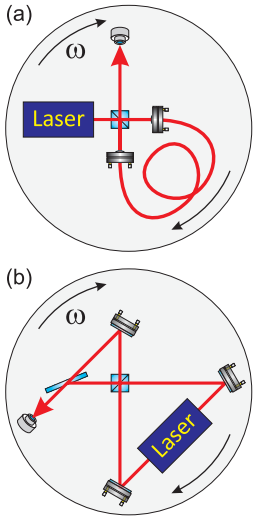

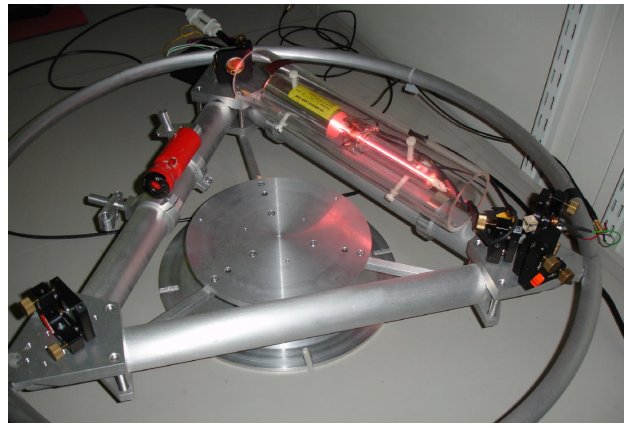

Figure 53.10: (a) Principle scheme of a fiber-based Sagnac interferometer. (b,c) Laser gyroscope realized with a HeNe gain tube.

that is,

$$\Delta t \equiv t_+ - t_- = \frac{4\pi r^2 \Omega}{c^2 - \Omega^2 r^2} \simeq \frac{4\pi r^2 \Omega}{c^2} \equiv \frac{4A\Omega}{c^2} \ , \tag{53.33}$$

where A is the area enclosed by the path. This formula can be generalized to arbitrary paths.

For example, assuming an interferometer with $A = 1\,\mathrm{m}^2$ at rest in an Earth-based system, $\Omega \simeq 2\pi/24\,\mathrm{h}$, the time difference for light propagating along the two directions is $\Delta t \approx 3 \cdot 10^{-21}\,\mathrm{s}$ and the path difference $\Delta L = c\Delta t \approx 100\,\mathrm{fm}$. The frequency shift is,

$$\boxed{\Delta v = k(v_+ - v_-) = k(2\Omega r) = \frac{\sqrt{4\pi A}\Omega}{\lambda}} \ , \tag{53.34}$$

yielding for the given example of an Earth-based interferometer $\Delta\nu \approx 400\,\mathrm{Hz}$.

53.1.10 Exercises

53.1.10.1 Ex: Characterizing a piezo actuator

In order to characterize a recently purchased piezo actuator (Thorlabs, TA0505D024W) a Scientific Initiation student sets up a Michelson interferometer driven by a HeNe laser beam. Scanning the voltage applied to the piezo through the entire permitted range, he observes 8.8 oscillations of the interference fringes. What is the piezo displacement per volt?

Solution: *The allowed voltage range is* $\Delta U = 0 \,..\, 75\,\mathrm{V}$. *With* N *the number of observed oscillations, the piezo displacement per volt is,*

$$\frac{\Delta z}{\Delta U} = \frac{N\lambda/2}{\Delta U} = 37.3\,\mathrm{nm/V} \ .$$

53.1.10.2 Ex: Michelson interferometer

The figure 53.11 shows a Michelson interferometer containing in one arm an airtight 5 cm long cell with glass windows. Light with wavelength $\lambda = 500\,\mathrm{nm}$ is used. After the cell has been evacuated, the interference pattern shifts by 60 fringes. Use this information to calculate the refractive index of air at atmospheric pressure. With what accuracy can you determine the refractive index with this method?

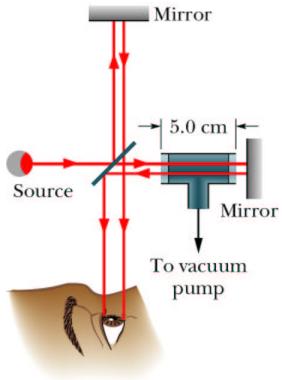

Figure 53.11:

Solution: *The variation of the path length of the interferometer arm containing the cell due to the refractive index is, after the passage of* $N = 60$ *fringes,*

$$N\frac{\lambda}{2} = n_{refr}L - L \ .$$

Hence,

$$n_{refr} - 1 = \frac{N\pi}{kL} \approx 3 \cdot 10^{-4} \ .$$

Assuming that the uncertainty of $\Delta N = 1$ fringe, the refractive index can be measured with an precision of,

$$\Delta n_{refr} = \frac{\partial n_{refr}}{\partial N}\Delta N = \frac{\pi}{kL} \approx 5 \cdot 10^{-6} \ .$$

53.1.10.3 Ex: Michelson interferometer

Assume that a signal-to-noise ratio of 50 has been achieved in measuring the fringe pattern of a Michelson interferometer with one continuously moving mirror. Estimate the minimum path length ΔL that the mirror has to travel in order to reach an accuracy of $\Delta\lambda = 10^{-4}\,\mathrm{nm}$ in the measurement of a laser wavelength at $\lambda = 600\,\mathrm{nm}$.

Solution: *The spectral resolution is,*

$$\frac{\lambda}{\Delta\lambda} = 50\frac{\Delta L}{\lambda}$$

yields $\Delta L = 7.2\,\mathrm{cm}$.

53.1.10.4 Ex: Rotating the polarization with a Mach-Zehnder interferometer

Using the Jones matrix formalism demonstrate how to use the Mach-Zehnder interferometer setup sketched in the figure to rotate the polarization of a linearly polarized laser beam in an electronically controlled way using a piezo actuator mounted in ones of the interferometer arms.

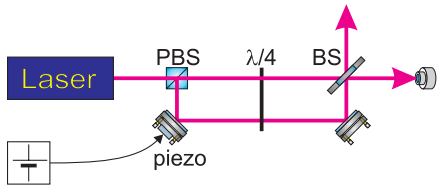

Figure 53.12:

Solution: *We assume initially linearly polarized light,* $\begin{pmatrix}1\\1\end{pmatrix}$. *The x and y-components, having been separated by a PBS and passed through the same $\lambda/4$-plate, yield contrary circular polarizations $\sigma^{\pm}$. If one of the polarizations is phase-shifted by a piezo, the recombined field reads,*

$$\begin{pmatrix}1\\ \imath\end{pmatrix} + \begin{pmatrix}1\\ -\imath\end{pmatrix} e^{\imath\phi} = 2e^{\imath\phi/2}\begin{pmatrix}\cos\phi\\ \sin\phi\end{pmatrix} \ .$$

The fact that the polarization vector is purely real shows that the polarization is linear and can be rotated by simply varying the piezo voltage.

53.1.10.5 Ex: Lyot filter

Consider a Lyot filter with two plates ($L_1 = 1\,\text{mm}$ and $L_2 = 4\,\text{mm}$) with the refraction indices $n_o = 1.40$ in the fast axis and $n_e = 1.45$ in the slow axis.
a. Calculate the transmission peaks of the Lyot filter as a function of λ for the rotation angle $\phi = 45°$.
b. Determine the transmitted intensity $I(\phi)$ as a function of the rotation angle ϕ for a fixed wavelength λ. What is the contrast of the transmitted intensity for arbitrary values of λ if the absorption losses are 2%?

Solution: *a. From (53.20) we have for* $\phi = 45°$,

$$T(\lambda) = T_0 \cos^2 \frac{\pi \Delta n L_1}{\lambda} \cos^2 \frac{\pi \Delta n L_2}{\lambda} \ ,$$

with 2% absorption losses $T_0 = 0.98$. *Transmission peaks appear for the condition,*

$$\frac{\pi \Delta n L_1}{\lambda} = m_1 \pi \qquad \textit{and} \qquad \frac{\pi \Delta n L_2}{\lambda} = m_2 \pi \ ,$$

with $m_1, m_2 \in \mathbb{N}$. *For* $\lambda = 500\,\text{nm}$ *we obtain* $m_1 = 100$ *and* $m_2 = 400$. *For* $m_1 = 101$ *we get* $\lambda = 495\,\text{nm}$, *such that the thin plate has a free spectral range* $\Delta\lambda_{fsr} = 5\,\text{nm}$. *For* $m_2 = 401$ *we get* $\lambda = 498.75\,\text{nm}$, *such that the thick plate has* $\Delta\lambda_{fsr} = 1.25\,\text{nm}$.
b. From (53.19) we have,

$$T(\phi, \lambda) = T_0 \left[1 - \sin^2 \left(\frac{2\pi}{\lambda} \Delta n L \right) \sin^2 2\phi \right] \ ,$$

where $\lambda = 2\Delta nL/m$ m *is the first factor 0 and* $T(\phi, \lambda_{max})$ *has a maximum transmission* T_0, *independent of* ϕ. *For* $\lambda = 2\Delta nL/(m + \frac{1}{2})$ *this factor becomes 1 and the transmission is* $T(\phi) = T_0(1 - \sin^2 2\phi)$. *The contrast is then:*

$$\frac{T_{max}}{T_{min}} = \frac{1}{1 - \sin^2 2\phi} \ .$$

53.1.10.6 Ex: Wedge-shaped etalon

A beam of light of wavelength $\lambda = 683\,\text{nm}$ with large diameter is incident perpendicularly on the first of two quadratic plates. Each plate has the edge length 120 mm; at the left edge the plates touch each other, at the right edge they are separated by a wire of $d_w = 0.048\,\text{mm}$ in diameter. The air between the plates acts as a thin layer.
a. How many interference fringes does an observer see from above this arrangement?
b. Now suppose that the incident light be white. Will the interference pattern at the far left be bright or dark?

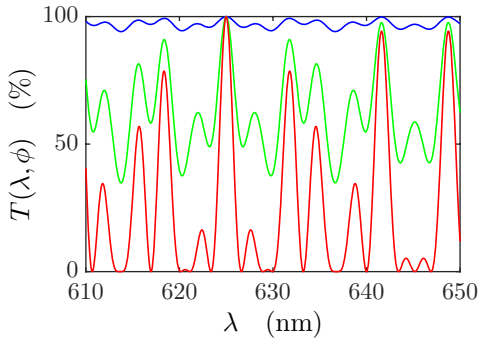

Figure 53.13: Transmission curve of a Lyot filter for (blue) $\alpha = 5^\circ$, (green) $\alpha = 20^\circ$, and (red) $\alpha = 45^\circ$.

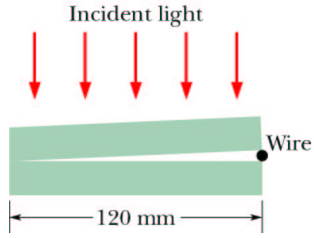

Figure 53.14:

c. Starting from the left edge there will be a series of interference minima, whose position depend on the wavelength of the light. For what light color (blue or red) will the minimum be closer to the edge?

Solution: *a. Light is only transmitted when the distance between the plates (as a function of the x-position) is close to* $d(z) \simeq N\frac{\lambda}{2}$. *Therefore, we see in reflection alternating as a function of z, between 0 and* $N_{max} = 2\frac{d_w}{\lambda} \approx 140$ *fringes.*
b. At the left end, where the distance is less than $\lambda/2$, *the reflection has a minimum, because 5% of the light (in case of a glas-air surface) are reflected at the interface upper plate-gap with no phase-shift and another* $95\% \times 5\%$ *at the interface gap-lower plate with* 180° *phase shift. If the distance between the reflective layers is much smaller than* $\lambda/2$, *the two reflected beams will interfere destructively. However, the contrast will not be perfect, because the two reflected intensities are not exactly equal. In any case, at least* $95\%^2$ *of the intensity are transmitted at any distance fro the edge.*
c. For blue light, the first minimum is closer to the edge.
Note added:
This can be calculated explicitly using the transfer matrix formalism [4]. *The T-matrix* $M_{inter}(n_0, n_1)$ *for transfer through an interface between two layers with different refractive indices* n_0 *and* n_1 *and the T-matrix* $M_{prop}(n_1)$ *for propagation within a*

[4] See script on *Electrodynamics* (2023), Sec. 7.1.7.

medium with a given refractive index n_1 are,

$$M_{inter}(n_0,n_1)=\frac{1}{2n_1}\begin{pmatrix}n_1+n_0 & n_1-n_0\\ n_1-n_0 & n_1+n_0\end{pmatrix}\quad and\quad M_{prop}(n_1)=\begin{pmatrix}e^{\imath n_1 kL} & 0\\ 0 & e^{-il\not{\Lambda}kL}\end{pmatrix}\ .$$

In our case, we have two layers $n_2=n_0$ separated by an air-gap $n_1=1$. Hence,

$$\begin{aligned}M_{total}&=\frac{1}{2n_0}\begin{pmatrix}n_0+1 & n_0-1\\ n_0-1 & n_0+1\end{pmatrix}\begin{pmatrix}e^{\imath kL} & 0\\ 0 & e^{-\imath kL}\end{pmatrix}\frac{1}{2}\begin{pmatrix}1+n_0 & 1-n_0\\ 1-n_0 & 1+n_0\end{pmatrix}\\ &=\frac{1}{n_0}\begin{pmatrix}n_0\cos kL+(1+n_0^2)\frac{\imath}{2}\sin kL & -\frac{\imath}{2}(n_0^2-1)\sin kL\\ \frac{\imath}{2}(n_0^2-1)\sin kL & n_0\cos kL-(1+n_0^2)\frac{\imath}{2}\sin kL\end{pmatrix}\ ,\end{aligned}$$

yielding the reflection,

$$R=\frac{\mathcal{E}_0^-}{\mathcal{E}_0^+}=-\frac{M_{21}}{M_{22}}=\frac{\imath(1-n_0^2)\sin kL}{2n_0\cos kL-(1+n_0^2)\imath\sin kL}\overset{kL\to 0}{\longrightarrow}0\ .$$

53.1.10.7 Ex: Fabry-Perot interferometer

The dielectric coatings of each plate of a Fabry-Perot interferometer have the following specifications: $R=98\%$, $A=0.3\%$. The flatness of the surfaces is $\lambda/100$ at $\lambda=500\,\text{nm}$.
a. Estimate the finesse from (53.24) and (53.27), the maximum transmission, and the spectral resolution of the FPI for a plate separation of 5 mm.
b. Show that, for a given absorption, the transmitted intensity decreases with increasing reflectivity. Explain why. **Note:** A trade-off between high finesse and high transmission at a given absorption $A>0$, called *impedance matching*, is reached by maximizing the intracavity intensity. For a symmetric cavity, it can be shown that impedance matching is reached for $A=T$.

Solution: *a. The field transmitted through the two mirrors of the cavity is,*

$$\mathcal{E}_{trns}=\mathcal{E}_{in}\frac{t_1t_2e^{\imath kL}}{1-r_1r_2e^{2\imath kL}}\ .$$

Assuming $r_1=r_2$ and $t_1=t_2$ and $T=t_1t_2=1-R-A$, the transmitted intensity is,

$$\frac{I_{trns}}{I_{in}}=\left|\frac{\mathcal{E}_{trns}}{\mathcal{E}_{in}}\right|^2=\frac{(1-R-A)^2}{1+R^2-2R\cos 2kL}\overset{kL=n\pi}{\longrightarrow}\frac{(1-R-A)^2}{(1-R)^2}\ .$$

With $R=0.98$, $A=0.003$, we get $I_{trns}/I_{in}=0.72$. The reflectivity finesse is $F_R=\frac{\pi\sqrt{R}}{1-R}=155.5$. The flatness finesse per mirror is: $F_f=100$. The total finesse is,

$$F_{tot}=\left(\frac{1}{F_R}+\frac{1}{F_f}\right)^{-1}\approx 60.9\ .$$

The cavity line width is,

$$\frac{\kappa}{2\pi} = \frac{\delta_{fsr}}{F} = \frac{1}{F}\frac{c}{2L} = 492\,\mathrm{MHz} \ .$$

Hence, for $d = 5$ nm and we get the spectral resolution,

$$\frac{\kappa}{2\pi\nu} = \frac{\kappa\lambda}{2\pi c} = \frac{\lambda}{F2L} \approx 8.2 \cdot 10^{-7} \ .$$

b. Absorption eats intensity upon each reflection. As the number of cavity round trip with reflections increases with R, the intensity eaten by absorption increases with R, as well.

53.1.10.8 Ex: Confocal and concentric cavities

a. Calculate the spectrum of longitudinal and transverse modes for (i) a confocal cavity ($\rho_a = \rho_b = L$) and (ii) a concentric cavity ($\rho_a = \rho_v = L/2$). Interpret the results. b. Assuming radii of curvature $\rho_a = \rho_b = 5$ cm and a finesse of $F = 500$ for the cavity, how precise must the length of the cavity be adjusted in order to observe only longitudinal modes in the transmission spectrum?

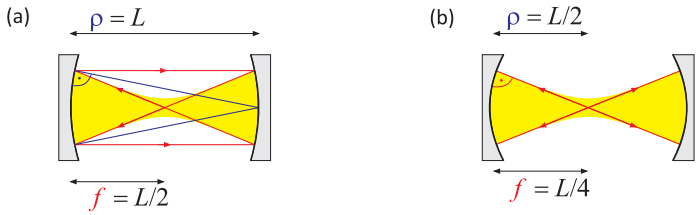

Figure 53.15: (a) Confocal cavity and (b) concentric cavity.

Solution: *a. For the case (i) the formula (53.28) gives,*

$$\frac{\nu}{\delta_{fsr}} = N + 1 + \frac{m+n+1}{\pi}\frac{\pi}{2} \ .$$

For the case (ii) the formula (53.28) gives,

$$\frac{\nu}{\delta_{fsr}} = N + 1 + \frac{m+n+1}{\pi}\,0 \ .$$

In case (i) an additional semi-integer mode appears. It is due to the fact that in this geometry, the complete 'round-trip' is doubled.
b. From (53.28) we derive the longitudinal and transverse spectrum of a symmetric cavity,

$$\nu = \delta_{fsr}\left[(q+1) + \tfrac{1}{\pi}(m+n+1)\arccos\left(1 - \tfrac{L}{\rho}\right)\right] \ .$$

We now ask, how much we may vary L in order for the frequency shift of the transverse mode TEM_{01} with respect to any (half-)longitudinal mode to be smaller than κ.

Expanding the arccos term for small deviations of $L = \rho + \Delta L$ from ρ we obtain for case (i):

$$\frac{\kappa}{2\pi} > \frac{2\delta_{fsr}}{\pi} \arccos\left(1 - \frac{\rho + \Delta L}{\rho}\right) \simeq \delta_{fsr}\left(1 + \frac{2\Delta L}{\pi\rho}\right) ,$$

that is,

$$\Delta L < \frac{\kappa}{4\delta_{fsr}}\rho = \frac{\pi}{2F}\rho \approx 160\,\mu\text{m} .$$

And for case (ii) expanding the arccos term for small deviations of $L = \rho/2 + \Delta L$ from $\rho/2$ we obtain:

$$\frac{\kappa}{2\pi} > \frac{2\delta_{fsr}}{\pi} \arccos\left(1 - \frac{2\rho + \Delta L}{\rho}\right) \simeq \delta_{fsr}\frac{2}{\pi}\sqrt{\frac{2\Delta L}{\rho}} ,$$

that is,

$$\Delta L < \frac{\rho}{2}\left(\frac{\kappa}{4\delta_{fsr}}\right)^2 = \frac{\pi^2\rho}{8F^2} \approx 25\,\mu\text{m} .$$

53.1.10.9 Ex: Thermal drift of a laser cavity

Estimate the frequency drift of a laser oscillating at $\lambda = 500\,\text{nm}$ because of thermal expansion of the resonator at a temperature drift of $1^\circ\,\text{C/h}$, when the resonator mirrors are mounted on distance-holder rods a. made of invar and b. made of fused quartz.

Solution: *We have,*

$$\frac{\Delta\nu}{\nu} = \frac{\Delta d}{d} = \alpha T .$$

A temperature drift of $1\,\text{C/h}$ gives, for invar rods ($\alpha = 1.2 \cdot 10^{-6}\,\text{K}^{-1}$), a frequency drift per hour of $\frac{\Delta\nu}{\nu} = 1.2 \cdot 10^{-6}$. For $\nu = c/\lambda = 6 \cdot 10^{14}\,\text{s}^{-1}$, hence $\Delta\nu = 720\,\text{MHz/h}$. For fused quartz ($\alpha = 0.4 - 0.5 \cdot 10^{-6}\,\text{K}^{-1}$ the drift is three times smaller, while for Zerodur it is more than 12 times smaller.

53.1.10.10 Ex: Stability of a supercavity

Consider a non-confocal optical cavity of 10 cm length whose spacer is made of (i) aluminum, (ii) stainless steel, (iii) invar steel, (iv) fused quartz, (v) Zerodur, and (vi) ULE. The cavity is maintained at constant temperature with a precision of 0.001 C. What maximum drift do you estimate for its resonance frequency at 633 nm?

Solution: *The resonance frequency is a multiple of the FSR, $\nu = N\delta_{fsr} = Nc/2L$. Hence, it depends on length variations like,*

$$\Delta\nu = \frac{\partial\nu}{\partial L}\Delta L = -\frac{Nc}{2L^2}\Delta L = -\frac{\nu}{L}\Delta L ,$$

which in turn depend on temperature variation like,

$$\Delta L = L\alpha\Delta T \ ,$$

where α is the thermal expansion coefficient. Hence,

$$\Delta\nu = -\nu\alpha\Delta T \ .$$

The thermal expansion coefficients for the specified materials are:

material	α $[10^{-6}\,\mathrm{K}^{-1}]$	$\Delta\nu$
Al	23.1	11 MHz
steel	11.0..13.0	≈ 5.7 MHz
invar	1.2	570 kHz
fused quartz	0.59	280 kHz
Zerodur	0.007..0.1	3.3..47 kHz
ULE	0	0

53.1.10.11 Ex: Fabry-Perot interferometer as optical spectrum analyzer

A confocal FPI shall be used as optical spectrum analyzer, with a free spectral range of $\delta_{fsr} = 3\,\mathrm{GHz}$. Calculate the mirror separation L and the finesse that is necessary to resolve spectral features in the laser output within $\Delta\nu = 10\,\mathrm{MHz}$. What is the minimum reflectivity R of the mirrors, if the surface finesse is $F_S = 500$?

Solution: *For a radius of curvature much smaller than the radius of the mirror $\rho \ll r$ the free spectral range of a confocal cavity is $\Delta\nu = c/4L$, hence,*

$$L = \frac{c}{4\delta_{fsr}} \approx 2.5\,\mathrm{cm} \ .$$

From this we obtain the total finesse,

$$F^* = \frac{\delta\nu}{\Delta\nu} \approx 300 \ ,$$

and with,

$$\frac{1}{F^{*2}} = \frac{1}{F_R^2} + \frac{1}{F_S^2} \ ,$$

the reflectivity finesse becomes, $F_R = 375$. Finally, the reflectivity must be chosen $R > 1 - \pi/F^* \approx 99.16\%$.

53.1.10.12 Ex: Interference and colors filters

Strontium atoms resonantly driven by two lasers at 461 nm and 689 nm emit fluorescence light at both wavelengths. Because the red transition is 5000 times narrower than the blue one, the red fluorescence is much weaker and difficult to detect. Find

a suitable low-pass filter in the Thorlabs® catalogue suppressing the blue light sufficiently to be sure that any fluorescence recorded after the filter must be resulting from the red transition. What signal ratios can you achieve with a single filter? Consider interference filters as well as color filters.

Solution: *Our best choice would be the model FELH0650 long pass filter at* 650 nm *with 0.0000872186% transmission at* 461 nm *and 96.5242% transmission at* 689 nm.

53.1.10.13 Ex: Interference filter

An interference filter shall be designed with peak transmission at $\lambda = 550\,\text{nm}$ and a bandwidth of 5 nm. Estimate the reflectivity R of the dielectric coatings and the thickness of the etalon, if no further transmission maximum is allowed between 350 and 750 nm.

Solution: *The free spectral range must be chosen such that* $2\Delta\lambda_{fsr} > 750\,\text{nm} - 350\,\text{nm}$. *Hence,*

$$\Delta\lambda_{fsr} \geq 200\,\text{nm} \ .$$

This corresponds to a free spectral range of,

$$\delta_{fsr} = \frac{c}{2L} = \frac{\partial\nu}{\partial\lambda}\Delta\lambda_{fsr} = -\frac{c}{\lambda^2}\Delta\lambda_{fsr} = -198\,\text{THz} \ ,$$

or to an etalon thickness of $L \leq 756\,\text{nm}$. *If the bandwidth is* $\Delta\lambda = 5\,\text{nm}$, *the finesse must be* $F = \delta_{fsr}/\Delta\nu = |\Delta\lambda_{fsr}/\Delta\lambda| = 40$. *If the finesse is solely determined by the reflectivity* R, *then,*

$$F = \frac{\pi\sqrt{R}}{1-R} \ ,$$

that is, $R = 0.9245$.

53.1.10.14 Ex: Cut-off wavelength of a single-mode fiber

You want to transport 461 nm light via a polarization maintaining single-mode fiber. How do you need to choose the cut-off wavelength of the fiber? Assuming a 50% coupling efficiency, how much power can you get through the 5 nm long fiber? Choose a model from the Thorlabs catalog and justify your choice.

Solution: *The cut-off wavelength must be somewhere between* $\lambda/2$ *and* λ *in order to prevent the formation of a transverse standing wave other than the fundamental mode* $\lambda/2$. *In our case,* $\lambda_{co} = 230..460\,\text{nm}$.
A possible model would be 'P1-405B-FC-5', Single Mode Patch Cable, $405 - 532\,\text{nm}$, *FC/PC,* $\emptyset 3\,\text{mm}$ *Jacket,* 5 m *Long.*
The typical insertion loss (connector to connector) is specified as 2.5 dB, *the attenuation is something like* 40 dB/km. *Hence, we expect* $(2.5 + 0.2)\,\text{dB}$ *total loss. However, the free space to fiver coupling is generally less efficient.*

53.1.10.15 Ex: Exc Numerical aperture of a fiber

Calculate the numerical aperture of a step-index fiber with core refraction index n_{core} and cladding refraction index $n_{cladding}$ considering the scheme 53.16.

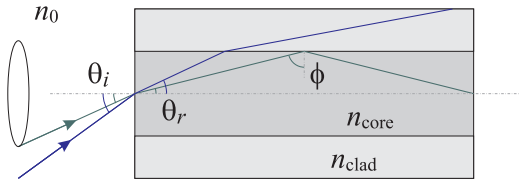

Figure 53.16:

Solution: *The numerical apertures is defined by,*

$$NA = \sin\theta_i \ .$$

Snell's law hold for the incoupled beam,

$$\frac{\sin\theta_i}{\sin\theta_r} = \frac{n_{core}}{n_0} = n_{core} \ .$$

Total internal reflection occurs between core and cladding,

$$\frac{\sin 90^\circ}{\sin\phi} = \frac{n_{core}}{n_{cladding}} \ .$$

With $\sin\theta_r = \cos\phi$ *we finally get,*

$$NA = n_{core}\sin\theta_r = n_{core}\cos\phi = n_{core}\sqrt{1-\sin^2\phi} = \sqrt{n_{cladding}^2 - n_{core}^2} \ .$$

53.1.10.16 Ex: Tuning by tilting an etalon

a. It is a common method to tune an etalon (or dielectric mirror or waveplate) to a certain transmission wavelength by tilting it as a whole with respect to the optical axis (without changing its intrinsic alignment. Does the tilt increase or decrease the wavelengths of the transmission peaks? Justify your answer. What is the implication for a dielectric mirror to be used under a non-normal angle of incidence?
b. A narrow band interference filter consisting of a glas plate coated on both surfaces has the following characteristics: thickness $L = 0.5\,\text{mm}$, refractive index $n_{rfr} = 1.45$, central wavelength $\lambda_{eff} = 706\,\text{nm}$, and bandwidth $\Delta\lambda = 0.3\,\text{nm}$. Considering the filter as Fabry-Pérot etalon, calculate its free spectral range, its finesse, and the reflectivity of its surfaces.
c. Assuming that the filter of part (b) can be tilted from normal incidence up to an angle $\theta_{max} = 35^\circ$, how far will the center frequency shift. Prepare a graph showing

λ_{eff} as a function of θ.

Solution: *a. A seemingly plausible but wrong argument is, that tilting makes the beam path longer, and that this must be compensated by a longer wavelength. A closer look shows, where the above argument is wrong. Following a ray from one layer to the next one under some angle, and back to the first layer along a 'reflected' beam, we actually don't get back to the place where we started, but rather to some offset position. But it doesn't make sense to compare the phases of two beams as measured at two different positions. A correct way to understand the issue is to consider the phase shift along a direction perpendicular to the coating layers, which is obviously reduced for tilted incidence, as illustrated in Fig. 53.17(a).*
Dielectric multilayer mirrors can be highly reflecting only in a limited spectral bandwidth. When such a mirror, designed for use with normal incidence of the light, is tilted against an incident beam, the reflection features are shifted toward shorter wavelengths.
b. From the given characteristics we calculate,

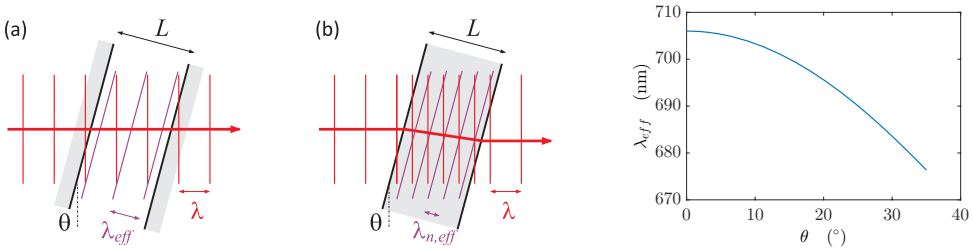

Figure 53.17: (a) Reducing the effective phase shift in a tilted air-spaced etalon. (b) Reducing the effective phase shift in a tilted dielectric etalon. (c) Tuning range of a tilted interference filter.

$$\delta_{fsr} = \frac{c}{2Ln_{refr}} \approx 207\,\mathrm{GHz} \quad , \quad \frac{\kappa}{2\pi} = \frac{c\Delta\lambda}{\lambda^2} \approx 190\,\mathrm{GHz} \quad , \quad F = \frac{2\pi\delta_{fsr}}{\kappa} = 1.1 = \frac{\pi\sqrt{R}}{1-R} \,,$$

from which we get $R = 10\%$.
c. By geometry the effective resonant wavelength of a tilted etalon is reduced. For an air-spaced etalon, $\lambda_{eff} = \lambda\cos\theta$, as seen in Fig. 53.17(b) For a dielectric etalon, we have to take into account Snell's law,

$$n_{rfr} = \frac{\sin\theta}{\sin\beta} = \frac{\lambda}{\lambda_n} \,.$$

Hence, we expect the tuning curve exhibited in Fig. 53.17(c), and parametrized by,

$$\begin{aligned}\lambda_{eff} = \lambda_n\cos\theta &= \frac{\lambda}{n_{rfr}}\cos\left(\arcsin\frac{\sin\theta}{n_{rfr}}\right) \\ &= \frac{\lambda}{n_{rfr}}\sqrt{1-\sin^2\left(\arcsin\frac{\sin\theta}{n_{rfr}}\right)} = \lambda_{max}\sqrt{1-\frac{\sin^2\theta}{n_{rfr}^2}} \,.\end{aligned}$$

53.1.10.17 Ex: Double MZI as a model for Coherent Back-Scattering

Consider the setup shown in Fig. 53.18 and calculate the signal observed on the photodetector for arbitrary phase shifts ϕ and arbitrary rotation angles α by the $\lambda/2$-waveplate.

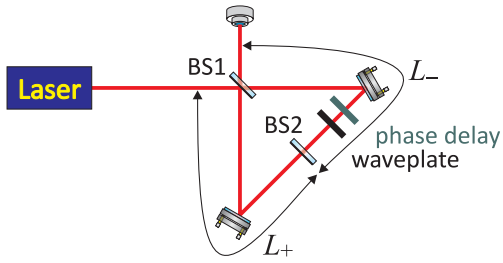

Figure 53.18: Double Mach-Zehnder interferometer.

Solution: *The electric field reaching the detector is the superposition of 4 paths. Without waveplate ($\alpha = 0$),*

$$\begin{aligned}\frac{\mathcal{E}_d}{\mathcal{E}_0} &= \sqrt{1-R_1}e^{\imath kL_+}(-\sqrt{R_2})e^{\imath kL_+}(-\sqrt{R_1}) \\ &\quad + \sqrt{R_1}e^{\imath kL_-}\sqrt{1-R_2}e^{\imath kL_+}(-\sqrt{R_1}) \\ &\quad + \sqrt{1-R_1}e^{\imath kL_+}\sqrt{1-R_2}e^{\imath kL_-}\sqrt{1-R_1} \\ &\quad + \sqrt{R_1}e^{\imath kL_-}\sqrt{R_2}e^{\imath kL_-}\sqrt{1-R_1} \\ &= e^{\imath kL}\left[2\sqrt{1-R_1}\sqrt{R_1}\sqrt{R_2}\cos 2k\Delta L + (1-2R_1)\sqrt{1-R_2}\right]\end{aligned}$$

introducing the abbreviation $L_\pm \equiv L/2 \pm \Delta L$. In particular, for $R_1 = 50\%$ we get,

$$\frac{E_d}{E_0} = \sqrt{R_2}e^{ikL}\cos 2k\Delta L \ .$$

For $R_2 = 0$ the double MZI is a model for CBS, because all the light reflected from the setup is going into backward direction.
With the $\lambda/2$-waveplate described by the Jones-matrix,

$$M_{\lambda/2}(\alpha) = \begin{pmatrix} \cos 2\alpha & -\sin 2\alpha \\ -\sin 2\alpha & -\cos 2\alpha \end{pmatrix} \qquad \textit{with} \qquad M_{\lambda/2}(\alpha)^2 = \mathbb{I} \ ,$$

we can generalize the ansatz:

$$\begin{aligned}
\begin{pmatrix}\mathcal{E}_\perp\\ \mathcal{E}_\parallel\end{pmatrix} &= \sqrt{1-R_1}e^{\imath kL_+}(-\sqrt{R_2})e^{\imath kL_+}(-\sqrt{R_1})\begin{pmatrix}\mathcal{E}_{0\perp}\\ \mathcal{E}_{0\parallel}\end{pmatrix}\\
&\quad+\sqrt{R_1}e^{\imath kL_-}M_{\lambda/2}(\alpha)e^{\imath\phi}\sqrt{1-R_2}e^{\imath kL_+}(-\sqrt{R_1})\begin{pmatrix}\mathcal{E}_{0\perp}\\ \mathcal{E}_{0\parallel}\end{pmatrix}\\
&\quad+\sqrt{1-R_1}e^{\imath kL_+}\sqrt{1-R_2}e^{\imath\phi}M_{\lambda/2}(\alpha)e^{\imath kL_-}\sqrt{1-R_1}\begin{pmatrix}\mathcal{E}_{0\perp}\\ \mathcal{E}_{0\parallel}\end{pmatrix}\\
&\quad+\sqrt{R_1}e^{\imath kL_-}M_{\lambda/2}(\alpha)e^{\imath\phi}\sqrt{R_2}e^{\imath\phi}M_{\lambda/2}(\alpha)e^{\imath kL_-}\sqrt{1-R_1}\begin{pmatrix}\mathcal{E}_{0\perp}\\ \mathcal{E}_{0\parallel}\end{pmatrix}\\
&= e^{\imath kL+\imath\phi}\begin{pmatrix}E_\perp\\ E_\parallel\end{pmatrix}\left[2\sqrt{1-R_1}\sqrt{R_1}\sqrt{R_2}\cos(2k\Delta L-\phi)+(1-2R_1)\sqrt{1-R_2}M_{\lambda/2}(\alpha)\right] .
\end{aligned}$$

In particular, for $R_1 = 50\%$ the setup becomes insensitive on the polarization of the waveplate:

$$\begin{pmatrix}E_\perp\\ E_\parallel\end{pmatrix} = e^{\imath kL+\imath\phi}\sqrt{R_2}\cos(2k\Delta L-\phi)\begin{pmatrix}E_{0\perp}\\ E_{0\parallel}\end{pmatrix} .$$

53.1.11 *Experiment: Mach-Zehnder interferometer*

The Mach-Zehnder interferometer and the Michelson interferometer are the two most common two-beam interferometers. For the realization of the following project prior knowledge of 1. Gaussian beams (see Sec. 51.2), 2. photodetectors (see Sec. 52.2.1), and 3. piezo-electric transducers (see Sec. 53.1.2) is required.

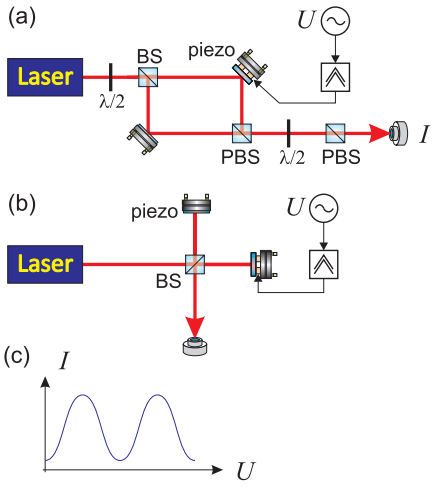
1. Set up a Mach-Zehnder interferometer with a piezo in one of the arms according to Fig. 53.3(a). Optimize the phase matching of the two beams onto a photodetector and the rotation of the $\lambda/2$-waveplates until you obtain visible interference patterns.

2. Vary the length of one arm of the interferometer using the piezo. Measure the contrast of the interference fringes and discuss from which parameters it depends and how it can be maximized.

3. Rotate the first $\lambda/2$-waveplate (behind the laser). What do you observe? Explain the observation!

4. Remove the PBS in front of the photodetector. What do you observe? Explain the observation!

5. If a piezo is used, vary the voltage applied to the piezo-electric actuator and measure the voltage expansion coefficient d.



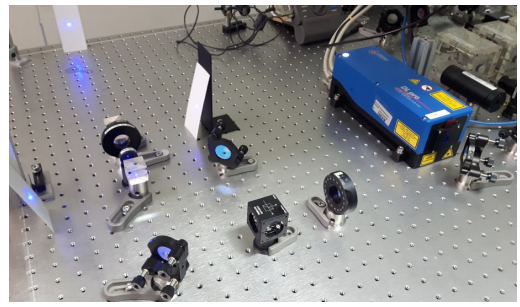


Figure 53.19: Setup for (a) a Mach-Zehnder interferometer or (b) a Michelson interferometer. (BS) non-polarizing beamsplitter, (PBS) polarizing beamsplitter. (c) Signal on the photodetector as a function of the length variation of an arm of the interferometer.

53.1.12 *Experiment: Fabry-Pérot cavity*

A Fabry-Pérot cavity is a typical multi-beam interferometer.

1. Set up a Fabry-Pérot cavity according to Fig. 53.20 and mode-match a laser beam into the cavity. Scan the cavity length using a piezo and observe the transmitted spectrum on an oscilloscope. What do you observe?

2. If an ECDL is used, vary the current and the temperature of the laser diode. What do you observe? Vary the frequency of the diode laser by scanning the piezo transducer of the laser cavity. Observe the mode spectrum of the laser in the transmission signal of the cavity. Measure its free spectral range, the transmission linewidth, and the finesse of the cavity.

Optical cavities are frequently used as *optical spectrum analyzers*. For this application, it is helpful to simplify the intrinsic mode spectrum of the cavity by using a confocal design, where all transerse modes are degenerated. We will now set up an optical cavity and characterize it by its free spectral range and its finesse. Then we will analyze its mode spectrum and modify its geometry to make it confocal.

1. Couple a laser beam into a cavity as shown in Fig. 53.20. The cavity provided by this tinker course consists of a plane incoupler ($\rho_1 = \infty$, $R_1 = 98\%$) and a high reflector ($\rho_2 = 25\,\text{mm}$, $R_2 = 99.8\%$). Position the mirror at a distance L, where the cavity is stable. Calculate the free spectral range, the finesse, the diameter of the beam waist.

2. Optimize the phase-matching of the laser beam to the cavity. In order to do this, (a) measure the diameter of the diode laser beam, (b) determine the lens

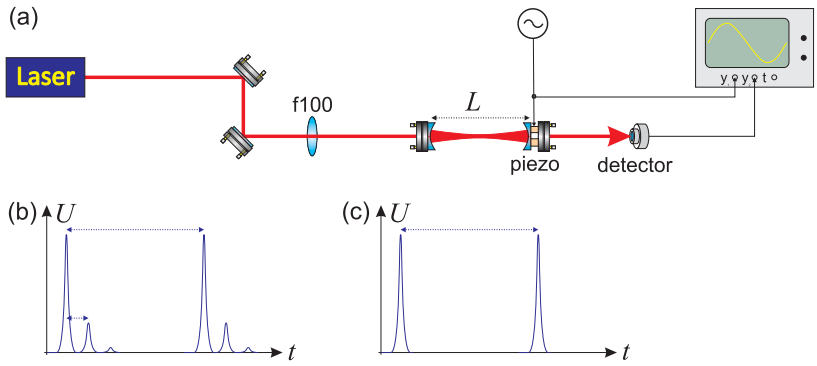

Figure 53.20: (a) Setup for aligning a confocal resonator. (b) Transmission spectrum of the cavity for non-confocal alignment. (c) Same as (b) but for the case of confocal alignment.

which can be used to focus down to the beam waist of the cavity. How does the transmission spectrum change upon the beam matching?

53.1.13 *Experiment: Fizeau interferometer*

A *Fizeau interferometer* is a device allowing to analyze the rugosity of surfaces.

1. Set up a Fizeau interferometer according to Fig. 53.20.

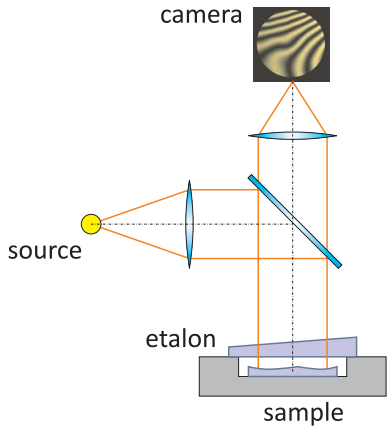

Figure 53.21: Principle of operation of a Fizeau interferometer.

53.1.14 *Experiment: Coupling light into an optical fiber*

Coupling a laser beam into an optical fiber is a delicate task, requiring a good collimation optics and full control over the 6 degrees of freedom defining a laser beam: horizontal and vertical position, horizontal and vertical tilt, beam diameter and divergence.

1. Redirect the light of a HeNe laser via two adjustable mirrors into a fiber collimator in such a way that the beam is not deviated from the optical axis by the collimator.

2. Now connect (a) a multimode fiber and (b) a single mode fiber to the collimator. Optimize the coupling by walking the laser beam and by adjusting the focus of the fiber collimator. What differences do you observe for multi- and single mode fibers?

53.2 Conventional light sources and lasers

For the first half of the 20-th century these assumptions matched the available light sources, usually incandescent, arc or plasma discharge lamps. After the invention of the laser in 1958, single mode and pulsed lasers quickly replaced the lamps as a source for optical excitation. These new light sources initiated a revolution in optical science, the consequence of which continue to reverberate through modern sciences and applied technologies. The characteristics of laser sources are far superior to the old lamps in all respects. They are intense, collimated, spectrally narrow and phase coherent. The laser gave rise to a multitude of new spectroscopic techniques and new disciplines, such as quantum electronics, the study of statistical properties of light in quantum optics, optical cooling and trapping of microscopic particles, the control of chemical reactivity, and new technologies for imaging and high resolution microscopy. The impact the laser had on technology is only comparable to that of to the invention of the transistor. See also (watch talk).

The laser produces light through an optical quantum amplification process based on the stimulated emission of electromagnetic radiation. The term 'laser' is an acronym for 'Light Amplification by Stimulated Emission of Radiation'. A laser differs from other light sources in that it emits *coherent* light. Its spatial coherence allows the light to be focused on a very tiny spot, where the concentration of energy is sufficient for applications such as laser cutting and lithography. The spatial coherence also allows it to collimate a laser beam over large distances, that is, the light forms a concentrated beam propagating in a straight line. Lasers can also have a very high temporal coherence, which corresponds to a very narrow spectrum, that is, lasers usually emit a single very well defined color of light. The extreme temporal coherence can be used to produce pulses of light as short as a femtosecond. In addition, laser light is polarized.

In 1917, Albert Einstein established the theoretical foundations of the laser in an article 'Zur Quantentheorie der Strahlung' through a rederivation of Max Planck's radiation law. He proposed a mechanism explaining how light is absorbed and emitted from atoms. The fundamental ingredient is that the photon can be emitted in two different ways, by spontaneous emission, an indeterministic process that occurs without physical reason, or by stimulated emission. This latter emission process occurs because of stimulation by light, which is already present in the system and represents the fundamental mechanism of the laser. In the following decade German and American researchers experimentally confirmed the phenomena of stimulated emission and negative absorption, that is, gain. In 1950, Alfred Kastler (French physicist and No-

bel Prize in Physics of 1966) proposed the method of optical pumping, confirmed experimentally two years later by other French physicists.

In 1953, Charles Townes produced the first microwave amplifier called *maser*, a device that operates similarly to the laser but amplifies microwave radiation instead of visible or infrared radiation. However, Townes' maser was unable to emit light continuously. In 1955, in the Soviet Union, Nikolay Basov and Aleksandr Prokhorov solved the problem of continuous operation using atoms with more than two energy levels. These level systems were able to sustain a permanent population inversion of an energetic level decaying to a less energetic system by releasing light via stimulated emission. Despite the fact that several prominent physicists, including Niels Bohr, John von Neumann, and Isidor Rabi, argued that the maser violates Heisenberg's uncertainty principle and therefore could not work, in 1964, Charles Townes, Nikolay Basov and Aleksandr Prokhorov shared the Nobel Prize in Physics for fundamental work in the field of quantum electronics that led to the realization of oscillators and amplifiers based on the maser principle.

In 1957, Charles Townes and Arthur Schawlow, from the Bell labs, began to seriously study feasibility of an 'optical maser'. In 1958, the Bell labs submitted a patent proposing a scheme for optical radiation, and Schawlow and Townes presented a scientific paper. Simultaneously, at the Columbia University, the PhD student Gordon Gould was working on the energy levels of excited thallium. In 1957-8, Gould and independently Prokhorov, Schawlow and Townes proposed the use of an open resonator, which later became an essential component of the laser. Gould also proposed several possible applications for a laser, such as spectrometry, interferometry, the radar, and nuclear fusion. He continued to develop the idea, and filed a patent application in April 1959. The United States Patent Office dismissed his application, and granted a patent to the Bell Labs in 1960. Gould won his first minor patent in 1977 after a 28-year fight, and it took him until 1987 to win his first significant process in the struggle, when a federal judge ordered the United States Patent Office to issue to Gould patents for optical pumping and the invention of a laser based on the principle of electrical gas discharge.

It was Theodore Maiman, who on May 16, 1960, operated the first working laser at the Hughes Research Laboratories, Malibu, California, evincing several other research teams, including the ones of Townes at Columbia University, of Schawlow at Bell Labs, and Gould at the company TRG (Technical Research Group). Maiman's laser used a synthetic solid-state ruby crystal pumped by a flash lamp to produce red laser light at 694 nm wavelength; however, the device was only capable of pulsed operation due to its three-level pumping scheme. Later in 1960, the first gas laser was built, using a helium-neon mixture, which was capable of continuous operation in the infrared spectrum. Basov and Javan proposed the concept of a semiconductor laser diode. In 1962, the first laser diode device, made of gallium arsenide, was realized emitting near-infrared light. Nowadays, laser diodes are available in various spectral regimes up to the UV.

Interestingly, despite many attempts, it has not yet been possible to manufacture yellow or green laser diodes.

Figure 53.22: First suggested application in 1964 of a (left) HeNe laser and (right) a diode laser.

53.2.1 Features and operation of lasers

To understand how a laser operates, we consider the process of absorption and emission of light by an atom. Following Bohr's model an absorbed photon raises an electron from a lower orbit to a higher orbit, and when the electron returns back to the ground state, it re-emits a photon in an arbitrary direction.

When we illuminate a sample of N atoms, N_1 atoms of which are in the ground state, by a radiation field, the absorption rate depends on the field intensity $I(\nu)$ and a constant B_{12}, which is characteristic for the transition,

$$R_{abs} \propto B_{12} I(\nu) N_1 \ . \tag{53.35}$$

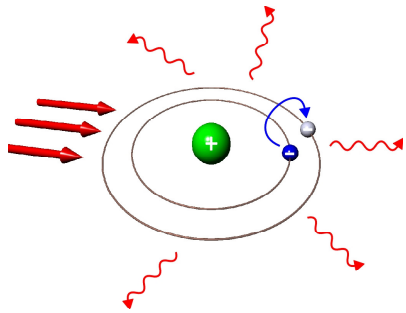

Figure 53.23: Bohr's model of photon absorption.

The emission rate depends on the number of atoms N_2 in the excited state, such that,

$$R_{sp} \propto A_{21} N_2 \ . \tag{53.36}$$

As the excited state has more energy, it can decay by itself (i.e. spontaneously) to a lower energy state. Einstein's brilliant idea now was to postulate a third process, which he called stimulated emission,

$$R_{st} \propto B_{21} I(\nu) N_2 \ . \tag{53.37}$$

In this process, an incident photon stimulates an excited atom to transfer the electron to a lower orbit. The released energy is then used to form a second photon, which is in all respects identical to the first. This process is necessary to ensure that, in thermal equilibrium, the population of the states follows Boltzmann's law.

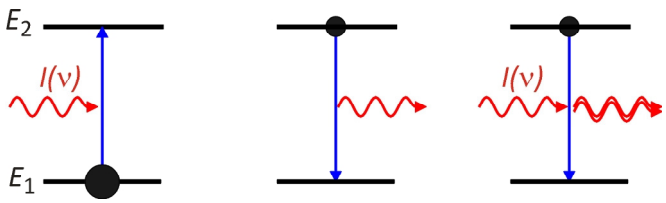

Figure 53.24: Einstein's model of absorption and spontaneous and stimulated emission.

Obviously, absorption decreases the intensity of a light beam crossing the atomic sample, while stimulated emission amplifies it. In order to amplify incident light, the gain in intensity must overcome the losses. Therefore, we need the absorption processes to be less frequent than the stimulated emission processes, i.e. the number of atoms in the excited state N_2 must exceed the number of atoms in the ground state $N_1 < N_2$.

We can easily write the rate equation,

$$\frac{dN_2}{dt} = -A_{21}N_2 - B_{21}I(\nu)N_2 + B_{21}I(\nu)N_1 = -\frac{dN_1}{dt} \ , \tag{53.38}$$

with $N = N_1 + N_2$. It is easy to solve this equation. The result is,

$$N_2 = \frac{I(\nu)B_{21}N}{A + 2B_{21}I(\nu)}[1 - e^{-(A_{21}+2B_{21}I(\nu))t}] < N_1 \ . \tag{53.39}$$

The graphical representation 53.25 shows the temporal behavior of the populations

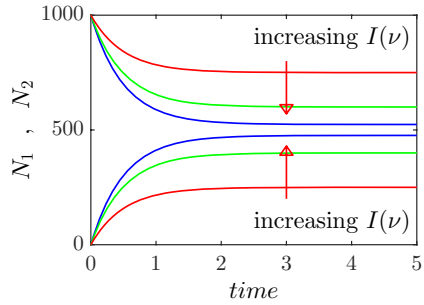

Figure 53.25: (code) Impossibility of achieving inversion in a two-level system.

N_1 (in green in the figure) and N_2 (in blue), reaching a state of equilibrium after a certain time. By increasing the intensity of the incident light, we observe that the curves approach each other but never cross. That is, in a two-level system, we always get $N_1 > N_2$ and the populations are never inverted. Therefore, amplification of light as in the laser does not happen.

Fortunately, we can resort to a trick by inserting a third level. Ensuring that the decay rate of the (metastable) state E_3 is much slower than the optical pumping to this state via the driven transition $E_1 \rightarrow E_2$ followed by a rapid decay $E_2 \rightarrow E_3$, we can reach the situation $N_3 > N_1$. Now it is possible to amplify light, which is resonant with the transition $E_2 \rightarrow E_3$.

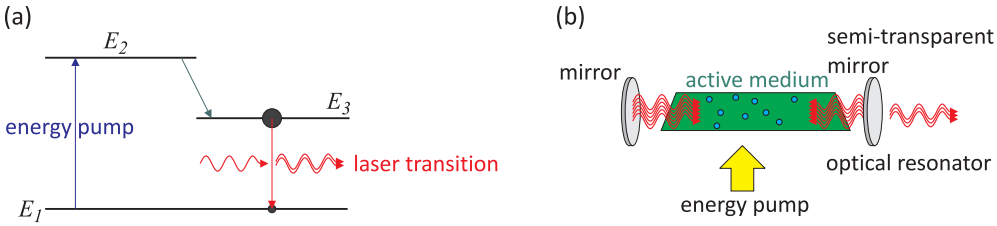

Figure 53.26: Basics of a laser: (a) Level system and (b) principle scheme.

What are the minimum requirements for the realization of a laser? The first condition is that the *pumping cycle is irreversible* to ensure that the processes of stimulated emission and absorption do not compensate. Spontaneous emission is irreversible and can be incorporated into a three-level system.

The second condition is the existence of a *stimulated emission process*, because we want the amplified photon to be an exact copy of the incident photon.

The third requirement is a *feedback mechanism* that synchronizes the amplification processes by different atoms in a disordered environment, such as a gas. Mirrors are ideal because they increase the effective gain path, i.e. the distance within which inverted atoms can amplify light. Also, the mirrors define the phase of the light wave, since the standing wave formed by the counterpropagating light fields must have nodes on the surfaces of the mirrors.

53.2.1.1 Threshold condition

According to the *Lambert-Beer law* the intensity of a monochromatic laser beam evolves, on its way through a gas of two-level atoms with energies $E_2 - E_1 = \hbar\omega_0$ like,

$$I(z,\nu) = I(0,\nu)e^{-\alpha(\nu)z} \ , \tag{53.40}$$

where the frequency-dependent absorption coefficient,

$$\boxed{\alpha(\nu) = [N_1 - \tfrac{g_1}{g_2}N_2]\sigma(\nu)} \ , \tag{53.41}$$

is determined by the absorption cross section $\sigma(\nu)$ for the transition and by the inversion,

$$\Delta N \equiv \tfrac{g_1}{g_2}N_2 - N_1 \ , \tag{53.42}$$

which determines whether stimulated emission prevails or absorption: For $\Delta N > 0$, the absorption coefficient $\alpha(\nu)$ becomes negative and the incident wave is amplified instead of attenuated [351].

If the active medium is placed between two mirrors [Fig. 53.26(b)], the wave is reflected back and forth, and traverses the amplifying medium many times, which

increases the total amplification. With the length L of the active medium the total gain factor per single round-trip without losses is,

$$G(\nu) = \frac{I(\nu, 2L)}{I(\nu, 0)} = e^{-2\alpha(\nu)L} \ . \tag{53.43}$$

A mirror with reflectivity R reflects only the fraction R of the incident intensity. The wave therefore suffers at each reflection a fractional reflection loss of $(1 - R)$. Furthermore, absorption in the windows of the cell containing the active medium, diffraction by apertures, and scattering due to dust particles in the beam path or due to imperfect surfaces introduce additional losses. When we summarize all these losses by a loss coefficient γ, which gives the fractional energy loss $\Delta W/W$ per round-trip time T, the intensity I decreases without an active medium per round-trip as,

$$I(2d, \nu) = I(0, \nu)e^{-\gamma} \ . \tag{53.44}$$

Including the amplification by the active medium with length L, we obtain for the intensity after a single round-trip through the resonator with length d, which may be larger than L:

$$I(2d, \nu) = I(0, \nu)e^{-2\alpha(\nu)L-\gamma} \ . \tag{53.45}$$

The wave is amplified if the gain overcomes the losses per round-trip. This implies that,

$$-2L\alpha(\nu) = 2L\Delta N\sigma(\nu) > \gamma \ , \tag{53.46}$$

which yields the threshold condition for the population difference,

$$\Delta N > \Delta N_{thr} = \frac{\gamma}{2L\sigma(\nu)} \ . \tag{53.47}$$

If the inverted population difference ΔN of the active medium is larger than ΔN_{thr}, a wave that is reflected back and forth between the mirrors will be amplified in spite of losses, therefore its intensity will increase.

The wave is initiated by spontaneous emission from the excited atoms in the active medium. Those spontaneously emitted photons that travel into the right direction (namely, parallel to the resonator axis) have the longest path through the active medium and therefore the greater chance of creating new photons by induced emission. Above the threshold they induce a photon avalanche, which grows until the depletion of the population inversion by stimulated emission just compensates the repopulation by the pump. Under steady-state conditions the inversion decreases to the threshold value ΔN_{thr}, the saturated net gain is zero, and the laser intensity limits itself to a finite value I_L. This laser intensity is determined by the pump power, the losses γ, and the gain coefficient $\alpha(\nu)$.

The frequency dependence of the gain coefficient $\alpha(\nu)$ is related to the line profile $g(\nu - \nu_0)$ of the amplifying transition. Without saturation effects (i.e. for small intensities), $\alpha(\nu)$ directly reflects this line shape, for homogeneous as well as for inhomogeneous profiles. According to (53.41) and (22.87) we obtain with the Einstein coefficient B_{ik},

$$\alpha(\nu) = \Delta N\sigma(\nu) = -\Delta N(h\nu/c)B_{12}(\nu - \nu_0) \ , \tag{53.48}$$

which shows that the amplification is largest at the line center ν_0. For high intensities, saturation of the inversion occurs, which is different for homogeneous and for inhomogeneous line profiles.

The loss factor γ also depends on the frequency ν because the resonator losses are strongly dependent on ν. The frequency spectrum of the laser therefore depends on a number of parameters.

53.2.1.2 Applications of lasers in industry and fundamental research

Among their many applications, lasers are nowadays used in compact disc players, laser printers, and bar code scanners, optical fibers and optical communication, laser surgery and skin treatments, welding, cutting and machining, military devices, distance and velocity measurements, projectors, laser pointers, etc..

In fundamental research (in particular on atomic gases, metamaterials, etc.), the laser plays elementary roles in the areas of photonics, quantum computers, metrology, frequency combs, and atomic clocks (laser-based clocks are up to 1000 times more stable than the best state-of-the-art microwave clocks).

We all know that light is a wave. With the invention of the laser we found a process and a device to make this light coherent. On the other hand, since de Broglie's assertion we know that *matter is a wave, as well.* Is it conceivable to construct a matter laser? Yes, it is! The first coherent matter wave was in fact observed in 1995. This state of matter, also called Bose-Einstein condensate, was predicted by Bose and Einstein in 1924. To create a Bose-Einstein condensate, we need, similarly to the laser, that the matter waves interfere constructively in a way that they amplify each other. For this, the Broglie wavelength of the particles, which constitute the matter, must be longer than the distance between them. Assuming a typical average distance on the order of µm, this corresponds to an average velocity of the particles of mm/s or a temperature of some 100 nK.

53.2.2 HeNe laser

HeNe lasers are gas lasers, whose gain medium consists of a mixture of 90% helium and 10% neon at a total pressure of about 1 Torr excited by a small electrical discharge. The most widely used transition wavelength is at 632.8 nm.

Fig. 53.27(a) shows the principle scheme of a commercial HeNe laser. The distance between the high-reflecting mirror (R_{hr}) and the output coupler (R_{oc}) determines the free spectral range δ_{fsr}. Typically, a HeNe laser operates on two or three longitudinal modes separated by δ_{fsr}. As illustrated in Fig. 53.27(b), the numbers of lasing modes above threshold depends on the ratio of gain-to-loss. Fig. 53.27(c) shows the optical pumping scheme to reach inversion on three of the lasing transitions at 632.8 nm, 1.15 µm, and 3.39 µm.

53.2.3 Diode laser

A laser diode is electrically a *pin*-diode. The active region of the laser diode is in the intrinsic (i) region, and the carriers (electrons and holes) are pumped into that depletion region from the n- and p-doped regions respectively. The depletion region, devoid of any charge carriers, forms as a result of the difference in electrical potential

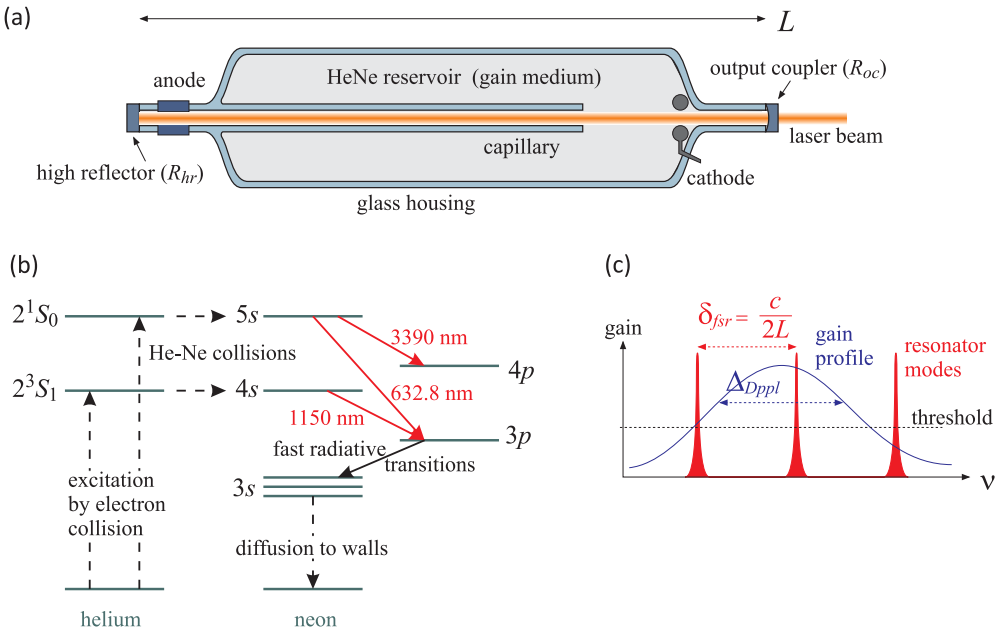

Figure 53.27: (a) Construction scheme of a HeNe laser. (b) Gain and emission profile. (c) Optical pumping scheme.

between n- and p-type semiconductors wherever they are in physical contact. Unlike a regular diode, the goal for a laser diode is to recombine all carriers in the i region, and produce light.

Figure 53.28: (Left) Laser diode with protective housing removed, e.g. using a can opener. (Right) Laser diode collimator.

53.2.3.1 Generation of light

Electrons and holes present in the same region may recombine or 'annihilate' by spontaneous emission of photons with energy equal to the difference between the electron's original state and hole's state (see Fig. 52.10). This is in contrast to a conventional semiconductor junction diode, where the energy released from the recombination is carried away as phonons, i.e. lattice vibrations. Spontaneous emission below the lasing

threshold is the operating mode of an LED. While spontaneous emission is necessary to initiate laser oscillation, it contributes to reduce the efficiency of a laser operating above threshold.

One condition for lasing is that, in the absence of stimulated emission, electrons and holes may coexist in proximity to one another without recombining immediately. For typical diode laser materials the 'upper-state lifetime' or 'recombination time' is on the order of a nanosecond. A nearby photon with energy equal to the recombination energy can cause recombination by stimulated emission. This generates another photon of the same frequency, polarization, and phase, traveling in the same direction as the first photon. In this way stimulated emission will cause gain for an optical wave in the injection region, and the gain increases as the number of electrons and holes injected across the junction increases.

53.2.3.2 Optical cavity and laser modes

As in other lasers, the gain region needs to be surrounded by an optical cavity providing optical feedback. In its simplest form, a laser diode is made in the shape of a narrow optical waveguide on a the surface of a crystal. The two ends of the crystal are cleaved to form perfectly smooth, parallel edges, forming a Fabry-Pérot resonator. Emitted photons will travel along the waveguide, be amplified by stimulated emission and reflected several times from each end face before exiting. If the losses due to absorption and incomplete reflection from the end facets are smaller than the gain, the diode begins to 'lase'.

Important properties of laser diodes are determined by the geometry of the optical cavity. If the waveguide is thick compared to the wavelength of the light, it can support higher-order transverse optical modes. The laser is then called 'multi-mode'. These transversely multi-mode lasers are adequate for application where high power is needed, for example, in printing, activating chemicals, or pumping other types of lasers.

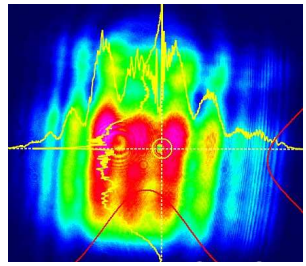

Figure 53.29: Typical beam profile of a multimode laser diode (Thorlabs, L450P1600MM.

For applications requesting small focused beams the waveguide must be made narrow, on the order of the optical wavelength, such that only a single transverse mode is supported, and one ends up with a diffraction-limited beam. Such single spatial mode devices are used for optical storage, laser pointers, and fiber optics. Note that these lasers may still support multiple longitudinal modes, and thus can lase simultaneously at multiple wavelengths. The wavelength emitted is a function of the band-gap of the semiconductor material and the modes of the optical cavity. In

general, the maximum gain will occur for photons with energy slightly above the band-gap energy, and the modes nearest the peak of the gain curve will lase most strongly. The width of the gain curve will determine the number of additional 'side modes' that may also lase, depending on the operating conditions. Single spatial mode lasers that can support multiple longitudinal modes are called Fabry-Pérot (FP) lasers. A FP laser will lase at multiple cavity modes within the gain bandwidth of the lasing medium. The number of lasing modes in an FP laser is usually unstable, and can fluctuate due to changes in current or temperature.

Single spatial mode diode lasers can be designed so as to operate on a single longitudinal mode. These single frequency diode lasers exhibit a high degree of stability, and are used in spectroscopy and metrology, and as frequency references. Single frequency diode lasers are classed as either distributed feedback (DFB) lasers or distributed Bragg reflector (DBR) lasers.

Due to diffraction, the beam diverges (expands) rapidly after leaving the chip, typically at 30 degrees vertically by 10 degrees laterally. A lens must be used in order to form a collimated beam like that produced by a laser pointer. If a circular beam is required, cylindrical lenses and other optics are used. For single spatial mode lasers, using symmetrical lenses, the collimated beam ends up being elliptical in shape, due to the difference in the vertical and lateral divergences.

53.2.3.3 Distributed Bragg reflector lasers and distributed feedback lasers

The simple diode described above has been heavily modified in recent years to accommodate modern technology, resulting in a variety of types of laser diodes. One example is the distributed Bragg reflector laser (DBR). It consists of a monolithic single frequency laser diode, characterized by an optical cavity consisting of an electrically or optically pumped gain region between two mirrors to provide feedback. One of the mirrors is a broadband reflector and the other mirror is wavelength selective so that gain is favored on a single longitudinal mode, resulting in lasing at a single resonant frequency. The broadband mirror is usually coated with a low reflectivity coating to allow emission. The wavelength selective mirror is a periodically structured diffraction grating with high reflectivity. The diffraction grating is etched into the semiconductor within a non-pumped, or passive region of the cavity.

A distributed feedback laser (DFB) is a monolithic single frequency laser diode with a diffraction grating etched close to the *pn*-junction of the diode aiming at stabilizing the lasing wavelength. This grating acts like an optical filter, causing a single wavelength to be fed back to the gain region and lase. Since the grating provides the feedback that is required for lasing, reflection from the facets is not required. Thus, at least one facet of a DFB is anti-reflection coated. The DFB laser has a stable wavelength that is set during manufacturing by the pitch of the grating, and can only be tuned slightly with temperature. DFB lasers are widely used in optical communication applications, where a precise and stable wavelength is critical.

53.2.3.4 ECDL

An *extended-cavity diode laser* (*ECDL*) is an optical setup based on a laser diode chip, which typically has one end anti-reflection (AR) coated, and the laser resonator is completed with a collimating lens and a mirror, as shown in Fig. 53.30(a). The

extended external laser resonator introduces various new features and options: Compared to a standard laser diode, the longer resonator increases the damping time of the intracavity light according to Eq. (53.26), and thus allows for lower phase noise and a smaller emission linewidth (in single-frequency operation). Furthermore, it opens the way for inserting frequency-selective optical components into the extended laser resonator, such as narrow-band Fabry-Pérot etalons or diffraction gratings, which can further *reduce the linewidth* and even allow to *tune and control the frequency* of the laser.

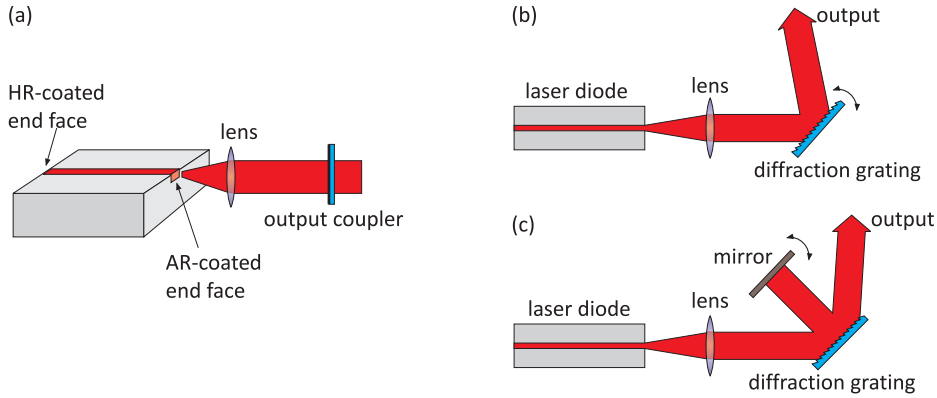

Figure 53.30: (a) ECDL with an AR-coated laser diode and an external mirror. (b) Littrow configuration. (c) Littmann configuration.

Tunable ECDLs based on diffraction grating as the wavelength-selective element are also called grating-stabilized diode lasers. The common Littrow configuration Fig. 53.30(b) generates optical feedback to the laser diode chip by retro-reflecting the first-order diffracted beam from the grating. The emission wavelength can be tuned by slightly tilting the diffraction grating. A disadvantage of this configuration is, that the tilt also changes the direction of the output beam, which is inconvenient for many applications.

In the Littman-Metcalf configuration Fig. 53.30(c), the grating angle is held fixed, and an additional mirror is used to reflect the first-order beam back into the laser diode. The wavelength can be tuned by rotating that mirror. This configuration offers a fixed direction of the output beam, and also tends to exhibit a smaller linewidth, as the wavelength selectivity is stronger, because the wavelength-dependent diffraction occurs twice per resonator round trip. A disadvantage is that the zero-order reflection of the beam reflected by the tuning mirror is lost, so that the output power is lower than that of a Littrow laser.

New concepts have recently become popular, such as the so-called *cat-eye laser* [75, 510, 124], where the frequency-selective element is an extremely narrow-band (0.3 nm) optical filter [5].

By adjusting the tilt angle of a grating or a narrow-band filter by means of a piezo an extremely fine tuning of the emission frequency is possible, while coarse tuning of the frequency over a range of several nanometers is typically achieved by changing

[5] Available from Semrock or Laseroptik.

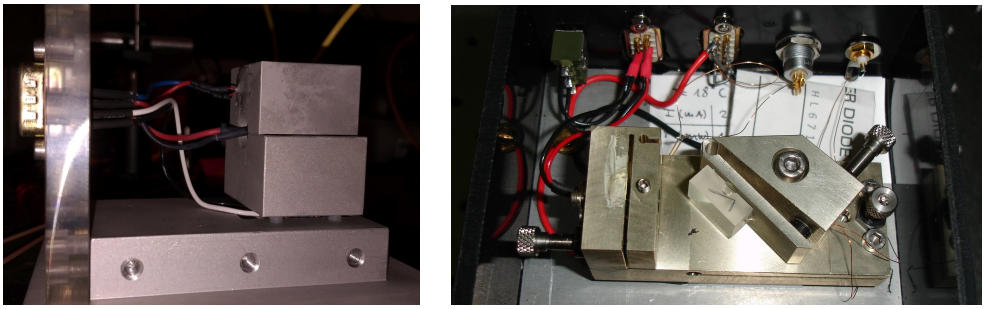

Figure 53.31: (Left) Side view of a 'free-running' laser diode mounted in a collimator (Thorlabs, LT110P-B) clamped in an aluminum block cooled by a Peltier element (Thorlabs, TEC3-6) and whose temperature is measured by a thermistor (Thorlabs, TH10K). (Right) Top view of a home-built ECDL laser in Littrow configuration. The diode collimator is clamped into the left mount. a holographic grating (Newport, 10HG2000-475-1) is glued to the right mount, whose angle can be adjusted mechanically and via a piezo. The whole setup is cooled by a Peltier element mounted on the bottom of the base plate.

the temperature and the laser current. Typical linewidths of free-running ECDLs are well below 5 MHz. Controlling the laser temperature, current, and piezo voltage by active feedback circuits (e.g. within a Pound-Drever-Hall servo electronics) emission bandwidths in the milliHertz range have been achieved, which corresponds to quality factors of the laser oscillator of up to 10^{18}.

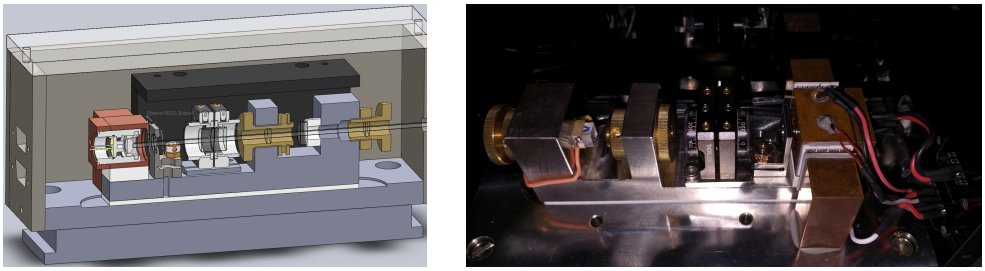

Figure 53.32: (Left) Construction plan of a home-built ECDL lasers in cat-eye configuration. (Right) Side view of the cat-eye laser.

In comparison to other laser types, a *diode laser* exhibits, the advantage of a very small size and a compact design. They are, in general, easy to handle and can be controlled conveniently via current and temperature. However, they also have the disadvantage of a large beam divergence and a broad emission spectrum. The beam divergence can be compensated by a collimation optics in front of the laser diode.

The temperature has an impact on the band structure of the *pn*-transition of the laser diode and hence on the frequency. Therefore, it is stabilized via a Peltier element, which is mounted underneath the laser diode holder. The degree of freedom is used for tuning the laser frequency in wide steps.

53.2.3.5 Pulsed diode lasers

Diode lasers can be used for generating ultrashort pulses either with various techniques of mode locking or with gain switching. Typically, pulses with durations between 0.5 and 5 ps and pulse repetition rates between 1 GHz and hundreds of giga-Hertz are generated with mode locking. In extreme cases, the repetition rate can even be above 1 THz. The main application of ultrafast diode lasers is in optical fiber communications systems, where such lasers function as pulse sources of fast data transmitters or for all-optical signal processing.

Common techniques for mode locking of diode lasers are active ore passive mode locking. Active mode locking can be accomplished with an optical modulator in the laser resonator. This is usually either an electro-absorption modulator in the form of an unpumped region with some modulated voltage, or an amplifying section where the drive current is modulated. Passive mode locking relies on a saturable absorber in the resonator. This can simply be an unpumped section of the device. It is common to apply an electrical bias for adjusting the absorber properties. However, the recovery time of that kind of absorber is fairly long. Shorter recovery times are achieved e.g. by implanting nitrogen (N^+ or N_2^+) ions from one facet. This introduces crystal defects, where carriers can recombine. The absorber is often placed at a resonator end, but it can also be placed somewhere within the resonator so that different pulses can meet in the absorber (colliding pulse mode locking).

For pulse repetition rates roughly below 10 GHz, an external cavity setup is usually required, as a monolithic device would become too long. The extended cavity may be an ECDL setup. Another technical approach is to incorporate the semiconductor chip into a ring laser resonator made of optical single-mode fiber. In the latter case, the resonator is typically much longer, and allows the use of fiber-optic components. The semiconductor device may then be a fiber-coupled semiconductor optical amplifier (SOA).

External-cavity lasers have various advantages: The pulse repetition rate can be chosen in a wide range, and can easily be tuned e.g. by moving the end mirror, or with a fiber resonator by stretching a piece of fiber with a piezo transducer. It is possible to insert an optical filter for fixing the emission wavelength, or use a diffraction grating as the end mirror (Littrow configuration; see the article on external-cavity diode lasers). Even for higher pulse repetition rates, where harmonic mode locking is required, external-cavity devices can be advantageous, because they have a potential for lower laser noise, e.g. in the form of timing jitter. Therefore, mode-locked external-cavity diode lasers sometimes compete with mode-locked fiber lasers in areas where monolithic laser diodes would not be suitable. On the other hand, a monolithic setup with fundamental mode locking can be very compact, much cheaper to manufacture, and can exhibit very robust pulse emission.

On the other hand, mode-locked diode lasers are subject to various limitations, which do not allow them to reach the full performance potential of, e.g., mode-locked fiber lasers: The pulse energy is fairly limited often far below 1 pJ. Average output powers are often below 1 mW. Due to the short upper-state lifetime, ultrafast semiconductor lasers are generally not suitable for lower repetition rates of e.g. well below 1 GHz, except with synchronous pumping. Although the gain bandwidth of semiconductors would be compatible with pulse durations of a few tens of femtoseconds, the pulse durations achieved are usually much longer at least hundreds of femtoseconds,

and often picoseconds. The pulse formation dynamics are relatively complicated, e.g. due to nonlinear phase changes associated with gain saturation, and difficult to optimize. The pulse quality is normally not as good as e.g. for mode-locked fiber lasers. In particular, there are often additional satellite pulses, caused e.g. by imperfections of the anti-reflection coating. Also, the pulses are often chirped, i.e. they are not bandwidth-limited. The timing jitter and the noise of other pulse parameters are higher than for other mode-locked lasers. This is partly a consequence of the low power level.

53.2.3.6 Tapered amplifiers and injection locking

Other ways to amplify a the power of a laser without altering its coherence properties are using a *tapered amplifier* or via *injection locking* also called *master-slave locking* [208, 807] (see Fig. 53.33).

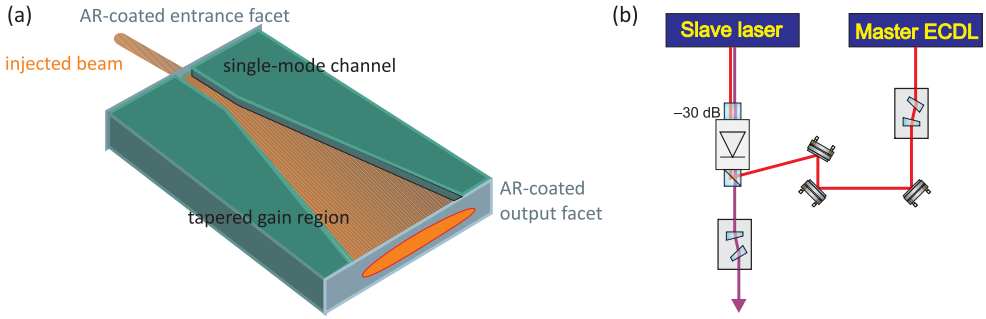

Figure 53.33: (a) Tapered amplifiers are available e.g. from Eagleyard. (b) Principle of injection locking.

The description presented here uses semi-classical laser rate equations [806]. Assuming that the master and the slave laser field are given by, respectively,

$$E_{inj} = A_{inj} e^{-\imath\omega_{inj} t} e^{\imath\phi_{inj}(t)} \quad \text{and} \quad E = A e^{-\imath\omega_s t} e^{\imath\phi_s(t)} \,, \tag{53.49}$$

The phase difference between the both fields is denoted by $\phi(t) = \phi_s(t) - \phi_m(t)$. Now, Considering the semi-classical laser rate equations we can describe the impact of the master laser field in the slave laser,

$$\begin{aligned} \frac{dA(t)}{dt} &= \frac{1}{2} g[N(t) - N_{th}]A(t) + \kappa A_{inj} \cos\phi(t) \\ \frac{d\phi(t)}{dt} &= \frac{\alpha}{2}[N(t) - N_{th}] - \kappa \frac{A_{inj}}{A(t)} \sin\phi(t) - \Delta\omega \\ \frac{dN(t)}{dt} &= J - \gamma_N N(t) - [\gamma_p + g[N(t) - N_{th}]A(t)^2 \,, \end{aligned} \tag{53.50}$$

where $A(t)$ is the field amplitude normalized as $A^2(t) = S(t)$, and $S(t)$ is the photon number. $N(t)$ is the number of carriers in the slave laser, and the other parameters are g laser gain coefficient, N_{th} threshold carrier number, κ coupling coefficient, α linewidth enhancement factor, γ_p photon decay rate, N carrier recombination rate,

J pump current normalized by electron charge, $\Delta\omega$ frequency difference between the master and the free running slave $\omega_m - \omega_s$. The parameter κ describes the rate at which the photons of the master laser enter into the slave laser cavity and is given in terms of the cavity quality factor,

$$\kappa = \frac{\omega_s}{2Q} \ . \tag{53.51}$$

From the steady state solutions of above equations, we can obtain the frequency locking range,

$$-\kappa\sqrt{(1+\alpha^2)}\sqrt{\frac{P_{inj}}{P_s}} < \Delta\omega < \kappa\sqrt{\frac{P_{inj}}{P_s}} \ , \tag{53.52}$$

where P_{inj}/P_s is the master laser fraction power used for the injection locking and P_s is the power of slave laser. From equation 4.25 we can see that the locking range is determined by the amplitude ratio between the fields and by the cavity quality factor since $\kappa \propto Q^{-1}$. Therefore, lasers with low Q are easier to lock. On the other hand, this leads to increased laser linewidth that reduces the phase noise performance of the injection locking systems. For higher injection ratio P_{inj}/P_s also results in a large locking range, which also makes the lock easier to achieve.

53.2.4 Exercises

53.2.4.1 Ex: Conventional light sources and lasers

Compare the properties of an incandescent light and a laser.

Solution:

53.2.4.2 Ex: Threshold inversion for lasing 1

Calculate the necessary threshold inversion of a gas laser transition at $\lambda = 500\,\text{nm}$ with the transition probability $A_{ik} = 5{\cdot}10^7\,\text{s}^{-1}$ and a homogeneous linewidth $\Delta\nu_{hom} = 20\,\text{MHz}$. The active length is $L = 20\,\text{cm}$ and the resonator losses per round-trip are $\gamma = 5\%$.

Solution: *The inversion n_{thr} is the density of excited atoms producing gain by stimulated emission. According to (53.46), this inversion is at threshold, when the gain along the optical path equalizes the losses,*

$$2Ln_{thr}\sigma = \gamma \ ,$$

where $2L$ is the round trip length. The absorption cross-section is related to the Einstein coefficient B_{ik} by Eq. (22.87),

$$B_{ik} = \frac{c}{h\nu}\int \sigma d\nu \simeq \frac{c}{h\nu}\bar{\sigma}\Delta\nu_{hom} \ ,$$

With $B_{ik} = \frac{c^3}{8\pi h\nu^3}A_{ik}$ we obtain,

$$\bar{\sigma} = \frac{h\nu}{c\Delta\nu_{hom}}B_{ik} = \frac{\lambda^2}{8\pi\Delta\nu_{hom}}A_{ik} \ ,$$

and finally,

$$n_{thr} = \frac{8\pi\Delta\nu_{hom}\gamma}{2\lambda^2 L A_{ik}} \approx 5 \cdot 10^6\,\mathrm{cm}^{-3} \ .$$

53.2.4.3 Ex: Threshold inversion for lasing 2

A laser medium has a Doppler-broadened gain profile of halfwidth $\delta\nu = 2\,\mathrm{GHz}$ and central wavelength $\lambda = 633\,\mathrm{nm}$. The homogeneous width is 50 MHz, and the transition probability $A_{ik} = 10^8\,\mathrm{s}^{-1}$. Assume that one of the resonator modes ($L = 40\,\mathrm{cm}$) coincides with the center frequency ν_0 of the gain profile. What is the threshold inversion for the central mode, and at which inversion does oscillation start on the two adjacent longitudinal modes if the resonator losses are 10%?

Solution: *The spacing of the longitudinal modes is,*

$$\delta_{fsr} = \frac{c}{2L} = 375\,\mathrm{MHz} \ .$$

The population density due to thermal broadening is,

$$n(v_z) = n(v_z = 0)e^{-(\nu-\nu_0)^2/\delta\nu^2} \ .$$

At $\nu = \nu_0 \pm \delta_{fsr}$ the population density for the adjacent modes has decreased to $n_1 = 0.83 n_0$. We already verified in Exc. 53.2.4.2 that the threshold inversion is,

$$\Delta n_{thr} = \frac{8\pi\nu_{hom} fsr\gamma}{2\lambda^2 L A_{ik}} \approx 3.9 \cdot 10^6\,\mathrm{cm}^{-3} \ .$$

Oscillation begins at the adjacent modes if threshold is reached for this mode. Then the inversion at the central mode is (without saturation) $n_0 = n_1/0.83$.

53.2.4.4 Ex: Mode pulling in an active resonator

The frequency of a passive resonator mode ($L = 15\,\mathrm{cm}$) lies $0.5\Delta\nu_D$ away from the center of the Gaussian gain profile of a gas laser at $\lambda = 632.8\,\mathrm{nm}$. Estimate the mode pulling if the cavity resonance width is 2 MHz and $\Delta\nu_D = 1\,\mathrm{GHz}$.

Solution: *The mode pulling is weighed with the quality factors of the resonances $\Delta\nu_{cav}/\Delta\nu_{gain}$ and the distance between the centers of the resonator mode and the gain curve:*

$$\nu_{pulled} = \nu_{cav} + \frac{\Delta\nu_{cav}}{\Delta\nu_{gain}}(\nu_{cav} - \nu_{gain}) = \nu_{cav} + \frac{\Delta\nu_{cav}}{\Delta\nu_{gain}} 0.5\Delta\nu_D \approx \nu_{cav} + 1\,\mathrm{MHz} \ .$$

53.2.4.5 Ex: Spatial hole-burning

Assume a laser transition with a homogeneous width of 100 MHz, while the inhomogeneous width of the gain profile is 1 GHz. The resonator length is $d = 200\,\text{cm}$ and the active medium with length $L \ll d$ is placed $a = 20\,\text{cm}$ from one end mirror. Estimate the spacing of the spatial hole-burning modes. How many modes can oscillate simultaneously if the unsaturated gain at the line center exceeds the losses by 10%?

Solution: *We have,*

$$\delta\nu_{spa} = \frac{2L}{ap}\delta_{fsr} \ ,$$

with $p = 2, 3, 4, ..$ *and* $\delta_{fsr} = c/2d = 150\,\text{MHz}$. *Hence, for* $p = 2$ *we expect* $\delta\nu_{spa} = 1.5\,\text{MHz}$. *For* $p = 3$ *we get* $\delta\nu_{spa} = 1.0\,\text{GHz}$. *For a Doppler width of* $\delta\nu_D = 1\,\text{GHz}$ *the gain at the first adjacent spatial hole burning mode is* $g = g_0 e^{-1/0.36} = 0.06 g_0$. *This mode does not reach the threshold. The adjacent resonator mode is* 150 MHz *away from the line center. Its unsaturated gain is* $g = g_0 e^{-0.15^2/(0.36\cdot 1)} = 0.94 g_0$. *Here, the net gain is* $0.94 \cdot 1.1 = 1.03$ *without mode competition. The two adjacent resonator modes reach the threshold. Therefore three longitudinal modes can oscillate.*

53.2.4.6 Ex: Optimizing the transmission of laser output mirrors

Estimate the optimum transmission of the laser output mirror if the unsaturated gain per round trip is 2 and the internal resonator losses are 10%.

Solution: *The total output intensity of a laser with unsaturated gain* g_0, *internal cavity losses* γ_0, *length* L *of the active medium, and mirror losses* $T + A = 1 - R = \gamma_M$ *is:*

$$I_{out} = \gamma_M \left[\frac{2g_0 L}{\gamma + \gamma_M} - 1\right] \frac{I_{sat}}{2} \ .$$

Differentiating gives,

$$\frac{dI_{out}}{d\gamma_M} = \left[\left(\frac{2g_0 L}{\gamma + \gamma_M} - 1\right) - \gamma_M \frac{2g_0 L}{(\gamma + \gamma_M)^2}\right] \frac{I_{sat}}{2} = 0 \ .$$

This yields,

$$\gamma_M^{opt} = \sqrt{2g_0 L \gamma_0} - \gamma_0 \ .$$

With $\gamma_0 = 0.1$ *and* $2g_0 L = 2$ *follows,*

$$\gamma_M^{opt} = 34.7\% = 1 - R \ .$$

The output mirror should have a reflectivity of $R = 65.3\%$.

53.2.4.7 Ex: Mode selection in a HeNe laser

A HeNe laser with an unsaturated gain of $G(\nu_0) = 1.3$ per round trip at the center of the Gaussian gain profile with halfwidth $\Delta\nu_D = 1.5\,\text{GHz}$ has a resonator length

of $d = 50\,\text{cm}$ and total losses of 4%. Single-mode operation at ν_0 is achieved with a coated tilted etalon inside the resonator. Design the optimum combination of etalon thickness and finesse.

Solution: *The axial modes are separated by* $\delta_{fsr} = c/2L = 300\,\text{MHz}$. *The gain factor G follows the Doppler profile,*

$$G(\nu) = G(\nu_0)e^{-(\nu-\nu_0)^2/(0.36\Delta\nu_D^2)} \ .$$

such that at $\nu_1 = \nu \pm \delta_{fsr}$ *the gain is* $G(\nu_1) = 0.896G(\nu_0) = 1.16$. *With 4% losses the net gain at* ν_1 *is reduced to 1.12. Hence, the losses of the etalon at* ν_1 *must be at least 12% in order to prevent laser oscillation. The transmission of the etalon with thickness t and refractive index* $n_{refr} = 1.4$ *is,*

$$T = \frac{1}{1 + F\sin^2\frac{\phi}{2}} \ ,$$

with $\phi = \frac{2\pi\nu\Delta s}{c} = \frac{2\pi\nu}{c}2n_{refr}t$. *For* $\nu = \nu_0$ *we get* $T = 1$ *and* $\phi/2 = m\pi = \frac{2\pi\nu_0}{c}n_{refr}t$. *For* $\nu = \nu_1$ *we get* $T \leq 0.88$ *and* $\sin\frac{\phi_1}{2} \geq \sqrt{0.12/F}$. *We have* $\phi_1 = \phi_0 + \Delta\phi$ *or* $\Delta\phi = \frac{1}{c}4\pi(\nu_1 - \nu_0) = 2\pi \cdot 10^{-4}n_{refr}t$. *The thickness t of the etalon should be small in order to minimize walk-off losses by the tilted etalon. If we assume as a reasonable number* $t = 0.5\,\text{cm}$, *we get,* $\Delta\phi = 2.5°$. *Hence,* $\sin\frac{\Delta\phi}{2} = \sin\frac{\phi_1}{2} = 0.044$ *and* $F \geq \frac{0.12}{0.044^2} = 63$. *With* $F^* = \frac{\pi}{2}\sqrt{F}$, *we obtain for the necessary finesse* F^* *the relation* $F \geq 12.5$. *Since* $F^* = \frac{\pi\sqrt{R}}{1-R}$, *web get* $R_E \geq 0.78$, *i.e. the etalon reflectivity should be larger than 78%.*

53.2.4.8 Ex: Mode hopping in a HeNe laser

A single-mode HeNe laser with resonator length $L = 15\,\text{cm}$ is tuned by moving a resonator mirror mounted on a piezo. Estimate the maximum tuning range before a mode hop will occur, assuming an unsaturated gain of 10% at the line center and resonator losses of 3%. What voltage has to be applied to the piezo (expansion 1 nm/V) for this tuning range?

Solution: *The free spectral range is* $\delta_{fsr} = c/2L = 10^9\,\text{GHz}$, *so that only one mode can oscillate if this mode is close to the center of the gain profile. The unsaturated gain at* ν_0 *is 10%. With losses of 3% the net gain is 7%, hence,* $G(\nu_0) = 1.07$. *When tuning away from the gain center, the net gain factor should always be* > 1. *Hence,*

$$G = 1.1 \cdot e^{-(\nu-\nu_0)^2/(0.36\Delta\nu_D^2)} - 0.03 \leq 1 \ .$$

With $\Delta\nu_D = 1.5\,\text{GHz}$ *we estimate* $\nu - \nu_0 \leq 213\,\text{MHz}$. *The maximum tuning range is from* $\nu_0 - 213\,\text{MHz}$ *up to* $\nu_0 + 213\,\text{MHz}$. *In order to tune over one free spectral range, the mirror separation must change by* $\Delta L = \lambda/2$ *Hence,*

$$\Delta L = \frac{\lambda}{2}\frac{2(\nu - \nu_0)}{\delta_{fsr}} = 135\,\text{nm}$$

at 633 nm. *The required voltage is,*

$$\Delta U = \frac{dU}{dx}\Delta x = 135\,\mathrm{V} \ .$$

53.2.4.9 Ex: Mode selection with an intracavity etalon

Mode selection in an argon laser is often accomplished with an intracavity etalon. What is the frequency drift of the transmission maximum
a. for a solid fused quartz etalon with thickness $d = 1$ cm due to a temperature change of 2° C?
b. For an air-space etalon with $d = 1$ cm due to an air pressure change of 4 mbar?
c. Estimate the average time between two mode hopes (cavity length $L = 100$ cm) for a temperature drift of 1° C/h or a pressure drift of 2 mbar/h.

Solution: *a. For the solid etalon* ($n_{refr} = 1.4$, $\alpha = 4 \cdot 10^{-7}\,\mathrm{K^{-1}}$*), we estimate,*

$$\frac{\Delta\nu}{\nu} = \frac{\Delta d}{d} + \frac{\Delta n_{refr}}{n_{refr}} \ .$$

The second term is small and can be neglected,

$$\Delta\nu = \nu\alpha\Delta T \approx 4.9 \cdot 10^7\,\mathrm{Hz} \ .$$

b. For an air-spaced etalon we can neglect the first term if the spacers are made of Zerodur or the distance is temperature-compensated. The optical path due to air at a pressure p is, for a length d equal to $s = nd$ *with* n_{refr}*(air at* $p = 1$ *bar)=1.00028. The change in s is,*

$$\Delta s = (n-1)d\frac{\Delta p}{p} \ .$$

Hence,

$$\left|\frac{\Delta\nu}{\nu}\right| = \frac{\Delta s}{s} = \frac{n_{refr}-1}{n_{refr}}\frac{\Delta p}{p} = 1.12 \cdot 10^{-6} \ .$$

For $\nu = 6 \cdot 10^{14}\,\mathrm{s^{-1}}$ *follows* $\Delta\nu = 6.72 \cdot 10^8\,\mathrm{s^{-1}} = 672$ MHz. *This illustrates that an air-spaced etalon is less stable than a solid etalon.*
c. With $L = 100$ cm *the mode spacing is* $\delta\nu = 150$ MHz. *For a temperature drift of* 1° /h *the solid etalon has a frequency drift of* 336 MHz/h.

53.2.4.10 Ex: Frequency and intensity noise of a laser

A single-mode laser is frequency stabilized onto the slope of the transmission maximum of an external reference Fabry-Perot interferometer made of invar with a free spectral range of 8 GHz. Estimate the frequency stability of the laser
a. against temperature drifts, if the FPI is temperature stabilized within 0.01°C,
b. against acoustic vibrations of the mirror distance L in the FPI with amplitudes of

100 nm.
c. Assume that the intensity fluctuations are compensated to 1% by a difference amplifier. Which frequency fluctuations are still caused by the residual intensity fluctuations, if a FPI with a free spectral range of 10 GHz and a finesse of 50 is used for frequency stabilization at the slope of the FPI transmission peak?

Solution: *The length of the etalon is,*

$$L = \frac{c}{2\delta_{fsr}} \approx 1.8\,\mathrm{cm} \ .$$

a. The change of L with temperature is for invar ($\alpha = 1.2 \cdot 10^{-6}\,\mathrm{K^{-1}}$),

$$\Delta L = d\alpha\Delta T \ ,$$

hence,

$$\left|\frac{\Delta\nu}{\nu}\right| = \frac{\Delta L}{L} = 1.2 \cdot 10^{-8} \ .$$

For $\nu = 5 \cdot 10^{14}\,\mathrm{s^{-1}}$ ($\lambda = 600\,\mathrm{nm}$) we get $\Delta\nu = 6\,\mathrm{MHz}$.
b. If L changes by 1 nm due to acoustic vibrations,

$$\frac{\Delta L}{L} = 5.8 \cdot 10^{-8} = \left|\frac{\Delta\nu}{\nu}\right| \ .$$

Hence, $\Delta\nu = 28\,\mathrm{MHz}$.
c. With a free spectral range $\delta\nu_{FPI} = 10\,\mathrm{GHz}$ of the FPI and a finesse $F^* = 50$, the full halfwidth of the transmission peak is $\Delta\nu_{FPI} = \delta\nu_{FPI}/F^* = 200\,\mathrm{MHz}$. The transmitted intensity is,

$$I_t = I_0 T = I_0 \frac{1}{1 + F\sin^2\frac{\phi}{2}} \ ,$$

with $F = (\frac{2}{\pi}F^*)^2 = 1000$. The stabilization system interprets an intensity change of 1% as a transmission change ΔT, i.e., a change $\Delta\phi$ of ϕ, and because $\phi = \frac{2\pi}{\lambda}\Delta s$ we get $\Delta\phi = \frac{2\pi}{c}\Delta s\Delta\nu$ also as a change of ν. A rough estimation of $\Delta\nu$ goes as follows. A frequency change of 100 MHz changes (at a fixed plate separation $L = 0.5\Delta s$) the transmission by 100% from 0 to 1. A transmission change of 1% therefore corresponds to a frequency change of $0.01 \cdot 100\,\mathrm{MHz} = 1\,\mathrm{MHz}$. A more elaborate calculation uses the relation,

$$\Delta T = \frac{dT}{d\phi}\Delta\nu \ ,$$

because $\Delta T = 0.01$. Now, we just need,

$$\frac{dT}{d\phi} = \frac{F\sin\frac{\phi}{2}\cos\frac{\phi}{2}}{(1 + F\sin^2\frac{\phi}{2})^2} \qquad \textit{and} \qquad \frac{d\phi}{d\nu} = \frac{2\pi\Delta s}{c} \ .$$

53.2.5 *Experiment: Analyzing the mode structure of a HeNe laser*

Here we will analyze the mode structure of a HeNe laser via (i) an optical spectrum analyzer and (ii) a radiofrequency spectrum analyzer. We will also try to unravel the polarization of the laser light.

1. Couple the light of a HeNe laser simultaneously into an optical spectrum analyzer and a radiofrequency spectrum analyzer. What do you observe when you slightly heat the laser housing? Calculate from your observations the length of the laser cavity.

2. Pass the light through a $\lambda/4$-plate and then through a polarizing beam splitter. What do you observe in the two output ports of the PBS?

53.2.6 *Experiment: Adjusting the threshold of an ECDL laser*

Here we will construct a diode laser in Littmann configuration.

1. Take a laser diode, a Peltier cooler, a thermistor, a piezo transducer, and a diffraction grating. Put everything together.

2. Optimize the threshold. Analyze the emission spectrum with an optical spectrum analyzer.

53.3 Introduction to optical phase and frequency modulation

53.3.1 Acousto-optic modulator

The *acousto-optic modulator AOM* permits fast frequency and amplitude variations of a laser beam. Because it does not incorporate mechanical parts, it works without fatigue. AOMs are used, for instance, in laser printers, where the gray tone of a pixel can be adjusted via the intensity of the laser beam, while its position (rows and columns) is varied by a rotating mirror and the drum propagating the paper sheet. In quantum optics labs they are frequently used for fast (down to μs) switching on and off, intensity control, and super-fine frequency-tuning of laser beams. The angular deflection of the first-order diffracted beam upon frequency tuning, which is often perceived as an inconvenience, can be circumvented by double-passage through the AOM.

The acousto-optic modulator consists of a piece of crystal (or glass) excited by an acoustic wave with frequency f produced by a piezo-electric transducer (see Sec. 53.3.1) mounted perpendicularly to propagation direction of the laser beam. The sound waves propagate through the crystal as density fluctuations periodically changing the refraction index n. The incident light is diffracted through Brillouin scattering at the spatial modulation of the refraction index. In a wave picture, the process can be interpreted as Bragg scattering of a light wave (with its wavelength inside the crystal

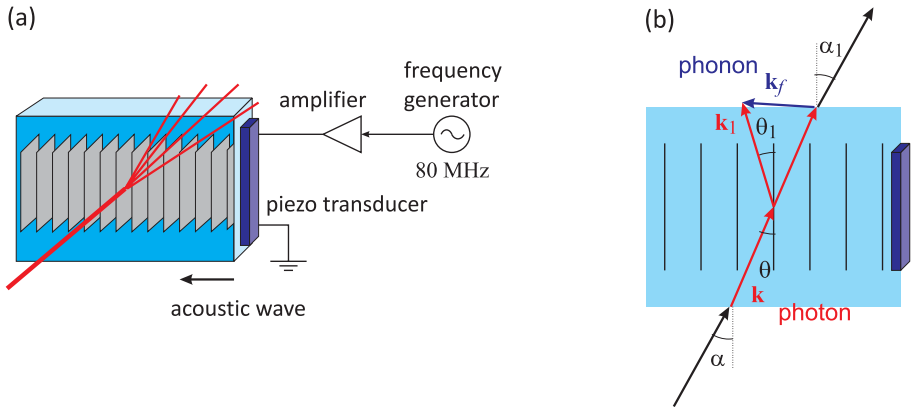

Figure 53.34: (a) Principle of the acousto-optic modulator. (b) Scheme of the diffraction in an acousto-optic modulator: A photon with wavevector k is scattered by a phonon with wavevector k_1 resulting in a photon with wavevector k_f.

$\lambda_n = 2\pi/k_n = c/n\nu$) from a density grating. c/n is the propagation velocity of light inside the crystal. Since phonons (with their wavelength $\lambda_f = 2\pi/k_f = c_f/f$, where c_f is the sound velocity in the crystal) are quantized and can only be emitted and absorbed entirely, the frequency of the first-order diffraction is $\nu_1 = \nu + f$. In case of an ideal adjustment of the Bragg angle, the *Bragg condition* results in $\theta_1 = \theta$ (see Fig. 53.34),

$$\sin\theta = \frac{k_f}{2k} = \frac{f\lambda_n}{2c_f} \ . \tag{53.53}$$

Since the laser beam is refracted when it enters the crystal, the relation between the incidence and exit angle is given by *Snell's law*, $\sin\alpha = n\sin\theta$. With this, the Bragg condition can be written,

$$\boxed{\sin\alpha = \frac{f\lambda}{2c_f}} \ . \tag{53.54}$$

The angle between the 0^{th} and the 1^{st} order is, hence, 2α.

In a corpuscular picture, the process can be understood as a *four-wave mixing* (*4WM*) between photons and phonons. The deflection of the laser beam is a consequence of momentum, $\mathbf{k}_1 = \mathbf{k} + \mathbf{k}_f$. The frequency shift corresponds exactly to the Doppler shift induced by the Brillouin scattering (absorption and reemission of a phonon in reverse direction), and we obtain a relationship that is equivalent to the Bragg condition,

$$f = \nu_1 - \nu = 2\nu\frac{c_f\sin\theta}{c/n} \ . \tag{53.55}$$

From the Bragg condition, knowing the deflection angle and the (fixed) frequency shift, we can calculate the sound velocity. A typical value is $c_f \simeq 4200$ m/s [6]

An AOM works best (highest diffraction efficiency in to the first Bragg order, which may reach more than 90%) at a specific radiofrequency, which typically is located

[6]The result (53.55) can be derived from conservations laws for energy $\omega_1 = \omega + \omega_f$ and momentum

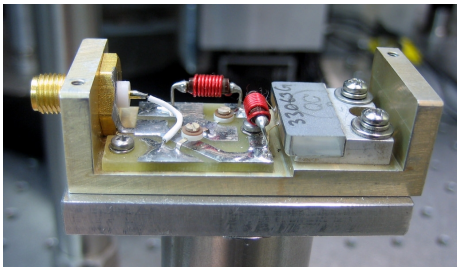

Figure 53.35: Image of an AOM without cover.

somewhere in the range $f = 40...800\,\mathrm{MHz}$, the most common one being 80 MHz. Deviations from this 'center frequency' are possible within a range of typical $\pm 10\%$ of the center frequency.

53.3.2 Electro-optic modulator

An *electro-optic modulator* is an optical device with which, by an applied voltage, the phase, frequency, amplitude or direction of a light beam can be modulated. Modulation bandwidths in the GHz regime are possible. In the simplest case, the EOM consists of a crystal (e.g., lithium niobate), whose refractive index depends on the amplitude of the local electric field. That is, when a lithium niobate crystal is exposed to an electric field the speed of light propagation is reduced. One can thus control the phase of a light beam at the output of a crystal by inserting it into a plate capacitor and applying a voltage. The phase shift of the light depends linearly on the applied voltage.

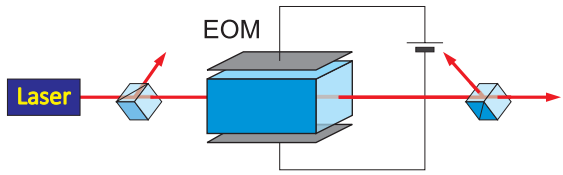

Figure 53.36: Electro optic modulator.

EOMs are often used to generate sidebands in a monochromatic laser beam. They are also used as *Pockels cell*, i.e., as a voltage-controlled phase-plate. The Pockels effect produces in a medium a *birefringence*, which depends linearly on the applied electric field. This is in contrast to the *Kerr effect*, in which the birefringence depends in a quadratic form of the electric field.

$\mathbf{k}_1 = \mathbf{k} + \mathbf{k}_f$. Defining $\omega \equiv 2\pi\nu$, $\omega_1 \equiv 2\pi\nu_1$ and $\omega_f \equiv 2\pi f$ we find,

$$\frac{\omega_f^2}{c_f} = \mathbf{k}_f^2 = (\mathbf{k}_1 - \mathbf{k})^2 = k_1^2 + k^2 - 2\mathbf{k}_1 \cdot \mathbf{k} = \frac{\omega_1^2}{c_n^2} + \frac{\omega^2}{c_n^2} - \frac{2\omega\omega_1}{c_n^2}\cos(2\theta) \simeq \frac{4\omega\omega_1}{c_n^2}\sin^2\theta \ .$$

With $\omega_1 \simeq \omega$ we reproduce the result [1407, 1408].

Suppose the optically inactive axis is x. In this case, the influence of EOM on the polarization of a laser beam is described by

$$\mathcal{M}_{EOM}(\theta) = \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} . \tag{53.56}$$

For operation as a Pockels cell, the EOM is inserted between two crossed polarizers oriented, e.g., along the x and y axis. The EOM itself is rotated by an angle ϕ,

$$\begin{aligned} \mathcal{M}_{Pockels}(\theta,\phi) &= \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \cos\phi & \sin\phi \\ -\sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & e^{\imath\theta} \end{pmatrix} \begin{pmatrix} \cos\phi & -\sin\phi \\ \sin\phi & \cos\phi \end{pmatrix} \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \\ &= 2\imath e^{\imath\theta/2} \sin\tfrac{\theta}{2} \sin\phi\cos\phi \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} , \end{aligned} \tag{53.57}$$

For $\phi = \pi/4$ we get,

$$\mathcal{M}_{Pockels}(\theta, \tfrac{\pi}{4}) = \imath e^{\imath\theta/2} \sin\tfrac{\theta}{2} \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} . \tag{53.58}$$

That is, an incident beam of light, $\mathbf{E} = E\hat{\mathbf{e}}_x$, linearly polarized in x-direction is rotated into the y-direction and, depending on the phase shift θ, it is completely blocked or transmitted through the Pockels cell [see Fig. 53.37(a)],

$$I_{tr} = I_0 \sin^2\tfrac{\theta}{2} . \tag{53.59}$$

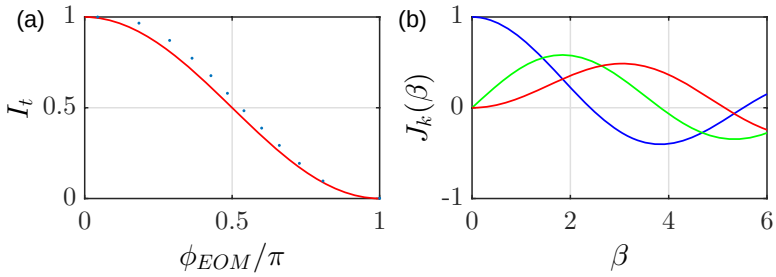

Figure 53.37: (code) (a) Effect of a Pockels cell. The solid line was calculated with the Eq. (53.57), the dotted was measured experimentally. (b) Lowest-order Bessel functions.

53.3.3 Optical phase modulation

The frequency and the phase of a laser beam can be influenced and modulated similarly to radiofrequency signals. We can therefore use the calculation of Sec. 52.3.1 completely, only changing the carrier frequency to be the frequency of the light: The

Fourier expansion of a complex-valued periodic function $s(x)$ into a series is defined as,

$$s_N(x) = \sum_{k=-N}^{N} c_k e^{\imath kx} \qquad \text{where} \qquad c_k = \frac{1}{2\pi}\int_{2\pi} s(x) e^{-\imath kx} dx \ . \tag{53.60}$$

Applying this to the modulated phase shift factor $s(\Omega t) = e^{\imath\theta(t)}$ with $\theta(t) \equiv \beta \sin \Omega t$, we get,

$$s_N(\Omega t) = \sum_{k=-\infty}^{\infty} c_k e^{\imath k\Omega t} \qquad \text{where} \qquad c_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{\imath\beta \sin \Omega t} e^{-\imath k\Omega t} d\Omega t \ , \tag{53.61}$$

but the Fourier coefficients are nothing else than the integral definition of the k-th order Bessel function,

$$J_k(\beta) \equiv \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{\imath(\beta \sin \tau - k\tau)} d\tau \ , \tag{53.62}$$

where $J_{-k}(\beta) = -J_k(\beta)$. Hence, we may write the electric field,

$$\boxed{\begin{aligned} E(t) &= e^{\imath[kz-\omega t+\imath\theta(t)]} = e^{\imath(kz-\omega t)} \sum_{k=-\infty}^{\infty} J_k(\beta) e^{\imath k\Omega t} \\ &\simeq J_0(\beta) e^{\imath\omega t} + J_1(\beta) e^{\imath\omega t+\imath\Omega t} + J_{-1}(\beta) e^{\imath\omega t-\imath\Omega t} \end{aligned}} \ . \tag{53.63}$$

For small modulation indices β only the lowest-order Bessel function contribute noticeable amplitudes, as illustrated in Fig. 53.37(b).

The interpretation of this is, that *phase modulation* imprints sidebands onto a monochromatic laser beam. These sidebands are independent modes which can be resolved, e.g. with an optical spectrum analyzer, as illustrated in Fig. 53.38.

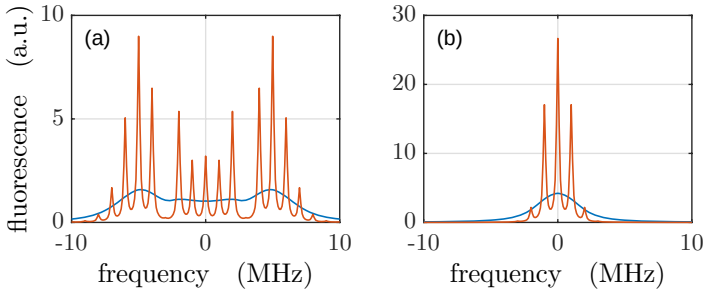

Figure 53.38: (code) Phase modulation sidebands with high (left) and low (right) modulation index resolved by a narrow (red) or broad (blue) filter.

Technically the phase can be modulated by means of an electro-optical modulator, as shown in Fig. 53.39(b). Alternatively, one may apply a periodic modulation of the current which controls a diode laser, as shown in Fig. 53.39(a), which can be done e.g. by inductive coupling using a *bias-T*.

From (53.63) we immediately see that phase modulation remains invisible for a photodetector measuring $|E(t)|^2$. Imagine, however, that the light passes through a

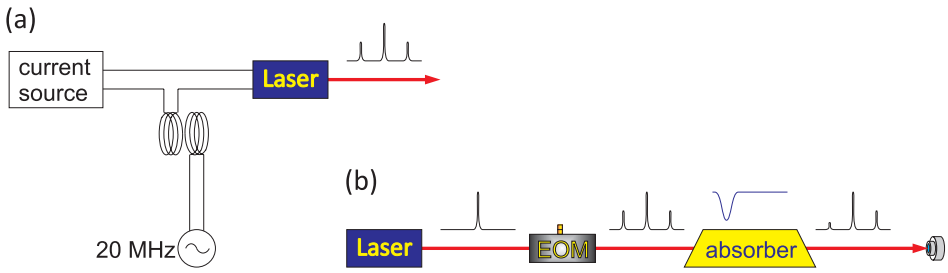

Figure 53.39: (a) Scheme for phase modulation of a diode laser by modulating the drive current. (b) Phase modulation with an external EOM followed by frequency-selective absorption of the lower sideband.

frequency-selective absorber, as illustrated in Fig. 53.39(b), such that the sidebands suffer unequal losses. Then the photodetector will record (apart from a constant offset) a signal oscillating at the frequency Ω,

$$\begin{aligned} |E(t)|^2 &= \left|J_0(\beta)e^{\imath\omega t} + aJ_1(\beta)e^{\imath\omega t+\imath\Omega t} + bJ_{-1}(\beta)e^{\imath\omega t-\imath\Omega t}\right|^2 \\ &= J_0(\beta)^2 + (a+b)J_1(\beta)^2 + (a-b)J_0(\beta)J_1(\beta)2\cos\Omega t + \dots \ . \end{aligned} \tag{53.64}$$

This idea is at the heart of powerful spectroscopic techniques, such as *frequency modulation spectroscopy*, *modulation transfer spectroscopy*, and the *Pound-Drever-Hall* frequency stabilization technique.

53.3.4 Exercises

53.3.4.1 Ex: Response time of an AOM

A beam of light at 689 nm focused to a waist of 100 µm passes through the crystal of an 80 MHz AOM, characterized by a sound velocity of $c_s = 4200\,\mathrm{m/s}$.
a. By how much the first diffraction order is deflected by the AOM? Regarding the beam divergence of the Gaussian beam, will it be possible to spatially separate the diffraction orders?
b. An experimentalist ramps the driving frequency between 70 and 90 MHz by means of a voltage-controlled oscillator. What is the range of diffraction angles covered?
c. Estimating the response time of the AOM by the time that the traveling sound wave needs to cover a distance corresponding to the focus of the light beam, how fast can the experimentalist switch off the light beam by suddenly interrupting the driving signal? What is the modulation bandwidth of the AOM?
d. The light beam passes through the AOM at a distance of $d = 2\,\mathrm{mm}$ from the piezo transducer generating the sound wave. How will this fact limit response time?

Solution: *a. The deflection angle is given by,*

$$\sin\alpha = \frac{f\lambda}{2c_f} \approx 0.376^\circ \ .$$

The divergence angle of the Gaussian beam is,

$$\frac{w_0}{z_R} = \frac{\lambda}{\pi w_0} \approx 0.126^\circ \ .$$

Hence, the beams can still be separated.
b. The deflection angle varies between 0.329° *and* 0.423°.
c. The response time would be,

$$\tau = \frac{w_0}{c_f} \approx 23.8\,\text{ns} \ ,$$

and the bandwidth correspondingly $\tau^{-1} \approx 42\,\text{MHz}$.
d. The response time would be then limited to,

$$\tau = \frac{d}{c_f} \approx 476\,\text{ns} \ .$$

53.3.4.2 Ex: Intensity stabilization with a Pockels cell

Assume that the output power of a laser shows random fluctuations of about 5%. Intensity stabilization is accomplished by a Pockels cell with a halfwave voltage of 600 V. Estimate the ac output voltage of the amplifier driving the Pockels cell that is necessary to stabilize the transmitted intensity if the Pockels cell is operated around the maximum slope of the transmission curve.

Solution: *The Jones matrix for the Pockels cell is,*

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix} = (1 - e^{\imath\theta}) \begin{pmatrix} 1 & -1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} E_{x0} \\ E_{y0} \end{pmatrix} = (1 - e^{\imath\theta})(E_{x0} - E_{y0}) \begin{pmatrix} 1 \\ 1 \end{pmatrix} \ .$$

Hence, the transmitted intensity is,

$$\begin{aligned} I = |E_x \hat{\mathbf{e}}_x + E_y \hat{\mathbf{e}}_y|^2 &= 2(E_{x0} - E_{y0})^2 (1 - e^{\imath\theta})(1 - e^{-\imath\theta}) \\ &= 4(E_{x0} - E_{y0})^2 (1 - \cos\theta) = 8(E_{x0} - E_{y0})^2 \sin^2 \frac{\theta}{2} \ . \end{aligned}$$

The transmission of the Pockels cell is,

$$T = T_0 \cos^2 aU \ ,$$

where V *is the applied voltage and* a *is a constant which depends on the electro-optic coefficient and the dimensions of the modulator. If for* $U_0 = 0$ *we have total transmission,* $T(U_0) = T_0$*, and for* $U_m = 600\,\text{V}$ *zero transmission,* $T(U_m) = 0$*, then* $aV = \pi/2$*. The system should operate at the maximum slope of* dT/dV*. Then,*

$$\Delta T = \frac{\partial T}{\partial U} \Delta U = -2aT_0 \cos aU \sin aU \Delta U \ .$$

For a fluctuation in intensity of 5% the transmission must change by $\Delta T = -0.05T_0$ in order to compensate for the fluctuations. Hence,

$$\Delta U = \frac{0.05}{2a\cos aU \sin aU} \ .$$

The maximum slope is realized for $aV = 45°$. Hence, $U = 19\,\mathrm{V}$.

53.3.4.3 Ex: Generating sidebands with an EOM

An EOM (e.g. Thorlabs, EO-PM-NR-C1) characterized by a half-wave voltage of $U_{hwv} = 230\,\mathrm{V}$ at 689 nm is to be used to generate optical sidebands at 20 MHz.
a. Estimate numerically, how much voltage amplitude at what frequency a frequency generator must provide in order to generate optical sidebands having half the light power as the carrier?
b. How high must the finesse of a 5 cm confocal Fabry-Pérot spectrum analyzer be in order to resolve the sidebands.

Solution: *a. The height of the sidebands is given by the Bessel functions. The ratio between the first-order sidebands and the carrier is given by,*

$$\left|\frac{J_1(\beta)}{J_0(\beta)}\right|^2 \stackrel{!}{=} \frac{1}{2} \ ,$$

with the modulation index $\beta = U/U_{hwv}$ where U is the voltage provided by the frequency generator. Numerically one finds that $\beta \approx 1.16$ solves the above condition. This corresponds to,

$$U = \beta U_{hwv} \approx 267\,\mathrm{V} \ .$$

b. The free spectral range of the etalon being $\delta_{fsr} = c/2L$, the resolution must be,

$$20\,\mathrm{MHz} > \frac{\kappa}{2\pi} = \frac{\delta_{fsr}}{F} \ .$$

Hence, $F > 150$.

53.3.4.4 Ex: Reflection of a phase-modulated signal from an optical cavity

A phase-modulated light beam (modulation frequency $f = 20\,\mathrm{MHz}$) is reflected from an optical cavity and recorded by a fast photodetector, whose bandwidth is larger than f. Using the Airy formulae for the electric field of a light beam reflected from a cavity (53.24) calculate the reflection spectrum, that is, the intensity of reflected light as a function of detuning $\Delta = \omega - \omega_c$, where ω is the frequency of the light and ω_c a resonant frequency of the cavity. What frequency components does the photodetector signal contain.

Solution: *See Sec. 55.3.3.*

53.3.5 *Experiment: Characterizing an AOM*

Fig. 53.40 illustrates the setup, use, and test of an AOM. It is recommended familiarizing with the operation principle of a *voltage-controlled oscillator* (*VCO*) (see Sec. 52.3.1) and a voltage-controlled *variable attenuator*. We will also learn how to use a spectrum analyzer [7].

1. Optimize a diffraction efficiency of the AOM. What are the impacts of the Bragg angle, the radiofrequency power, and the laser beam diameter.

2. Measure the deflection angle as a function of the applied radiofrequency. Based on this result, calculate the sound velocity in the crystal.

3. Measure the diffraction efficiency as a function of the applied radiofrequency power at a fixed Bragg angle. Repeat the measurement optimizing the Bragg angle for every value of the radiofrequency.

4. Reduce the radiofrequency power using the variable voltage-controlled attenuator. Determine the diffraction efficiency as a function of radiofrequency power.

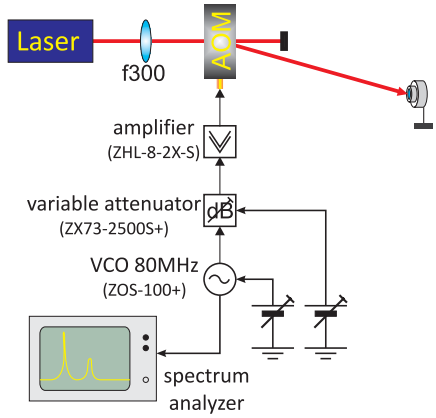

Figure 53.40: Setup for testing an acousto-optic modulator.

See Fig. 53.41.

53.3.6 *Experiment: EOM in a Mach-Zehnder interferometer*

Here we will learn to operate an EOM as Pockels cell and as phase modulator.

1. Align a laser beam through an electro-optic modulator. Supply a voltage between 0 V and 500 V to the EOM. Test its operation by beating the ordinary with the extraordinary beam. Modulate the supply voltage at a low frequency.

[7] Data sheet for the VCO see appendix Fig. 56.16,
data sheet for the AOM see appendix Fig. 56.20

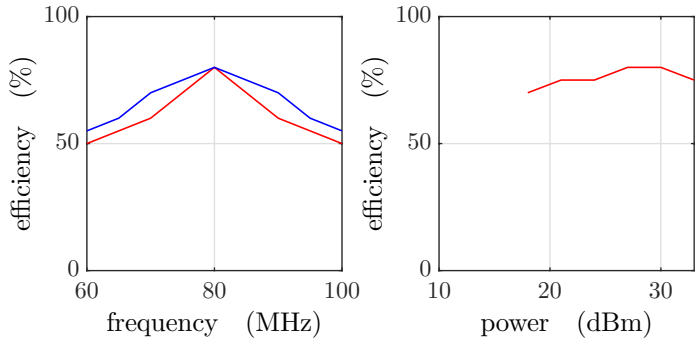

Figure 53.41: Example of measured efficiency curves.

2. Set up a Mach-Zehnder interferometer by phase-matching the exit beam of the EOM with a part of the input beam.

3. The interferometer provides a mean to convert a phase modulation into an amplitude modulation. Describe this feature theoretically using the Eqs. (52.12) and (52.13).

4. Use the EOM as a Pockels cell. Rotate the EOM by 45° around the optical axis. Probe the polarization of the outgoing beam with a polarization filter.

5. Modulate the EOM and show that the light acquires sidebands.

53.3.7 *Experiment: Creating sidebands with an EOM*

EOMs can be used to generate optical sidebands [8].

1. Apply the required voltages to a VCO (MiniCircuits, ZOS100), until it generates a variable frequency between 40 and 60 MHz. Attenuate the power with a variable attenuator up to −20 dBm. Check the amplitude and frequency with a spectrum analyzer.

2. Add a bias-T to the power supply of a laser diode. Observe the transmission spectrum of a Fabry-Pérot cavity for various frequencies and modulation amplitudes. Determine the modulation index. Use the known distance of the sidebands to estimate the finesse of the Fabry-Pérot cavity.

53.4 Radiofrequency techniques and the transfer of information

It often happens that information is coded within a frequency band corresponding to wavelengths which are not easily transported to other locations. For example, audio

[8] Datasheet for the VCO see appendix Fig. 56.16,
data sheet for the power divider see appendix Fig. 56.18,
data sheet for the mixer see appendix Fig. 56.19

frequencies (speech or music), ones they are converted to electromagnetic vibrations, correspond to wavelengths of hundreds of kilometers. Such waves are very difficult to radiate and are subject to diffraction.

For this reason, audio frequencies are often used to *modulate* so-called carriers, which in turn are chosen in frequency ranges which are easy to radiate by antennas. This is the basic idea of the radio, where the carrier frequencies are typically chosen in the MHz regime. But information can as well be encoded into laser beams, as illustrated in Fig. 53.42.

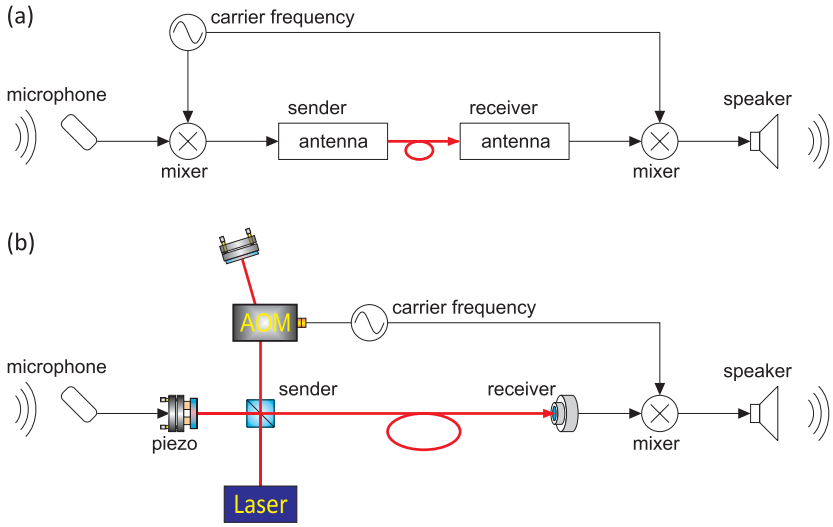

Figure 53.42: Analogy between radio transmission (a) and heterodyne techniques with a laser (b).

53.4.1 Measurement of a frequency beat

Interferometry is always based on the splitting and recombination of a wave, e.g., a laser beam or a matter wave. The recombination of laser beams is always a little technical challenge, as it requires a perfect phase matching of the Gaussian laser modes. Let us consider two plane waves $\mathcal{E}_1 = Ae^{\imath\omega_1 t}$ and $\mathcal{E}_2 = Ae^{\imath\omega_2 t}$ impinging on a photodiode. We suppose that they are phase-matched, such that their wavevectors are parallel. The photodiode then generates a *beat signal*,

$$\boxed{I = |\mathcal{E}_1 + \mathcal{E}_2|^2 = AB[2 + 2\cos(\omega_1 - \omega_2)t]} \,. \tag{53.65}$$

In practice, laser beams are usually not plane waves, but have a finite diameter and radius of curvature. In order to get a high contrast signal, a good phase-matching of the beams is important in order to obtain a strong photodiode signal.

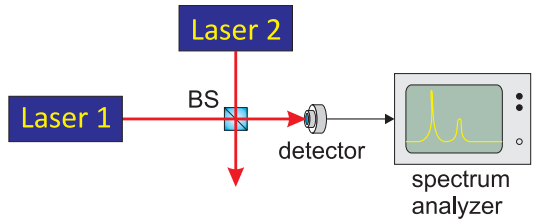

Figure 53.43: Principle of a beat frequency measurement.

53.4.2 Homodyne method

For the *homodyne method* the field amplitude of a laser beam, E_i, with frequency, $\omega = ck$, is divided by a beam splitter (reflectivity $R = |\eta|^2 \simeq 50\%$) into a reference beam (reflection at an optically dilute medium) and a probe beam, exactly as we have done for the Michelson interferometer in Sec. 53.1.3, when we obtained the formula (53.13) [9],

$$I \propto 1 + \cos[k(L_t - L_r)] \; . \tag{53.66}$$

However, we will now modulate the path length of one interferometer arm, e.g. using an EOM, $L_r = L_r(t)$. The modulation can, but does not need to be sinusoidal. In fact it may be an arbitrary radiofrequency signal, e.g. generated by acoustic sound. Restricting to small modulation amplitudes, $kL_r \ll \pi$, and choosing the length of the interferometer arms such that,

$$\boxed{I(t) \propto \sin kL_r \simeq kL_r(t)} \; , \tag{53.67}$$

we see, that the photodetector signal will reproduce the modulation signal. In other words, we encoded information on a laser beam, which carries it (e.g. through an optical fiber) to another place.

53.4.3 Heterodyne method

The *heterodyne method* is similar to the homodyne one, except that the probe beam is frequency-shifted (e.g., by the passage through an AOM operated at frequency Ω),

$$\mathcal{E}'_t = \mathcal{E}_t e^{\imath kL_t + \imath\Omega t} \; . \tag{53.68}$$

The photodetector signal generated by the beams after their recombination at the beam splitter is,

$$\begin{aligned} I &\propto \left|(1-\eta)\mathcal{E}_r e^{\imath kL_r} + \eta\mathcal{E}_t e^{\imath kL_t + \imath\Omega t}\right|^2 \\ &= \left|-(1-\eta)\eta\mathcal{E}_i e^{\imath kL_r} + \eta(1-\eta)\mathcal{E}_i e^{\imath kL_t + \imath\Omega t}\right|^2 \\ &= \left|(1-\eta)\eta\mathcal{E}_i\right|^2 \left|-e^{2\imath kL_r} + e^{\imath kL_t + \imath\Omega t}\right|^2 \; . \end{aligned} \tag{53.69}$$

[9] Here, we call $L_{t,r}$ the total length of the interferometer arm (back and forth for Michelson, one-way for Mach-Zehnder).

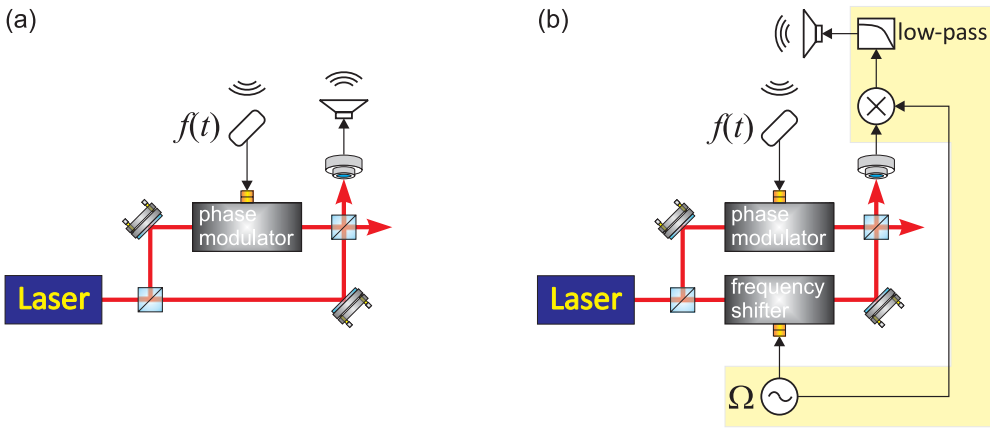

Figure 53.44: Principle scheme of the (a) homodyning and (b) heterodyning technique at the example of a Mach-Zehnder interferometer. The components in the yellow area of (b) constitute a Lock-In amplifier.

This signal is now demodulated with the AOM frequency,

$$Ie^{\imath\Omega t} \propto \left|-e^{\imath kL_r} + e^{\imath kL_t + \imath\Omega t}\right|^2 e^{i\Omega t} = e^{2\imath\Omega t} - e^{\imath k(L_t-L_r)+2\imath\Omega t} - e^{-\imath k(L_t-L_r)} \ . \quad (53.70)$$

A low-pass filter cuts all ac-components of the signal,

$$\boxed{I_{filtered}(t) \propto -e^{-\imath k(L_t-L_r)} \simeq -1 + \imath k[L_t - L_r(t)]} \ , \quad (53.71)$$

for small signal amplitudes $L_r(t)$.

53.4.4 Measuring the quadrature components of an electric field

Photodetectors measure intensities $I \propto |\vec{\mathcal{E}}|^2$. Sometimes, however, we are interested in the electric field itself, for example, when we want to get the correlation function $g^{(1)}(\tau)$ and the spectrum $S_{\mathcal{E}}(\omega)$ of a signal. A frequently used procedure consists in beating the signal of interest with a frequency-shifted local oscillator and demodulating the *quadrature components* of the beat signal.

Let us consider a signal of interest $\mathcal{E}_{sig}(t) = |\mathcal{E}_{sig}|e^{\imath\phi(t)}$ with information encoded in the temporal behavior of the phase $\phi(t)$. The first step consists in beating this signal on a photodetector with a frequency-shifted local oscillator $\mathcal{E}_{lo}(t) = |\mathcal{E}_{lo}|e^{\imath\omega_{lo}t}$, yielding a photocurrent,

$$S \propto |\mathcal{E}_{sig} + \mathcal{E}_{lo}|^2 = |\mathcal{E}_{sig}|^2 + |\mathcal{E}_{lo}|^2 + 2|\mathcal{E}_{lo}||\mathcal{E}_{sig}|\cos[\omega_{lo}t - \phi(t)] \ . \quad (53.72)$$

Now, demodulating this signal simultaneously with the local oscillator frequencies $\cos\omega_{lo}t$ and $\sin\omega_{lo}t$, we get,

$$\begin{aligned} U_c &= S\cos\omega_{lo}t = |\mathcal{E}_{lo}||\mathcal{E}_{sig}|\cos\phi(t) + \text{oscillating terms} \quad (53.73)\\ U_s &= S\sin\omega_{lo}t = |\mathcal{E}_{lo}||\mathcal{E}_{sig}|\sin\phi(t) + \text{oscillating terms} \ , \end{aligned}$$

where the oscillating terms can be removed by a low-pass filtering. Finally, we calculate,

$$|\mathcal{E}_{sig}| = \frac{\sqrt{U_c^2+U_s^2}}{|E_{lo}|} \qquad \text{and} \qquad \tan\phi(t) = \frac{U_s}{U_c} \ , \tag{53.74}$$

and obtain the electric field via,

$$\boxed{\mathcal{E}_{sig} = |\mathcal{E}_{sig}|e^{\imath\phi(t)} = \frac{\sqrt{U_c^2+U_s^2}}{|\mathcal{E}_{lo}|}e^{\imath \arctan\frac{U_s}{U_c}}} \ . \tag{53.75}$$

53.4.5 Exercises

53.4.5.1 Ex: Pound-Drever-Hall signal

Consider the photodetector signal of Exc. 53.3.4.4. What signal do you observe when demodulating the signal with an oscillation of frequency f? Calculate the derivative of the signal close to resonance; from which parameters does the slope depend, and how must you choose the modulation index to maximize it?

Solution: *As shown in Sec. 55.3.3, the reflection profile of a cavity is (ω in radians and δ_{fsr} in Hertz),*

$$\mathcal{E}_r(\omega) = \mathcal{E}_{in}(\omega)\sqrt{R}\frac{1-e^{\imath 2kL}}{1-Re^{\imath 2kL}} = \mathcal{E}_{in}(\omega)\sqrt{R}\frac{1-e^{\imath\Delta/\delta_{fsr}}}{1-Re^{\imath\Delta/\delta_{fsr}}} \ ,$$

where $\omega = N2\pi\delta_{fsr}$ and $kL = \frac{kc}{2\delta_{fsr}} = \frac{\omega}{2\delta_{fsr}} = \pi N + \frac{\Delta}{2\delta_{fsr}}$. The sideband spectrum,

$$e^{\imath(\omega t+\beta\sin\Omega t)} \simeq e^{\imath\omega t}\left[J_0(\beta)+J_1(\beta)e^{\imath\Omega t}+J_{-1}(\beta)e^{-\imath\Omega t}\right]$$

reflected from the cavity generates in the photodetector, among others, frequency components oscillating with $e^{-\imath\Omega t}$,

$$|\mathcal{E}_r|^2 = e^{-\imath\Omega t}J_0(\beta)J_1(\beta)\mathcal{E}_r(\omega)\mathcal{E}_r^*(\omega+\Omega) + e^{-\imath\Omega t}J_0(\beta)J_{-1}(\beta)\mathcal{E}_r^*(\omega)\mathcal{E}_r(\omega-\Omega) + ...$$

Demodulation with $e^{\imath\Omega t+\imath\theta}$ yields,

$$\begin{aligned} S \equiv c|\mathcal{E}_r|^2 e^{\imath\Omega t+\imath\theta} &\simeq Re\ e^{\imath\theta}J_0(\beta)J_1(\beta)\left[\mathcal{E}_r(\omega)\mathcal{E}_r^*(\omega+\Omega)-\mathcal{E}_r^*(\omega)\mathcal{E}_r(\omega-\Omega)\right] \\ &= \mathfrak{Re}\ e^{\imath\theta}J_0(\beta)J_1(\beta)\mathcal{E}_{in}(\omega)R\times \\ &\times\left(\frac{1-e^{\imath\Delta/\delta_{fsr}}}{1-Re^{\imath\Delta/\delta_{fsr}}}\frac{1-e^{-\imath(\Delta+\Omega)/\delta_{fsr}}}{1-Re^{-\imath(\Delta+\Omega)/\delta_{fsr}}} - \frac{1-e^{-\imath\Delta/\delta_{fsr}}}{1-Re^{-\imath\Delta/\delta_{fsr}}}\frac{1-e^{\imath(\Delta-\Omega)/\delta_{fsr}}}{1-Re^{\imath(\Delta-\Omega)/\delta_{fsr}}}\right) \end{aligned}$$

close to resonance we expand the exponential,

$$\frac{1-e^{\imath\Delta/\delta_{fsr}}}{1-Re^{\imath\Delta/\delta_{fsr}}} \simeq \frac{-\imath\Delta/\delta_{fsr}}{1-R-\imath R\Delta/\delta_{fsr}} = \frac{1}{R+\imath T\delta_{fsr}/\Delta} \ .$$

Hence, approximating $R \simeq 1$, we get,

$$
\begin{aligned}
S &= \mathfrak{Re}\ e^{\imath\theta} J_0(\beta) J_1(\beta) \mathcal{E}_{in}(\omega) R \times \\
&\times \left(\frac{1}{R + \imath T\delta_{fsr}/\Delta} \frac{1}{R - \imath T\delta_{fsr}/(\Delta+\Omega)} - \frac{1}{R - \imath T\delta_{fsr}/\Delta} \frac{1}{R + \imath T\delta_{fsr}/(\Delta-\Omega)} \right) \\
&\simeq \mathfrak{Re}\ e^{\imath\theta} J_0(\beta) J_1(\beta) \mathcal{E}_{in}(\omega) \left(\frac{1}{\imath T\delta_{fsr}/\Delta} \frac{1}{1 - \imath T\delta_{fsr}/\Omega} - \frac{1}{-\imath T\delta_{fsr}/\Delta} \frac{1}{1 + \imath T\delta_{fsr}/(-\Omega)} \right) \\
&= Re\ e^{\imath\theta} J_0(\beta) J_1(\beta) \mathcal{E}_{in}(\omega) \frac{\Delta}{\imath T\delta_{fsr}} \frac{2}{1 - \imath T\delta_{fsr}/\Omega} \ .
\end{aligned}
$$

Choosing $\theta = \pi/2$ and using $T\delta_{fsr} = \kappa/2$, we finally get,

$$
S \simeq J_0(\beta) J_1(\beta) \mathcal{E}_{in}(\omega) \frac{\Delta}{\kappa/2} \frac{2}{1 + \kappa^2/4\Omega^2} \simeq J_0(\beta) J_1(\beta) \mathcal{E}_{in}(\omega) \frac{4\Delta}{\kappa} \ .
$$

Therefore, the slope of the PDH error signal is simply the inverse cavity linewidth.

53.4.6 *Experiment: Beating two lasers*

In this exercise, we will ...

1. Take two independent lasers operating at nearly the same frequency (within $\sim 1\,\mathrm{GHz}$) and overlap them at a (non-polarizing) beam splitter.
2. Focus one of the ports of the beam splitter on a photodetector with large band width ($\sim 1\,\mathrm{GHz}$).
3. Analyze the beat signal on a spectrum analyzer.
4. Focus a helium-neon laser onto a fast photodetector and determine the free spectral range of the laser resonator.

53.4.7 *Experiment: Homo- and heterodyning with a Michelson interferometer*

In this exercise, we will ...

1. Set up a Michelson interferometer.

Chapter 54

Optical spectroscopy

Modern 'optics' is to be understood as 'physics of light-matter interaction' in the optical energy regime. In this sense, this area of physics comprises quantum optics, photonics, atomic physics, and atom optics. Since the invention of the laser the field of optics has seen a huge technological progress leading to the development of extremely powerful and precise tool for investigating and manipulating matter. The femtosecond laser, the frequency comb, atomic interferometers and clocks, and Bose-Einstein condensation are just a few examples.

Spectroscopy is the art of taking and interpreting spectra, i.e. frequency-dependent response functions. The variety of spectroscopic techniques is so overwhelming that a survey is hopeless. As the course also aims at familiarizing the student with applications, a major part of this course will concentrate on techniques employed and available in quantum optics labs. These techniques are mostly oriented toward ultra-high resolution spectroscopy and techniques of manipulating the motion of atoms.

In Sec. 54.1 to 54.4.3, we will try various spectroscopic techniques applied to atomic or cavity resonances.

54.1 Spectrometer and monochromator

Typical dispersive devices are *prisms* and *gratings*.

- lateral displacement as a function of λ
- spectral resolving power $R = |\lambda/\Delta\lambda| = |\nu/\Delta\nu|$
- Rayleigh criterion

54.1.1 Prism spectrometer

For a symmetrical arrangement ($\alpha_1 = \alpha_2 = \alpha$) it is easy to see from Fig. 54.1 that, $\beta = \frac{1}{2}\epsilon$ and $\theta = 2(\alpha - \beta)$. Snell's law the yields,

$$n = \frac{\sin\alpha}{\sin\beta} = \frac{\sin\frac{1}{2}(\theta+\epsilon)}{\sin\frac{1}{2}\epsilon} \ . \tag{54.1}$$

Hence,

$$\frac{dn}{d\theta} = \frac{1}{2}\frac{\cos\frac{1}{2}(\theta+\epsilon)}{\sin\frac{1}{2}\epsilon} \ , \tag{54.2}$$

or

$$\frac{d\theta}{dn} = \frac{\sin\frac{1}{2}\epsilon}{1 - n^2 \sin\frac{1}{2}\epsilon} \ . \tag{54.3}$$

The angular dispersion is therefore,

$$\frac{d\theta}{d\lambda} = \frac{\sin\frac{1}{2}\epsilon}{1 - n^2 \sin\frac{1}{2}\epsilon} \frac{dn}{d\lambda} \ . \tag{54.4}$$

The spectral dispersion of typical transparent materials is on the order of $-dn/d\lambda \approx 10^{-4}$.

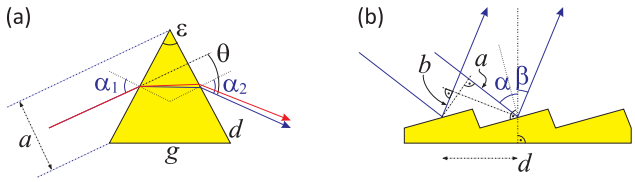

Figure 54.1: Illustration of (a) the prism spectrometer and (b) the grating spectrometer.

Example 300 (*Prism spectrometer*): We calculate the angular dispersion for an equilateral prism ($\sin\frac{1}{2}\epsilon = 0.5$) made of BK7 for two superposed wavelength $\lambda_1 = 461\,\text{nm}$ ($n_{\lambda_1} = 1.5243$) and $\lambda_2 = 633\,\text{nm}$ (with $n_{\lambda_2} = 1.5151$) to be,

$$d\theta = \frac{1}{\sqrt{1 - (n/2)^2}} dn \approx 0.8^\circ \ .$$

The resolving power can be calculated, once we have expressed the limiting aperture $a = d\cos\alpha$ where $d = g/(2\sin\frac{\epsilon}{2})$,

$$\left|\frac{\lambda}{\Delta\lambda}\right| = a\frac{d\theta}{d\lambda} = \frac{g\cos\alpha}{1 - n^2\sin\frac{1}{2}\epsilon}\frac{dn}{d\lambda} = g\frac{dn}{d\lambda} \ . \tag{54.5}$$

Solve Exc. 51.2.3.14.

54.1.2 Grating spectrometer

Destructive interference occurs for,

$$\Delta s = m\lambda = a - b = d\sin\alpha - d\sin\beta \ . \tag{54.6}$$

Frequently used is the so-called *Littrow configuration* for which $\alpha = -\beta$.

The grating represents a multiple beam interferometer, because the beams reflected from every groove of the grating are phase-shifted by amounts (setting $\alpha = 0$,

$$\delta = \tfrac{2\pi}{\lambda}\Delta s = -2\pi\frac{d}{\lambda}\sin\beta \ . \tag{54.7}$$

The sum of the reflections from N grooves of an incident plane wave $E_{in} = E_0 e^{\imath(\mathbf{k}\cdot\mathbf{r}-\omega t}$ is therefore,

$$\mathcal{E}_r = \sqrt{R}\mathcal{E}_0 \sum_{m=0}^{N} e^{\imath \mathbf{k}_r\cdot\mathbf{r}-\omega t} e^{\imath m\delta} = \sqrt{R}E_0 e^{\imath \mathbf{k}_r\cdot\mathbf{r}-\omega t} \frac{1-e^{\imath N\delta}}{1-e^{\imath\delta}} \ . \tag{54.8}$$

Consequently, the intensity is,

$$I_r = RI_0 \frac{\sin^2 \frac{N}{2}\delta}{\sin^2 \frac{1}{2}\delta} \ . \tag{54.9}$$

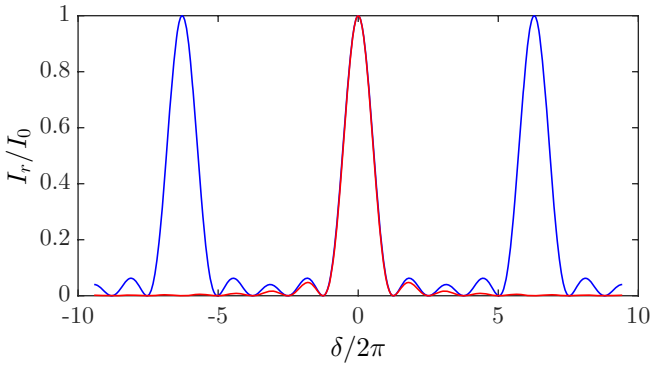

Figure 54.2: (code) Reflection curve of a diffraction grating.

The angular dispersion is, using Eqs. (54.7) and (54.6),

$$\frac{d\beta}{d\lambda} = \left(\frac{d\lambda}{d\beta}\right)^{-1} = -\frac{m}{d\cos\beta} = -\frac{\sin\alpha - \sin\beta}{\lambda\cos\beta} \ . \tag{54.10}$$

The resolving power is,

$$\left|\frac{\lambda}{\Delta\lambda}\right| = \frac{Nd(\sin\alpha - \sin\beta)}{\lambda} = mN \ . \tag{54.11}$$

Solve Exc. 54.1.3.1, 54.1.3.2, and 54.1.3.3.

54.1.3 Exercises

54.1.3.1 Ex: Resolution of a grating spectrometer

Calculate the spectral resolution of a grating spectrometer with an entrance slit width of 10 µm, focal lengths $f_1 = f_2 = 2\,\mathrm{m}$ of the mirrors M1 and M2, a grating with 1800 grooves/mm and an angle of incidence $\alpha = 45°$. What is the useful minimum slit width if the size of grating is $100 \times 100\,\mathrm{mm}^2$?

Solution: *From the equation*

$$\frac{\lambda}{\Delta\lambda} = mN$$

we obtain with $N = 1800 \cdot 100$ *and* $m = 1$, $\lambda/\Delta\lambda = 1.8 \cdot 10^5$. *However, this does not take into account the finite width* b *of the entrance slit* s_1. *The two spectral lines at* λ_1 *and* λ_2 *can be resolved if the images* $s_2(\lambda_1)$ *and* $s_2(\lambda_2)$ *can be resolved. The width of these slit images is*

$$\Delta s_2 = f_2\lambda/a + bf_2/f_1 \ .$$

For $a = 10\,\mathrm{cm}$, $f_2 = f_1 = 2\,\mathrm{m}$, *hence* $\Delta s_2 = 20\lambda + 10\,\mu\mathrm{m}$. *For* $\lambda = 500\,\mathrm{nm}$, *hence* $\Delta s_2 = 20\,\mu\mathrm{m}$. *The separation of* $s_2(\lambda_1)$ *and* $s_2(\lambda_2)$ *is:*

$$\Delta s_2 = f_2 \frac{d\beta}{d\lambda}\Delta\lambda$$

with β *being the diffraction angle. From the grating equation for* $m = 1$*:* $d(\sin\alpha + \sin\beta) = \lambda$ *we get,*

$$\frac{d\beta}{d\lambda} = \left(\frac{d\lambda}{d\beta}\right)^{-1} = \frac{1}{d\cos\beta} \ .$$

Now $\cos\beta = \sqrt{1-\sin^2\beta} = \sqrt{1-\left(\frac{\lambda}{d} - \sin\alpha\right)^2}$, *such that,*

$$\Delta s_2 = \frac{f_2\Delta\lambda}{d\cos\beta} \geq \Delta s_2 \qquad or \qquad \Delta\lambda \geq \frac{\Delta s_2 d\cos\beta}{f^2} \ .$$

For $\alpha = 45°$, $\lambda = 500\,\mathrm{nm}$, $d = (1/18000)\,\mathrm{cm} = 0.56\,\mu\mathrm{m}$, $\cos\beta = 0.9825$, *we get* $\beta = 11°$. *Now,* $\Delta\lambda \geq 1.1 \cdot 10^{-11}\,\mathrm{m}$, *that is* $\frac{\lambda}{\Delta\lambda} = \frac{500\cdot 10^{-9}}{1.1\cdot 10^{-11}} = 4.5 \cdot 10^4$. *This is three times smaller than mN. The useful minimum entrance slit width is given by,*

$$b_{min} = \frac{2f_1}{d}\lambda = \frac{2}{0.1} \cdot 5 \cdot 10^{-7}\,\mathrm{m} = 10\,\mu\mathrm{m} \ .$$

54.1.3.2 Ex: Grating spectrometer

The spectrometer in Exc. 54.1.3.1 shall be used in first order for a wavelength range around 500 nm. What is the optimum blaze angle, if the geometry of the spectrometer allows an angle of incidence α about 20°?

Solution: *The optimum blaze angle is* $\theta = (\alpha - \beta)/2$. *With* $\alpha = 20°$, $\lambda = 500\,\mathrm{nm}$, β *can be obtained from the grating equation with* $m = 1$*:*

$$d(\sin\alpha + \sin\beta) = \lambda \ .$$

With $d = 1/18000\,\mathrm{cm}$ *we get* $\beta = -33.5°$ *and then* $\theta = 26.7°$.

54.1.3.3 Ex: Littrow grating

Calculate the number of grooves/mm for a Littrow grating for a 25° incidence at $\lambda = 488\,\mathrm{nm}$ (i.e., the first diffraction order is being reflected back into the incident beam at an angle $\alpha = 25°$ to the grating normal).

Solution: *The condition for a Littrow grating to first order is:*

$$2d \sin \alpha = \lambda \ ,$$

from which $d = 580.9\,\mathrm{nm}$. *Hence, the number of grooves is* $1721\,/\mathrm{mm}$.

54.1.3.4 Ex: Combining spectrometers

A fluorescence spectrum shall be measured with a spectral resolution of $10^{-2}\,\mathrm{nm}$. The experimenter decides to use a crossed arrangement of grating spectrometer (linear dispersion: $0.5\,\mathrm{nm/mm}$) and FPI of Exc. 53.1.10.7. Estimate the optimum combination of spectrometer slit width and FPI plate separation.

Solution: *For* $\Delta\lambda = 10^{-2}\,\mathrm{nm}$ *and* $\lambda = 500\,\mathrm{nm}$ *the spectral resolution has to be at least:*

$$\frac{\lambda}{\Delta\lambda} \geq 5 \times 10^4 \ .$$

The effective finesse of the FPI in Exc. 53.1.10.7 is $F^*_{total} = 47.6$. *The plate separation then has to be,*

$$d = \tfrac{1}{2}\Delta s = \frac{1}{2}\frac{\lambda^2}{\Delta\lambda}F^* = 0.26\,\mathrm{mm} \ .$$

The free spectral range is $\Delta\nu = c/2d$, *hence,*

$$|\delta\lambda| = +\frac{c}{\nu^2}|\delta\nu| = \frac{\lambda^2}{2d} = 0.38\,\mathrm{nm} \ .$$

The spectral interval $\delta\lambda$ *transmitted by the spectrograph should be smaller than* $\delta\nu$ *in order to avoid the overlap of different orders. This means that the spectral resolution of the spectrograph* $\delta\lambda = d\lambda/dx\ \Delta s \leq 0.38\,\mathrm{nm}$ *with a linear dispersion of* $d\lambda/dx = 5 \times 10^{-2}\,\mathrm{nm/mm}$. *Therefore,* $\Delta s \leq 0.38\,\mathrm{mm}\,/5 \times 10^{-1} = 0.76\,\mathrm{mm}$.

54.1.4 *Experiment: Separating bichromatic light by prisms and gratings*

In this experiment we will study the dispersive power of a prism and a grating.

1. Combine the beams of a helium-neon laser and a laser at 461 nm via a beam-splitter. Pass this combination through a prism and quantify the dispersion.
2. Calculate the minimum angle between the two beams.
3. Shine the combination onto a reflection grating and quantify the dispersion.

54.1.5 *Experiment: Thorlabs optical spectrum analyzer*

CCS175, characterization, Thorlabs ® tour.
Czerny-Turner CCD spectrometer

1. Irradiate light on OSA and observe the spectrum.

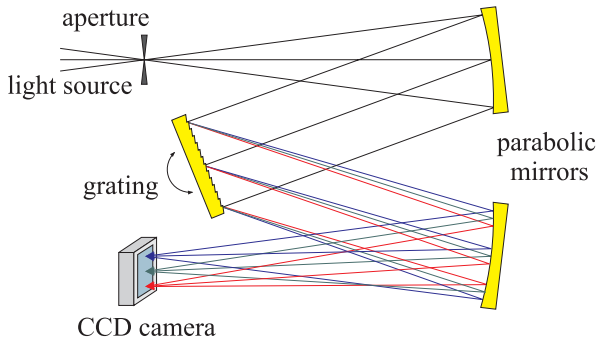

Figure 54.3: Principle of operation of a Czerny-Turner monochromator.

54.1.6 *Experiment: HighFinesse wavemeter*

Wavemeters measure the wavelength of monochromatic light sources by interference. One type of wavemeter is based on a Michelson interferometer, where the length of one interferometer arm is uniformly increased while the interference fringes are counted. Counting the fringes of a known reference laser simultaneously and comparing the counts of the unknown and the reference laser, the wavelength of the unknown laser can be determined with high precision (down to 2 MHz resolution).

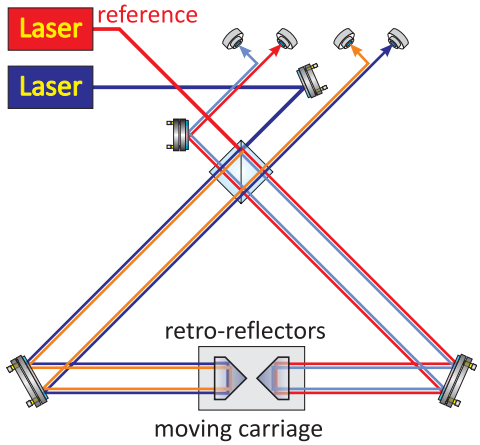

Figure 54.4: Principle of operation of a Michelson-type wavemeter.

1. HighFinesse WSU30, characterization.

54.2 Fluorescence, excitation, and absorption spectroscopy

Depending on the information we want to extract from a sample and on the available instrumentation various types of spectroscopic techniques are possible, which will be discussed on the following sections.

54.2.1 Classification of spectroscopic methods

It is important to distinguish *fluorescence spectra* from *excitation spectra*: Fluorescence spectra are taken by processing the light emitted from a radiator in a monochromator. That is, the light is shone onto a spectral band filter, which only transmits a narrow fraction of the fluorescence spectrum. The power of the transmitted light is measured with a detector. Upon changing the center frequency of the band filter, different components of the fluorescence spectrum are measured, thus yielding a curve $u(\nu)$, which represents the spectral energy density of the radiator [see Fig. 54.5(a,d)].

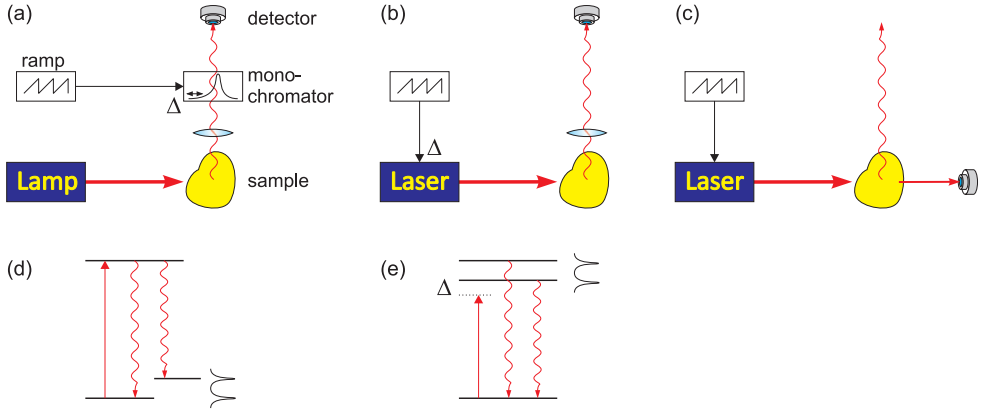

Figure 54.5: (a) Taking a fluorescence spectrum, (b) an excitation spectrum, and (c) an absorption spectrum. Typical level schemes for (d) fluorescence spectroscopy and (e) excitation or absorption spectroscopy.

In contrast to fluorescence spectroscopy, excitation or absorption spectra are taken by varying the frequency of the light exciting a sample. The reemitted light is then measured by a detector without discriminating its frequency components. Obviously, both method yield very different information about the scatterer [see Fig. 54.5(b,c,e)]. Depending on whether the scattered of the transmitted light is detected, we speak of excitation and absorption spectroscopy.

54.2.2 Saturated absorption spectroscopy

One of the most popular spectroscopic technique is *saturation spectroscopy*, as it is simple, robust, and allows to avoid Doppler-broadening. There are, however, many

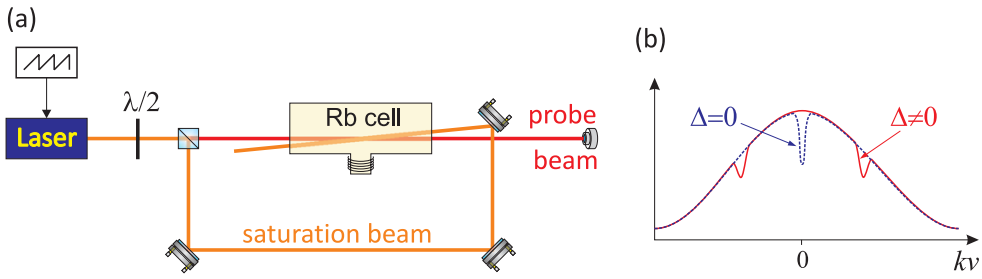

Figure 54.6: (a) Experimental scheme for saturated absorption spectroscopy. (b) Spectral hole burning by the counter-propagating saturation and probe beams for (red) detuned and (blue) resonant light.

possible implementations of saturation spectroscopy, f.ex. *frequency modulation spectroscopy* or *modulation transfer spectroscopy*, which we will present in the following.

54.2.2.1 Calculation of the Lamb-dip

The scheme known as *Lamb-dip spectroscopy* and which is illustrated in Fig. 54.6(a), consists in a cell filled with a gas [for example, atomic rubidium whose resonance frequency is $\omega_0 = ck = 2\pi c/780\,\text{nm}$ and decay rate is $\Gamma = (2\pi)\ 6\,\text{MHz}$] and two laser beams with the same frequency ω, but propagating in opposite directions. One is called the saturating beam, the other probe beam.

The basic idea is that, if the laser frequency is detuned from resonance, $\omega \neq \omega_0$, the counter-propagating beams will interact with different velocity classes (i.e. atomic velocities projected on the optical axis, $v = \mathbf{v}\cdot\hat{\mathbf{e}}_\mathbf{k}$), which results in two distinct 'holes' in the excitation profile [red curve in Fig. 54.6(b)]. Only for resonant light, $\omega = \omega_0$, will the counter-propagating beams interact with the same velocity class (i.e. atomic velocities with $v = 0$). The 'holes' in the excitation profile then overlap thus leading to a deeper depression called Lamb-dip [blue curve in Fig. 54.6(b)].

For a quantitative description of the Lamb-dip we consider Maxwell's one-dimensional and normalized velocity distribution,

$$\rho(v)dv = \sqrt{\frac{m}{2\pi k_B T}} e^{-mv^2/2k_B T} dv \ . \tag{54.12}$$

As an example, we consider a gas at $T = 300\,\text{K}$ temperature, where the partial pressure of rubidium is about $P = 10^{-1}\,\text{mbar}$, such that the particle density is,

$$n(T) = \frac{P}{k_B T} \ . \tag{54.13}$$

We also assume a cell length of $L = 10\,\text{cm}$.

The probe laser intensity is below saturation, such that the optical cross section for an atom moving with velocity v, is,

$$\sigma(v) = \frac{6\pi}{k^2} \frac{\Gamma^2}{4(\omega - \omega_0 - kv)^2 + \Gamma^2} \ , \tag{54.14}$$

where we considered the fact that the atoms moving with the velocity v along the optical axis perceive the probe laser beam as Doppler-shifted by an amount kv.

The saturating laser now has high intensity. Let us suppose here, $\Omega \equiv 10\Gamma$, where Ω is the Rabi frequency caused by the saturating laser. In this way, it creates a population of N_e atoms in the excited state. Since this population is missing in the ground state, $N_g = N - N_e$, the absorption is reduced for the probe beam by a factor,

$$\frac{N_e}{N} = \frac{\Omega^2}{4(\omega - \omega_0 + kv)^2 + 2\Omega^2 + \Gamma^2} \ . \tag{54.15}$$

In contrast to (54.14), we now have to consider saturation broadening.

We will now calculate the spectrum of the optical density for the probe laser, $O_D(\omega)$, and the light intensity transmitted through the cell, $\frac{I}{I_0} = e^{-O_D}$, according to the Lambert-Beer law.

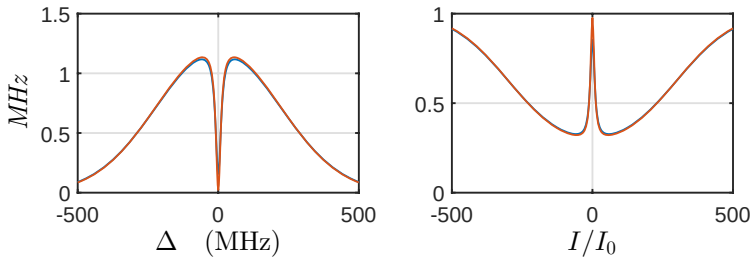

Figure 54.7: (code) (a) Optical density and (b) absorption. (Blue) Integral formula and (green) approximation for high temperature and high saturation.

The optical density with Doppler broadening is,

$$O_D(T,\omega) = Ln(T) \int_{-\infty}^{\infty} \tfrac{N_g - N_e}{N} \sigma(v)\rho(v) dv \tag{54.16}$$

$$= L\frac{P}{k_B T}\sqrt{\frac{m}{2\pi k_B T}}\frac{6\pi}{k^2}\int_{-\infty}^{\infty}\left(1 - \frac{2\Omega^2}{4(\Delta + kv)^2 + 2\Omega^2 + \Gamma^2}\right)\frac{\Gamma^2}{4(\Delta - kv)^2 + \Gamma^2} e^{-mv^2/2k_B T} dv \ ,$$

with $\Delta \equiv \omega - \omega_0$ and substituting $N_g - N_e = N - 2N_e$. The widths of the three distribution functions are, respectively,

$$\begin{aligned}
\delta\nu_{sat} &= \sqrt{\tfrac{1}{2}\Omega^2 + \tfrac{1}{4}\Gamma^2} \approx (2\pi)\ 68\,\text{MHz} && \text{for the saturating beam} \\
\delta\nu_{Dpp} &= k\sqrt{\tfrac{k_B T}{m}} \approx (2\pi)\ 217\,\text{MHz} && \text{for the Doppler broadening} \\
\delta\nu_{prb} &= \tfrac{1}{2}\Gamma \approx (2\pi)\ 3\,\text{MHz} && \text{for the probe beam}
\end{aligned} \tag{54.17}$$

where $\bar{v} = \sqrt{k_B T/m}$ is the mean atomic velocity (or the *rms* width) of Maxwell's distribution. Since the spectral width of the probe laser spectrum is much smaller, we can replace it by a δ-function,

$$\frac{\Gamma^2}{4(\Delta - kv)^2 + \Gamma^2} \longrightarrow \frac{\pi\Gamma}{2}\delta(\Delta - kv) \ , \tag{54.18}$$

which gives,

$$O_D(T,\omega) \simeq L\frac{P}{k_BT}\sqrt{\frac{m}{2\pi k_BT}}\frac{6\pi}{k^3}\int_{-\infty}^{\infty}\left(1-\frac{2\Omega^2}{4(\Delta+kv)^2+2\Omega^2+\Gamma^2}\right)\times \quad (54.19)$$
$$\times\frac{\pi\Gamma}{2}\delta(\Delta-kv)e^{-mv^2/2k_BT}dkv$$
$$= L\frac{P}{k_BT}\sqrt{\frac{m}{2\pi k_BT}}\frac{6\pi}{k^3}\frac{\pi\Gamma}{2}\left(1-\frac{2\Omega^2}{8\Delta^2+2\Omega^2+\Gamma^2}\right)e^{-m(\Delta/k)^2/2k_BT}\,.$$

The *Lamb dip* is the narrow (Doppler-free) feature in the center of the the spectrum exhibited in Fig. 54.7. Lamb-dip spectra are commonly serve as frequency references for laser frequency stabilization schemes.

54.2.3 Frequency modulation and modulation transfer spectroscopy

Variations of the saturation spectroscopic idea are the *frequency modulation spectroscopy* (FMS) and the *modulation transfer spectroscopy* (MTS). The basic scheme of those techniques is shown in Fig. 54.8. As in saturation spectroscopy, two counterpropagating beams interact with the same atoms of a molecular gas, but now one of the beams is frequency-modulated (e.g. using an electro-optic modulator). In the FMS configuration, the probe beam is modulated, and the sidebands are discriminated at the spectral feature generated by the saturation beam in a very similar way as for the Pound-Drever-Hall technique. The profile of the FMS signal is calculated in Exc. 54.2.4.3 [795, 147, 576, 1225, 692, 231, 393, 1201, 1153, 628, 831].

In the MTS configuration, the saturation beam is modulated, and the sidebands are transferred to the probe beam via nonlinear four-wave mixing processes. In both cases, the sidebands are demodulated with the local oscillator frequency driving the EOM.

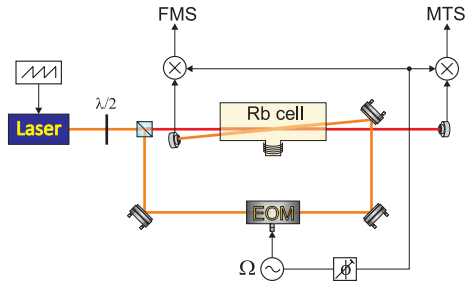

Figure 54.8: Schemes of frequency-modulation and modulation transfer spectroscopy.

The advantages of both techniques is, that they generate dispersive Doppler-free lineshapes. The FMS signal appears as a sharp feature on top of a large Doppler background (similarly to the Lamb-dip). In contrast, the MTS signal is free from

Doppler background. The MTS signal recorded by the photodetector is given by,

$$I(\Delta) = \sum_{a,b} \frac{\mu_{ab}^2}{\gamma_j + \imath\delta} \left(\frac{1}{\gamma_{ab} + \imath(\Delta + \delta/2)} - \frac{1}{\gamma_{ab} + \imath(\Delta + \delta)} + \frac{1}{\gamma_{ab} - \imath(\Delta - \delta)} - \frac{1}{\gamma_{ab} - \imath(\Delta - \delta/2)} \right) , \tag{54.20}$$

where a and b denote the lower and upper levels, μ_{ab}^2 is the electric dipole moment, γ_{ab} is the optical relaxation rate, γ_j is the decay of the energy level j of the molecule, and δ is the modulation frequency. Behind the mixer we see the electric signal,

$$S(\Delta, \vartheta) = \mathrm{Re}\,[I(\Delta) e^{-\imath\varphi}] , \tag{54.21}$$

where ϑ is the demodulation phase [830]. The curves are shown in Fig. 54.8.

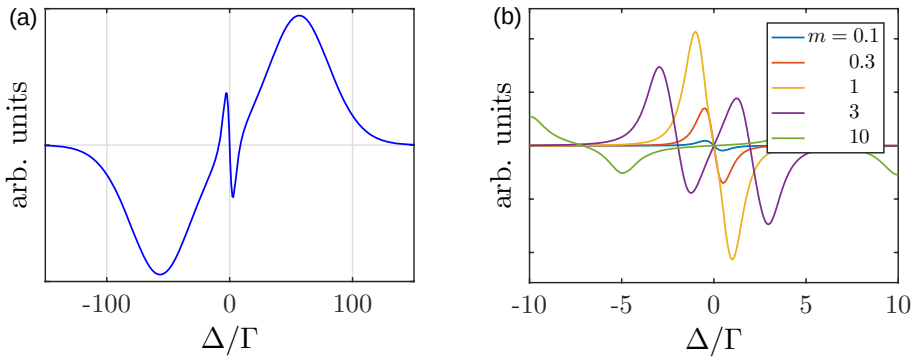

Figure 54.9: (code) (a) Calculated FMS signals and (b) MTS signals as a function of detuning for various modulation indices.

Example 301 (*Modulation transfer spectroscopy*): Modulation transfer spectroscopy is caused by four-wave mixing (4WM) processes, which have the general form $P(\omega+\Omega) = \chi^{(3)}(\omega+\Omega)E_s(\omega_s)E_p(\omega_s)E_s^*(\omega_s-\Omega)$, or similar. When the beams ω and ω_s are counter-propagating, and the atoms are moving, their resonances shift toward $\omega \mp \mathbf{k}\cdot\mathbf{v}$, respectively in the atomic rest system. Resonant enhancement of 4WM occurs, when one of the intermediate levels coincides with ω_0:

$$\begin{aligned} &\omega - \mathbf{k}\cdot\mathbf{v} = \omega_0 \\ &(\omega - \mathbf{k}\cdot\mathbf{v}) - (\omega + \mathbf{k}\cdot\mathbf{v} - \Omega) = 0 \\ &(\omega - \mathbf{k}\cdot\mathbf{v}) - (\omega + \mathbf{k}\cdot\mathbf{v} - \Omega) + (\omega + \mathbf{k}\cdot\mathbf{v}) = \omega_0 \\ &(\omega - \mathbf{k}\cdot\mathbf{v}) - (\omega + \mathbf{k}\cdot\mathbf{v} - \Omega) + (\omega + \mathbf{k}\cdot\mathbf{v}) - (\omega - \mathbf{k}\cdot\mathbf{v} + \Omega) = 0 . \end{aligned}$$

Assuming $\omega = \omega_s = \omega - 0$, these resonances reduced to,

$$\mathbf{k}\cdot\mathbf{v} = 0, \pm\Omega ,$$

and similarly for the other 4WM processes. This means, that the saturation beam burns holes in the velocity distribution at $\mathbf{k}\cdot\mathbf{v} = 0, \pm\frac{1}{2}\Omega, \pm\Omega$, which modulate the probe beam.

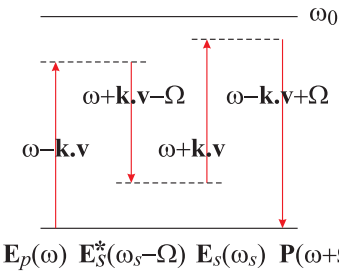

Figure 54.10: Levels involved in 4WM upon MTS.

54.2.4 Exercises

54.2.4.1 Ex: Width of the absorption band

The resonator of a dye laser with a large emission bandwidth additionally contains an absorbing (dense) gas. The absorption spectrum of the gas is Lorentzian with a width of 3 GHz, and the absorption coefficient has, in the middle of the absorption line (at 600 nm), the value of 0.2. What are the maximum and minimum relative spectral distances $\Delta f/\Delta f_0$ of the axial modes within the spectral range of the absorption, compared to the distances Δf_0 of the empty resonator?

Solution: *The susceptibility of the absorption line can also be described as complex refractive index,*

$$n = n' + \imath n'' = 1 + C\left[\frac{(\nu_0-\nu)\frac{1}{2}\Delta\nu}{(\nu_0-\nu)^2+\left(\frac{1}{2}\Delta\nu\right)^2} + \imath\frac{\left(\frac{1}{2}\Delta\nu\right)^2}{(\nu_0-\nu)^2+\left(\frac{1}{2}\Delta\nu\right)^2}\right] ,$$

where n' is the dispersion and n'' the absorption. In resonance the dispersion disappears, therefore $C = 0.2$ is the absorption. The real part of the refraction index gives the dispersion, such that the distances of the modes is, $\nu_{n+1} - \nu_n = \frac{c}{n2L}$. The relationship between the mode distances in the full resonator and the empty resonator is $\frac{\Delta f}{\Delta f_0} = \frac{1}{n}$.

54.2.4.2 Ex: Lorentz and Gaussian profiles

At which detuning is a Doppler-broadened line dominated by Lorentzian profile of the transition?

Solution: *We consider a cell of length L at temperature T. With the optical cross section,*

$$\sigma = \frac{6\pi}{k^2}\frac{\Gamma^2}{4(\omega-\omega_0-kv)^2+2\Omega^2+\Gamma^2}$$

and the Maxwell-Boltzmann distribution,

$$\rho dv = \sqrt{\frac{m}{2\pi k_B T}}e^{-mv^2/2k_BT}dv$$

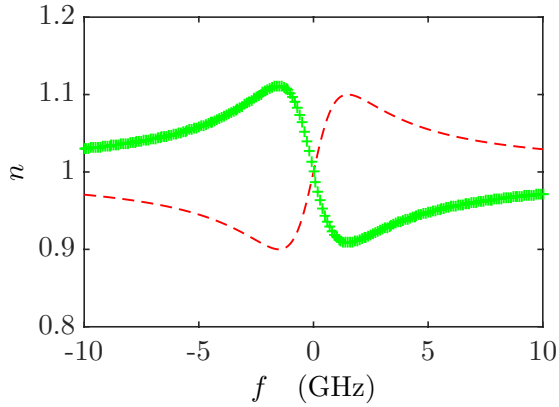

Figure 54.11: (code) Refraction index (red,–) and mode distance (green, +) as a function of the detuning.

the optical density is,

$$O_D(T,\omega) = L\frac{P}{k_BT}\sqrt{\frac{m}{2\pi k_BT}}\frac{6\pi}{k^2}\int_{-\infty}^{\infty} e^{-mv^2/2k_BT}\frac{\Gamma^2}{4(\omega-\omega_0-kv)^2+2\Omega^2+\Gamma^2}dv \ .$$

We consider the normalized spectra,

$$\sigma = \frac{a/\pi}{x^2+a^2} \qquad \textit{and} \qquad \rho = \frac{1}{b\sqrt{\pi}}e^{-x^2/b^2} \ .$$

54.2.4.3 Ex: Frequency-modulation spectroscopy

Calculate the FMS spectrum for a rubidium gas (describing the atoms as a two-level system) under the conditions specified in Sec. 54.2.2 and assuming a modulation frequency of $f = 10\,\mathrm{MHz}$ and a modulation index of $\beta = 1$.

Solution: *The optical density derived in (54.19),*

$$O_D(\Delta) = C\left(1-\eta\frac{2\Omega^2}{8\Delta^2+2\Omega^2+\Gamma^2}\right)e^{-\Delta^2/2\delta_{Dpp}^2} \ ,$$

describes the Lamb-dip spectrum, where we now additionally account for imperfections in the saturation (misalignment, time-of-flight broadening, etc.) by a factor $\eta \in [0,1]$. The probe beam is now frequency-modulated,

$$E_{prb,0}(\Delta) = J_0(\beta)e^{\imath\Delta t} + J_1(\beta)e^{\imath(\Delta+f)t} + J_{-1}(\beta)e^{\imath(\Delta-f)t} \ ,$$

and transmitted through the cell, counter-propagating to the (unmodulated) saturation beam, where the sidebands suffer different frequency-dependent attenuations,

$$E_{prb}(\Delta) = E_{prb,0}(\Delta)e^{-\frac{1}{2}O_D(\Delta)} \ .$$

The photodetector records the signal,

$$\begin{aligned} I_{prb}(\Delta) &= |E_{prb}(\Delta)|^2 \\ &= |J_0(\beta)e^{-\frac{1}{2}O_D(\Delta)}e^{\imath\Delta t} + J_1(\beta)e^{-\frac{1}{2}O_D(\Delta+f)}e^{\imath(\Delta+f)t} + J_{-1}(\beta)e^{-\frac{1}{2}O_D(\Delta-f)}e^{\imath(\Delta-f)t}|^2 \\ &= J_0(\beta)^2 e^{-O_D(\Delta)} + J_0(\beta)J_1(\beta)e^{-\frac{1}{2}O_D(\Delta)-\frac{1}{2}O_D(\Delta+f)}(e^{\imath ft} + e^{-\imath ft}) \\ &\qquad + J_0(\beta)J_{-1}(\beta)e^{-\frac{1}{2}O_D(\Delta)-\frac{1}{2}O_D(\Delta-f)}(e^{\imath ft} + e^{-\imath ft}) + \dots \ . \end{aligned}$$

The demodulated signal is,

$$S(\Delta) = I_{prb}(\Delta)e^{-\imath ft+\imath\varphi} \ ,$$

which, after low-pass filtering, becomes,

$$S(\Delta) = J_0(\beta)J_1(\beta)e^{\imath\varphi}e^{-O_D(\Delta/2)}\left[e^{-\frac{1}{2}O_D(\Delta+f)} - e^{-\frac{1}{2}O_D(\Delta-f)}\right] \ .$$

The FMS spectrum is shown in Fig. 54.9(a).

54.2.5 *Experiment: Rubidium Lamb-dips*

In this exercise, we will spectroscopically identify the various lines of the rubidium D_2-transition of the isotopes ^{87}Rb and ^{85}Rb. The hyperfine splittings of the ground and excited states are reproduced in Fig. 54.12.

1. Set up the optics for a Lamb-dip spectroscopy as shown in Fig. 54.12.

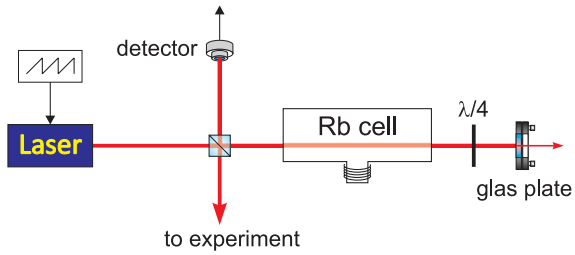

Figure 54.12: Saturation spectroscopy.

2. Fig. 54.13 shows a typical spectrum recorded with a rubidium gas cell. Find an interpretation for the various lines of the spectrum.

54.3 Polarization spectroscopy

The *Hänsch-Couillaud technique* uses the *birefringence* of certain materials, devices, or gases.

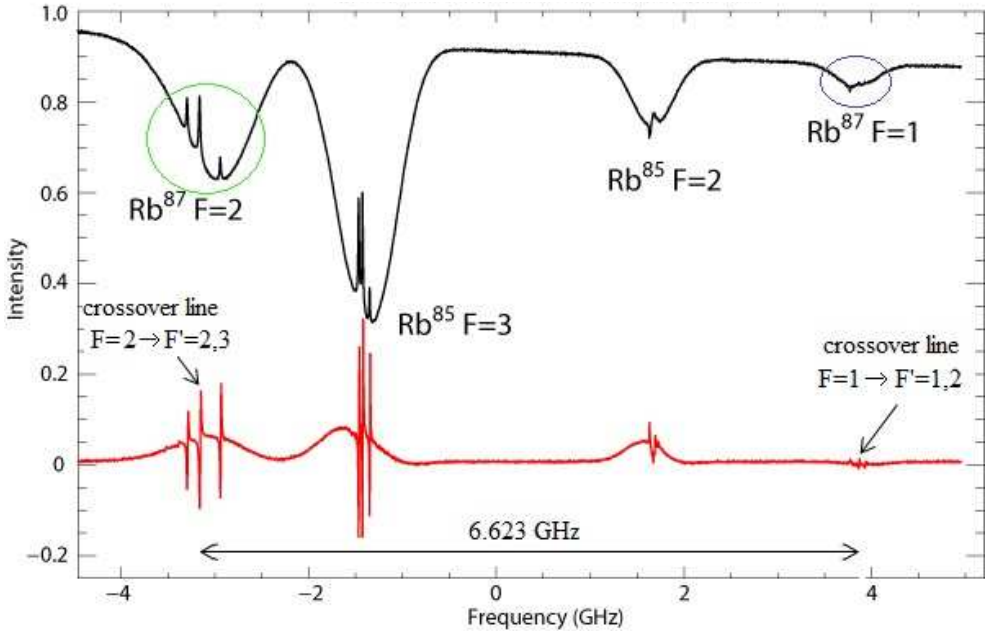

Figure 54.13: (Black) Lamb-dip spectroscopy of a rubidium gas (natural isotope mixture of ^{85}Rb and ^{87}Rb) showing the hyperfine structure transitions of the D2-line. (Red) Derivative of the spectrum in (a).

54.3.1 Birefringent cavity

We consider a birefringent cavity exhibiting slightly different path lengths for two axis that we will call, respectively, *ordinary* and*extraordinary*. Fig. 54.14(a) shows the optical setup. The detector signals may be calculated via a concatenation of the Jones matrices for a $\lambda/2$-plate, the transmissive response of the cavity, another $\lambda/2$-plate, and finally a polarizing beam splitter,

$$\begin{pmatrix} E_o \\ E_e \end{pmatrix} = M \begin{pmatrix} 1 \\ 0 \end{pmatrix} \qquad with \tag{54.22}$$

$$M \equiv \begin{pmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} \frac{T}{1-Re^{2\imath k_o L}} & 0 \\ 0 & \frac{T}{1-Re^{2\imath k_e L}} \end{pmatrix} \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} . \tag{54.23}$$

For the particular polarization angles $\alpha = \frac{\pi}{4}$ and $\beta = 0$, we derive the difference of the photodetector signals,

$$\Delta I = |E_o|^2 - |E_e|^2 = \frac{T^2}{2} \left[\frac{1}{1 - R^2 - 2R\cos 2k_o L} - \frac{1}{1 - R^2 - 2R\cos 2k_e L} \right] . \tag{54.24}$$

As Fig. 54.14(b) demonstrates, the spectra corresponding to the axis, obtained by ramping the laser frequency are slightly shifted with respect to each other. Their subtraction leads to a dispersive lineshape that suits for laser locking purposes in the so-called *Hänsch-Couillaud* stabilization.

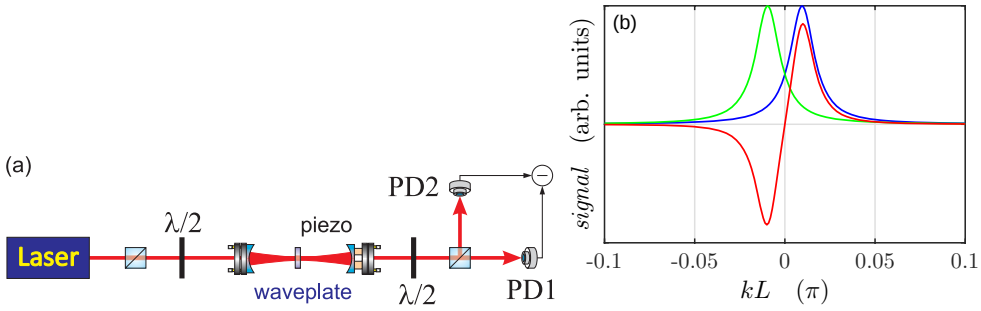

Figure 54.14: (code) (a) Generating a Hänsch-Couillaud error signal by transmission of a birefringent linear cavity. (b) Signals recorded by the two photodetectors (blue and green) and their difference (red).

54.3.2 *Experiment: Birefringence of a ring cavity*

Birefringence automatically occurs in a ring cavities. In this exercise, we will analyze the birefringence observed in reflection of a such a ring cavity. In a *ring cavity*, the resonance frequencies of the s-polarized and the p-polarized modes are slightly shifted from one another due to the different penetration depth of the s- and p-polarized light modes into the layers of the dielectric mirrors. For a moderate finesse of the cavity (say $\mathcal{F} = 2000$), the modes actually overlap. This leads to a birefringence used in the

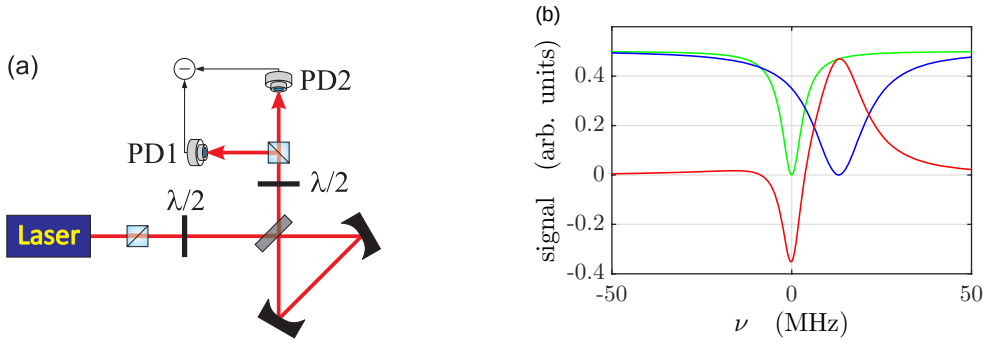

Figure 54.15: (code) (a) Generating a Hänsch-Couillaud error signal by (a) reflection from a ring cavity and (b) transmission of a linear cavity containing a Brewster plate. (b) Signals recorded by the two photodetectors (blue and green) and their difference (red). (a) Reflection signals $|E_s|^2$ and $|E_p|^2$ from a birefringent cavity with $\delta_{fsr} = 8.2\,\mathrm{GHz}$, $\varphi_s = 0$, $R_{hr,s} = 99.97\%$, $R_{ic,s} = 99.74\%$, $F_s = \pi(R_{hr,s}^2 R_{ic,s})^{1/6}/[1-(R_{hr,s}^2 R_{ic,s})^{1/3}]$, $\varphi_p = 0.01$, $R_{hr,p} = 99.92\%$, $R_{ic,p} = 99.34\%$, and $F_p = \pi(R_{hr,p}^2 R_{ic,p})^{1/6}/[1-(R_{hr,p}^2 R_{ic,p})^{1/3}]$. (b) Difference $|E_s|^2 - |E_p|^2$.

famous Hänsch-Couillaud locking scheme. The detector signal in the scheme shown in the figure may calculated via a concatenation of the Jones matrices for a $\lambda/2$-plate, the reflective response of the ring cavity, another $\lambda/2$-plate, and finally a polarizing

beam splitter,

$$\begin{pmatrix} E_s \\ E_p \end{pmatrix} = M \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad with \tag{54.25}$$

$$M \equiv \begin{pmatrix} \cos\beta & \sin\beta \\ -\sin\beta & \cos\beta \end{pmatrix} \begin{pmatrix} \frac{1-e^{-2\pi\imath\omega/\delta_{fsr}+\imath\phi_s}}{1-R_s e^{-2\pi\imath\omega/\delta+\imath\phi_s}} & 0 \\ 0 & \frac{1-e^{-2\pi\imath\omega/\delta_{fsr}+\imath\phi_p}}{1-R_p e^{-2\pi\imath\omega/\delta+\imath\phi_p}} \end{pmatrix} \begin{pmatrix} \cos\alpha & \sin\alpha \\ -\sin\alpha & \cos\alpha \end{pmatrix} .$$

Calculating $|E_s|^2$ and $|E_p|^2$ as a function of the laser frequency ω reproduces the curves plotted in Fig. 54.15(a).

54.4 Other spectroscopic techniques

54.4.1 Mode-locked femtosecond laser

Mode-locking is a technique in optics by which a laser can be made to produce pulses of light of extremely short duration, down to the order of femtoseconds. The basis of the technique is to induce a fixed-phase relationship between the longitudinal modes of the laser's resonant cavity. Constructive interference between these modes can cause the laser light to be produced as a train of pulses.

In a simple laser, each of these cavity modes amplified within the bandwidth of the gain medium oscillates independently, with no fixed relationship between each other. The individual phase of the light waves in each mode is not fixed, and may vary randomly due to such things as thermal changes in materials of the laser. In lasers with only a few oscillating modes, interference between the modes can cause beating effects in the laser output, leading to fluctuations in intensity; in lasers with many thousands of modes, these interference effects tend to average to a near-constant output intensity.

If instead of oscillating independently, each mode operates with a fixed phase relation to the other modes. Instead of a random or constant output intensity, the modes of the laser will periodically constructively interfere with one another, producing an intense burst or pulse of light. Such a laser is said to be *mode-locked* or *phase-locked*. These pulses occur separated in time by $\tau = 2L/c$, where τ is the laser cavity round trip time and corresponds to the cavity's inverse free spectral range.

54.4.1.1 Active mode-locking

The most common active mode-locking technique places a standing wave electro-optic modulator (EOM) into the laser cavity. When driven with a sinusoidal electrical signal, this produces an amplitude modulation of the light in the cavity. Considering this in the frequency domain, if a mode has optical frequency ν, and is amplitude-modulated at a frequency f, the resulting signal has sidebands at optical frequencies $\nu \pm f$. The modulation frequency is now chosen to coincide with the cavity's free spectral range, $f = \delta_{fsr}$, and since the sidebands are driven in-phase, the central mode and the adjacent modes will be phase-locked together. Further operation of the

modulator on the sidebands produces phase-locking of the $\nu \pm 2f$ modes, and so on until all modes in the gain bandwidth are locked.

This process can also be considered in the time domain. The amplitude modulator acts as a weak 'shutter' to the light bouncing between the mirrors of the cavity, attenuating the light when it is 'closed', and letting it through when it is 'open'. If the modulation rate f is synchronized to the cavity round-trip time τ, then a single pulse of light will bounce back and forth in the cavity. The actual strength of the modulation does not have to be large; a modulator that attenuates 1% of the light when 'closed' will mode-lock a laser, since the same part of the light is repeatedly attenuated as it traverses the cavity.

Related to this amplitude modulation (AM), active mode-locking is frequency modulation (FM) mode-locking, which uses a modulator device based on the acousto-optic effect. This device, when placed in a laser cavity and driven with an electrical signal, induces a small, sinusoidally varying frequency shift in the light passing through it. If the frequency of modulation is matched to the round-trip time of the cavity, then some light in the cavity sees repeated upshifts in frequency, and some repeated downshifts. After many repetitions, the upshifted and downshifted light is swept out of the gain bandwidth of the laser. The only light which is unaffected is that which passes through the modulator when the induced frequency shift is zero, which forms a narrow pulse of light.

The third method of active mode-locking is synchronous mode-locking, or synchronous pumping. In this, the pump source (energy source) for the laser is itself modulated, effectively turning the laser on and off to produce pulses.

54.4.1.2 Passive mode-locking

Passive mode-locking techniques are those that do not require a signal external to the laser to produce pulses. Rather, they use the light in the cavity to cause a change in some intracavity element, which will then itself produce a change in the intracavity light. A commonly used device to achieve this is a saturable absorber.

A saturable absorber is an optical device that exhibits an intensity-dependent transmission. For passive mode-locking, ideally a saturable absorber will selectively absorb low-intensity light, and transmit light which is of sufficiently high intensity. When placed in a laser cavity, a saturable absorber will attenuate low-intensity constant wave light (pulse wings). However, because of the somewhat random intensity fluctuations experienced by an un-mode-locked laser, any random, intense spike will be transmitted preferentially by the saturable absorber. As the light in the cavity oscillates, this process repeats, leading to the selective amplification of the high-intensity spikes, and the absorption of the low-intensity light. After many round trips, this leads to a train of pulses and mode-locking of the laser.

Considering this in the frequency domain, if a mode has optical frequency ν, and is amplitude-modulated at a frequency nf, the resulting signal has sidebands at optical frequencies $\nu \pm nf$ and enables much stronger mode-locking for shorter pulses and more stability than active mode-locking, but has startup problems.

Saturable absorbers are commonly liquid organic dyes, but they can also be made from doped crystals and semiconductors. Semiconductor absorbers tend to exhibit very fast response times ($\sim$100 fs), which is one of the factors that determines the

final duration of the pulses in a passively mode-locked laser. In a colliding-pulse mode-locked laser the absorber steepens the leading edge while the lasing medium steepens the trailing edge of the pulse.

There are also passive mode-locking schemes that do not rely on materials that directly display an intensity dependent absorption. In these methods, nonlinear optical effects in intracavity components are used to provide a method of selectively amplifying high-intensity light in the cavity, and attenuation of low-intensity light. One of the most successful schemes is called Kerr-lens mode-locking (KLM), also sometimes called 'self mode-locking'. This uses a nonlinear optical process, the optical Kerr effect, which results in high-intensity light being focussed differently from low-intensity light. By careful arrangement of an aperture in the laser cavity, this effect can be exploited to produce the equivalent of an ultra-fast response time saturable absorber.

54.4.2 Frequency comb

In optics, a frequency comb is a laser source whose spectrum consists of a series of discrete, equally spaced frequency lines. Frequency combs can be generated by a number of mechanisms, including periodic modulation (in amplitude and/or phase) of a continuous-wave laser, four-wave mixing in nonlinear media, or stabilization of the pulse train generated by a mode-locked laser. The invention of the *frequency comb* represents a breakthrough in ultrahigh resolution spectroscopy, which was honored with the Nobel price attributed to Theodor Hänsch in 2005 [1411, 681, 629, 630, 934, 11, 1294].

The frequency domain representation of a perfect frequency comb is a series of delta functions spaced according to,

$$f_n = f_{ceo} + n f_{rep} \ , \tag{54.26}$$

where n is an integer, f_{rep} is the comb tooth spacing (equal to the mode-locked laser's repetition rate or, alternatively, the modulation frequency), and f_{ceo} is the carrier offset frequency, which is less than f_{rep}. Combs spanning an octave in frequency (i.e., a factor of two) can be used to directly measure (and correct for drifts in) f_{ceo}. Thus, octave-spanning combs can be used to steer a piezoelectric mirror within a carrier-envelope phase-correcting feedback loop. Any mechanism by which the combs' two degrees of freedom (f_{rep} and f_{ceo}) are stabilized generates a comb that is useful for mapping optical frequencies into the radio frequency for the direct measurement of optical frequency.

54.4.2.1 Spectrum of a frequency comb

The field emitted by a pulsed laser characterized by its pump laser frequency ν, the *repetition rate* f_{rep}, and the pulse width T, can be given as a temporal sequence of Gaussian shaped pulses. The repetition is mathematically described as a convolution of the Gaussian profile with a sum of temporal δ-functions displaced in time,

$$\boxed{E(t) = \cos 2\pi\nu t \left(\sum_n \delta(t - \tfrac{n}{f_{rep}}) \star e^{-t^2/T^2} \right) = \cos 2\pi\nu t \sum_n e^{-(t-\frac{n}{f_{rep}})^2/T^2}} \ . \tag{54.27}$$

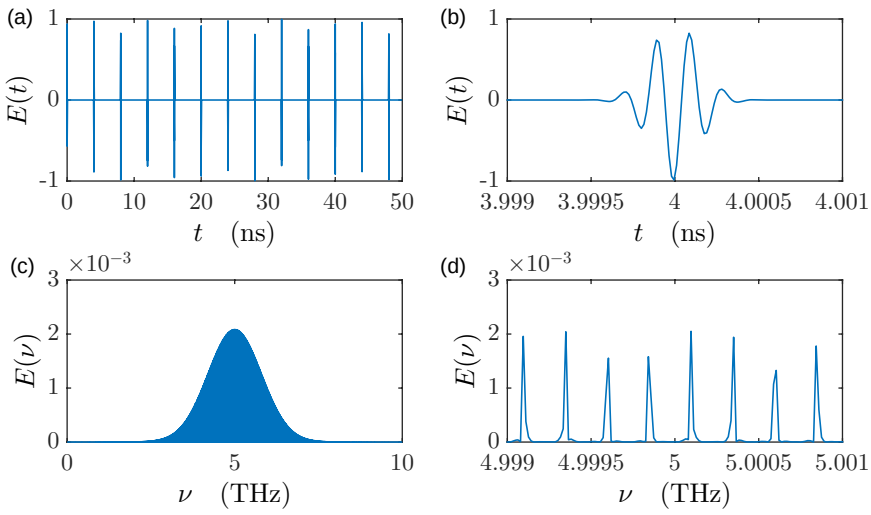

Figure 54.16: (code) Pulse train (a,b) and spectrum (b,c).

The carrier under each pulse is phase-shifted with respect to the adjacent pulse, except when the laser is mode-locked, that is, when,

$$\cos 2\pi\nu t = \cos 2\pi\nu(t + \tfrac{1}{f_{rep}}) \ . \tag{54.28}$$

The Fourier transform of the laser field (54.27) is,

$$\begin{aligned} \mathcal{F}[E(t)] &= \int_{-\infty}^{\infty} e^{-\imath\omega t} \cos 2\pi\nu t \sum_n e^{-(t-n/f_{rep})^2/T^2} dt \\ &= \tfrac{1}{2} \sum_n \int_{-\infty}^{\infty} e^{-\imath(\omega-2\pi\nu)t} e^{-(t-n/f_{rep})^2/T^2} dt \ , \end{aligned} \tag{54.29}$$

where neglect negative frequency components. Using the rules,

$$\mathcal{F}[f(t)e^{\imath\Omega t}] = \int_{-\infty}^{\infty} e^{-\imath\omega t} f(t) e^{\imath\Omega t} dt = (\mathcal{F}f)(\omega - \Omega) \tag{54.30}$$

$$\text{and} \qquad \mathcal{F}[f(t-T)] = \int_{-\infty}^{\infty} e^{-\imath\omega t} f(t-T) dt = e^{-\imath\omega T}(\mathcal{F}f)(\omega)$$

$$\text{and} \qquad \mathcal{F}[e^{-t^2/T^2}] = \int_{-\infty}^{\infty} e^{-\imath\omega t} e^{-t^2/T^2} dt = T\sqrt{\pi} e^{-T^2\omega^2/4}$$

we get,

$$E(\omega) = \mathcal{F}[E(t)] = \tfrac{1}{2} T\sqrt{\pi} e^{-T^2(\omega-2\pi\nu)^2/4} \sum_n e^{-\imath(\omega-2\pi\nu)n/f_{rep}} \ . \tag{54.31}$$

We now write the pump laser frequency as,

$$\nu \equiv m f_{rep} + f_{ceo} \ , \tag{54.32}$$

where we set $m \in \mathbb{N}$ and call $|f_{ceo}| < f_{rep}$ the *carrier envelope offset*. We also express the Fourier frequency by,

$$\omega \equiv 2\pi(\eta f_{rep} + f_{ceo}) \ , \tag{54.33}$$

firstly *without* specifying that η be an integer number. The spectrum is,

$$|E(\omega)|^2 = \tfrac{1}{4}\pi T e^{-T^2(\omega-2\pi\nu)^2/2} \left| \sum_n e^{-2\pi i n(\eta-m)} \right|^2 \ , \tag{54.34}$$

which only gives contributions for,

$$\eta = \frac{\omega - 2\pi f_{ceo}}{2\pi f_{rep}} \in \mathbb{N} \ . \tag{54.35}$$

I.e. the spectrum of comb frequencies is,

$$\boxed{|E(\omega)|^2 = \tfrac{1}{4}\pi T e^{-T^2(\omega-2\pi\nu)^2/2} \sum_n \delta[\omega - (n f_{rep} + f_{ceo})]} \ . \tag{54.36}$$

The δ-function comes from the fact that the sum of (54.35) over many oscillations $e^{-2\pi i n(\eta-m)}$ vanishes by destructive interference, except when they are *in phase*, which is just the case when $\omega = n f_{rep} + f_{ceo}$.

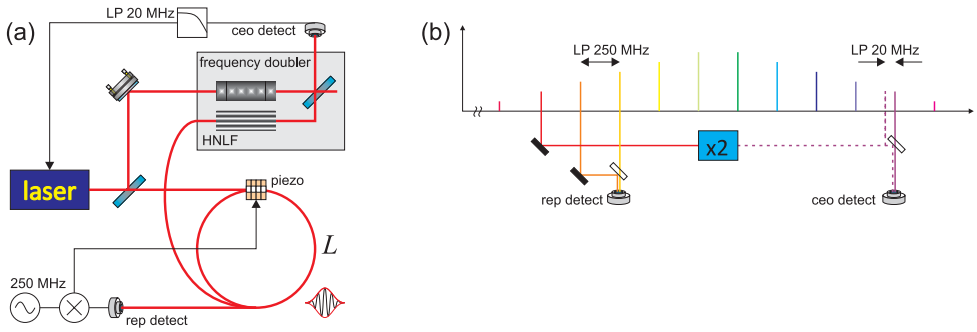

Figure 54.17: (a) Scheme and (b) operation principle of a frequency comb with control of the repetition rate and the carrier envelope offset.

54.4.2.2 Mode-locking of a frequency comb

From Eq. (54.28) we see that *mode-locking* is achieved when,

$$\frac{\nu}{f_{rep}} = m + \frac{f_{ceo}}{f_{rep}} \in \mathbb{N} \ , \tag{54.37}$$

which implies $f_{ceo} = 0$. Eq. (54.36) then becomes,

$$|E(\omega)|^2 = \frac{\pi T}{4} e^{-T^2(\omega-2\pi\nu)^2/2} \sum_n \delta(\omega - n f_{rep}) \ , \tag{54.38}$$

which means that all comb frequencies are locked.

54.4.2.3 Referencing radio and optical frequencies

In a frequency comb f_{rep} is easy to measure, as one just has to filter the beat of the comb light with a low pass filter cutting off frequency components higher than f_{rep}, as illustrated in Fig. 54.17. In contrast, measuring f_{ceo} is more complicated. Unless we have an octave spanning frequency comb, i.e. there are two frequencies in the comb,

$$\nu_1 = m_1 f_{rep} + f_{ceo} \quad \text{and} \quad \nu_2 = m_2 f_{rep} + f_{ceo} \ , \tag{54.39}$$

such that $\nu_2 = 2\nu_1 + \Delta\nu$ with $|\Delta\nu| < |f_{ceo}|$, i.e. $m_2 = 2m_1$. We get,

$$m_2 f_{rep} + f_{ceo} = 2m_1 f_{rep} + 2f_{ceo} + \Delta\nu \ , \tag{54.40}$$

or,

$$f_{ceo} = -\Delta\nu \ . \tag{54.41}$$

54.4.2.4 Dual comb spectroscopy

Optical sensors are based on the interaction of light with matter and are often implemented like some kind of spectrometer. The ideal sensor should detect a given substance with great sensitivity, identify it (especially in the presence of many other substances or a noisy background) and quantify it. Add to these features the ability to perform measurements in real time, if possible remotely, in a compact and easy-to-use assembly at affordable price, and we have an absolutely non-trivial problem. Broadband sources allow to detect multiple substances, but have limitations in resolution, calibration or acquisition time. Monochromatic sources allow good resolution, but in general have limitations on tunability and spectral coverage. The sensitivity can be increased by increasing the optical path of interaction, requiring multi-pass cells or resonant optical cavities, which augment the complexity of the setup. Finally, the detection method places limits on the acquisition rate and also on the sensitivity. Particularly the Fourier transform spectroscopy uses broadband incoherent light sources and the time of acquisition and resolution are limited by the speed of translation of a mechanical stage, as well as the range of its displacement. Here, the use of optical frequency combs replacing the incoherent sources, combined with *dual comb spectroscopy*, brings important advantages [1337, 613].

54.4.3 Multi-photon spectroscopy

54.4.4 Raman spectroscopy

Raman spectroscopy is a spectroscopic technique typically used to determine vibrational modes of molecules, although rotational and other low-frequency modes of systems may also be observed. Raman spectroscopy is commonly used in chemistry to provide a structural fingerprint by which molecules can be identified. Raman spectroscopy relies upon inelastic scattering of photons, known as Raman scattering. A source of monochromatic light, usually from a laser in the visible, near infrared, or near ultraviolet range is used, although X-rays can also be used. The laser light interacts with molecular vibrations, phonons or other excitations in the system, resulting in the energy of the laser photons being shifted up or down. The shift in energy

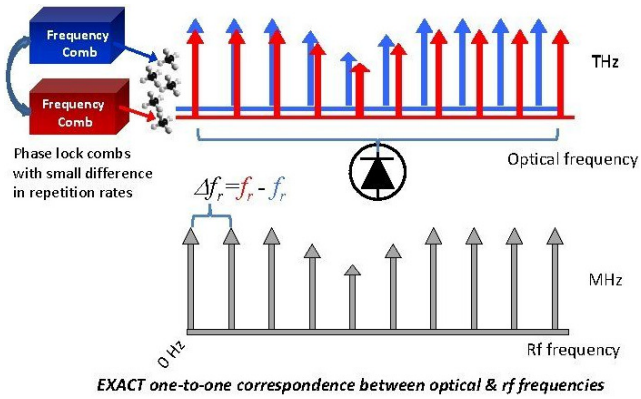

Figure 54.18: Principle of dual comb spectroscopy.

gives information about the vibrational modes in the system. Infrared spectroscopy typically yields similar, complementary, information.

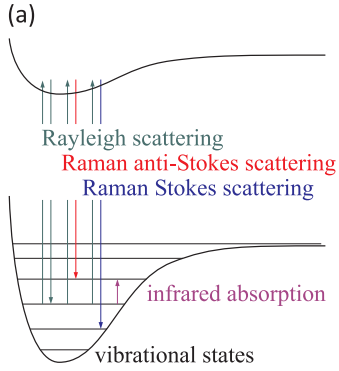

Figure 54.19: Energy-level diagram showing the states involved in Raman spectra.

Typically, a sample is illuminated with a laser beam. Electromagnetic radiation from the illuminated spot is collected with a lens and sent through a monochromator. Elastic scattered radiation at the wavelength corresponding to the laser line (Rayleigh scattering) is filtered out by either a notch filter, edge pass filter, or a band pass filter, while the rest of the collected light is dispersed onto a detector.

Spontaneous Raman scattering is typically very weak; as a result, for many years the main difficulty in collecting Raman spectra was separating the weak inelastically scattered light from the intense Rayleigh scattered laser light (referred to as 'laser rejection'). Historically, Raman spectrometers used holographic gratings and multiple dispersion stages to achieve a high degree of laser rejection. In the past, photomultipliers were the detectors of choice for dispersive Raman setups, which resulted in long acquisition times. However, modern instrumentation almost universally employs notch or edge filters for laser rejection. Dispersive single-stage spectrographs, for example Czerny-Turner (CT) monochromators (see Sec. 54.1.5), paired with CCD

detectors are common.

The name 'Raman spectroscopy' typically refers to vibrational Raman using laser wavelengths which are not absorbed by the sample. Raman spectroscopy is used in chemistry to identify molecules and study chemical bonding and intramolecular bonds. Because vibrational frequencies are specific to a molecule's chemical bonds and symmetry (the fingerprint region of organic molecules is in the wavenumber range $500 - 1500\,\mathrm{cm}^{-1}$, Raman provides a fingerprint to identify molecules.

In solid-state physics, Raman spectroscopy is used to characterize materials, measure temperature, and find the crystallographic orientation of a sample. As with single molecules, a solid material can be identified by characteristic phonon modes. Information on the population of a phonon mode is given by the ratio of the Stokes and anti-Stokes intensity of the spontaneous Raman signal. Raman spectroscopy can also be used to observe other low frequency excitations of a solid, such as plasmons, magnons, and superconducting gap excitations. Distributed temperature sensing (DTS) uses the Raman-shifted backscatter from laser pulses to determine the temperature along optical fibers.

Chapter 55

Locking circuits

In a laboratory we are often confronted with the need to control the value of a physical parameter, f.ex., room temperature, currents and voltages, or the frequency and intensity of laser beams. The physical discipline dealing with the fundamental concepts of this field is called *control theory* and its application to development of automatic control systems is called *control engineering*.

In this chapter, after a brief introduction into *control theory*, we will design and construct a few automatic control systems, which are common in quantum optics labs.

55.1 Introduction to control theory

The minimum ingredients of a control system are 1. a *sensor* measuring the actual value of the parameter to be controlled (e.g., a thermometer), 2. an *actuator* capable of correcting the value (e.g., a heater or cooler), and 3. a suitable *controller* (*servo system*) linking sensor and actuator thus providing a feedback.

The controller comprises a *comparator* comparing the measured value with a reference and delivers the difference to a controller, which may be implemented electronically by proportional control, *PID control*, bistable hysteretic control, or programmable logic control. Older controller units have been mechanical, as in a carburetor. Finally, the value computed by the controller is delivered to an actuator, which manipulates and changes a variable in the controlled system (or *plant*).

55.1.1 Open- and closed-loop control

Fundamentally, there are two types of control loop: *open loop* control, and *closed loop* (feedback) control.

In open loop control, the control action from the controller is independent of the 'process output' (or 'controlled process variable'). An example of this is a central heating boiler controlled only by a timer, so that heat is applied for a constant time, regardless of the temperature of the building. The control action is the switching on/off of the boiler. The process output is the building temperature.

In closed loop control, the control action from the controller is dependent on the process output. In the case of the boiler analogy, this would include a thermostat to monitor the building temperature, and thereby feed back a signal to ensure the controller maintains the building at the temperature set on the thermostat. A closed loop controller therefore has a feedback loop which ensures the controller exerts a

control action to give a process output the same as the 'reference input' or 'set point'. For this reason, closed loop controllers are also called feedback controllers.

The definition of a closed loop control system is *a control system capable of canceling the deviation of a system variable from a reference value by means of a feedback signal computed from a measured value of the variable and used to act on the system in a controlled way* [1249]. Automatic feedback control has revolutionized all areas of human activities.

To overcome the limitations of the open-loop controller, control theory introduces *feedback*. A closed-loop controller uses feedback to control states or outputs of a dynamical system. Its name comes from the information path in the system: process inputs (e.g. voltage applied to an electric motor) have an effect on the process outputs (e.g. speed or torque of the motor), which is measured with sensors and processed by the controller; the result (the control signal) is 'fed back' as input to the process, closing the loop.

Closed-loop controllers have the following advantages over open-loop controllers:

- disturbance rejection (such as hills in the cruise control example above)
- guaranteed performance even with model uncertainties, when the model structure does not match perfectly the real process and the model parameters are not exact
- unstable processes can be stabilized
- reduced sensitivity to parameter variations
- improved reference tracking performance

In some systems, closed-loop and open-loop control are used simultaneously. In such systems, the open-loop control is termed feedforward and serves to further improve reference tracking performance.

55.1.1.1 Closed-loop transfer function

Due to noise the variables of the system become time-dependent. The output of the system $y(t)$ is fed back through a sensor measurement F to a comparison with the reference value $r(t)$. The controller C then takes the error $e(t)$ (difference) between the reference and the output to change the inputs $u(t)$ to the system under control P. This is shown in the figure. This kind of controller is a closed-loop controller or feedback controller. We will restrain here to *single-input-single-output control* systems (SISO) disregarding the possibility of having multiple and interdependent inputs and outputs.

If we assume the controller C, the plant P, and the sensor F are linear and time-invariant (i.e. elements of their transfer function $C(s)$, $P(s)$, and $F(s)$ do not depend on time), the systems above can be analyzed using the Laplace transform on the variables, $U(s) = \mathcal{L}u(t)$, $Y(s) = \mathcal{L}y(t)$, and $R(s) = \mathcal{L}r(t)$. Here,

$$s \equiv \imath f \tag{55.1}$$

is an abbreviation for the imaginary Fourier frequency component f of the noise. In the following sections we will, however, characterize the transfer functions in terms

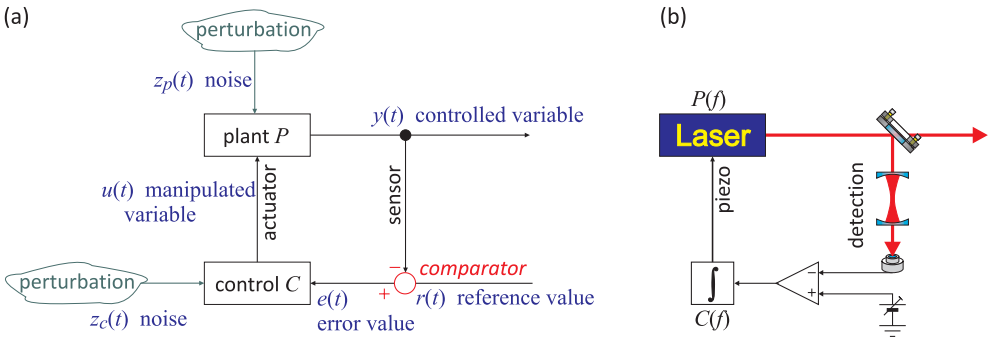

Figure 55.1: (a) General schematic diagram of a feedback loop. (b) Possible implementation for the frequency stabilization of a laser to a cavity resonance,

of real Fourier frequencies. The theoretical foundation of Linear Time-Independent (LTI) systems is outsourced to Sec. 56.2.

For a control to work, it needs to know in which direction to act and when the control point is reached. Therefore, each control needs a slope (*discriminator*) crossing zero. This can be implemented by comparing the signal $Y(f)$ delivered by the detector (for simplicity assumed to be frequency-independent) with a reference signal R. The error signal $E(f) = R(f) - Y(f)$ is then processed by a controller C, and the control signal $U(f)$ is passed, via an actuator (for simplicity assumed to be frequency-independent), to the controlled device P. The controlled device (and obviously all other components of the circuit) are subject to perturbations Z. The transfer functions form a closed control circuit described by the following relations:

$$Y(f) = P(f)U(f) \quad \text{and} \quad U(f) = C(f)E(f) \quad \text{and} \quad E(f) = R(f) - Y(f)\,. \tag{55.2}$$

Solving the system of equations (55.2) for $Y(f)$ in terms of $R(f)$ gives,

$$\boxed{Y(f) = \frac{P(f)C(f)}{1 + P(f)C(f)}\, R(f) \equiv H(f)R(f)}\,. \tag{55.3}$$

$H(s)$ is referred to as the closed-loop transfer function of the system. The numerator $V(f) \equiv P(f)C(f)$ is called the *forward gain* (*open-loop gain*) from R to Y, and the denominator is one plus the gain in going around the feedback loop, the so-called *loop gain*. If $|P(f)C(f)| \gg 1$, i.e. it has a large norm with each value of f, and then $Y(f) \simeq R(f)$ and the output closely tracks the reference input.

55.1.1.2 Noise reduction via feedback circuits

We have seen that the idea of *locking*, whether mechanical or electronic, is to bring a given physical signal Y to a predetermined value R and lock it there, which is the role of the control circuit or *regulator*. Now, considering a possible perturbation of the plant (see Fig. 55.1) by noise Z_p and also of the regulator by noise Z_c, the result (55.3) must be generalized,

$$Y(f) = \frac{P(f)C(f)}{1 + P(f)C(f)} R(f) + \frac{P(f)C(f)}{1 + P(f)C(f)} Z_c(f) + \frac{1}{1 + P(f)C(f)} Z_p(f)\,, \tag{55.4}$$

or,

$$\boxed{Y(f) = \frac{1}{1+V(f)^{-1}}[R(f)+Z_c(f)] + \frac{1}{1+V(f)}Z_p(f)} \,. \tag{55.5}$$

This shows that, provided the open loop gain is high enough, perturbations affecting the plant can be efficiently be neutralized. In contrast, noise entering via the control cannot be suppressed, and this fact is independent on the chosen controller transfer function: *Perturbations entering between the measurement point and the input of the regulator are not eliminated*! Consequently, the detector (which generally works with very low signals) should not introduce or let penetrate noise, because this affects the variable to be controlled: Any variation of the steering variable at the regulator will be transmitted 1 to 1.

In the following, we will discuss the most common controller called PID-servo.

55.1.2 PID feedback control

A *PID controller* continuously calculates an error value $e(t)$ as the difference between a desired setpoint and a measured process variable and applies a correction based on proportional, integral, and derivative terms. PID is an acronym for Proportional-Integral-Derivative, referring to the three terms operating on the error signal to produce a control signal.

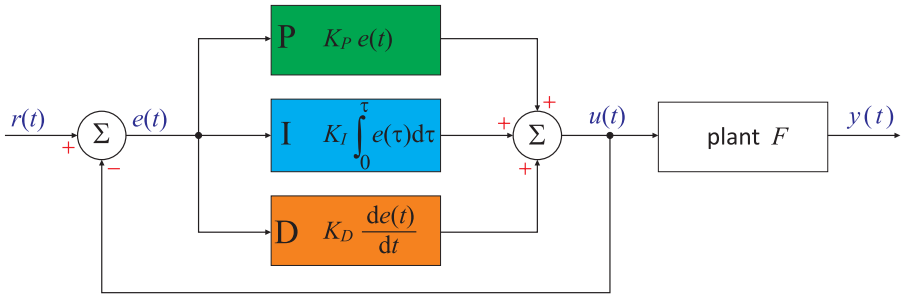

Figure 55.2: A block diagram of a PID controller in a feedback loop, $r(t)$ is the desired process value or 'set point', and $y(t)$ is the measured process value. A proportional-integral-derivative controller (PID controller) is a control loop feedback mechanism control technique widely used in control systems.

The theoretical understanding and application dates from the 1920s, and they are implemented in nearly all analogue control systems; originally in mechanical controllers, and then using discrete electronics and latterly in industrial process computers. The PID controller is probably the most-used feedback control design.

If $u(t)$ is the control signal sent to the system, $y(t)$ is the measured output and $r(t)$ is the desired output, and tracking error $e(t) = r(t) - y(t)$, a PID controller has the general form,

$$\boxed{u(t) = K_P e(t) + K_I \int e(\tau)d\tau + K_D \frac{de(t)}{dt}} \,. \tag{55.6}$$

The desired closed loop dynamics is obtained by adjusting the three parameters K_P, K_P, and K_I, often iteratively by 'tuning' and without specific knowledge of a plant model. Stability can often be ensured using only the proportional term. The integral term permits the rejection of a step disturbance (often a striking specification in process control). The derivative term is used to provide damping or shaping of the response [1].

Applying Laplace transformation results in the transformed PID controller equation,

$$\boxed{U(f) = \left(K_P + K_I \frac{1}{\imath f} + K_D \imath f\right) E(f) \equiv C(f)E(f)}\,, \tag{55.7}$$

defining the PID controller transfer function $C(f)$.

From equations (55.6) or (55.7) we immediately see that the PID transfer functions can readily be implement in electronic circuits using resistors (P), capacitors (I), and inductances (D).

Example 302 (*Comparing servo controllers*): We now assume a low-pass behavior for the plant,

$$P(f) = \frac{1}{1 + \imath f/f_c}\,,$$

and analyze the feedback circuit for four cases.

- The first one is that of a proportional servo, $C(f) = K_P$. Then, Eq. (55.5) reads,

$$Y = \frac{K_P}{1 + \imath f/f_c + K_P}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + \imath f/f_c + K_P} Z_p$$
$$\begin{cases} \stackrel{s\to 0}{\longrightarrow} \frac{K_P}{1+K_P}(R + Z_c) + \frac{1}{1+K_P} Z_p \\ \stackrel{s\to\infty}{\longrightarrow} \frac{K_P f_c}{\imath f}(R + Z_c) + Z_p \end{cases}.$$

  We see that, for limited open-loop gain, noise affecting the plant Z_p is not eliminated at low frequencies. Additionally, at high frequencies, the gain for the error signal R drops like -6dB/oct.

- The second case is that of an integral servo $C(f) = K_I/\imath f$. Then Eq. (55.5) reads,

$$Y = \frac{K_I/\imath f}{1 + \imath f/f_c + K_I/\imath f}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + \imath f/f_c + K_I/\imath f} Z_p$$
$$\begin{cases} \stackrel{f\to 0}{\longrightarrow} R + Z_c + \frac{\imath f}{K_I} Z_p \\ \stackrel{\to\infty}{\longrightarrow} \frac{K_I f_c}{(\imath f)^2}(R + Z_c) + Z_p \end{cases}.$$

  Apparently, the noise Z_p is now eliminated at low frequencies. However, the gain for R drops even faster at high frequencies.

[1] PID controllers are the most well established class of control systems: however, they cannot be used in several more complicated cases, especially if MIMO systems are considered.

- The third case is that of a PI-servo, $C(f) = K_P + K_I/\imath f$. Then Eq. (55.5) reads,

$$Y = \frac{K_P + K_I/\imath f}{1 + \imath f/f_c + K_P + K_I/\imath f}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + \imath f/f_c + K_P + K_I/\imath f} Z_p$$
$$\begin{cases} \stackrel{f\to 0}{\longrightarrow} R + Z_c + \frac{\imath f}{K_I} Z_p \\ \stackrel{f\to\infty}{\longrightarrow} \frac{f_c K_P}{\imath f}(R + Z_c) + Z_p \end{cases},$$

  which represents a viable compromise, since it has the same low-frequency behavior as the I-servo, but at high frequencies the gain for R drops only like -6dB/oct.

- Finally, the forth case is that of a PID-servo, $C(f) = K_D \imath f + K_P + K_I/\imath f$. Then Eq. (55.5) reads,

$$Y = \frac{K_D \imath f + K_P + K_I/\imath f}{1 + \imath f/f_c + K_D \imath f + K_P + K_I/\imath f}(R + Z_c) + \frac{1 + \imath f/f_c}{1 + K_D \imath f + K_P + K_I/\imath f} Z_p$$
$$\begin{cases} \stackrel{f\to 0}{\longrightarrow} R + Z_c + \frac{\imath f}{K_I} Z_p \\ \stackrel{f\to\infty}{\longrightarrow} \frac{1}{1+1/f_c K_d}(R + Z_c) + \frac{1}{f_c K_D} Z_p \end{cases}.$$

  The low-frequency behavior remains still the same, but at high frequencies the gain for R stays constant.

A time domain analysis shows that P regulators have little phase lag, but the controlled variable can not be zeroed. On the other hand, I regulators have finite control bandwidth, but the controlled variable can be zeroed. PI regulators (parallel circuit of P and I regulators) have a reaction time $T_n = K_P/K_I$; that is, the jump response is advanced by T_n in comparison to the regulator I.

In the time domain we can summarize that regulators

- D are characterized by the absence of memory, but they are very fast,
- P have no idea of the strength of their impact,
- I increase their impact in time until the error disappears.

For practical PID controllers, a pure differentiator is neither physically realizable nor desirable due to amplification of noise and resonant modes in the system. Therefore, a phase-lead compensator type approach is used instead, or a differentiator with low-pass roll-off [635, 461, 462, 1306]. See Excs. 55.2.3.1 and 55.2.3.2.

Like any real system, the controlled device behaves as a low-pass for manipulations or perturbations at high frequency. In other words, the device can only respond to external perturbations with finite speed. This delay of the response leads to a phase shift that can reverse the sign of the error signal $E(f)$ and transform a negative feedback into a positive feedback. Now, in the case that there are high frequency perturbations, for which the amplification of the closed control circuit is > 1, these perturbations can be amplified to form oscillations. These oscillations, which occur at the bandwidth of the closed loop gain are called *servo oscillations*.

Fig. 55.3 illustrates the necessity of optimizing the gain and the frequency response of the servo circuit: A proportional servo simply providing a frequency-independent gain $C(f) = K_P$ will lead to a forward gain $R(f) \propto P(f)$ exhibiting a low-pass behavior, i.e. a phase-shift $\phi = -\pi/2$ transforming negative to positive feedback. The gain at the frequency where this happens need to be lower than 1, otherwise the feedback servo will generate servo-oscillations, i.e. it will oscillate at the lowest Fourier frequencies where noise is amplified. A PI-servo alleviates this problem by a phase shift in opposite direction.

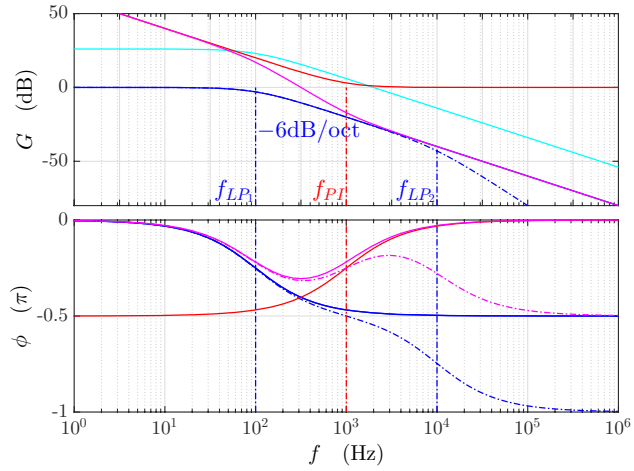

Figure 55.3: (code) Bode diagram for a plant subject to low-pass behavior and for a PI-servo. (blue solid) Low-pass filter with 100 Hz bandwidth; (blue dash-dotted) another low-pass filter at 100 kHz; (cyan) same as blue, but amplified by 20 dB; (red) PI-servo; (magenta) open-loop amplification.

55.1.3 Noise transfer in feedback loops

In order to develop a model for noise transfer we must understand what noise is and how it can be measured. This is not a simple task and we therefore outsourced a proper discussion to Sec. 56.3. Here, we will only use the information that noise affecting a signal $y(t)$ is quantified by a *spectral noise density* defined as the Fourier transform of the signal's autocorrelation function (56.59),

$$S_y(f) \equiv \mathcal{F}[\overline{y^*(t)y(t+\tau)}] \; . \tag{55.8}$$

Now, we can see how noise is transmitted through an LTI device $P(f)$:

$$\boxed{Y(f) = P(f)X(f) \quad \Rightarrow \quad S_y(f) = |P(f)|^2 S_x(f)} \; . \tag{55.9}$$

This result can be applied to our formula (55.5) describing a feedback loop,

$$\boxed{S_y(f) = \left|\frac{1}{1+V(f)^{-1}}\right|^2 S_c(f) + \left|\frac{1}{1+V(f)}\right|^2 S_p(f)} \; . \tag{55.10}$$

This formula describes how a servo control shapes the noise spectrum of a feedback-controlled variable $y(t)$.

Example 303 (*Noise reduction by feedback*): As an example, let us study the control circuit for stabilizing a laser to a cavity mode depicted in Fig. 55.1(b) using the following additional background information: The laser frequency ω be perturbed by $1/f$ noise described by the power spectral density,

$$S_p(f) \equiv 2 \cdot 10^{-24}/f \ .$$

This noise enters the feedback loop via the fluctuations $z_p(t)$ depicted in

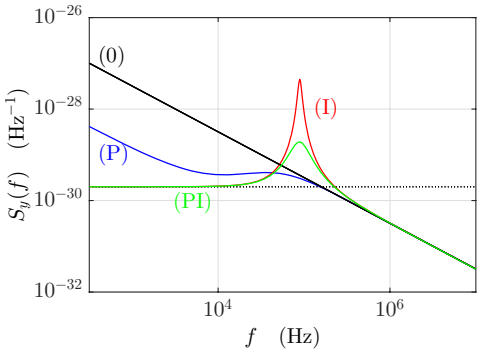

Figure 55.4: (code) Spectral density of frequency fluctuations of the servo system exhibited in Fig. 55.2. Shown is the spectral noise density $S_y(f)$ of the laser light for 4 different feedback gain curves: (black solid) no feedback control $C(f) = 0$, (blue) P-regulator with $C(f) = 4$, (red) I-regulator with $C(f) = 5 \cdot 10^6/\imath f$, and (green) PI-regulator $C(f) = 4 + 5 \cdot 10^6/\imath f$.

Fig. 55.1(a). The black solid line in Fig. 55.4 traces the noise spectrum $S_p(f)$, which is also the noise expected for the laser without feedback loop. Furthermore the optical cavity, which constitutes the essential part of the regulator, is itself afflicted by acoustic noise and thermal drifts which, for simplicity, we describe by a white Fourier frequency spectrum given by,

$$S_c(f) \equiv 2 \cdot 10^{-30}\,\mathrm{Hz}^{-1} \ ,$$

and represented by the black dotted line in Fig. 55.4. As we have seen, servos systems always have a finite bandwidth beyond which noise is fully coupled to the system. For example in laser frequency locks, the weakest point of a servo chain is often the small bandwidth of a piezo transducer used to correct the length of the laser cavity. We describe this behavior by a low-pass filter for the transfer function of the laser,

$$P(f) = \frac{1}{1 + \imath f/f_c}$$

with a bandwidth of $f_c = 10\,\mathrm{kHz}$.
Fig. 55.4 demonstrates how the $1/f$ noise $S_p(f)$ can be efficiently suppressed at frequencies below the low-pass filter cut-off f_c to a value limited by the white noise $S_c(f)$ entering through the regulator. As predicted by the formula (55.10), the suppression of the noise $S_p(f)$becomes all the better, as the open-loop gain

$V(f)$ gets higher. However, with the amplification of the controller, also the gain of the closed control circuit increases, and this necessarily causes phase shifts, which lead to (servo-)oscillations in the circuit appearing as a strong peak of strong noise around a certain Fourier frequency f_{bw} characterizing the bandwidth of the closed loop servo system. Note that high-frequency noise, to which the cavity might be subject, is not coupled to the laser, because it is filtered by the low-pass filter $P(f)$ to the same extend as the error signal itself.

The next example, exhibited in Fig. 55.5, shows the experimental characterization of a dye laser locked via the Pound-Drever-Hall technique (see Sec. 55.3.3) to an optical cavity.

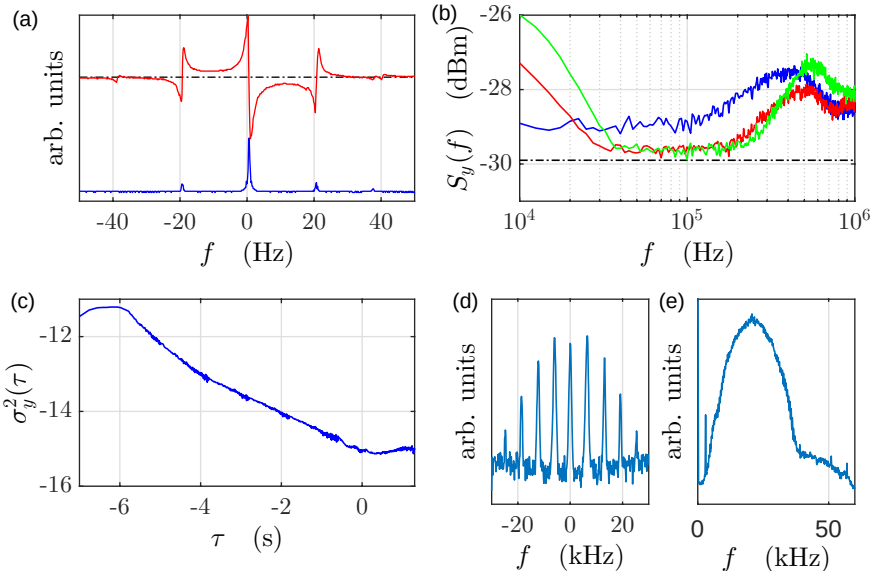

Figure 55.5: Characterization of a Pound-Drever-Hall stabilization of a dye laser. (a) PDH error signal (red) and cavity transmission signal (blue), (b) spectral density of frequency fluctuations, (c) Allan variance. (d-e) Beat signals of Mach-Zehnder interferometers. In (d) one interferometer arm is passed through an optical fiber attached to a piezo transducer to which a sinusoidal 5 kHz modulation of is applied. This demonstrates the sensitivity of optical fibers to acoustic noise. In (e) one interferometer arm is send to another optical table and back. This demonstrates how mechanical vibrations of optical components in the beam path can broaden the spectrum of a laser field.

55.2 Amplitude stabilization circuits

55.2.1 Laser intensity stabilization with an AOM

The light emitted from lasers is generally subject to *frequency fluctuations* and *intensity fluctuations*, which are unacceptable for many applications. In this section we will construct an *intensity stabilization* for a laser beam.

One way of stabilizing the light intensity of a laser beam consists in using the an acousto-optic modulator, as shown in Fig. 55.6. The first Bragg diffraction order (see Sec. 53.3.1) is focused onto a photodiode. Intensity fluctuations of the light recorded by the photodiode are converted into voltage fluctuations, processed by an electronic circuit fed back to the AOM. The intensity of light diffracted into the first order can be controlled via the power of the radiofrequency alimenting the AOM. The control circuit can now be conceived such as to neutralize the intensity fluctuations recorded by the photodiode.

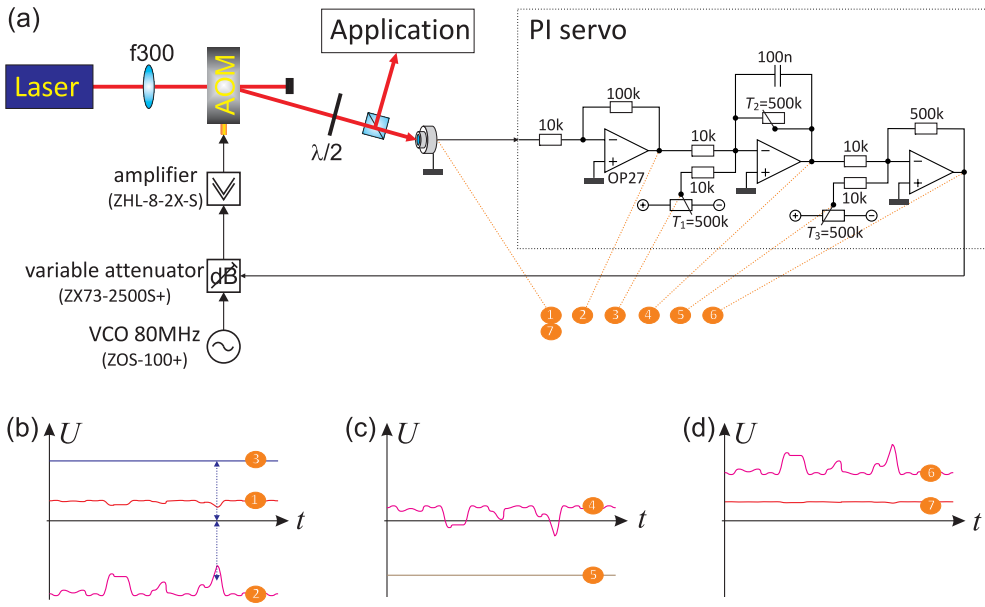

Figure 55.6: (a) Layout of the intensity control. The variable attenuator controls the amplitude of the radiofrequency driving the AOM: low voltage (0 V) increases the attenuation, high voltage (+16 V) reduces it. The sketched control circuit realizes a negative feedback, when the photodetector produces a positive signal. (b-d) Signals recorded at the test points of the circuits shown in (a). See text for explanations.

55.2.1.1 Operation principle and adjustment procedure

The idea of the intensity stabilization is illustrated in Fig. 55.6(b-d): The laser intensity scattered into the first diffraction order is recorded by a photodiode (test point 1 in the figure). The signal is then amplified (and inverted) by a first OpAmp (test point 2). The trimmer T_1 (test point 3) is now adjusted to a positive voltage compensating the DC part of the signal (2), i.e., the sum (2+3) after being inverted and amplified by the second OpAmp (test point 4), should be around zero DC. The signal (2+3) is called *error signal*, since it is this signal which tells us in which direction the control circuits has to work to counteract the power fluctuation. In the present design, the second OpAmp also incorporates the PI servo (see Sec. 55.1), which can be adjusted via the amplification of the trimmer T_2 and the capacity C.

It is now important to realize, that the variable attenuator works best around a given control voltage, which is provided by adding via the trimmer T_3 (test point 5) and a third OpAmp an appropriate offset. Furthermore, we note that variable attenuator reduces its attenuation with increasing control voltage. Thus, the control signal (test point 6) works to enhance the efficiency of the AOM, when the photodiode signals a power drop, and vice versa. As a result, the light power in the first diffraction order is stabilized, however, at a level inferior to the unstabilized power [1306, 462].

The trimmers of the servo circuits can be adjusted using the following procedure:

1. Observe the light intensity and its fluctuations at test point (1), set test point (4) to ground (e.g. short-circuiting the trimmer T_2), and adjust trimmer T_3 until the light intensity level is at bit lower than the lowest fluctuations.

2. Reconnect test point (4) to the circuit and adjust trimmer T_1 until the voltage at test point (4) cancels to zero.

55.2.2 PI servo for a current stabilization

Many applications in quantum optics require very stable high currents, for instance, in coils generating magnetic field for atomic trapping potentials. Here, we will construct a *PI servo* to para realize a *current stabilization*.

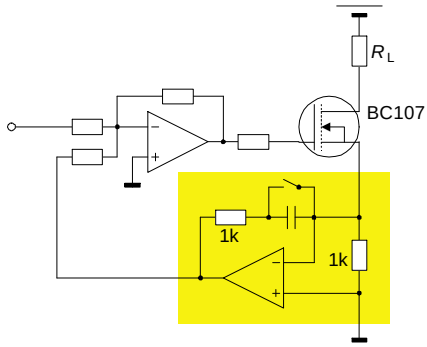

Figure 55.7: Current stabilization.

55.2.3 Exercises

55.2.3.1 Ex: Integrator

Determine the transfer function of the circuit depicted in Fig. 55.8. What kind of control circuit is it?

Solution: *The transfer function is that of a PI-servo,*

$$G(\omega) = -\frac{1}{R_1}\left(R_n + \frac{1}{\imath f C}\right) .$$

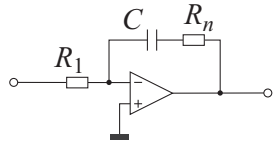

Figure 55.8:

55.2.3.2 Ex: PID controller

Consider the PID controller transfer function in series,

$$C(f) = K\left(1 + \frac{1}{\imath f T_I}\right)(1 + \imath f T_D) \ ,$$

a first-order low-pass filter in the feedback loop,

$$F(f) = \frac{1}{1 + \imath f T_F} \ ,$$

and a linear actuator with low-pass behavior,

$$P(f) = \frac{A}{1 + \imath f T_P} \ .$$

How do you have to choose the various time constants in order to let the closed-loop transfer function be $H(f) = 1$.

Solution: *Insert the components C, F, and P into the expression for closed-loop transfer function $H(f)$, then tuning is very easy simply choosing,*

$$K = \frac{1}{A} \quad , \quad T_I = T_F \quad , \quad T_D = T_P$$

and get $H(f) = 1$ identically.

55.2.4 *Experiment: Development of an intensity stabilization*

We will now set up up an intensity stabilization. For the realization of the project prior knowledge of 1. photodetectors (see Sec. 52.2.1), 2. acousto-optic modulators (AOM) (see Sec. 53.3.1), 3. electronic circuits (see Sec. 52.1.3), and 4. control circuits (see Sec. 55.1) is required.

1. Realize the optical setup illustrated in Fig. 55.6. Optimize the alignment of the AOM (in particular, the focus and the Bragg angle) in order to maximize the efficiency of the AOM. Take care not to saturate the photodiode, if necessary adapt the load resistance (see Sec. 52.1.). Study the data sheet of the variable attenuator.

2. Derive and plot the transfer function for ac-signals of the electronic circuit. What kind of control circuit is it?

3. Set up the electronic circuit exhibited in Fig. 55.6. Test it by observing the signals at the six test points marked in the circuit diagram. Understand and interprete the roles of the three adjustable parameters: input offset, amplification, and output offset.

4. Incorporate the servo circuit into the optical setup as shown in Fig. 55.6. How to make sure the circuit is operating properly? [2].

55.2.5 *Experiment: PI servo for a current stabilization*

How to control high currents? How to dramatically increase the switching speed despite inductive loads and eddy currents?

1. Connect a resistive charge to a voltage source. Insert a *MOSFET* into the circuit and a small resistor. Control the gate of the MOSFET with a voltage and measure the current of the circuit via the voltage drop at the small resistor as a function of the gate voltage.

2. Now control the gate voltage via the voltage measured at the small resistor and measure again the dependency voltage-to-current.

55.3 Frequency stabilization circuits

Although lasers are often monochromatic, they generally have a poor intrinsic frequency stability, that is, the frequency of the light field $E(t) = \sin \omega t$ drifts in time, $\omega = \omega(t)$ on a time scale, which is slow in comparison to the oscillation period $1/\omega$. The reasons for these drifts are typically acoustic noise or thermal drifts to which the laser device is subject and which are difficult to avoid.

Often it is much easier to guarantee the mechanical and thermal stability of a passive device exhibiting resonances, such as an optical cavity. Furthermore, nature provides intrinsically stable resonances, such as narrow atomic transitions. These resonances can be used to actively stabilize the frequency of lasers via feedback servo circuits. In the following sections we will present a few common techniques.

55.3.1 Side-of-fringe stabilization to/of a Fabry-Pérot cavity

Resonances are generally characterized by peaked profiles symmetrically centered about a resonance frequency ω_0. Excited by a laser field of frequency ω, they respond by an oscillation whose amplitude depends on the detuning $\omega - \omega_0$. Unfortunately, the amplitude of the response signal does not tell us, whether the detuning is positive

[2] Datasheet for the VCO see appendix Fig. 56.16,
data sheet for the variable attenuator see appendix Fig. 56.17,
data sheet for the amplifier see appendix Fig. 56.15.

or negative. We have to invent techniques allowing us to extract this information from the response signal and to generate a true error signal.

One of these techniques is the *side-of-fringe stabilization* technique illustrated in Fig. 55.9. Here, the laser tuned to one side of the optical resonance such that, when the laser frequency drifts, the response signal increases or decreases correspondingly. Technically, this is achieved by comparing (i.e. subtracting) the response signal with a stable reference signal.

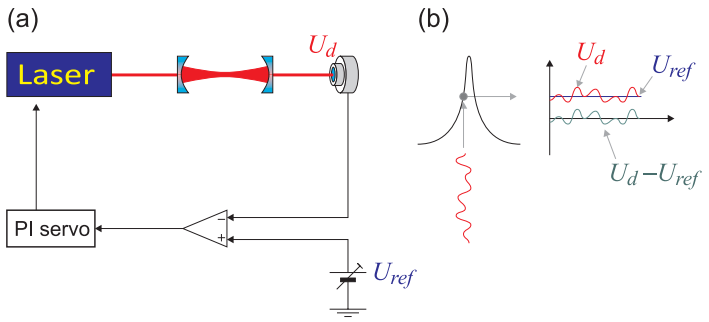

Figure 55.9: (a) Frequency stabilization to a cavity using the side-of-fringe method. (b) The laser is tuned to rising (or falling) slope of a transmission curve of a Fabry-Pérot cavity. The error signal is compared with reference voltage.

55.3.2 Lock-in method for frequency stabilizing to/of a cavity

One method of stabilizing a laser on a resonator consists in modulating the frequency slightly and then demodulating the transmission signal of the resonator at the same frequency. This is the so-called *lock-in method*. Frequency modulation of the laser beam can be done by modulating the laser diode feed current, the piezo of the extended laser cavity or using an AOM. Fig. 55.10 shows the layout of the optical assembly.

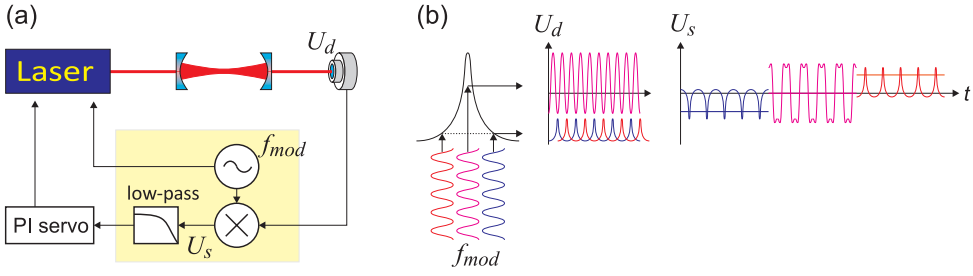

Figure 55.10: (a) Frequency stabilization to a cavity using the lock-in method. (b) Frequency-modulated signals applied to a resonance suffer a period doubling, when the signal frequency is close to resonance. By demodulating the signals discriminated at the resonance profile, we obtain, after averaging over a period, a DC voltage that is proportional to the frequency detuning. The yellow area denotes the components constituting the lock-in amplifier.

The principle of control through modulation is explained in Fig. 55.10(a). A laser beam passes twice (round-trip) through an *acousto-optic modulator* fed by a radiofrequency voltage with modulated frequency, $\omega(t) = \omega_c + M \cos ft$. Here, the modulation frequency is much lower than its amplitude (or frequency excursion), $f \ll M$. The laser beam is now injected into an optical cavity and the frequency of the laser tuned near a resonance of the cavity. The dependence of the transmission on the frequency is described in good approximation of the *Airy formula* by a Lorentzian,

$$I(\omega) = \frac{\gamma^2}{4(\omega - \omega_0)^2 + \gamma^2} \ . \tag{55.11}$$

The signal transmitted through the cavity [see Fig. 55.10(b)],

$$U_d(t) = I(\omega(t)) = \frac{\gamma^2}{4\left(\omega_c + M \cos ft - \omega_0\right)^2 + \gamma^2} \ , \tag{55.12}$$

is demodulated by a lock-in amplifier [see Fig. 55.10(c)],

$$U_s(t) = U_d(t) \cos(ft + \phi) \ , \tag{55.13}$$

integrated with a locking electronics [see Fig. 55.10(d)]

$$\bar{U}_s(t) = \frac{1}{T} \int_0^T U_s(t) dt \ . \tag{55.14}$$

and used to control the piezo of the laser's extended cavity.

55.3.3 Pound-Drever-Hall stabilization

When the frequency of a carrier wave ω is modulated by a frequency Ω [3], the spectrum consists of sidebands the frequencies and phases of which can be calculated from an expansion of the wave in Bessel functions. Let N be the modulation excursion and $J_k(x)$ the Bessel function of the order k. Higher-order sidebands $k > 1$ are usually dropped in the calculation,

$$e^{\imath(\omega t + N \sin \Omega t)} = e^{\imath\omega t}[-J_1(N)e^{\imath\Omega t} + J_0(N) + J_1(N)e^{-\imath\Omega t}] \ . \tag{55.15}$$

From the latter expression, it can be seen that the spectrum of sidebands is formed

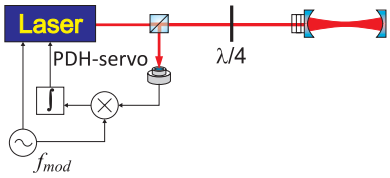

Figure 55.11: Frequency stabilization to a cavity using the Pound-Drever-Hall method.

by the frequencies ω and $\omega \pm \Omega$. A resonator responds to a field of incident light

[3] Remember that we specify all frequencies except the free spectral range δ_{fsr} in radians.

$E_0(\omega)$ oscillating with frequency ω by reflecting the field (R: reflectivity of mirrors, δ_{fsr}: free spectral range)

$$E_r(\omega) = E_0(\omega)\sqrt{R}\frac{1-e^{-\imath\omega/\delta_{fsr}}}{1-R\ e^{-\imath\omega/\delta_{fsr}}}\ , \tag{55.16}$$

where the amplitude and the phase of the reflected light field follow from the relation $E_r(\omega) = |E_r(\omega)|e^{\imath\phi(\omega)}$. Obviously the field of the reflected light is strong only, when the laser frequency is close to one mode of the resonator (when ω/δ is an integer number). By inserting Eq. (55.16) into Eq. (55.15), we obtain the response of the resonator to a field containing sidebands as a function of the frequency of light ω, of the modulation frequency Ω, and of the cavity finesse,

$$\begin{aligned}|E_{tot}|^2 &= |e^{\imath\omega t}[J_1(N)E_r(\omega+\Omega)e^{\imath\Omega t} + J_0(N)E_r(\omega) - J_1(N)E_r(\omega-\Omega)e^{-\imath\Omega t}]|^2 \\ &= J_0(N)J_1(N)E_r(\omega+\Omega)e^{\imath\Omega t} + J_0(N)J_1(N)E_r^*(\omega-\Omega)e^{\imath\Omega t} + ... + c.c.\ .\end{aligned} \tag{55.17}$$

The contributions of the reflected field to the current in the photodetector, $|E_r|^2$, oscillating with frequency Ω and extracted by the alternating current $e^{-i\Omega t+i\theta}$ (θ is an arbitrarily chosen phase angle), are

$$\begin{aligned}S_{PDH} &= |E_{tot}|^2 e^{-i\Omega t+i\theta} \\ &= J_0(N)J_1(N)\mathfrak{Re}\ \{e^{\imath\theta}[E_r^*(\omega)E_r(\omega+\Omega) - E_r(\omega)E_r^*(\omega-\Omega)]\} + ...\ .\end{aligned} \tag{55.18}$$

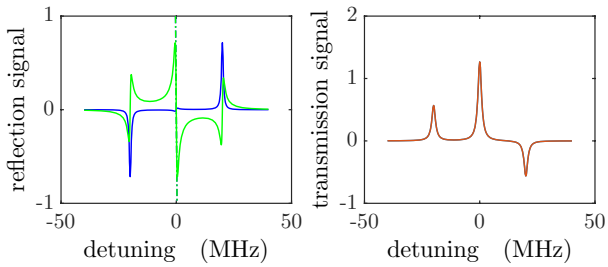

Figure 55.12: (code) (Left) Pound-Drever-Hall reflection signal for $\theta = 0, \pi/2$. (Right) Transmission signal.

By a suitable choice of the modulation index, the pre-factor containing Bessel functions (and therefore the signal amplitude) can be maximized. That is the case, for $M \simeq 1.1$ (see Exc. 53.4.5.1). Each of the two parts of the summation in the above equation is the result of a beating of the carrier $E_r(\omega)$ with one of the sidebands $E_r(\omega \pm \Omega)$. Only those optical sidebands being close to a mode of the resonator provide, along with the radiofrequency sidebands, contributions to the reflection signal

The dependence of the reflection signal S_{PDH} on the frequency ω is shown in Fig. 55.12(a). The antisymmetric shape and the zero-crossing slope are ideal for use as a discriminator generating an *error signal* for a frequency stabilization. This method is called *Pound-Drever-Hall method*.

55.3.4 Phase stabilization of standing waves

For the stabilization of the phase of a standing wave one can use the following scheme. It is similar to the homodyne method used with the Michelson interferometer with the difference that laser beam separation and recombination are done at different beam splitters.

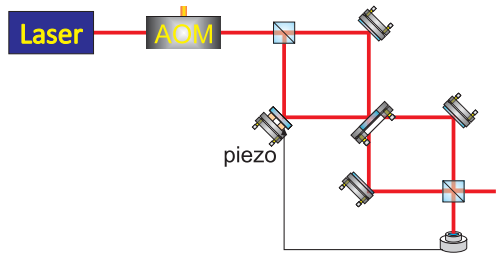

Figure 55.13: Phase stabilization.

55.3.5 Frequency-offset locking with phase-locked loops

Many application in spectroscopy require two stable lasers emitting at different but well-defined and tunable frequencies. Examples are stimulated Raman transitions, or the spectroscopy of atoms interacting with optical cavities [224]. In the following we will discuss and compare different approaches to locking one laser to another laser using a phase-locked loop (PLL). See also (watch talk).

55.3.5.1 VCO and mixing

In a *phase-locked loop* one tries to synchronize a self-sustained oscillator, in general realized by a VCO, with a local oscillator. The VCO generates an ac-voltage U_{rf}, whose frequency is tuned via a dc-control-voltage U_{ct} around a center frequency ω_0, as shown in Fig. 55.14(a). It can be modeled by,

$$\boxed{U_{rf}(t) = 2B\cos\phi(t) \qquad \text{with} \qquad \frac{d\phi}{dt} = \omega_0 + KU_{ct}(t)} \; . \tag{55.19}$$

The local oscillator produces an ac-voltage, $U_{lo}(t) = A\sin\phi_{lo}(t)$. A mixer multiplies both signals,

$$U_d(t) = AB\left(\sin[\phi_{lo}(t) - \phi(t)] + \sin[\phi_{lo}(t) + \phi(t)]\right) \; . \tag{55.20}$$

See also Exc. 55.3.7.1.

55.3.5.2 Low-pass filtering

The multiplied signal U_d contains all information about frequency deviations of the VCO from the LO. To extract them, we *low-pass filter* this signal, cutting off all high frequency components, i.e. apply the filter transfer function,

$$F(f) = (1 + sRC)^{-1} \; . \tag{55.21}$$

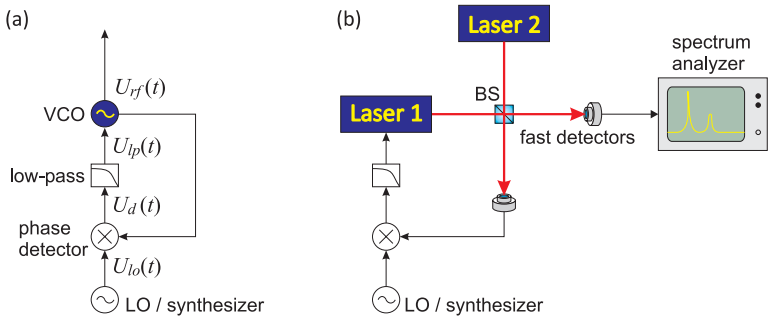

Figure 55.14: (a) PLL to lock a VCO to a reference oscillator LO. (b) PLL to lock the difference frequency of two lasers to a LO.

The signal of the filter is $U_{lp}(f) \equiv F(f)U_d(f)$. In time domain, which is obtained by a Laplace transform, $F(t) = (RC)^{-1}\theta(t)e^{-t/RC}$, such that

$$U_{lp}(t) = F \star U_d(t) = \int_{-\infty}^{\infty} F(t-\tau)U_d(\tau)d\tau = \frac{e^{-t/RC}}{RC}\int_{-\infty}^{t} e^{\tau/RC}U_d(\tau)d\tau \ . \quad (55.22)$$

The derivative is obviously,

$$\frac{dU_{lp}}{dt} + \frac{U_{lp}}{RC} = \frac{U_d(t)}{RC} = \frac{AB}{RC}\sin\left[\phi_{lo}(t) - \phi(t)\right] \ , \quad (55.23)$$

inserting the above expression for U_d. Note, that we would have obtained the same result using control theory (see Sec. 55.1).

55.3.5.3 Phase synchronization

The phase synchronization servo is closed by setting $U_{ct} = U_{lp}$. Thus we may substitute $U_{lp}(t)$ and define $\psi \equiv \phi - \phi_{lo}$,

$$\frac{d^2\psi}{dt^2} + \frac{1}{RC}\frac{d\psi}{dt} + \frac{KAB}{RC}\sin\psi = -\frac{d^2\phi_{lo}}{dt^2} - \frac{1}{RC}\left(\frac{d\phi_{lo}}{dt} - \omega_0\right) \ . \quad (55.24)$$

In most cases the LO frequency varies slowly, so that we may assume $\dot{\phi_{lo}} = \omega_{lo}$,

$$\frac{d^2\psi}{dt^2} + \frac{1}{RC}\frac{d\psi}{dt} + \frac{KAB}{RC}\sin\psi = -\frac{1}{RC}\left(\omega_{lo} - \omega_0\right) \ . \quad (55.25)$$

Hence, a PLL generates a signal $U_{rf}(t)$ having approximately the same (time-dependent) frequency as the local oscillator $U_{lo}(t)$. The equation is identical to that of an overdamped rotator or a resistively shunted Josephson junction [1031].

We observe that the PLL is locking to servo oscillations. The spectrum of signal produced by the VCO exhibits sidebands as soon as the loop is closed. Their amplitude depends on the gain, their frequency varies with the offset voltage controlling the VCO.

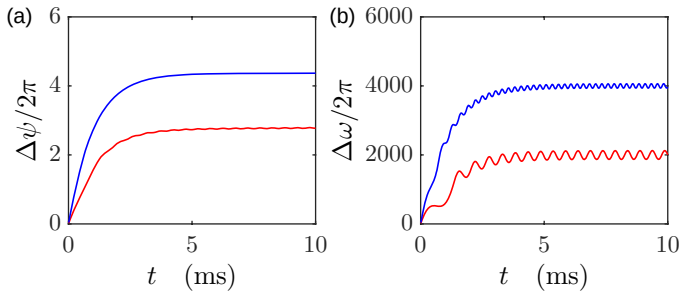

Figure 55.15: (code) Simulation of (a) the phase and (b) frequency difference in a PLL for (red) $\omega_{lo} - \omega_0 = (2\pi)$ 2 kHz and (blue) 4 kHz.

55.3.6 Frequency-offset locking using transfer cavities

Sometimes we want to take a ultra-high resolution spectrum in a frequency region, where there is no reference frequency available nearby. By nearby we mean frequency regimes which can be reached by PLLs based on frequency beats on fast photodetectors, as studied in Sec. 55.3.5. A possible method consists in the use of an optical *transfer cavity*.

Here, a reference laser stabilized to a known frequency ω_{ref}, e.g. via a saturation spectroscopy to an atomic transition, is used to lock a piezo-tunable optical cavity (called transfer cavity), as shown in Fig. 55.16. The cavity in turn is used to lock the spectroscopy laser $\omega_{blu-las}$, e.g. via the Pound-Drever-Hall method.

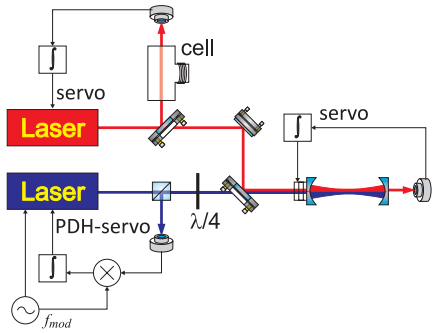

Figure 55.16: Schematic view of a transfer cavity locking system involving three cascaded servo systems for (i) the stabilization of the reference laser to a known frequency; (ii) of the transfer cavity to the reference laser, and (iii) of the spectroscopy laser to the transfer cavity.

Two issues need to be considered when using the transfer cavity scheme:

- The scheme does not permit tuning of the spectroscopy laser; this feature must be included using, e.g. AOMs (see Sec. 53.3.1) of PLL offset locks (see Sec. 55.3.5).

- The use of piezo in the transfer cavity is incompatible with its high-level thermal and mechanical stabilization. This means that special care must be taken in

the design of the reference laser in order to avoid degradation of the stability of the transfer cavity via the servo lock.

The whole locking scheme consists of three cascaded servo loops (see Fig. 55.16). To model the transfer of stability from the reference to the spectroscopy laser, we write down the following relations,

$$\begin{aligned} \omega_{red-las} &= H_{sat}(f)\omega_{ref} \\ N_{red-trns}\delta_{fsr} &= H_{trns}(f)\omega_{red-las} \\ \omega_{blu-las} &= H_{pdh}(f)N_{blu-trans}\delta_{fsr} \ . \end{aligned} \tag{55.26}$$

In the absence of noise or for perfect servos, $H_x \to 1$, we get,

$$\omega_{blu-las} = \frac{N_{blu-trans}}{N_{red-trans}}\omega_{red-las} \ . \tag{55.27}$$

We assume specific transfer functions for the closed-loop gains of the three servos and describe the impact of noise by adding frequency deviations $\Delta\omega$ entering at various points.

55.3.7 Exercises

55.3.7.1 Ex: Schemes for laser tuning

Discuss the two PLL-setups shown in Fig. 55.17.

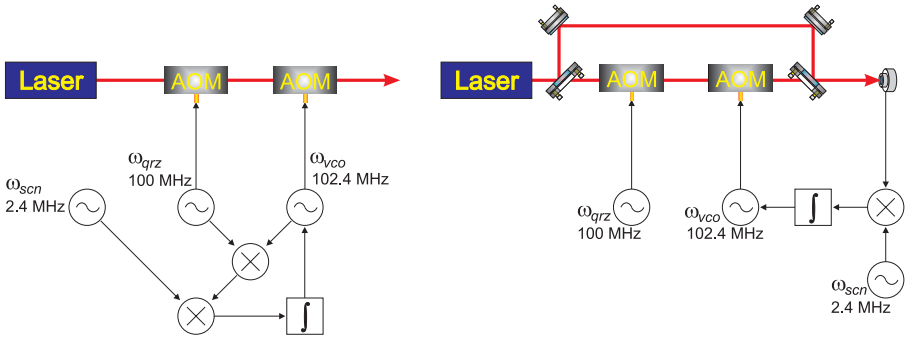

Figure 55.17: Two schemes for laser tuning.

Solution:

55.3.8 *Experiment: Stabilizing a laser to a cavity*

Here is, how we are going to stabilize a laser to a cavity:

1. Stabilize a helium-neon laser to a Fabry-Pérot cavity, generating a frequency modulation by modulating the laser diode current or the piezo of the extended

cavity. Choose a modulation frequency in the range of $f \simeq 1\,\text{kHz}$ and a modulation amplitude in the range of $M \simeq 5$ MHz. Adjust the reference voltage of the control electronics until the error signal is symmetrical.

2. If you do not have a lock-in amplifier available, construct one following the project Sec. 52.4.3.

3. Now, do the opposite, stabilizing the optical cavity to the laser frequency using the resonator piezo as control element.

4. Vary the optical setup now modulating the frequency using an AOM (see Fig. 55.18).

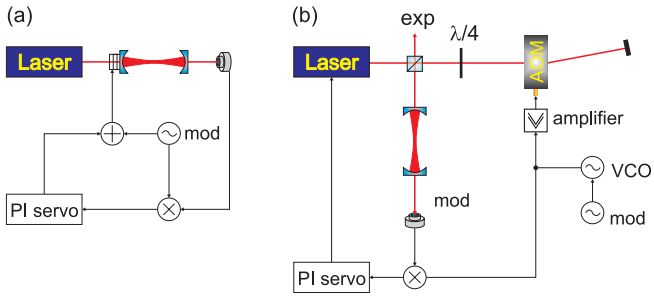

Figure 55.18: Variations on the same theme: (a) Frequency stabilization of a cavity to a laser frequency using the lock-in method. This method is often used for spectral filtering of a laser beam by a transmission etalon. (b) Frequency stabilization of a laser to a cavity using an AOM. The advantage of using an AOM compared to the scheme shown in Fig. 55.10 is, that only the beam injected into the cavity is modulated, but not the beam used for the main experiment.

55.3.9 *Experiment: Pound-Drever-Hall locking*

Now we will stabilize a laser to a cavity using the Pound-Drever-Hall technique [180, 388]:

1. Consider the reflected signal. To do this, separate the beam injected into the resonator from the reflected beam by means of a $\lambda/4$ waveplate and a polarizing beam splitter.

2. Now analyze the reflected signal with a fast photodetector at a spectrum analyzer.

3. Demodulate the signal with the modulation frequency. Vary the length of the cables. Optimize the slope of the error signal by a suitable choice of frequency and modulation excursion [4].

[4] Datasheet for the VCO see appendix Fig. 56.16,
data sheet for the power splitter see appendix Fig. 56.18,
data sheet for the mixer see appendix Fig. 56.19.

Appendices to 'Instrumentation of a Quantum Optics Lab'

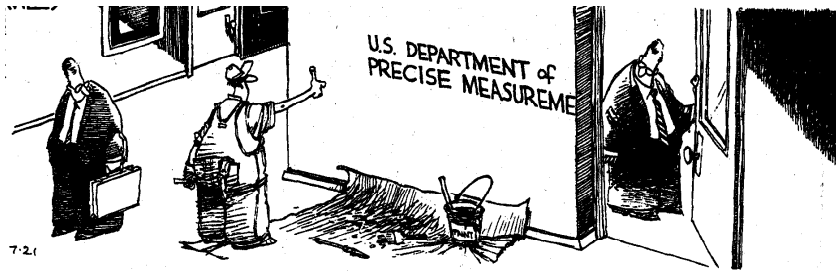

Figure 56.1: At the National Institute for Standards and Technology (NIST).

56.1 Calculating the uncertainty of measured quantities

56.1.1 Mean value and standard deviation

Mean value and *standard deviation* are defined by,

$$\bar{x} \equiv \frac{1}{N}\sum_k x_k \qquad \text{and} \qquad \sigma_{\bar{x}} \equiv \sqrt{\frac{1}{N-1}\sum_k (x_k - \bar{x})^2}\ . \tag{56.1}$$

The standard deviation can be weighed by a confidence parameter,

$$\bar{x} \equiv \frac{\sum_k w_k x_k}{\sum_k w_k} \qquad \text{and} \qquad \sigma_{\bar{x}} \equiv \frac{1}{\sqrt{\sum_k w_k}} \tag{56.2}$$

Weighing by individual standard deviation,

$$w_k \equiv \frac{1}{\sigma_k^2} \qquad \text{for} \qquad \sigma_k = \sigma_0 \tag{56.3}$$

gives,

$$\bar{x} \equiv \frac{\sum_k \frac{x_k}{\sigma_k^2}}{\sum_k \frac{1}{\sigma_k^2}} = \sigma_{\bar{x}}^2 \sum_k \frac{x_k}{\sigma_k^2} \overset{\sigma_k=\sigma_0}{\longrightarrow} \frac{1}{N}\sum_k x_k \quad \text{with} \quad \sigma_{\bar{x}} \equiv \frac{1}{\sqrt{\sum_k \frac{1}{\sigma_k^2}}} \overset{\sigma_k=\sigma_0}{\longrightarrow} \frac{\sigma_0}{\sqrt{N}} \tag{56.4}$$

or,

$$\hat{\sigma}_{\bar{x}} \equiv \sigma_{\bar{x}}\chi_v \overset{\sigma_k=\sigma_0}{\longrightarrow} \sqrt{\frac{1}{N-1}\sum_k (x_k - \bar{x})^2} \tag{56.5}$$

$$\chi_v = \sqrt{\frac{1}{N-1}\sum_k \frac{(x_k-\bar{x})^2}{\sigma_i^2}} \; .$$

From error propagation

$$\Delta\bar{x} \equiv \sqrt{\frac{1}{N}\sum_k \Delta x_k^2} \; . \tag{56.6}$$

56.1.1.1 χ^2-fit

The χ^2-fit of a constant of a function $y = f(x)$ to a measured data set (x_k, y_k) is,

$$\chi^2 = \frac{1}{N(N-1)}\sum_k [f(x_k) - y_k]^2 \; . \tag{56.7}$$

The above formula suggest that, increasing the number of measurements $N \to \infty$ we could pull the error to zero. This, however, is NOT TRUE. If the standard deviation is smaller than the precision Δ of the measurement tool, the error will be limited by Δ,

$$\bar{y} \pm \max(\sigma, \Delta) \; . \tag{56.8}$$

56.1.2 Error propagation

The *error propagation* for a function $f(x_1, x_2, ..)$ is given by,

$$\Delta f = \sqrt{\left(\frac{\partial f}{\partial x_1}\right)^2 \Delta x_1^2 + \left(\frac{\partial f}{\partial x_2}\right)^2 \Delta x_2^2 + ...} < \left|\frac{\partial f}{\partial x_1}\right| \Delta x_1 + \left|\frac{\partial f}{\partial x_2}\right| \Delta x_2 + ... \; . \tag{56.9}$$

Calculations can often be simplified by noting that the four fundamental operations, $f = x_1 \pm x_2$, $f = x_1 x_2$, and $f = \frac{x_1}{x_2}$ allow us to simply add the relative errors,

$$\frac{\Delta f}{f} = \frac{\Delta x_1}{x_1} + \frac{\Delta x_2}{x_2} \; . \tag{56.10}$$

Alternatively, we may use the following quick rules,

$$\begin{array}{rrcrl}
\textit{sum}: & f \pm \Delta f = & (x \pm \Delta x) + (y \pm \Delta y) & = & (x+y) \quad \pm (\Delta x + \Delta y) \\
\textit{subtraction}: & f \pm \Delta f = & (x \pm \Delta x) - (y \pm \Delta y) & = & (x-y) \quad \pm (\Delta x + \Delta y) \\
\textit{multiplication}: & f \pm \Delta f = & (x \pm \Delta x)\cdot(y \pm \Delta y) & = & (x\cdot y) \quad \pm (x\Delta y + y\Delta x) \\
\textit{division}: & f \pm \Delta f = & \frac{x\pm\Delta x}{y\pm\Delta y} & = & \frac{x}{y} \quad \pm \frac{1}{y^2}(x\Delta y + y\Delta x) \\
\textit{power}: & f \pm \Delta f = & (x \pm \Delta x)^n & = & x^n \quad \pm n x^{n-1}\Delta x
\end{array} \; . \tag{56.11}$$

Example 304 (*Error propagation*): Let us study the following example,

$$f = \frac{x_1}{x_2 + a}$$
$$\Longrightarrow \Delta f = f\frac{\Delta x_1}{x_1} + f\frac{\Delta(x_2+a)}{x_2+a} = f\frac{\Delta x_1}{x_1} + f\frac{\Delta x_2}{x_2+a} \ .$$

56.1.3 Fitting a curve

We start defining the following prescription to calculate mean values,

$$\bar{x} \equiv \frac{1}{N}\sum_{k=1}^{N} x_k \quad , \quad \overline{xy} \equiv \frac{1}{N}\sum_{k=1}^{N} x_k y_k \ . \tag{56.12}$$

For a *fit* of a *linear curve* $f(x) = ax + b$ to a data set $\{x_k, y_k\}_{k\in[1,N]}$, we calculate (see also Exc. 27.2.3.3),

$$\boxed{f(x) = ax + b \quad , \quad a = \frac{\overline{xy} - \bar{x}\,\bar{y}}{\overline{x^2} - \bar{x}^2} = \frac{\overline{(x-\bar{x})y}}{\overline{(x-\bar{x})^2}} \quad , \quad b = \frac{\bar{y}\,\overline{x^2} - \overline{xy}\,\bar{x}}{\overline{x^2} - \bar{x}^2} = \bar{y} - a\bar{x}} \ . \tag{56.13}$$

The uncertainties are obtained via,

$$\Delta y = \sqrt{\frac{N}{N-2}\overline{(ax+b-y)^2}} \quad , \quad \Delta a = \Delta y\sqrt{\frac{1}{N\ (\overline{x^2} - \bar{x}^2)}} = \frac{\Delta y}{\sqrt{N\ \overline{x-\bar{x}}}} \tag{56.14}$$
$$, \quad \Delta b = \Delta y\sqrt{\frac{\overline{x^2}}{N\ \overline{x^2} - \bar{x}^2}} = \Delta y\sqrt{\frac{\overline{x^2}}{N\ \overline{x-\bar{x}}}} \ .$$

To fit an *exponential curve* $f(x) = \beta e^{\alpha x}$, we simply convert the data set $\{x_k, v_k\} \equiv \{x_k, \lg y_k\}$, calculate the mean values of the decadal logarithm using the recipe (56.12), and fit a linear curve $\tilde{f}(x) = \lg f(x) = \frac{\alpha}{\ln 10}x + \lg\beta \equiv ax + b$ in a semi-logarithmic scale to the data set $\{x_k, v_k\}$. This gives,

$$\boxed{f(x) = \beta e^{\alpha x} \quad , \quad \frac{\alpha}{\ln 10} = a = \frac{\overline{x\lg y} - \bar{x}\ \overline{\lg y}}{\overline{x^2} - \bar{x}^2} \quad , \quad \lg\beta = b = \frac{\overline{\lg y}\ \overline{x^2} - \overline{x\lg y}\ \bar{x}}{\overline{x^2} - \bar{x}^2}} \ . \tag{56.15}$$

To fit a *power law curve* $f(x) = \beta x^\alpha$, we simply convert the data set $\{u_k, v_k\} \equiv \{\lg x_k, \lg y_k\}$, calculate the mean values of the decadal logarithm using the recipe (56.12), and fit the linear curve $\tilde{f}(x) = \lg f(x) = \alpha\lg x + \lg\beta \equiv ax + b$ in a double-logarithmic scale to the data set $\{u_k, v_k\}$. This gives,

$$\boxed{f(x) = \beta x^\alpha \quad , \quad \alpha = a = \frac{\overline{\lg x\lg y} - \overline{\lg x}\ \overline{\lg y}}{\overline{\lg x^2} - \overline{\lg x}^2} \quad , \quad \lg\beta = b = \frac{\overline{\lg y}\ \overline{\lg x^2} - \overline{\lg x\lg y}\ \overline{\lg x}}{\overline{\lg x^2} - \overline{\lg x}^2}} \ . \tag{56.16}$$

56.1.4 Probability density

Consider a function $P(x)$ having the meaning of a *probability* depending on a variable $x \in [-\infty, \infty]$. The *probability density* $\rho(x)$ is defined as its derivative, $\rho(x) = P'(x)$, such that,

$$P(x) = \int_{-\infty}^{\infty} \rho(t)dt \qquad \text{with} \qquad P(-\infty) = 0 \qquad \text{and} \qquad P(\infty) = 1 \ . \tag{56.17}$$

Every probability must have the same likeliness, i.e.,

$$P(x) = \zeta_n \ , \tag{56.18}$$

where $\zeta_n \in [0, 1]$ is a uniformly distributed *random variable*. In order to numerically generate a *stochastic distribution*, we have to invert the distribution function, i.e. when ζ_n is generated by a computer, then

$$\boxed{x_n = P^{-1}(\zeta_n)} \tag{56.19}$$

is the distribution of the random variable x_n. In other words, a histogram of x_n reproduces the probability density $\rho(x)$.

Let us, for example, consider the Boltzmann distribution,

$$P(x) \equiv 1 - e^{-\beta x} \ . \tag{56.20}$$

Probing the probability with a random number, as in (56.18), we obtain the random variable via (56.19),

$$x_n = P^{-1}(\zeta_n) = -\frac{1}{\beta} \ln(1 - \zeta_n) \ . \tag{56.21}$$

The histogram of this random variable x_n can directly be compared with the probability density $\rho(x)$ given by,

$$\rho(x) = P'(x) = \beta e^{-\beta x} \ . \tag{56.22}$$

This is illustrated in Fig. 56.2(a).

Example 305 (*Probability density of a Gaussian distribution*): Another example is the *error function* given by,

$$\mathrm{erf}(x) \equiv \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \ .$$

By define the probability function,

$$P(x) \equiv \frac{1}{2}[\mathrm{erf}(x) - \mathrm{erf}(-\infty)] = \frac{1}{\sqrt{\pi}} \int_{-\infty}^x e^{-t^2} dt \ .$$

Probing the probability with a random number, as in (56.18), we obtain the random variable via (56.19),

$$x_n = P^{-1}(\zeta_n) = \mathrm{erf}^{-1}(2\zeta_n - 1) \ .$$

The histogram of this random variable x_n can directly be compared with the probability density $\rho(x)$, which is nothing else than the Gauss function,

$$\rho(x) = P'(x) = \frac{1}{\sqrt{\pi}} e^{-x^2} = 2\mathrm{erf}'(x) \ .$$

This is illustrated in Fig. 56.2(b).

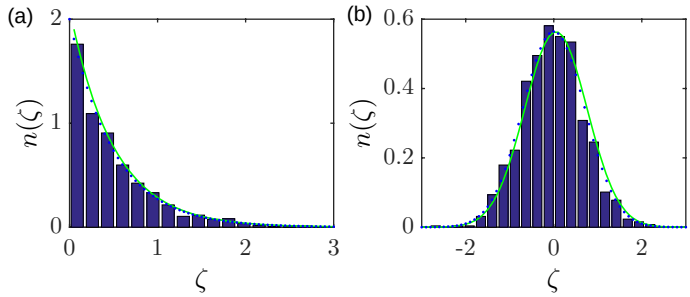

Figure 56.2: (code) (a) Boltzmann distribution simulated by random numbers (histogram). The numerical derivative of this distribution is shown as a blue dotted line, and the probability density as a green solid line. (b) Error function probability distribution simulated by random numbers (histogram). The numerical derivative of the error function is shown as a blue dotted line, and the Gauss function as a green solid line.

56.2 Deepening control theory

The variation of a physical quantity (e.g., a voltage or a temperature) in time is called *signal*. In a specific environment or technical device, such a variation may cause other physical quantities to change as well. For example, the rise in temperature of an optical cavity may modify its length and its resonance frequency, while the inverse is not true. This feature is illustrated by a block diagram as shown in Fig. 56.3, where $x(t)$ denotes the variation of a physical quantity (called *input*) that causes the variation of another quantity $y(t)$ (called *output*). The precise way how $y(t)$ depends on $x(t)$ depends on the particularities of the device, which is labeled by a symbol $\mathcal{T}$ called transfer function. $\mathcal{T}$ is in fact an operator acting on functions and transforming input signals into output signals.

Figure 56.3: Transfer and modification of a time-dependent signal.

While we have described above the transfer of (time-varying) signals, the same feature can be treated in frequency domain via Fourier or Laplace-transforms. This script is not the right place to recapitulate the mathematics of these transforms, and we will restrict ourselves to reproducing some on the most fundamental results, as we may need them in the following.

56.2.1 Analysis techniques - frequency domain and time domain

Mathematical techniques for analyzing and designing control systems fall into two different categories:

Frequency domain: In this type the values of the state variables, the mathematical variables representing the system's input, output and feedback are represented

as functions of frequency. The input signal and the system's transfer function are converted from time functions to functions of frequency by a transform such as the Fourier transform, Laplace transform, or Z transform. The advantage of this technique is that it results in a simplification of the mathematics; the differential equations that represent the system are replaced by algebraic equations in the frequency domain which are much simpler to solve. However, frequency domain techniques can only be used with linear systems, as mentioned above.

Time-domain state space representation: In this type the values of the state variables are represented as functions of time. With this model the system being analyzed is represented by one or more differential equations. Since frequency domain techniques are limited to linear systems, time domain is widely used to analyze real-world nonlinear systems. Although these are more difficult to solve, modern computer simulation techniques such as simulation languages have made their analysis routine.

In contrast to the frequency domain analysis of the classical control theory, modern control theory utilizes the time-domain state space representation, a mathematical model of a physical system as a set of input, output and state variables related by first-order differential equations. To abstract from the number of inputs, outputs and states, the variables are expressed as vectors and the differential and algebraic equations are written in matrix form (the latter only being possible when the dynamical system is linear). The state space representation (also known as the 'time-domain approach') provides a convenient and compact way to model and analyze systems with multiple inputs and outputs. With inputs and outputs, we would otherwise have to write down Laplace transforms to encode all the information about a system. Unlike the frequency domain approach, the use of the state-space representation is not limited to systems with linear components and zero initial conditions. 'State space' refers to the space whose axes are the state variables. The state of the system can be represented as a point within that space.

56.2.1.1 Signal transfer through LTI systems without delay

For an operator $\mathcal{T}$ transforming a temporal signal $x(t)$ into a signal $y(t)$,

$$y(t) = \mathcal{T}x(t) \ , \tag{56.23}$$

to be *linear* and time-independent, we require,

$$\begin{aligned} \mathcal{T}[\alpha x_1(t) + \beta x_2(t)] &= \alpha\mathcal{T}[x_1(t)] + \beta\mathcal{T}[x_2(t)] \\ \mathcal{T}[x(t-\tau)] &= \mathcal{T}[x(t)] \star \delta(t-\tau) \ , \end{aligned} \tag{56.24}$$

where the $\star$ denotes a convolution,

$$(f \star g)(t) = \int_{-\infty}^{\infty} f(\tau)g(t-\tau)d\tau \ . \tag{56.25}$$

Such system are called *Linear Time-Independent LTI* systems [1].

[1] To be more general, also the derivative and integral of the output signal must be included (see later sections).

56.2.1.2 Laplace transform

We define the *Laplace transform* $\mathcal{L}$ as a linear operator acting on a signal $x(t)$ defined through,

$$\mathcal{L}... \equiv \int_{-\infty}^{0} ...e^{st}d\tau \ . \tag{56.26}$$

The frequency variable is denoted by the imaginary quantity $s = \imath f$. The question is now, what is the meaning of the Laplace operator?

To answer this question, we start introducing the pulse response $h(t)$ via

$$h(t) = \mathcal{T}[\delta(t)] \tag{56.27}$$

as the reaction of a system $\mathcal{T}$ to a pulse $\delta(t)$. Now, it is easy to see, that the operator $\mathcal{P}$ defined as,

$$\mathcal{P}... \equiv h(t) \star ... \ , \tag{56.28}$$

and which describes the convolution of an arbitrary input signal with the pulse response, satisfies the above linearity condition. Now calculating,

$$\mathcal{P}e^{st} = h(t) \star e^{st} = \int_{-\infty}^{0} h(\tau)e^{s(t-\tau)}d\tau = \mathcal{L}[h(t)] \cdot e^{st} = (\mathcal{L}h)(s) \cdot e^{st} \ , \tag{56.29}$$

we find that the functions e^{st} are eigenfunctions of the operator $\mathcal{P}$ with the eigenvalues $\mathcal{L}[h(t)]$, which are just the Laplace transforms of the pulse response.

We can now expand arbitrary functions $x(t)\theta(t)$ in a Laplace series and obtain,

$$\mathcal{L}[h(t) \star x(t)] = \int_{-\infty}^{0} h(t) \star e^{st} \ x(t)dt = (\mathcal{L}h)(s) \int_{-\infty}^{0} e^{st}x(t)dt = (\mathcal{L}h)(s) \cdot (\mathcal{L}x)(s) \ . \tag{56.30}$$

The convolution on the left-hand side is in time domain, while the product on the right-hand side is in frequency domain.

56.2.1.3 Pulse and jump response from a transfer function

The transmission of a signal by an element of a control loop can be described in the temporal or spectral domain [462, 496, 839], and we can switch from one representation to another via Laplace transformation. Operators of LTI systems $\mathcal{T}$ are represented by products with spectral functions in frequency-domain, $\tilde{F}(s)\cdot... = (\mathcal{L}F)(s)\cdot...$ or convolutions with time-varying functions in time-domain, $F(t) \star ...$,

$$\begin{aligned} y(t) &= \mathcal{T}x(t) \\ &\overset{Laplace}{\longrightarrow} \tilde{y}(s) = \tilde{F}(s) \cdot \tilde{x}(s) \\ &\overset{inverse\ Laplace}{\longrightarrow} y(t) = F(t) \star x(t) \ . \end{aligned} \tag{56.31}$$

In practice, the function $\tilde{F}(f)$ can be determined by feeding a sinusoidal signal with amplitude $x(s)$ into the system, measuring $y(s)$ (which is a complex number) [2],

[2] From now on, we will drop the tilde $\sim$ on transfer functions and amplitudes, when it is clear that we are in frequency-domain.

and calculating

$$F(s) = \frac{y(s)}{x(s)} \ . \tag{56.32}$$

The transitory behavior $F(t)$ can in practice be extracted via an adequate choice of the test function, f.ex., the response to a pulse:

$$\begin{aligned} x(t) &= \delta(t) \\ \overset{Laplace}{\longrightarrow} \ y(s) &= F(s) \\ \overset{inverse\ Laplace}{\longrightarrow} \ y(t) &= F(t) \ , \end{aligned} \tag{56.33}$$

or to a sudden jump:

$$\begin{aligned} x(t) &= \theta(t) \\ \overset{Laplace}{\longrightarrow} \ y(s) &= F(s)/s \\ \overset{inverse\ Laplace}{\longrightarrow} \ y(t) &= \int_0^t F(\tau) d\tau \ . \end{aligned} \tag{56.34}$$

Here, $\theta(t)$ denotes the Heavyside function, which is 1 for $t > 0$ and 0 else. The time-dependent function, which describes the pulse response is often used as a symbol for a specific control loop element.

The pulse response works in a similar way as the Green's function procedure: Wanting to know how a loop control element F transforms a given input signal $x(t)$ into an output signal $y(t)$, i.e., $y(t) = F(t) \star x(t)$, we produce a rapid pulse leading to the output,

$$y_\delta(t) = F(t) \star \delta(t) = F(t) \ . \tag{56.35}$$

Now, once we know $F(t)$, the response to arbitrary input signals can be computed via,

$$y(t) = y_\delta(t) \star x(t) \ . \tag{56.36}$$

56.2.1.4 Bode diagram and polar diagram

The *Bode diagram* illustrates the transfer function in the spectral domain on a bilogarithmic scale separating the amplitude spectrum from the phase spectrum [see Fig. 56.4(a-b)]. Frequency regions, where $|F(s)|$ or $\varphi(s)$ vary particularly strongly are nicely emphasized in the polar representation [see Fig. 56.4(c-d)].

For LTI systems $F(s)$ is always a rational function and can, hence, be represented by its poles and zeros in the complex plane,

$$F(s) = A \frac{(s-a_1)(s-a_2)...(s-a_n)}{(s-b_1)(s-b_2)...(s-b_n)} \ . \tag{56.37}$$

With this, $F(s)$ is analytical and conform, i.e., multiple curves in the s-plane are represented in an isogonal way in the $F(s)$-plane. In order to avoid that the eigenfunctions e^{st} oscillate and diverge, it is necessary that all the poles and zeros are in the left halfplane.

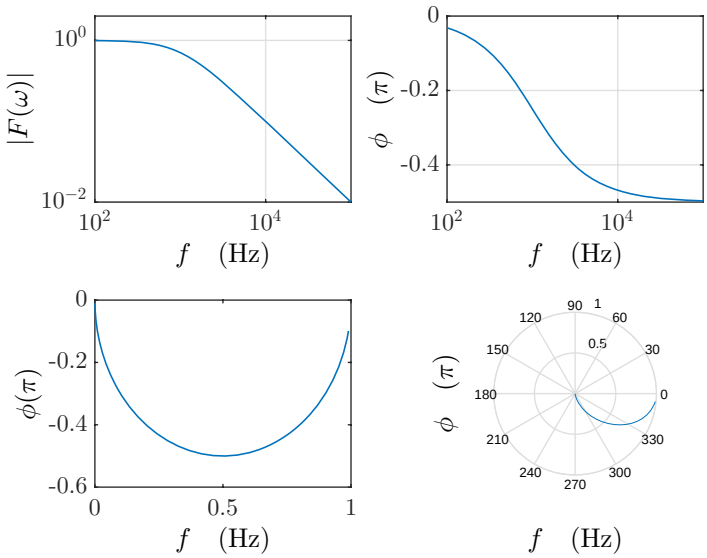

Figure 56.4: (code) Bode diagram.

56.2.2 Algebra of transfer circuits

A technical realization of a signal transfer circuit is illustrated by a signal flux diagram, which itself corresponds to the formalism of linear operators. As shown in Fig. 56.5, signals can be

- (a) added $(f_1 + f_2)(t) \equiv f_1(t) + f_2(t)$,
- (b) multiplied $(f_1 \cdot f_2)(t) \equiv f_1(t) \cdot f_2(t)$,
- (c) combined $f_1(t) = f_2(t)$,
- (d) transformed $f_2(t) = F[f_1](t) \equiv F(f_1(t))$,
- (e) connected in parallel $(F_1 + F_2)[f(t)] \equiv F_1[f(t)] + F_2[f(t)]$,
- (f) connected in series $(F_1 \circ F_2)[f(t)] \equiv F_1[F_2[f(t)]]$,

Mathematically, the functions $f(t)$ form a *vector space* and the operators $F[f]$ a *ring*. The linear operators generally are defined implicitly by a system of differential equations. The particular case of linear systems is considerably simpler. The general circuit shown in Fig. 56.5(g) corresponds to the differential equation,

$$0 = F[x_1, .., x_k, \partial_t x_1, .., \partial_t x_k, y_1, .., y_j] \ . \tag{56.38}$$

The linearity $F[\lambda f_1 + \mu f_2] = \lambda F[f_1] + \mu F[f_2]$ warrants that this equation becomes,

$$0 = [1 + \partial_t + ... + \int dt + ...]y_k = [1 + \partial_t + ... + \int dt + ...]x_j \ . \tag{56.39}$$

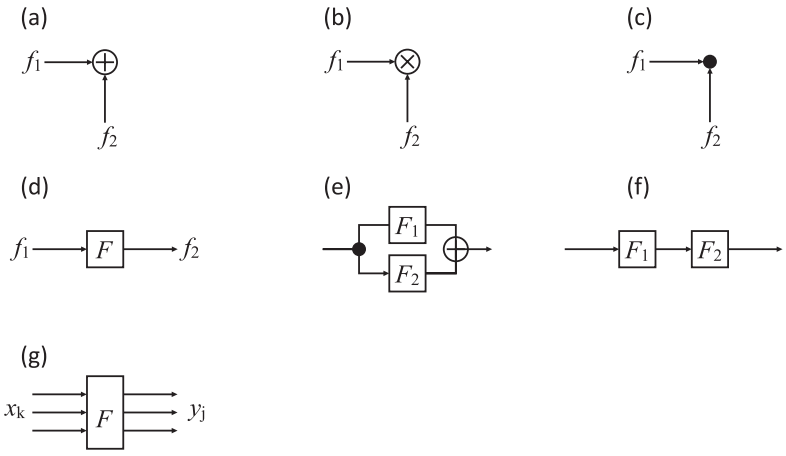

Figure 56.5: LTI circuits.

Note that the multiplication, the derivation, and the integration are linear operators in the same sense as the Fourier and the Laplace transformation.

Linear differential equations can be Laplace transformed. The corresponding transfer function is,

$$F(s) = F(-\delta + \imath\omega) \equiv \frac{\mathcal{L}y(t)}{\mathcal{L}x(t)} \ . \tag{56.40}$$

In the Laplace-transformed space the operations multiplication, derivation, and integration are all replaced by multiplications:

$$\mathcal{L}[\lambda + \partial_t + ... + \int dt + ...] = \lambda + s + ... + \frac{1}{s} \ . \tag{56.41}$$

With this, the control loop elements and the additive nodes can be used to completely represent a control circuit.

The characteristic responses of components are frequently non-linear (e.g. transistor). For small signal amplitudes, these response functions, and also multiplication points (e.g. mixers) can be linearized by Taylor expansion up to first order,

$$\begin{aligned} y_0 + \Delta y &= F[x_{01} + \Delta x_1, ..., x_{0k} + \Delta x_k] \\ &= F[x_{01}, ..., x_{0k}] + \left(\frac{\partial F}{\partial x_1}\right)_0 \Delta x_1 + ... + \left(\frac{\partial F}{\partial x_k}\right)_0 \Delta x_k \ , \end{aligned} \tag{56.42}$$

with $y_0 = 0 = F[x_{01}, ..., x_{0k}]$ giving,

$$\Delta y = \left(\frac{\partial F}{\partial x_1}\right)_0 \Delta x_1 + ... + \left(\frac{\partial F}{\partial x_k}\right)_0 \Delta x_k \ . \tag{56.43}$$

For example for a multiplication point,

$$\Delta y = K_1 \Delta x_1 + K_2 \Delta x_2 \ . \tag{56.44}$$

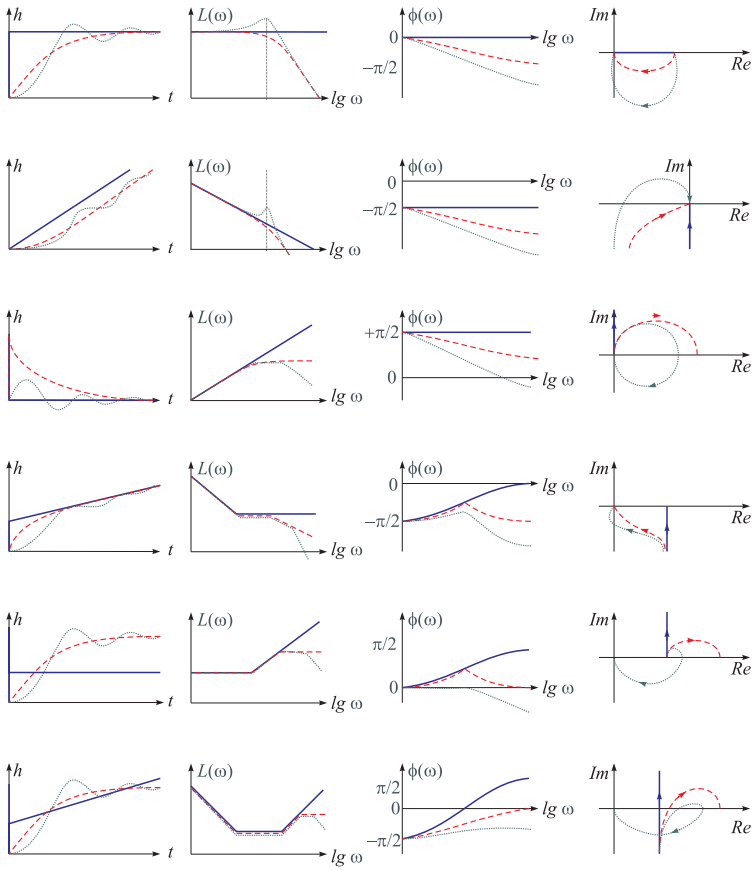

Figure 56.6: Transfer function $h(t) = \frac{y(t)}{x_w}$, Bode diagram amplitude $L(\omega) = 20 \lg |F_R|$ and phase $\varphi = \arctan \frac{\Im \mathfrak{m} \ F_R}{\Re \mathfrak{e} \ F_R}$, and polar representation $F(i\omega) = \Re \mathfrak{e} \ F_R + i \Im \mathfrak{m} \ F_R$ of the most common regulators. With delay time (—), $T_2 = T_1 = 0$, first order with delay time (- - -), $T_2 = 0 \neq T_1$, and second order $(\cdots)$, $T_2 \neq 0 \neq T_1$. From top to bottom, the diagrams show the regulators P, I, D, PI, PD, and PID, described by the equations (56.45) and (56.46).

56.2.2.1 Regulators

For many circuits, it is sufficient to restrict to combinations of resistive (proportional), capacitive (integral), and inductive (differential) circuits. Then, the general case of a control regulator is that of a $PID - T_1 ... T_n$-element, meaning that:

$$T_2^2 \ddot{y} + T_1 \dot{y} + y = K_D \dot{x} + K_P x + K_I \int dt x = K_P \left(x + T_v \dot{x} + \frac{1}{T_n} \int dt x \right) \ , \quad (56.45)$$

corresponding to the transfer function,

$$F(s) = \frac{K_D s + K_P + K_I / s}{1 + T_1 s + T_2^2 s^2} = \frac{(1 + T_v s + 1/T_n s)}{1 + T_1 s + T_2^2 s^2} \ . \quad (56.46)$$

In literature, two notations are used for the constants. They are linked via: $K_D \equiv K_P T_v$ and $K_I \equiv K_P / T_n$. The stationary behavior is obtained setting the delays to

zero: $T_n \equiv 0$.

Example 306 (*PID regulators*): For example, for a *proportional regulator*, we have,

$$y = K_P x_w \qquad \text{and} \qquad F_R = K_P \ , \tag{56.47}$$

for an *integral regulator* with time delay T_1, we have,

$$T_1 \dot{y} + y = K_I \int x_w dt \qquad \text{and} \qquad F_R = \frac{K_I}{s(1+sT_1)} \ , \tag{56.48}$$

or for a *PID regulator* without delay, we have,

$$y = K_P x_w + K_D \dot{x}_w + K_I \int x_w dt \qquad \text{and} \qquad F_R = K_P + \frac{K_I}{s} + K_D s \ . \tag{56.49}$$

Since there are three basic operations (multiplication with 1, s and $1/s$), in the end, all rational circuit elements can be reduced to an addition and concatenation of proportional $F(s) = K_P$, integral $F(s) = K_I/s$, and differentials elements, $F(s) = K_D s$. In particular, $PID{-}T_1 ... T_n$ circuits can be constructed by putting in parallel P, I, and D regulators concatenated with delay elements T_1. The possibility of feedback opens other possibilities [see Fig. 56.7(a)].

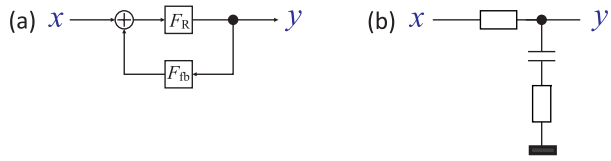

Figure 56.7: (a) Circuit with feedback, (b) low-pass filter circuit.

Example 307 (*Low-pass filter and time delays*): We consider the example of a low-pass filter exhibited in Fig. 56.7(b) and described by the equation,

$$F(\imath\omega) = \frac{R + \imath\omega L + 1/\imath\omega C}{R_i + R + \imath\omega L + 1/\imath\omega C} \ . \tag{56.50}$$

I.e., we have a $PID - T_1 T_2$ circuit.
Another example, is the dead time circuit,

$$y(t) = x(t - T_t) \quad \text{and} \quad F(s) = e^{-sT_t} \ . \tag{56.51}$$

We have,

$$F(\imath\omega) = e^{-\imath\omega T_t} F_0 \quad \text{and} \quad |F(\imath\omega)| = F_0 \quad \text{and} \quad \varphi(\imath\omega) = -\omega T_t \ . \tag{56.52}$$

Hence, dead time circuits produce phase shifts, which are proportional to the dead time interval T_t.

56.2.2.2 Heuristic rules for the Bode diagram

Any deviation of the amplitude spectrum from $n \cdot 6$dB/octave to $(n+1) \cdot 6$dB/octave causes a retardation in the phase spectrum of 90°. At the cut-off frequency, where the inclination changes its behavior, the phase shift is just 45°. A deviation to higher/lower inclinations shifts the phase by ±90°. (This does not hold for some phase-shifting circuits).

56.2.2.3 Transfer function of feedback circuits

Fig. 56.7 shows the idea underlying the feedback,

$$F(s) = \frac{1}{1/F_R - F_{fb}} \ . \tag{56.53}$$

For example, for $F_R = 1/T_1 s$ and $F_{fb} = -1$ we have,

$$F(s) = \frac{1}{1 + T_1 s} \ , \tag{56.54}$$

which corresponds to a delay element (or high-pass filter).

For F_r being a proportional element, we say that the feedback rigid, for F_r being differential, the feedback is anticipating, and for F_r being integral, the feedback is delaying.

56.2.3 Stability of feedback circuits

As discussed above, the transfer function of the feedback circuit is,

$$H(s) = \frac{F(s)}{1 + F(s)F_{fb}(s)} \ . \tag{56.55}$$

The *open loop gain* is $V(s) = F(s)F_{fb}(s)$. The circuit is stable, when for all the eigenfunctions e^{st}, that do not decay with $Re\ s \geq 0$, the transfer function of the feedback circuit is finite, $H(s) < \infty$.

An equivalent criterion is the *Nyquist criterion*: *The curve $V(i\omega)$ to $\omega \in [0; \infty[$ must always bypass the point of instability at $Re\ s = -1$ leaving it on the left side. That is, considering negative frequencies, the curve should not circle this point.* Fig. 56.9 shows an example.

56.2.4 Further topics in control theory

56.2.4.1 Nonlinear control theory

Linear control theory applies to systems made of devices which obey the superposition principle, which means roughly that the output is proportional to the input. They are governed by linear differential equations. A major subclass is systems which in addition have parameters which do not change with time, called linear time invariant (LTI) systems. These systems are amenable to powerful frequency domain mathematical techniques of great generality, such as the Laplace transform, Fourier transform, Z transform, Bode plot, root locus, and Nyquist stability criterion. These lead to a description of the system using terms like bandwidth, frequency response, eigenvalues, gain, resonant frequencies, poles, and zeros, which give solutions for system response and design techniques for most systems of interest.

Nonlinear control theory covers a wider class of systems that do not obey the superposition principle, and applies to more real-world systems, because all real control systems are nonlinear. These systems are often governed by nonlinear differential equations. If only solutions near a stable point are of interest, nonlinear systems can often be linearized by approximating them by a linear system using perturbation theory, and linear techniques can be used.

P-servo with rigid feedback		*P*	$K_P = \frac{K_R}{1+K_r K_R} \xrightarrow{K_P \to \infty} \frac{1}{K_r}$

		PI	$K_P = T_r/K_r \;,\; T_n = T_r$ for $K_R \to \infty$
P-servo with delayed feedback		*PD*-T_1	$K_P = \frac{K_R}{1+K_r K_R} \;,\; T_v = T_r \;,\; T_1 = \frac{T_r}{1+K_r K_R}$ for $K_R \ll \infty$
		PD	$K_P = 1/K_r \;,\; T_v = T_r$ for $K_R \to \infty$
P-servo with delayed yielding feedback		*PID*	$K_P = \frac{T_{r1}+T_{r2}}{K_{r1}K_{r2}} \;,\; T_v = \frac{T_{r1}T_{r2}}{T_{r1}+T_{r2}} \;,\; T_n = T_{r1}+T_{r2}$ for $K_R \to \infty$
P-servo with two delay circuits in the feedback		*PID*	$K_P = \frac{T_{r1}+T_{r2}}{K_{r1}(T_{r1}-T_{r2})} \;,\; T_v = \frac{T_{r1}T_{r2}}{T_{r1}+T_{r2}} \;,\; T_n = T_{r1}+T_{r2}$ for $K_R \to \infty$ and $T_{r1} > T_{r2}$
I-servo with rigid feedback		*P*-T_1	$K_P = \frac{1}{K_r} \;,\; T_1 = \frac{1}{K_I K_r}$
I-servo with yielding feedback		*PI*-T_1	$K_P = \frac{K_I T_r}{1+K_I K_r} \;,\; T_n = T_r \;,\; T_1 = \frac{T_r}{1+K_I K_r}$

Figure 56.8: Some examples for feedback regulators. The columns show from left to right: the nomenclature, the circuit diagram, the behavior, and the constants of the LTI system.

56.2.4.2 MIMO control systems

In this script we restrict to *single-input single-output control systems* (*SISO*), which is the simplest and most common type, in which one output is controlled by one control signal. Examples are the temperature control or an audio system, in which the control input is the input audio signal and the output is the sound waves from the speaker.

In contrast, *multiple-input multiple-output control systems* (*MIMO*) are found in more complicated systems. For example, modern large telescopes such as the Keck and MMT have mirrors composed of many separate segments each controlled by an actuator. The shape of the entire mirror is constantly adjusted by a MIMO active optics control system using input from multiple sensors at the focal plane, to compensate for changes in the mirror shape due to thermal expansion, contraction, stresses as it is rotated and distortion of the wavefront due to turbulence in the atmosphere.

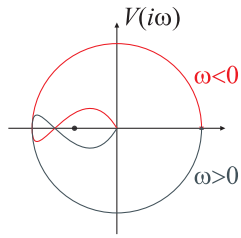

Figure 56.9: Illustration of the Nyquist criterion.

Another example are ultra-stable laser systems stabilized by combinations of fast actuators with low dynamic range and slow actuators with large dynamic range.

56.2.5.1 Ex: Step response

Calculate the step response of a low-pass filter using the Laplace transform formalism.

Solution:

56.3 Characterization of stability

The quality factor of a resonance measured with an oscillator in its function as a measuring apparatus for the resonance frequency is named *precision*. The precision also includes the perturbations to which the controlled oscillator is exposed and can be understood as the standard deviation of the frequency realized by the standard. The temporal or spectral behavior of precision, i.e. the stability can e.g. measured directly by comparing similar but independent standards. The reciprocal of the spread of the frequency realizations of an ensemble of similar standards is called *reproducibility*. The term reproducibility is also used to compare the frequencies of an individual standard before and after readjustment of all its technical parameters.

The *accuracy* is defined as the degree of agreement between the frequency realized by the standard and the defined standard frequency, i.e. the frequency that would be displayed in the fault-free ideal case [3]. The accuracy is always less than the quality of the resonance and the certainty of it center frequency. It includes the precision and limits the reproducibility [19]. The fact that the accuracy is related to the ideal case of absent errors implies that it cannot be measured directly. It must be inferred indirectly through model assumptions regarding the measuring apparatus estimating the probability for presumed or possible errors. We then speak of the *uncertainty* of the measured value [275].

The temporal or spectral behavior of *accuracy* is called *stability*. It is measurable and is quantified in the frequency domain by the *spectral density of fluctuations*

[3] For example, when a measurement apparatus for the constant π provided the value $x = 3.141\ 59\ (12)$, then the accuracy is $x - \pi$ and the precision 0.000 12.

and in the time domain best by the *Allan variance*. The noise is now the physical phenomenon that manifests itself as a deviation from the optimal stability.

The stability that an ideal frequency standard can achieve in principle is proportional to quality factor of the resonance $\omega/(\Delta\omega_{nat}+\Delta\omega_{broaden})$ and the signal-to-noise ratio of the control signal S/N. Hence, the stability can be optimized by choosing atomic transitions with small spontaneous decay rates $\Delta\omega_{nat}$. Appropriate techniques for the experimental preparation of the resonance limit the influence of line broadening mechanisms $\Delta\omega$. According to the Fourier theorem, the resolution of narrow lines requires long observation times. Now, the control signal of a feedback regulator can only be determined after a whole observation period. This means that the apparatus already must have an intrinsic stability good enough that the frequency does not leave the control range during a period of observation. Furthermore, a better signal-to-noise ratio can improve the precision with which the line center of the resonance can be determined.

Ultimately, the most promising way to increase the accuracy of a frequency standard seems to be to choose the highest possible transition frequencies ω, provided that the oscillations can still be counted electronically, or be linked in a phase-coherent way to oscillators generating countable oscillations, e.g. using frequency combs. The requirement of phase coherence at optical frequencies puts the laser in the focus of interest in metrology.

56.3.1 Quantifying frequency fluctuations

The following sections deal with perturbation-induced fluctuations of the laser frequency, i.e. frequency noise. To characterize the behavior of an oscillator (especially when used as a frequency standard), it is necessary to introduce some concepts that allow the quantitative description of the noise. The most important are reproducibility, stability, spectral density of fluctuations, Allan variance, and emission bandwidth. The basic work on this has been carried out at the National Bureau of Standards (NBS) in Boulder, Co, USA [18, 19, 97, 314].

56.3.1.1 Stability in the frequency domain, spectral fluctuation density

The instantaneous amplitude of an oscillator, e.g. the electric field of a laser radiation, can be written,

$$\mathcal{E}(t) = \mathcal{E}_0(t)e^{\imath\phi(t)} \ . \tag{56.56}$$

noise afflicts phase and amplitude. In the following we will neglect amplitude noise, $\mathcal{E}_0(t) = \mathcal{E}_0$, and if the frequency fluctuations only deviate slightly from a mean value, $\omega_0 \gg |\dot{\varphi}(t)|$, we may write,

$$\phi(t) \equiv \omega_0 t + \varphi(t) \ . \tag{56.57}$$

In the following, we will often consider normalized frequency fluctuations,

$$y(t) = \dot{\varphi}(t)/\omega_0 \ . \tag{56.58}$$

When measuring stability, one must differentiate between *deterministic fluctuations* and *stochastic noise*. Deterministic fluctuations are usually due to inadequate control of equipment parameters. They generate systematic errors and slow drifts

$y_{sys}(t)$ which, if one recognizes them as such in time domain measurements (measure for sufficiently long times!), can be subtracted and disregarded. Stochastic noise, however, is stationary:

$$\overline{y_{sto}(t)} = \overline{y(t) - y_{sys}(t)} = 0 \qquad \text{defining} \qquad \overline{y(t)} \equiv \lim_{T\to\infty} \frac{1}{T} \int_0^T y(t)dt \tag{56.59}$$

as the time average. In the following only stationary stochastic fluctuations are considered.

Let us take a look at the *autocorrelation function* of the phase defined as,

$$\boxed{R_y(\tau) \equiv \overline{y^*(t)y(t+\tau)} = \lim_{T\to\infty} \frac{1}{T} \int_0^T y^*(t)y(t+\tau)\rangle d\tau} \tag{56.60}$$

and the *spectral density of phase fluctuations* which, according to the *Wiener-Khintchine theorem*, can be obtained as the Fourier transform of the autocorrelation function,

$$\boxed{S_y(f) \equiv \mathcal{F}R_y(\tau) = \int_{-\infty}^{\infty} R_y(\tau)e^{-2\pi\imath f\tau}d\tau} \ . \tag{56.61}$$

The normalized density of frequency fluctuations $S_y(f)$ is a spectral quantity with the unit 1/Hz. Frequency and phase fluctuations are linked by:

$$S_{\dot{x}}(f) = f^2 S_x(f) \ , \tag{56.62}$$

as will be shown in Exc. 56.3.3.1. Also,

$$S_{ax}(f) = a^2 S_x(f) \ , \tag{56.63}$$

If the integral of the spectral fluctuation density is finite it corresponds, according to the definition (56.62), to the noise power or the mean square deviation of a measured variable:

$$\int_0^\infty S_y(f)df = R_y(0) = \overline{|y(t)|^2} < \infty \ . \tag{56.64}$$

56.3.1.2 Model of noise

Measurements seem to confirm today that stochastic fluctuations in frequency standards can be traced back to a few additive noise processes with different physical origins and different frequency responses [18]:

$$\boxed{S_y(f) = \sum_{\beta=-2}^{2} h_\beta f^\beta} \ . \tag{56.65}$$

The table below lists the most common ones.

This noise model is based on the assumption that the noise processes it describes operate in all Fourier frequency ranges, which violates the requirement (56.64). The dilemma does not arise in experiment, since the integration over an unlimited Fourier

noise type	$S_y(f)$	$\sigma_y^2(\tau)$
white phase noise	$h_2 f^2$	$\propto \frac{h_2}{\tau^2}$
flicker phase noise	$h_1 f^1$	$\propto \frac{h_1}{\tau^2}$
white frequency noise	$h_0 f^0$	$\frac{h_0}{2\tau}$
flicker frequency noise	$h_{-1} f^{-1}$	$h_{-1} 2 \ln 2$
random walk frequency drifts	$h_{-2} f^{-2}$	$h_{-2} \frac{(2\pi)^2}{6} \tau$

Table 56.1: *Spectral fluctuation density and Allan-variance for common noise processes [97].*

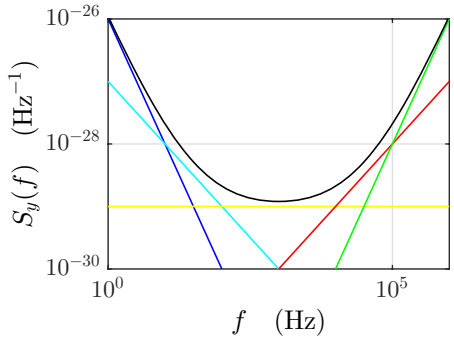

Figure 56.10: Noise model according to (56.65).

frequency range is not a realistic concept in that each measurement only takes a finite time τ, so that very low frequencies below a cut-off frequency $f_{min} = 2\pi/\tau$ are not perceived. In addition, every real data acquisition system has a low-pass behavior with a cut-off frequency f_{max}, so that high frequencies also do not contribute to the integral. These bandwidth constraints enforce the condition (56.64) for the five noise processes assumed by (56.65) [794]. The measure for the noise power in any case has the form: $\int_{f_{min}}^{f_{max}} S_y(f) df$.

56.3.1.3 Description of stability in the time domain, Allan variance

Temporal frequency fluctuations of an oscillator can be measured by *discriminating the frequency fluctuations at the dispersive profile of a resonance* (or error signal) and convert it into voltage fluctuations. It is just the curve exhibited by a spectrum analyzer to which the error signal is fed, as illustrated by the left setup of Fig. 56.12.

Like any physical quantity, frequency fluctuations can only be measured as an average over an *integration time interval* τ imposed by the measuring apparatus. The k-th measurement of the quantity y at the time t_k results in the measured value:

$$y_k(\tau) = \frac{1}{\tau} \int_{t_k}^{t_k+\tau} y(t) dt \ . \tag{56.66}$$

Assuming that the dead time of the measuring apparatus is negligible (if necessary, technical precautions must be taken to meet this requirement approximately), the variance of stochastic noise can be expressed as follows:

$$\sigma_y^2(\tau) = \frac{1}{N-1}\sum_{k=1}^{N} y_k^2 \qquad \text{where} \qquad \overline{y_k} = 0 \ . \tag{56.67}$$

The variance is a direct measure of the stability of an oscillator in time domain. It is measured from a discrimination of the error signal in a similar way as the fluctuation density $S_y(f)$. However, as illustrated by the left setup of Fig. 56.12, the discriminated signal is recorded in time domain, e.g. by an oscilloscope.

The variance can be linked to the spectral density of frequency fluctuations in frequency domain by Fourier transformation. With the Heaviside step function Θ the following relationship can be given [314, 18, 61],

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f)|\mathcal{F}\zeta_1(f)|^2 df \qquad \text{where} \qquad \zeta_1(t) = \frac{1}{\tau}\Theta_{[-\tau,0]}(t) \ , \tag{56.68}$$

is the area-normalized jump function, which models the duration of the integration time τ. Its Fourier-transform is the transfer function of the equivalent filter.

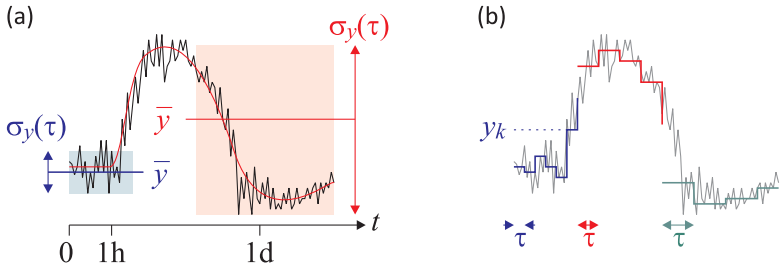

Figure 56.11: (a) Noise can exhibit very different short and long time behavior. (b) Any measurement needs a minimum integration time.

It turns out that the variance for $1/f$ noise and for stochastic drifts ($1/f^2$ noise) diverges at the lower limit, i.e. this variance is not useful for practical applications. The divergence comes from the fact that for longer and longer measurements ($N \to \infty$), respectively, smaller and smaller Fourier frequencies ($f \to 0$), longer and longer periodic fluctuations can be identified as such, while for shorter measurements they appear as linear drifts. One way out is to calculate the variance for a limited number k of measurement data and to average the variances of M of such data sets of length k. This variance converges for a larger number of noise processes. This so-called pair variance ($k = 2$) or *Allan variance* is widely used:

$$\boxed{\sigma_y^2(\tau) = \frac{1}{2M}\sum_{j=1}^{M}(y_{2j} - y_{2j-1})^2} \ . \tag{56.69}$$

Like the normal variance, the Allan variance can also be related to the spectral density

of frequency fluctuations:

$$\sigma_y^2(\tau) = \int_0^\infty S_y(f)|\mathcal{F}\zeta_2(f)|^2 df \qquad \text{where} \qquad \zeta_2(t) \equiv \tfrac{1}{\sqrt{2}}[\zeta_1(t) - \zeta_1(-t)] \ . \tag{56.70}$$

The Fourier transforms of the step functions $\zeta_1(t)$ and $\zeta_2(t)$ will be calculated in Exc. 56.3.3.2, as well as the variances for white noise.

56.3.2 Power spectral density

It is important not to confuse the spectral density of frequency fluctuations with the power spectral density of the oscillator defined via the *autocorrelation function of the field amplitude* [4],

$$\boxed{R_{\mathcal{E}}(\tau) \equiv \langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle = \mathcal{E}_0^2 \langle e^{\imath[\phi(t+\tau)-\phi(t)]}\rangle = \mathcal{E}_0^2 e^{\imath\omega_0\tau}\langle e^{\imath[\varphi(t+\tau)-\varphi(t)]}\rangle} \ , \tag{56.71}$$

as its Fourier transform,

$$\boxed{S_{\mathcal{E}}(\omega) = \mathcal{F}R_{\mathcal{E}}(\tau)} \ . \tag{56.72}$$

The power spectral density is typically measured as the beat frequency of two independent oscillators. It is just the curve exhibited by a spectrum analyzer to which the beat signal is fed, as illustrated in the right setup of Fig. 56.12.

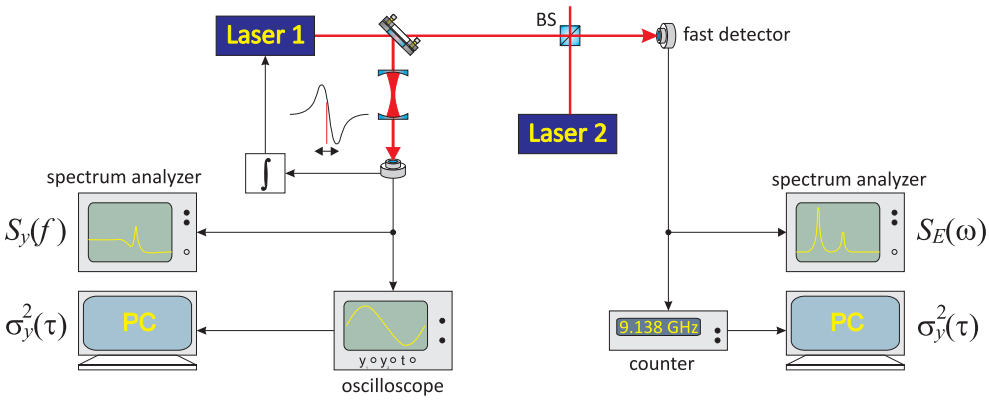

Figure 56.12: (left) Setup for measuring the spectral density of frequency fluctuations $S_y(f)$ and the Allan variance $\sigma_y^2(\tau)$ of laser 1 discriminating it at the slope of transmission signal of an optical cavity. (right) The power spectral density $S_{\mathcal{E}}(\omega)$ can be found as the beat signal between two lasers and either be exhibited on a spectrum analyzer $S_{\mathcal{E}}(\omega)$ or counted and processed to an Allan variance $\sigma_y^2(\tau)$.

The beat spectrum is the convolution of the emission bandwidth of the two oscillators,

$$S_{\mathcal{E}}(\omega) = S_{\mathcal{E},laser1}(\omega) * S_{\mathcal{E},laser2}(\omega) \ . \tag{56.73}$$

[4] Note that the *first-order coherence* is just the normalized autocorrelation,

$$g^{(1)}(\tau) \equiv \frac{\langle \mathcal{E}^*(t)\mathcal{E}(t+\tau)\rangle}{\langle \mathcal{E}^*(t)\mathcal{E}(t)\rangle} = \frac{R_{\mathcal{E}}(\tau)}{R_{\mathcal{E}}(0)} \ .$$

.

In particular, for the case that we have good reasons to believe that one laser is much narrower than the other, the power spectral density $S_{\mathcal{E}}(\omega)$ will reflect the emission spectrum of just the broader laser. Note that the power spectral density derived from a beat of two independent (uncorrelated) oscillators gives us information on their true emission bandwidths, which is relevant e.g. for resolving narrow atomic transitions. On the other hand, the stability measures $S_y(f)$ and $\sigma_y^2(\tau)$ derived from a discriminated error signal (left setup in Fig. 56.12) only tell us the stability of an oscillator with respect to the reference from which the error signal was derived, e.g. the transmission slope of an optical cavity.

56.3.2.1 Spectral noise power density in the case of white noise

The spectral noise power density $S_{\mathcal{E}}(\omega)$ of the field $\mathcal{E}(t)$ of an oscillator can, in the case of white frequency noise, be related to the spectral density of its frequency fluctuations. In the case of a laser oscillator, the half-width half maximum of the spectral noise power density, i.e. the emission bandwidth, is often specified. We will, in the following, derive the emission spectrum for the case of white Gaussian noise [1264, 414, 381].

In Exc. 56.3.3.3 we show that for a *Gaussian noise process* holds [326, 414],

$$\left\langle e^{-\imath[\varphi(t)-\varphi(t+\tau)]} \right\rangle = e^{-\left\langle [\varphi(t)-\varphi(t+\tau)]^2 \right\rangle/2} \,. \tag{56.74}$$

Now we set $\varphi(t) = \omega_0 \int_0^t y(t')dt'$ using (56.58) and obtain,

$$\begin{aligned} \left\langle [\varphi(t)-\varphi(t+\tau)]^2 \right\rangle &= \left\langle \omega_0^2 \left[\int_0^\tau y(t')dt' \right]^2 \right\rangle = \omega_0^2 \int_0^\tau \int_0^\tau \langle y(t')y(t'') \rangle \, dt'dt'' \\ &= \omega_0^2 \int_0^\tau \int_0^\tau R_y(t'-t'')dt'dt'' = 2\omega_0^2 \int_0^\tau (\tau - t) R_y(t)dt \,. \end{aligned} \tag{56.75}$$

Using (56.61), we now substitute the autocorrelation function by its Fourier transform, the spectral fluctuation density, $R_y(t) = \int_0^\infty S_y(f) e^{2\pi\imath f t} df$:

$$\begin{aligned} \left\langle [\varphi(t)-\varphi(t+\tau)]^2 \right\rangle &= 2\omega_0^2 \int_0^\infty S_y(f) \int_0^\tau (\tau - t) e^{2\pi\imath f t} dt df \\ &= 2\omega_0^2 \int_0^\infty S_y(f) \left(\frac{\sin \pi f \tau}{2\pi f} \right)^2 df + \text{imaginary part} \,. \end{aligned} \tag{56.76}$$

We neglect the imaginary part.

For Markovian white noise the phase fluctuations are δ-distributed, which means,

$$R_y \equiv \langle y^*(t) y(t+\tau) \rangle = h_0 \delta(\tau) \qquad \text{and} \qquad S_y(f) = h_0 = const. \tag{56.77}$$

I.e. the so-called *white noise* is characterized by a constant spectral density of phase fluctuations. Carrying on the calculation (56.76) for the case of white frequency noise we get,

$$\left\langle [\varphi(t)-\varphi(t+\tau)]^2 \right\rangle = \frac{h_0 \omega_0^2 |\tau|}{\pi} \int_0^\infty \left(\frac{\sin x}{x} \right)^2 dx = \frac{h_0 \omega_0^2 |\tau|}{2} \,. \tag{56.78}$$

With this result, we can undertake to calculate the autocorrelation function of the field amplitude (56.71),

$$R_{\mathcal{E}}(\tau) = \mathcal{E}_0^2 e^{\omega_0 \tau} e^{-h_0 \omega_0^2 |\tau|/2} \ . \tag{56.79}$$

The resulting *power spectral density* (56.72) is [5]:

$$\boxed{S_{\mathcal{E}}(\omega) = \mathcal{E}_0^2 \int_{-\infty}^{\infty} R_{\mathcal{E}}(\tau) e^{-\imath(\omega-\omega_0)\tau} d\tau = \frac{2h_0\omega_0^2}{4\Delta^2 + (h_0\omega_0^2/2)^2}} \ , \tag{56.80}$$

where $\Delta \equiv \omega - \omega_0$ is the deviation of the oscillator frequency from the center frequency ω_0. Thus, the the emission spectrum for the case of white Gaussian noise is a Lorentzian profile with the *laser emission bandwidth*,

$$\boxed{\beta = \tfrac{1}{2} h_0 \omega_0^2} \ . \tag{56.81}$$

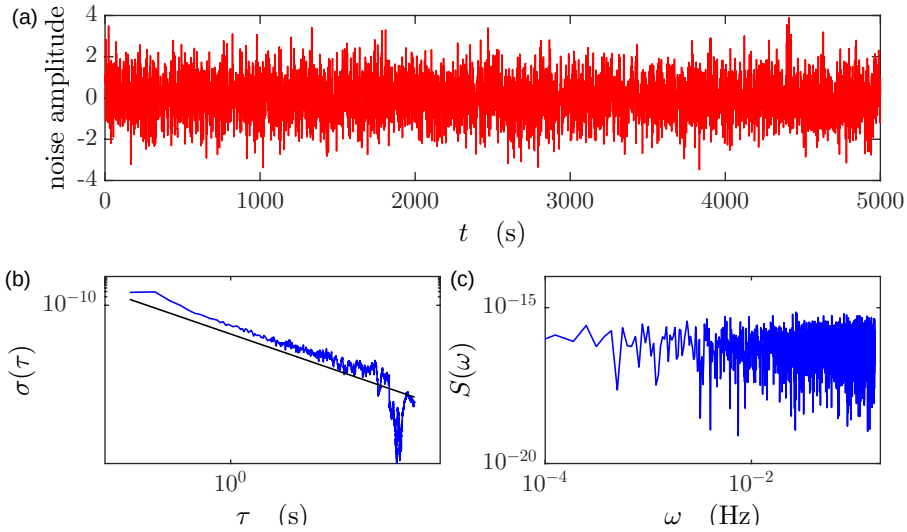

Figure 56.13: (code) Allan variance (b) and spectral density of frequency fluctuations (c) calculated from a randomly generated data set (a).

The Lorentz shape of the emission profile of an oscillator or a resonance always indicates white noise of the underlying frequency fluctuation density. In this sense, the Lorentz form of the natural broadening of an atomic resonance can also be traced back to the white noise of the vacuum fluctuations. Here, the emission bandwidth has to be replaced by the natural linewidth. The Allan variance in this case is:

$$\sigma_y^2(\tau) = \frac{h_0}{2\tau} = \frac{1}{Q^2} \frac{1}{\Gamma} \frac{1}{\tau} \ . \tag{56.82}$$

with the linewidth (FWHM) $\Gamma = h_0\omega_0^2/2$ and $Q = \omega_0/\Gamma$ and indicates the maximum achievable stability for a frequency standard that is coupled to the resonance ω_0.

[5] Using $\mathcal{F}[e^{-a|x|}] = \int_{-\infty}^{\infty} e^{-a|t|} e^{-\imath\omega t} dt = \frac{2a}{a^2+\omega^2}$.

56.3.2.2 Spectral noise power density in case of periodic phase perturbation

The momentary deflection of the oscillator can be described in the case of a harmonic phase disturbance by equation (56.60) with the additional condition: $\phi(t) = N \sin \Omega t$. The frequency fluctuation density and the Allan variance are obtained in this case:

$$S_y(f) = \left(\frac{fN}{2\omega_0}\right)^2 \delta(f-\Omega) \qquad \text{resp.} \qquad \sigma_y^2(\tau) = \left(\frac{\Omega N}{2\omega_0}\right)^2 \frac{\sin^2 \Omega\tau/2}{\Omega\tau/2} \ . \tag{56.83}$$

The spectral noise power density consists of a discrete spectrum of sidebands, the number and height of which is given by the modulation index N:

$$\boxed{S_{\mathcal{E}}(\omega) = \sum_{n=-\infty}^{\infty} |J_n(N)|^2 \delta(\omega - \omega_0 - \Omega)} \ . \tag{56.84}$$

A full width at half maximum of the spectral noise power density cannot be specified. However, as a measure of the emission bandwidth of the oscillator, the frequency spacing of the sideband of the highest order can be understood, the height of which corresponds to at least half the height of the carrier frequency ω_0.

56.3.3 Exercises

56.3.3.1 Ex: Spectral density of frequency fluctuations

Prove the relationship $S_{\dot{x}}(f) = f^2 S_x(f)$.

Solution: *We start showing* $(\mathcal{F}f')(\omega) = 2\pi\imath\omega(\mathcal{F}f)(\omega)$. *First we define* $u = e^{-2\pi\imath\omega t}$ *and* $v = f(t)$ *such that* $du = -2\pi\imath\omega e^{-2\pi\imath\omega t}dt$ *and* $dv = f'(t)dt$. *Then we integrate by parts,*

$$\begin{aligned}(\mathcal{F}f')(\omega) &= \int_{-\infty}^{\infty} f'(t)e^{-2\pi\imath\omega t}dt = f(t)e^{-2\pi\imath\omega t}\big|_{-\infty}^{\infty} - \int_{-\infty}^{\infty}(-2\pi\imath\omega)e^{-2\pi\imath\omega t}f(t)dt \\ &= 2\pi\imath\omega \int_{-\infty}^{\infty} e^{-2\pi\imath\omega t}f(t)dt = 2\pi\imath\omega(\mathcal{F}f)(\omega) \ .\end{aligned}$$

Furthermore,

$$[\mathcal{F}(f'g')](\omega) = [(Ff') * (Fg')](\omega) = (2\pi\imath\omega)^2[\mathcal{F}(fg)](\omega) \ .$$

Now, writing spectrum as,

$$\begin{aligned}S_{\dot{x}}(f) &= \int R_{\dot{x}}(\tau)e^{-2\pi i f\tau}d\tau = \int \left[\lim_{T\to\infty}\frac{1}{T}\int_0^T \dot{x}(t)\dot{x}(t+\tau)dt \ e^{-2\pi i f\tau}\right]d\tau \\ &= \lim_{T\to\infty}\frac{1}{T}\int_0^T \left[\int \dot{x}(t)\dot{x}(t+\tau)e^{-2\pi i f\tau}d\tau\right]dt \ ,\end{aligned}$$

and identifying $f(t) \equiv \dot{x}(t)$ *and* $g(t) \equiv \dot{x}(t+\tau)$ *we get,*

$$S_{\dot{x}}(f) = f^2 S_x(f) \ .$$

56.3.3.2 Ex: Allan variance for white noise

a. Calculate the Fourier transform of step function $\zeta_1(t)$ and the one-point variance for white noise from its definition (56.68).
b. Repeat the calculation for the step function $\zeta_2(t)$ and the Allan variance as defined in (56.70).

Solution: *a. The Fourier transform of step function* $\zeta_1(t) = \frac{\Theta_{[-\tau,0]}(t)}{\tau}$ *is,*

$$(\mathcal{F}\zeta_1)(f) = \int_{-\infty}^{\infty} \zeta_1(t) e^{2\pi\imath f t} dt = \frac{1}{\tau}\int_{-\tau}^{0} e^{2\pi\imath f t} dt = \frac{1 - e^{-2\pi\imath f\tau}}{2\pi i f\tau} \ ,$$

such that,

$$|(\mathcal{F}\zeta_1)(f)|^2 = \frac{\sin^2 \pi f\tau}{(\pi f\tau)^2} \ .$$

The one-point variance is now,

$$\sigma_y^2(\tau) = \int_0^{\infty} S_y(\tau) |\mathcal{F}\zeta_1(f)|^2 df = h_0 \int_0^{\infty} \frac{\sin^2 \pi f\tau}{(\pi f\tau)^2} df = \frac{h_0}{2|\tau|} \ .$$

b. The Fourier transform of the step function $\zeta_2(t) = \frac{\zeta_1(t) - \zeta_1(-t)}{\sqrt{2}}$ *is,*

$$(\mathcal{F}\zeta_2)(f) = \int_{-\infty}^{\infty} \zeta_2(t) e^{2\pi\imath f t} dt = \frac{1}{\sqrt{2}} \left(\frac{1 - e^{-2\pi\imath f\tau}}{2\pi\imath f\tau} - \frac{e^{2\pi\imath f\tau} - 1}{2\pi\imath f\tau} \right) \ .$$

such that,

$$|(\mathcal{F}\zeta_2)(f)|^2 = 2\frac{\sin^4 \pi f\tau}{(\pi f\tau)^2} \ .$$

The Allan variance is now,

$$\sigma_y^2(\tau) = \int_0^{\infty} S_y(\tau) |\mathcal{F}\zeta_2(f)|^2 df = h_0 \int_0^{\infty} \frac{2\sin^4 \pi f\tau}{(\pi f\tau)^2} df = \frac{h_0}{2|\tau|} \ .$$

56.3.3.3 Ex: Gaussian noise process

Prove the relationship (56.75) for a *Gaussian noise process* characterized by,

$$\frac{\langle A^{2n} \rangle}{(2n)!} = \frac{\langle A^2 \rangle^n}{2^n n!} \qquad \text{and} \qquad \langle A^{2n-1} \rangle = 0 \ .$$

Solution: *We calculate,*

$$\begin{aligned} \left\langle e^{-\imath[\varphi(t) - \varphi(t+\tau)]} \right\rangle &= \sum_n \frac{1}{(2n)!} \left\langle -\imath^{2n} [\varphi(t) - \varphi(t+\tau)]^{2n} \right\rangle \\ &= \sum_n \frac{1}{n!} \left\langle -\tfrac{1}{2} [\varphi(t) - \varphi(t+\tau)]^2 \right\rangle^n = e^{-\left\langle [\varphi(t) - \varphi(t+\tau)]^2 \right\rangle / 2} \ . \end{aligned}$$

56.4 Data sheets

The following pages contain the data sheets of the main components used in this course.

HL6722G

AlGaInP Laser Diode

opnext
Powered by HITACHI

ODE-208-220E (Z)

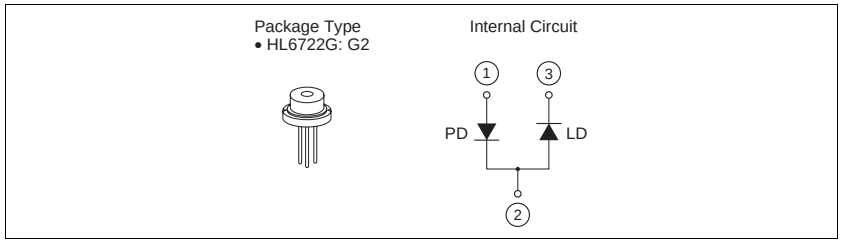
Rev.5
Mar. 2005

Description

The HL6722G is a 0.67 µm band AlGaInP index-guided laser diode with a multi-quantum well (MQW) structure. It is suitable as a light source for bercode scanner, and various other types of optical equipment. Hermetic sealing of the package assures high reliability.

Features

- Visible light output at wavelengths up to 680 nm
- Single longitudinal mode
- Continuous operating output: 5 mW CW
- Low voltage operation: 2.7 V Max
- Low current operation: 32 mA Typ
- Built-in monitor photodiode



opnext
Powered by HITACHI

Figure 56.14: Data sheet for the diode laser from Thorlabs, model Hitachi HL6722G.

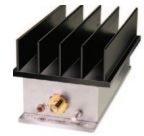
Coaxial

Amplifier

ZHL-2-8

50Ω Medium High Power 10 to 1000 MHz

ZHL-2-8X



ZHL-2-8

SMA version shown

Features

- wideband, 10 to 1000 MHz
- high IP3, +38 dBm typ.
- medium high power, 29 dBm min.

Applications

- VHF/UHF
- test equipment
- cellular
- instrumentation
- laboratory

CASE STYLE: T34

Connectors	Model	Price	Qty.

* Heat sink not included
Open load is not recommended, potentially can cause damage.
With no load derate max input power by 20 dB

To order without heat sink, add suffix X to model number. Alternative heat sinking and heat removal must be provided by the user to limit maximum temperature to 65°C, in order to ensure proper performance. For reference, this requires thermal resistance of user's external heat sink to be 1.35°C/W Max.

Maximum Ratings

Operating Temperature	-20°C to 65°C
Storage Temperature	-55°C to 100°C
DC Voltage	+25V Max.

Permanent damage may occur if any of these limits are exceeded.

Silicon PIN Photodiodes - Large Area, Fast Response Time – 400 nm to 1100 nm

The FFD series devices are high-quality, large-area, high-speed, N-type Si PIN photodiodes in hermetically sealed TO packages designed for the 400 nm to 1100 nm wavelength range. The FND-100Q has a quartz window to enhance UV responsivity.

Preamplifiers

Preamplifier modules incorporating these photodiodes are available on a custom basis.

Detectors

Silicon Epitaxial PIN Photodiodes - High Speed – 400 nm to 1100 nm

The C30736 series of high-speed epitaxial silicon PIN photodetectors provide fast response and good quantum efficiency in the spectral range between 400 nm and 1100 nm. These devices are optimized for high-speed, high volume and low cost applications. Standard sizes include 0.25 mm, 0.5 mm, 1.0 mm, 1.5 x 1.5 mm, and custom sizes can be accomodated depending on volume required. Available in plastic surface mount packages and in chip form.

Silicon Epitaxial PIN Photodiodes

Typical Characteristics @ T = 22º C

MAXIM

Precision, Dual-Supply, SPST Analog Switches

General Description

The MAX320/MAX321/MAX322 are precision, dual, SPST analog switches designed to operate from ±3V to ±8V dual supplies. The MAX320 has two normally open (NO) switches and the MAX321 has two normally closed (NC) switches. The MAX322 has one NO and one NC switch. Low power consumption (1.25mW) makes these parts ideal for battery-powered equipment. They offer low leakage currents (100pA max) and fast switching speeds (t_{ON} = 150ns max, t_{OFF} = 100ns max).

The MAX320 series, powered from ±5V supplies, offers 35Ω max on-resistance (R_{ON}), 2Ω max matching between channels, and 4Ω max R_{ON} flatness.

These switches also offer 5pC max charge injection and a minimum of 2000V ESD protection per Method 3015.7.

For equivalent devices specified for single-supply operation, see the MAX323/MAX324/MAX325 data sheet. For quad versions of these switches, see the MAX391/MAX392/MAX393 data sheet.

Applications

Battery-Operated Systems	Sample-and-Hold Circuits
Heads-Up Displays	Guidance and Control Systems
Audio and Video Switching	Military Radios
Test Equipment	Communications Systems
±5V DACs and ADCs	PBX, PABX

Features

- **Low On-Resistance, 35Ω max (16Ω typical)**
- **R_{ON} Matching Between Channels <2Ω**
- **R_{ON} Flatness <4Ω**
- **Guaranteed Charge Injection <5pC**
- **Bipolar Supply Operation (±3V to ±8V)**
- **Low Power Consumption, <1.25mW**
- **Low Leakage Current Over Temperature, <2.5nA at +85°C**
- **Fast Switching, t_{ON} <150ns, t_{OFF} <100ns**
- **Guaranteed Break-Before-Make (MAX322 only)**

LM741
Operational Amplifier

General Description

The LM741 series are general purpose operational amplifiers which feature improved performance over industry standards like the LM709. They are direct, plug-in replacements for the 709C, LM201, MC1439 and 748 in most applications.

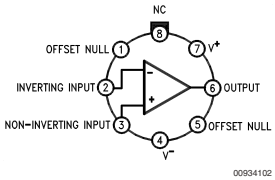
The amplifiers offer many features which make their application nearly foolproof: overload protection on the input and output, no latch-up when the common mode range is exceeded, as well as freedom from oscillations.

The LM741C is identical to the LM741/LM741A except that the LM741C has their performance guaranteed over a 0˚C to +70˚C temperature range, instead of −55˚C to +125˚C.

Features

Connection Diagrams

Metal Can Package



Note 1: LM741H is available per JM38510/10101

Order Number LM741H, LM741H/883 (Note 1), **LM741AH/883 or LM741CH**

ANALOG DEVICES

Low-Noise, Precision Operational Amplifier

OP27

FEATURES

Low Noise: 80 nV p-p (0.1 Hz to 10 Hz), 3 nV/$\sqrt{\text{Hz}}$
Low Drift: 0.2 μV/°C
High Speed: 2.8 V/μs Slew Rate, 8 MHz Gain Bandwidth
Low V_{OS}: 10 μV
Excellent CMRR: 126 dB at V_{CM} of ±11 V
High Open-Loop Gain: 1.8 Million
Fits 725, OP07, 5534A Sockets
Available in Die Form

GENERAL DESCRIPTION

The OP27 precision operational amplifier combines the low offset and drift of the OP07 with both high speed and low noise. Offsets down to 25 μV and drift of 0.6 μV/°C maximum make the OP27 ideal for precision instrumentation applications. Exceptionally low noise, e_n = 3.5 nV/$\sqrt{\text{Hz}}$, at 10 Hz, a low 1/f noise corner frequency of 2.7 Hz, and high gain (1.8 million), allow accurate high-gain amplification of low-level signals. A gain-bandwidth product of 8 MHz and a 2.8 V/μsec slew rate provides excellent dynamic accuracy in high-speed, data-acquisition systems.

A low input bias current of ±10 nA is achieved by use of a bias-current-cancellation circuit. Over the military temperature range, this circuit typically holds I_B and I_{OS} to ±20 nA and 15 nA, respectively.

The output stage has good load driving capability. A guaranteed swing of ±10 V into 600 Ω and low output distortion make the OP27 an excellent choice for professional audio applications.
